V.1
1830

SOUTHERN DISTRICT OF NEW-YORK, ss.

BE IT REMEMBERED, That on the 15th day of June, A. D. 1830, in the fifty-fourth year of the independence of the United States of America, J. & J. HARPER, of the said district, have deposited in this office the title of a book, the right whereof they claim as Proprietors, in the words following, to wit:

"A Dictionary of Practical Surgery: comprehending all the most interesting Improvements, from the earliest times down to the present period; an Account of the Instruments and Remedies employed in Surgery; the Etymology and Signification of the principal Terms; and numerous References to ancient and modern Works; forming a 'Catalogue Raisonne' of surgical Literature. By Samuel Cooper, Surgeon to the King's Bench, the Bloomsbury Dispensary, and his Majesty's Prison of the Fleet; Member of the Council of the Royal College of Surgeons in London; Surgeon to the Forces; Honorary Member of the Academy of Natural Sciences at Catania, the Medical Society of Marseilles; &c. From the Sixth London Edition; revised, corrected, and enlarged. With numerous Notes and Additions, embracing all the principal Improvements and greater Operations introduced and performed by American Surgeons. By David Meredith Reese, M.D., Licentiate in Surgery and Midwifery; Honorary Member of the Medical and Chirurgical Faculty of Maryland, and of the Medical Society of Maryland; Resident Member of the Medical and Philosophical Society of New-York; Practitioner of Physic and Surgery in the city of New-York, &c."

In conformity to the Act of the Congress of the United States, entitled "An Act for the encouragement of Learning, by securing the copies of maps, charts, and books, to the authors and proprietors of such copies, during the times therein mentioned." And also to an Act, entitled "An Act, supplementary to an Act, entitled an Act for the encouragement of Learning, by securing the copies of maps, charts, and books, to the authors and proprietors of such copies, during the times therein mentioned, and extending the benefits thereof to the arts of designing, engraving, and etching historical and other prints."

FREDERICK J. BETTS,
Clerk of the Southern District of New-York.

SURGEON GEN'S LIBRARY

PREFACE

BY THE AMERICAN EDITOR.

The exalted reputation acquired by this Dictionary having obtained for it almost exclusive preference in Great Britain, on the Continent, and throughout the United States, it will be altogether unnecessary for the publishers to introduce the work or its distinguished author to the American public by any new testimonials. Nor will it be expected of the American editor to attempt a laboured commendation of this compendium of surgical literature, with the view of attracting a larger share of attention from the profession than it has already received in its former publications in this country. It has long been esteemed a standard work, is adopted as a text-book in our universities, colleges, and schools of medicine generally, and finds a place in the library of every surgeon in the country.

The first republication in this country was edited by the late distinguished Dr. Dorsey, of Philadelphia; whose valuable improvements carried it through a second and third edition; and under the title of "Dorsey's Cooper," it rapidly gained upon public favour. The author availed himself of most of the American additions in revising his work for a fourth edition, from which it was again reprinted in America, with an appendix, by Mr. Wm. Anderson, of New-York.

Since that time, Mr. Cooper has published a fifth, and recently a sixth edition, improving and enlarging the work by availing himself of the new and valuable discoveries in surgical knowledge to which he has access; and from this last revision of 1830, the present stereotype edition is republished. And as it has passed through two revisions by the author since it was printed in America, and the last includes all that is novel and interesting among British and continental surgeons down to the present year; its republication, even without any semblance of improvement, will be acknowledged to be a desideratum by all who would keep pace with their improving profession.

As in every species of human science our highest attainments are but an approximation towards perfection, so in the science of surgery, each succeeding year demonstrates that all that is known of the principles or practice of our art, is but the prelude to still higher exhibitions of science and skill, alike honourable to the profession, and valuable to the cause of humanity. To condense and arrange all the novel and interesting facts which clinical experience is furnishing, and upon which alone the edifice of true science can be erected, is a task worthy of the immense labour which Mr. Cooper has bestowed on each succeeding reprint of his Dictionary, and one to which he has proved himself entirely adequate. The extensive and multiplied resources to which he has access, furnish him with facilities possessed by few; and in availing himself of these, he has exhibited an industry, and, for the most part, an impartiality, worthy of all praise.

Within the last few years, our profession, and especially the department of Chirurgery, has been making steady, and even rapid advances in almost every country. Many diseases formerly among the opprobria of our profession have yielded to the science and skill of modern surgeons. Besides the vast improvements made in the treatment of surgical diseases, operations have been performed with entire success for the relief of injuries, but a few years ago esteemed irremediable; and some of them of so bold and difficult a character, that to propose them would have been a hazard of reputation which but few could have then survived.

Learning is not indigenous to any country; and although national pride sometimes prompts to exclusive pretensions, yet the history of surgery, so far as this is concerned, forbids such presumptuous arrogance. The question, "Who hears of American surgeons?" is no longer tauntingly repeated; since the discoveries and operations of some of them have extorted a tribute of admiration from almost every country where this science is cultivated, and given to their names professional immortality. In this, as in the other departments of learning, we may be allowed to say, without the imputation of vanity, that our countrymen have shown to demonstration, that when the tree of science is transplanted across the Atlantic, it is capable of taking as firm a root as in its native soil.

The improvements which surgery has received in the United States, and especially within a few years, although highly important to the interests of the profession and to the cause of suffering humanity, are far from being generally known even in our own country, and still less to the profession abroad. Our periodicals containing them have but a limited circulation, and local views have multiplied their number, until many of the States, and most of our medical institutions, have a vehicle of their own; thus still farther contracting the sphere of their usefulness. And although several of them are most ably conducted, and are adapted to general circulation, we are yet without the advantages which would result from a periodical, strictly national, in which the whole profession might combine their energies for the promotion of science, and to which all might have free and equal access.

From these periodicals our European brethren obtain their information relative to the state and progress of medical and surgical science among us, and some of them never find their way either into Great Britain, France, or Germany. Hence foreign authors are so often charged with criminal remissness in their notices of American surgery. But when we advert to the small proportion of the surgical improvements of this country which have ever been published at all, and recollect that of these but a few are ever seen by our British or continental brethren, we may find an apology for much of the neglect of which we have complained.

That there has been a disposition on the part of some European writers to pass over in silence every thing American, has long been a subject of remonstrance; and in relation to some of these, there is doubtless just ground of complaint. How far Mr. Cooper will be found in the same condemnation will be estimated by those who peruse the present edition, and who will, of course, award him due praise for so much as he has said of American surgery. It is difficult to believe that he has introduced all he knew on this subject, and it is certain that he might have known much more equally worthy of his notice.

In preparing the present edition for the press, the publishers have desired that it might include all that is novel and interesting among American surgeons; and

have committed to the present editor the task of collecting and arranging the materials furnished by our periodicals and original publications, and of condensing these with such original matter as he might be able to obtain, sufficiently important to merit introduction into this Dictionary.

To perform this duty in a manner which should be acceptable to the profession and useful to the community, no pains or labour has been spared. How far he has succeeded in this humble task of compiling from the productions of his fellow-countrymen an epitome of American surgery, remains to be adjudged by those for whose benefit he has been thus employed. He claims no merit for himself, other than that of having rendered, as far as possible, equal and exact justice to the claims of gentlemen in every part of our common country, whether living or dead; and for this purpose, he has availed himself of every accessible means.

He has corresponded with distinguished surgeons in various and remote parts of the land, from many of whom he has received communications of great merit and practical importance. To the periodicals of the last few years he has had frequent recourse, and from most of them he has extracted improvements and inventions which cannot fail to interest and instruct. He must also acknowledge his obligations to Dr. Gross's edition of Tavernier's Operative Surgery; Dr. Sterling's translation of Valpeau's Surgical Anatomy; and to the late Philadelphia edition of Cooper's First Lines, with notes by Professor Stevens, of New-York, and the "Philadelphia Editor."

To a number of his professional friends in New-York, as well as in distant parts of the United States, the editor is greatly indebted, not only for the assistance rendered, but for the encouragement they have given him in the performance of this duty. And although he has not heard from some who had promised communications, yet he has availed himself of their published works, and introduced all the operations they claim, so far as his limits would permit.

The limits assigned him by the publishers for enlarging the work, have rendered it necessary to abbreviate and condense many new and important surgical improvements more than was agreeable to his own wishes; and this must be his apology for so frequent reference to the works and periodicals in which they are recorded at length. The same reason will account for the brevity of many of the notes, which consist of mere hints, upon which some amplification would have been more congenial to his own views, and perhaps more acceptable to the profession. It is but an act of justice, however, on the part of the editor towards the publishers to state, that they have suffered him to transcend their limits very considerably, and allowed him a brief appendix for the purpose of introducing some articles unavoidably omitted under their appropriate heads.

It will be perceived by those who have the opportunity of comparing this with the late London edition, as revised and enlarged by the author, that it contains the whole of the matter of that edition, although the size of the type has somewhat diminished the number of pages. Although many of the terms, doctrines, and operations are now obsolete, and might very plausibly be omitted, yet as Mr. Cooper has seen fit to retain them, it has been thought best to make no alteration whatever in the work, and hence also the long catalogue of references at the end of each article is preserved, although many of the works cannot be obtained in this country.

The original matter introduced by the American editor will be found im-

bodied in the text, in immediate connexion with the subject to which it refers, except where an occasional foot note for obvious reasons has been preferred. To distinguish it from the rest, it is included within brackets, and at the close of each of these additions will be found the surname of the editor.

This method of making interpolations in the body of the work may appear less imposing than an array of additions in an appendix at the end of the book, or a display of notes at the foot of the pages, distinguished by asterisks, obelisks, &c.; but they will certainly be found more convenient to the student, and more in conformity to the character of a dictionary. It is from this conviction that this course has been pursued; which, it is hoped, will be satisfactory to the profession.

As the work is stereotyped, it will be necessary in future editions to enlarge the appendix, which can be done to any desirable extent, and the Dictionary may thus keep pace with the steady advancement of surgical knowledge in this and other countries. For the purpose of supplying any omissions which may have been inadvertently made, it is intended at first to publish but a small edition, sufficient to supply the present demand, and any communications from American surgeons will receive respectful notice in a future edition, by being included in the appendix at the close of the second volume. Such communications are respectfully solicited, and may be forwarded to the editor without delay.

To rescue American surgery from unmerited neglect, and to present to our transatlantic brethren a brief epitome of what is doing in the United States for the promotion and improvement of surgical science, is the object at which the editor has directed this effort. That his task has been imperfectly performed he is fully conscious, nor will he affect to conceal his own misgivings in thus attempting to improve upon the work of one of the master-spirits of the other hemisphere. How far the haste with which the work has been hurried through the press, to supply the great demand which is every where felt and expressed, may have contributed to his imperfections, he will not attempt to determine; perhaps his inexperience in such a vocation may be more plausibly urged. His design, however, is now completed; and he submits the result to his brethren in the profession, and to students of this noble science, with no other wish than that it may contribute to elevate our national character, and excite to the still farther cultivation and improvement of surgical literature.

DAVID MEREDITH REESE, M.D.

New-York, August 22d, 1830.

PREFACE

TO THE

SIXTH LONDON EDITION.

The utility of this Dictionary to students and all classes of medical practitioners, has obtained for it in this country a larger share of patronage than was perhaps ever conferred upon any other book of surgery; while its translation into the French, German, Italian, and Russian languages, and several republications of it in America, may be taken as proofs of its being deemed worthy of considerable notice in various other parts of the world. At Milan, one translation of it was produced a few years ago; and I learn from a letter, with which I have lately been honoured by Dr. Crescimbini, president of the Medico-Chirurgical Society of Bologna, that he is preparing another Italian translation, into which he proposes to introduce additional subjects, and such remarks as are founded upon his own researches and experience. The diligent and enlightened Germans were not only the first to undertake and complete a translation; they have bestowed still greater attention upon my humble endeavours to promote the cultivation and diffusion of surgical science; for they have followed up their translation by a series of well-executed engravings, expressly designed to illustrate the nature of the diseases, accidental injuries, and curative methods, treated of in this Dictionary.—(See *Chirurgische Kupfertafeln*, 4*to*. *Weimar*, 1820—1829.) Of these valuable plates, the publication of which I regard as an honourable compliment to my surgical labours, nearly fifty numbers have already been brought out at an extremely moderate price; and it is with real pleasure that I recommend them to the notice of every surgeon who is a German scholar, as being the most useful collection of surgical and pathological plates ever offered to the profession.

In preparing this edition, which is enriched with an account of all the latest improvements in surgery, I have conscientiously endeavoured to deal fairly and impartially with every individual whose name I have had occasion to mention, or whose suggestions form subjects of consideration in the ensuing pages. My aim has been truth, wherever I could find her; and in every situation where any glimpse of her beautiful figure presented itself, I have ardently courted her, regardless of the name, school, or country on which she might deign to shed her glory. By steadily adhering to this principle; by zealously marking what the book of nature and the field of experience unfolded; by renouncing all obsequious submission to every other kind of authority; and by taking the liberty of sometimes thinking and judging for myself; I trust that the most likely plan has been adopted of maintaining the character of this book, and raising my own humble reputation.

According to my usual plan, I subjoin the notice of a few things, which were either inadvertently omitted in the articles to which they relate, or communicated to me after such articles had been printed.

[The several additions which follow in Mr. Cooper's preface, for the greater convenience of the student have been inserted in the body of the Dictionary, under the respective articles to which they refer. They will be found designated by the abbreviation *Pref.* affixed to the termination of each.]

SURGEON GEN'L'S OFFICE LIBRARY

SURGICAL DICTIONARY.

ABAPTISTON. (From ἀ, priv. and βαπτίζω, *immergo*, to sink under.) Galen, Fabricius ab Aquapendente, and especially Scultetus, in his *Armamentariam Chirurgicum*, so denominate the crown of the trepan, because it formerly had a conical shape, which kept it from penetrating the cranium too rapidly, and plunging its teeth in the dura mater and brain. While, however, it is admitted by modern surgeons that mischief may be done by letting the saw penetrate too deeply, they do not find it necessary to obviate the possibility of such an accident, by using a conical trepan, with which it would be difficult to make any perforation at all; but they guard against the danger, by observing particular rules and cautions laid down in another part of this book.—(See *Trephine.*)

ABDOMEN. The Belly. When a surgeon speaks of the cavity of the abdomen, he confines his meaning to the space included within the bag of the peritoneum. Hence, neither the kidneys nor the pelvis viscera are, strictly speaking, parts of the abdomen.

Anatomists have divided the abdomen into different regions, the terms allotted to which are so frequent in the language of surgical books, that some account of them in this Dictionary seems indispensable.

The middle of the upper part of the abdomen, from the ensiform cartilage as low down as a line drawn directly across the greatest convexity of the cartilages of the ribs, is called the *epigastric region.*

The spaces at the sides of the epigastric region are termed the *right* and *left hypochondria* or *hypochondriac regions.*

The *umbilical region* extends from the navel upwards to the line forming the lower boundary of the epigastric region, and downwards to a line drawn across from one anterior superior spinous process to the ileum of the other.

The middle space, below the last line, down to the os pubis, is named the *hypogastric region.*

The parts of the abdomen situated on the outside of the umbilical region to the right and left, or externally with respect to two perpendicular lines drawn from the greatest convexities of the cartilages of the seventh true ribs, are named the *ilia* or *flanks.* On each side of the hypogastric region is situated the *inguinal region* or *groin.* The whole of the back part of the abdomen has only one technical appellation, viz. the *lumbar region* or *loins.*

As the abdomen is the frequent situation of several important surgical diseases; is much exposed to wounds; and various operations on different parts of it are often indispensable; it claims the particular notice of every practical surgeon. One of the most common afflictions to which mankind are subject, is that in which some of the bowels protrude. This disease is called *hernia*, and ought to be well understood by every practitioner, who, however, can never acquire the necessary knowledge without being minutely acquainted with the anatomy of the abdomen. In dropsical cases it is frequently proper to tap the abdomen; and this operation, named *paracentesis*, simple as it may seem, requires more consideration and attention to the anatomy of the parts than many surgeons bestow.—(See *Hernia*, *Paracentesis*, and *Wounds.*)

Abdomen, Abscesses of the, may take place either within the cavity of the belly, or at some point of its circumference, may be either of an acute or chronic nature. Women are generally considered more liable than men to abscesses in and about the abdomen; the abscesses named *lumbar*, being elsewhere treated of, are here excluded from consideration. Collections of purulent matter, resembling turbid whey, and containing whitish or yellowish flakes, are not unfrequently formed in the cavity of the peritoneum, as one of the effects of inflammation accompanying puerperal fever.—(*Stoll, Rat. Med. t.* 4, *p.* 103; *Lassus, Pathologie Chir. t.* 1, *p.* 137, *nouvelle édit.* 8*vo. Paris*, 1809.)

In lying-in women, abscesses frequently form between the abdominal muscles and the peritoneum, especially just above the groin. They are cases which have been very correctly described by Conradi. Before the integuments project, the diagnosis is often attended with difficulty, and sometimes an obscurity prevails several weeks; for the patients seem as if affected with slight colic pains, which yield to common treatment, particularly external applications, but soon return. Thus, unless the vicinity of Poupart's ligament be carefully examined, where some painful point, hardness, or elevation can be detected, the abscess may remain concealed until a large prominence, or the extension of the matter down the thigh, lameness, &c., makes the nature of the case completely manifest. As the peritoneum adjoining the abscess is always thickened by the preceding inflammation, Conradi assures us that there is no danger of the collection of matter bursting inwards. Some abscesses, indeed, have been so enormous, that the matter actually pushed the viscera out of their places, yet all this happened without any inward bursting of the disease. The whole danger depends upon the duration of the complaint and the extent to which the matter spreads. A timely detection of the nature of the case, the use of emollient applications, and the making of an early opening, generally bring the disease to a speedy and favourable termination.—(See *Arnemann's Magazin für die Wundarzneiwissenschaft, b.* 1, *p.* 175, 8*vo. Gött.* 1797.)

Chronic tumours of the mesentery, which in scrofulous children sometimes terminate slowly in suppuration, and diseases of the ovary and other abdominal viscera, bringing on the formation of matter, are often the cause of purulent extravasation, great emaciation, hectic symptoms, and death. However, sometimes salutary adhesions are produced between the viscera, by which means an outlet is obtained for the matter through the bladder, anus, or vagina. Thus (says Lassus) in the case of a woman who had had for a long while pains in the right lumbar region, supposed to proceed from suppuration of the kidney, because pus was voided with the urine; the right kidney was found after death in the natural state; but there was an abscess in the right ovary, which was adherent to the bladder, into which the pus had passed through an ulcerated communication. In another patient, who had voided pus by the anus, the right kidney was suppurated and adherent to the colon, with which it communicated by a preternatural aperture. For many years a woman had a hard tumour of considerable size in the abdomen: at length the pain of it became intolerable; and just at the moment when her death was apprehended, an immense quantity of pus was suddenly discharged from the vagina. The pain abated; the swelling of the belly subsided; merely the remains of the induration were now perceptible; and the woman's health was perfectly re-established.—(*Lassus, Pathologie Chir. t.* 1, *p.* 138.)

The abscesses which sometimes form between the peritoneum and abdominal muscles, or between the layers of these muscles, or under the integuments of the abdomen, are attended with considerable variety, according as they happen to be chronic or acute, circumscribed or diffused, small or extensive. Those of the acute or phlegmonous kind, sometimes following stabs and contusions, are particularly noticed in the article *Wounds.* They are cases which demand especial care, because if not checked they may prove

fatal, many examples of which are upon record.—(See *Commerc. Literar. Noric.* 1741, *p.* 100; *Eller, Medic. and Chir. Anmerkungen, p.* 108, *&c.*) As for chronic external abscesses of the abdomen, they should be opened early, and treated on the principles explained in the article *Lumbar abscess.*

Hard, indigestible substances, after being swallowed, are not unfrequently discharged from abscesses in some of the abdominal regions.—(See *De La Grange, in Museum der Heilkunde, b.* 4, *p.* 154 : *a fish-bone, which had been swallowed, found in the abscess; Petit, Traité de Mal. Chir. t.* 2, *p.* 226 : *an awl, without a handle, extracted from an abscess of the abdomen; and many other analogous cases.*)

Encysted tumours are sometimes formed between the peritoneum and abdominal muscles, and attain an immense size before they burst; a remarkable specimen of which is detailed by Gooch.—(*Chir. Works, vol.* 2, *p.* 144, *&c.* 8*vo. Lond.* 1792.) In this case the spontaneous opening in the navel was enlarged with caustic, and the cyst extracted; but before a cure could be effected it became necessary to make a depending opening, and introduce a seton. Swellings of this nature, however, are only noticed here on account of their resemblance to circumscribed chronic abscesses of the parietes of the abdomen.

Abdomen, pulsations in the. From the article *Aneurism* the reader will understand that, though it be the common nature of this disease to be attended with throbbing, it is not every pulsating tumour that is an aneurism. The cases usually called *abdominal* or *epigastric pulsations* often furnish a proof of the correctness of the preceding remark. The authors who have treated of the latter affection with the greatest discrimination, are Dr. Albers, of Bremen, and Mr. Allan Burns, of Glasgow, two gentlemen whose high reputation and useful labours will long survive the recent termination of their meritorious lives. Some of the pulsations here referred to are the consequence of organic disease, and capable of demonstration by dissection; while the rest are not attended with any such appearance, and have therefore been regarded as nervous. The pulsation is not always produced by the impulse communicated to some solid tumour or substance between the hand and the artery, but was conceived by Mr. Burns to be sometimes dependent on a nervous affection of the vessel itself.—(*On the Diseases of the Heart, p.* 263.) Hippocrates, in his book "De Morbis Popularibus," makes mention of three patients affected with extraordinary pulsations in the abdomen. As one of these cases seemed to depend upon obstructed menses, it was probably not the result of any organic disease.—(*Hippocratis Opera Omnia, ex edit. Fæsii. Francof.* 1621, *lib.* 5, *sect.* 7, *p.* 1144.) In order to remove a difficulty in believing how an artery, not affected with aneurismal enlargement, can communicate to the superincumbent parts such movements as are frequently remarked in cases of abdominal pulsations, a fact pointed out by Mr. Hunter should be remembered: in speaking of the actual dilatation of an artery, he says, that when the vessel is "covered by the integuments, the apparent effect is much greater than it really is in the artery itself; for in laying such an artery bare, the nearer we come to it, the less visible is its pulsation; and when laid bare, its motion is hardly to be either felt or seen."—(*Treatise on the Blood, &c. p.* 175, 4*to. Lond.* 1794.) And this observation will apply to all tumours and indurations situated over a large artery. In the epigastric region of a certain patient Taberranus felt not only a pulsation, but a tumour as large as the fist, with all the other usual symptoms of an aneurism. On opening the body after death, he was therefore surprised to find, instead of this disease, a considerable scirrhous tumour in the middle of the mesentery, so closely connected to the large vessels as to compress the aorta, by the pulsations of which it had been lifted up.—(*Obs. Anat. ed.* 2, *No.* 9.)

Dr. Albers quotes an extraordinary case from Tulpius: the patient, a laborious man, but subject to bilious attacks, was sometimes affected with violent throbbings of the spleen. These were not only very painful, but could be heard at a distance, and their number distinctly counted when the hand was applied to the part. What seems almost incredible, it is alleged that Tulpius could hear them at the distance of thirty feet! Their violence increased or diminished according as the patient was more or less bilious, and sometimes they entirely ceased, when his health improved; but always recurred as soon as the chylopoietic organs became disordered again. After the patient's death, permission could not be obtained to open his body.—(*Tulpii Obs. Medicæ, Amst.* 1652, *lib.* 2, *cap.* 28.)

According to Bonetus, pulsations in the left hypochondrium are not unfrequent, and it was his belief that they were produced by the cœliac artery. He cites several cases of this disorder from other writers, the tenour of which is to prove that the cœliac artery and mesenteric vessels must have been affected, as they were found after death dilated and filled with black blood.—(*Sepulchretum Anatomicum, lib.* 1, *sect.* 9. *Obs.* 9, 25, 27, 30, 38, 42, 44, 45, and 46.) The conjecture of Bonetus and others, however, respecting the frequency of abdominal pulsations from dilatation of the cœliac and mesenteric arteries, by no means coincides with the results of modern observations. Mr. Wilson, whose dissections were numerous, met with only one instance of true aneurism affecting any of the branches of the aorta, distributed to the abdominal viscera. This case was an aneurism of the left branch of the hepatic artery.—(*Lectures on the Blood, and on the Anatomy, Physiology, and Surgical Pathology of the Vascular System, &c. p.* 379, 8*vo. Lond.* 1819.) Bontius was present at the opening of an inhabitant of Batavia, who had been afflicted three years with a disease, the exact nature of which could never be made out during life. When the hand was applied above or below the navel, a pulsation was felt like that of the heart or an artery, and as forcible as the motion of a child in the womb. It was synchronous to the pulsation of the heart and arteries. Hence Bontius concluded, that the case was owing to some affection of the heart. The vena cava, instead of containing blood, was filled with a medullary substance, which, pressing against the aorta, is supposed to have excited the extraordinary pulsations in that vessel. The heart was unusually dilated and flabby. The two ventricles were very large, and filled with dark-coloured blood. The liver was of nearly twice its natural size. The gall-bladder resembled that of a bullock, and was filled with viscid bile nearly as thick as an extract.—(*Jacobi Bontii de Medicina Indorum, libri* 4, *Lugd.* 1718, *Obs.* 8, *p.* 101.)

Lewenhoek met with an instance of a similar pulsation, which he imputed to irregular action of the diaphragm, the pulse at the wrist not being affected. The disorder lasted three days, during which the functions of the alimentary canal were so much disordered that the patient was expected to die.—(*Philosoph. Trans. from* 1719 *to* 1733, *abr. by J. Eames, &c. Lond.* 1734, *vol.* 7, *p.* 683.)

Dr. Albers has described the particulars of a case recorded by Burggraf, and entitled "Diuturna, magna, et valde molesta pulsatio in epigastrio."—(*Vid. Acta Natur. Cur. Norimb.* 1740, *vol.* 6, *Obs.* 131.) Burggraf gives his reasons for believing that in this instance, the pulsation arose neither from the aorta nor from the cœliac artery; and suspects that it was caused by a dilatation of that considerable branch of the inferior mesenteric artery, which inosculates with the branch of the superior mesenteric. This idea, however, which was merely surmise, could not be correct, as the patient was cured by taking, every morning and evening, half a drachm of a mass composed of equal parts of gum ammoniac, extr. centaur. minor, and Venice soap.

In an example recorded by Störk, the symptoms were found to have arisen from disease of the pancreas, which weighed thirteen pounds, and contained a large cyst filled with lamellated blood.—(*Annus Medicus, Vindob.* 1760, *p.* 245.)

The subsequent case somewhat analogous to the former, is from a different author.

A man, aged 60, complained of pain in the left side of the abdomen, midway between the umbilicus and crista of the ileum. Emaciation, weakness, distress of countenance, anorexia, constipation succeeded. At length a large pulsating tumour was discovered in the epigastric region. The case was now pronounced aneurism of the abdominal aorta. There was *no nausea nor vomiting*, except that some days before death a quantity of fetid blackish fluid was twice or thrice voided. *No fever.* The swelling caused a sense of constriction rather than pain, and the throbbings became more perceptible. The pulse was feeble, but *slow and regular.* After death, the stomach was found

adhering to the liver, pancreas, and abdomen; and a *cancerous tumour* occupying its internal surface from the duodenum to the insertion of the œsophagus, the coats of the stomach being an inch thick. The surface of the pancreas was also diseased, and the pylorus, situated in the midst of the cancerous mass, was contracted by the thickening of the parietes of the stomach, and obstructed by numerous fungi. The liver was large, but apparently sound; the spleen small. *The aorta, the cœliac trunk, and its branches, were quite natural.*—(See *Journ. de Méd. par Leroux, Oct.* 1815, *and Medico-Chir. Journ. vol.* 1, *p.* 289.)

Morgagni describes the case of a woman 44 years of age, who, after a suppression of the menses for some months, was attacked with palpitations in the epigastrium. Morgagni, on applying his hand to the part, felt a large hard body moving forcibly. At first, it was regarded as an aneurism in the abdomen; but, as there were no similar throbbings in the chest, and there was nothing extraordinary in the pulse at the wrists, Morgagni concluded that the movements in question could not depend upon the heart. Neither did he take the disease for an aneurism, because the throbbings did not correspond to the pulse. As for the large indurated mass, it appeared to him more easy to say what it was not, than what it was: it could not be merely a *globus hystericus*, which never beats like an aneurism. Morgagni considered the case as an hysterical spasmodic complaint, ordered the patient to be bled, and the following day the pulsations ceased.—(*Morgagni, de Sedibus et Causis Morborum, t.* 2, *Epist.* 39. 18.)

Senac has spoken of these abdominal pulsations as occurring in hypochondriacal and chlorotic patients; and, as they frequently subside without leaving any vestige behind, he sets them down as nervous affections.—(*Traité des Mal. du Cœur.*) De Haen had under his care a hypochondriacal patient, affected with pulsations in the abdomen; which, with other complaints, were dispelled by means of brisk opening medicines.—(*Heilungs Methode, übersetzt von Plattner, Leipz.* 1782, *b.* 2, *s.* 29.)

Thilenius observed a flatulence of the stomach, which he represents as having been epidemic, and attended, in some patients, with pulsations at the scrobiculus cordis.—(*Med. Chir. Bemerk. Frankf.* 1789, *s.* 211—217.) My friend Mr. Hodgson, also, in speaking of pulsations in the epigastrium, which are not the consequence of organic disease, and occur in irritable hypochondriac subjects, states his opinion, that, in some instances, these pulsations were a consequence of distention of the stomach with air, which was thrown against the abdominal muscles by the pulsation of the great blood-vessels; and in such cases, the throbbing was diminished by the eructations.—(*On the Diseases of Arteries and Veins, p.* 96.)

Abdominal pulsations are also described by Zuliani, as a symptom of hypochondriasis and hysteria.—(*De Apoplexia, Lips.* 1790, *p.* 79.) They also happen in certain ferbrile diseases.—(*Versuch über den Pemphygus und das Blasenfieber, von C. G. C. Braune, Leipz.* 1795, *s.* 23; and *Dr. R. Jackson on the Fevers of Jamaica, 8vo. Lond.* 1791.)

In a dissertation on cramp in the stomach, Haü remarks, "Quin immo, ubi diutius vexavit gastrodynia, continuos ægrotans persentit spasmos, ut et haud raro pulsationem quandam plane singularem, in cardia et ventriculo, pulsui autem cordis minime synchrone."—(*Diss. de Gastrodynia, Upsal,* 1797.) In the same essay, there is an account of a man, who had violent palpitations in the epigastric region, apparently first excited by the larvæ of the musca pendula, many of which were vomited up.

Pinel is another writer who describes these abdominal pulsations as an occasional symptom of hypochondriasis. "Palpitations du cœur, et quelquefois une sorte de pulsation irréguliere, dans quelque partie de l'abdomen."—(*Nosographie Philosophique, t.* 2, *p.* 25, *Paris, an.* 6.)

Dr. Albers details some cases which fell under his own notice. A young woman, whose menses were upon her, and who had been for some days constipated, was seized with frequent fainting fits and febrile symptoms, occasionally voiding from the bowels a quantity of dark matter, each evacuation of which was followed by a swoon. One morning at five o'clock Dr. Albers was sent for, as it was feared the patient was about to die. She was extremely exhausted, and the fainting fits followed each other with hardly any intervals. She could just say "I feel a throbbing in the belly;" and, when Dr. Albers applied his hand to the part, he felt a violent pulsation extending from the ensiform cartilage down to about the bifurcation of the aorta. The action of the heart was weaker than natural; the pulse at the wrist very small, but not quicker than it had been on the preceding day, and not synchronous to the throbbing in the abdomen. Dr. Albers confesses, that, at first, he took the case for an aneurism. Dr. Meyerhoff was of the same opinion. Another physician, however, Dr. Weinholt, entertained doubts of the complaint being aneurismal, saying, that he recollected having read similar cases in Morgagni. These gentlemen decided to persevere in the employment of opening medicines and clysters, combining opium with the former. Under this plan, the pulsations in the abdomen and tightness of the chest diminished in a few days. The stools were at first of the colour of chocolate, but afterward resumed their natural appearance. The throbbings, in a weakened form, however, were perceptible for six weeks longer. The patient at length got quite well, and was remaining so four years afterward.

A man about 40, severely afflicted with hypochondriasis, great oppression of the chest, constipation, and tension of the abdomen, tendency to fainting, &c., complained to Dr. Albers that he felt as if his heart had fallen down into his belly, where he was annoyed with an incessant throbbing. Indeed, when Dr. Albers examined the abdominal parietes he could feel a very strong pulsation, and, what is curious, could trace it not only along the track of the aorta, but in the course of the left iliac artery. The pulse at the wrist, which was small, frequent, and hard, did not correspond with the abdominal pulsations. For several days the evacuations from the bowels had been as black as pitch. After the employment of gentle purgatives, all the complaints quickly abated, though the throbbings were feebly perceptible for nine months afterward.

The next case which Dr. Albers met with is very interesting. A robust sailor, whose bowels were so constipated, that hardly the strongest purgative could affect them, was seized with constant pain in the left hypochondrium. With this complaint was soon joined great pain in the back, and a sensation as if something alive moved about in the belly from one side to the other, and thence extended up to the neck, followed by the vomiting of a greenish matter. At the same time, he felt in the left side a pulsation which he took for that of the heart, and which continued the whole of his illness. The pulse at the wrist was natural, and synchronous with that in the abdomen. In the beginning of the disorder, the patient was obliged to sit with his body very much inclined forwards, as no other posture could be endured. For the first week opening medicines afforded so much relief, that he was sometimes quite free from pain for six or eight hours. After a time, a round swelling formed in the left hypochondrium, reached to the navel, and attained with incredible quickness the size of a child's head. Indeed, it could now be traced beyond the umbilicus to the right side. The motions were quite of a dark colour, or else red blood and a puriform matter were discharged. Sometimes the blood voided was of a bright red colour, sometimes it was dark, coagulated, and mixed with bile. The patient was at length worn out with febrile symptoms, and died. On opening the body, Dr. Albers found a swelling in the middle of the mesentery, the texture of which cannot be easily described, and the circumference of which was 16 French inches. The stomach was filled with coagulated blood. The spleen, pancreas, and liver were sound; but the gall-bladder was of prodigious size, and contained thick viscid bile. The arteria cœliaca, arteria coronaria ventriculi, and the arteria mesenterica were preternaturally dilated, and full of dark-coloured blood. He speaks of them, however, only as being in an enlarged, not an aneurismal state. Dr. Albers thinks it highly probable, that it was one of these vessels by which the pulsations had been occasioned.

Dr. Albers has also seen these abdominal pulsations in a paralytic female; and in a lunatic, who was afterward seized with apoplexy. He likewise met with a married woman, the mother of several children, in whom these throbbings took place invariably at the commencement of pregnancy, and were a surer sign

of this state, than other common effects, as stoppage of the menses, &c. After the third month, however, they used to cease altogether.

Many valuable practical observations on cases attended with hemorrhages from the intestinal canal, my limits here oblige me to pass over. According to Dr. Albers, hemorrhoidal patients, especially when put to inconvenience by compression of the tumours, often complain of throbbings about the spleen, which are plain even to the hand.—(*J. F. Albers, über Pulsationen im Unterleibe*, 8vo. *Bremen*, 1803.)

Dr. Parry makes a few interesting remarks on such abdominal pulsations as excite suspicion of aneurism. In any persons not very fat, and lying upon their backs, he says, the pulse of the aorta can easily be felt, if strong pressure be made a little to the left of the median line, about half way between the navel and scrobiculus cordis. In certain instances, the pulsation is painfully felt by the patient himself. In many cases of this kind, particularly in nervous individuals, the sense of pulsation is merely the effect of preternatural action of the heart. While, in other examples, it is the effect of the pressure of some hard substance upon the descending aorta, determining a disproportionate quantity of blood to the head, "and giving to the hand placed on the abdomen, and sometimes even to the eye, the appearance of a beating so near the surface, as to lead inexperienced observers to conclude, that the aorta is morbidly dilated." According to Dr. Parry, the most common causes are collections of feces in the colon, requiring repeated and active purgatives, which must bring away almost incredible discharges of stercoraceous matter before the aortal pulsation subsides.—(See *Parry's Elements of Pathology*, &c. and the *Medico-Chir. Journ. and Review*, *vol.* 1, *p.* 157.)

Another cause of a temporary appearance of pulsation or movement in the abdomen, not mentioned by any of the preceding authors, is the power which some persons have of putting portions of the recti muscles separately into strong convulsive action. I have seen a large abcess of the loins attended with distinct and forcible pulsations, corresponding to those of the aorta.

According to Mr. Allan Burns, a beating is generally felt about the pit of the stomach, in the advanced stage of chronic inflammation of the heart: in this case, when the pericardium is closely adherent to the latter organ, it is corrugated at every contraction of the ventricles, and the diaphragm and liver are elevated. The ventricle, however, having completely emptied itself, is again distended, and, in proportion to the degree of dilatation, the liver and diaphragm descend, whereby an impulse is communicated in the epigastric region.—(*On Diseases of the Heart*, *p.* 263.) This valuable writer cites the remark of Morgagni (*Epist.* 17, *art.* 28), that sometimes, in dilatation of the heart, this organ descends so far as to push the diaphragm into the hypochondrium, and pulsate in that situation, so that the disease is mistaken for an aneurism of the cœliac artery. In Mr. Burns's work, a memorable case of this description is related. An erroneous judgment is the more likely to be formed in such examples, because the pulsations of the heart and tumour are not exactly simultaneous; for it is not the heart which is felt directly beating, but the liver, which, by the action of the heart, is thrown forwards. Hence the palpable interval between the stroke of the heart and the movement of the liver.

The following fact shows how circumspect a practitioner should be in the prognosis. An anonymous writer informs us, that he attended a gentleman, in consultation with an eminent surgeon and lecturer on anatomy, where the most distressing palpitations of the heart, and loud pulsations below the epigastrium, were awful symptoms. The pulsations could be both seen and heard at a distance on entering the room in which the patient sat. Several physicians were inclined to suspect some organic lesion of the arterial system; but their opinion was given with becoming diffidence:—not so the surgeon's; his impression was, that there existed *an aneurism of the descending aorta*; and such was the firm persuasion he had acquired of the reality of his impression, that he could grasp the aneurismal sac through the abdominal coverings, though nobody else could, and trace its magnitude and position. After death, the heart was found enlarged, and its left ventricle of enormous size. The inner surface of the stomach also exhibited traces of long existing disease; but the aorta was quite sound.—(See *Med. Intelligencer*, 1821, *p.* 71.)

Preternatural pulsation about the epigastrium is also stated by Mr. A. Burns to be sometimes occasioned by encysted tumours, attached either to the lower surface of the diaphragm, or formed between the layers of the pericardium towards the diaphragm, as happened in an instance recorded by Lancisi.

Another cause specified by Mr. A. Burns, is enlargement of the vena cava, or of the right auricle of the heart. Senac describes a case in which the vena cava was as large as the arm, and there had been a violent pulsation in the epigastrium.

The next cause enumerated by the same gentleman is increased solidity of the lungs, more especially of their lower acute margins, where they overlap the pericardium. In this case the pulsation is about the scrobiculus cordis.

Mr. A. Burns likewise notices several other causes of epigastric or abdominal pulsations, already illustrated in the foregoing part of this article, indurations of the pancreas, scirrhus of the pylorus, tumours in the mesentery, or any solid increase of substance about the abdominal aorta, or its principal branches; and, lastly, a peculiar affection of the vascular system itself.

The following observations on the criteria between various abdominal pulsations and those of aneurism, appear interesting.

According to Dr. Albers, an internal aneurism originates gradually, and the pulsations increase in strength by degrees. Other abdominal pulsations, on the contrary, begin suddenly, and are most violent in the beginning, abating after they have lasted some time

In an aneurism, the pulsation is synchronous with the stroke of the artery at the wrist; but this is not regularly the case with other pulsations.

Should the patient be affected with melancholia, hypochondriasis, hysteria, or other nervous complaints, void blood from the stomach, or a black matter from the bowels; should there be any hardness or swelling of any of the abdominal viscera discoverable by the touch, the probability is, that the pulsations are not owing to an internal aneurism.

With the exception of cases in which these pulsations are owing to mechanical impediments to the circulation, Dr. Albers believes, that they are mostly a symptom of some nervous affection. He also thinks, that the surprise excited by these throbbings arises only from their strength and situation, other analogous strong pulsations, as, for instance, those of the heart, or of the carotids being common enough in hypochondriacal and hysterical persons. The same gentleman adverts to the increased action, which, in inflammation and fevers, is often more conspicuous in some parts of the sanguiferous system, than in others.—(*Uber Pulsationen im Unterleibe*, *p.* 36, &c. *Bremen*, 8vo. 1803.) Much important additional information on this subject may be found in *Observations on some of the most frequent and important Diseases of the Heart; on Aneurism of the Thoracic Aorta; on Preternatural Pulsation in the Epigastric Region*, &c. *By Allan Burns*, *p.* 262, &c. 8vo. *Edinb.* 1809.

ABSCESS. A tumour containing pus, or a collection of purulent matter.

Abscesses are divided into two principal kinds, viz. *acute* and *chronic*. For information relative to the former, see *Suppuration*; and for that concerning the latter, refer to *Lumbar Abscess*. See also *Abdomen*, *Antrum*, *Anus Abscesses of*, *Bubo*, *Empyema*, *Hypopium*, *Mammary Abscess*, *Whitlow*, &c.

ABSORPTION. That nature has fully provided for the due execution of this important function, is a truth of which no doubt is entertained: it must be immediately manifest to every person who reflects upon the mutation which is continually taking place in the particles of every texture of the animal body; upon the gradual and harmonious removal of the old matter in proportion as the new is deposited by the secerning arteries; or upon the impossibility of accounting for the changes produced by growth in the size and figure of different organs, and, indeed, of the whole body, without constantly bringing into the explanation this interesting process, of which numerous and even the most essential particulars, it is true, yet remain obscure. But, besides these considerations in proof of absorption, many others must strike the con-

templative physiologist. By the action of the secreting and exhalent arteries, the whole mass of blood would soon be so lessened that life would unavoidable cease, if the sanguiferous system were not duly replenished in some way or another. The undiminished quantity of blood in the circulation, notwithstanding the constant deductions from it by secretion and exhalation; the regular fulness of the blood-vessels, notwithstanding the incessant drain from them; and the constant supply of materials for the numerous secretions; all imply the existence of a certain function, one principal design of which is to counteract the effect which, without it, would be rapidly and fatally produced upon the quantity of blood in the system. As M. Magendie observes, whenever any substance in the form of a liquid, gas, or vapour, is put, for a certain time, in immediate contact with an external or internal surface of the body, it is *absorbed*; that is to say, it passes into the blood-vessels, mixes with the blood, circulates with it, and thus occasions either salutary or noxious effects upon the system. This is particularly exemplified in the action of certain poisons; a drop of pure hydrocyanic acid, put on a dog's tongue, causes the animal's death in a few seconds, in consequence of being transmitted with the blood to the brain. Food, drink, medicines, and even air itself, only become useful to us, after having been absorbed. Many diseases, some of a very dangerous nature, are contracted by absorption. In fact our existence is so inseparably connected with this function, that the suspension of it for an instant would produce almost immediate death.—(See *Journ. de Physiol. Expérim. t.* 1, *p.* 1.)

The office of the absorbents, as a modern writer has remarked, is literally expressed by their name; it consists in receiving or taking up certain substances, and in transporting them from one part of the body to another. The substances which are thus taken up, are of two kinds, the chyle and the lymph; the former being received by the lacteals, and the latter by the lymphatics. The immediate object of the action of the two sets of vessels, he observes, is also essentially different; that of the first being to convey a fluid from the part where it is formed into the blood, in order that it may directly serve for the nutrition of the body; the latter serving, n the first instance, to remove what is useless or noxious, and to dispose of it in such a manner, that it may either be applied to some secondary purpose of utility, or be finally discharged from the system.—(*Bostock, in Elem. Syst. of Physiology, vol.* 2, *p.* 551.)

The uses of the absorbent system are far more numerous than would at first be supposed by a person only superficially acquainted with physiology and the phenomena of disease. If we wish to have a just comprehension of all the various purposes which this system fulfils in the animal economy, we must take the same enlarged view of the subject as Mr. Hunter did. We must contemplate all the modifications of absorption, and its effects both in health and disease, in the nutrition and growth of the body, as well as in its emaciation, or atrophy, and the diminution, or even total removal, of parts of it, become diseased or useless.

First, According to Mr. Hunter's explanation, the absorbents take up extraneous matter, in which is included nourishment.—(*On the Blood, &c. p.* 439.) By extraneous matter we are here to understand matter not originally contained within any texture of the body, not constituting any part of its natural structure, but introduced from without. Thus the absorption of mercury, arsenical paint, cantharides, and other substances applied to the skin, furnishes examples of the absorption of extraneous matter, which are also illustrated by the effects of the venereal, variolous, vaccine, and several other poisons. Sometimes the passage of the poison into the system and its pernicious operation, happen so rapidly, that suspicions are entertained that it must have a shorter track into the circulation than through the lymphatic vessels, their glands, and trunks. This has been suspected to be the case when animals are killed with hydrocyanic acid, the nux vomica, the poison of certain snakes, the upas tiente, &c. How far this opinion is true will be hereafter considered. Such is the rapidity with which the poisons of upas tiente, nux vomica, and St. Ignatius's bean are absorbed and carried into the sanguiferous system, that in twenty seconds after being put into the cavity of the peritoneum, their action reaches the spinal marrow.—(See *Magendie's Journ. de Physioli Expérim. t.* 1, *p.* 18.)

Secondly, As Mr. Hunter has noticed, the absorbents take up superfluous and extravasated matter, whether natural or diseased. Thus, the removal of the old particles of the body, after they have become unfit to continue longer in their respective situations and textures, —an action that is reciprocal with the deposition of new matter by the secerning arteries; and the incessant regulation of the quantity of serous fluid in the cavities of the abdomen, chest, pericardium, and tunica vaginalis, so that, though the arteries unremittingly secrete this fluid, the absorbents prevent its redundant accumulation, and combine with the blood-vessels in maintaining a continual renovation of it; are examples of the absorption of natural but superfluous matter. On the contrary, the dispersion of extravasated blood, of the fluid of ascites and anasarca, of coagulating lymph, or air, effused in the cellular tissue; and of an infinite number and variety of swellings and thickenings of parts; are instances of what Mr. Hunter has termed the absorption of superfluous diseased matter, or, as I should say, of superfluous matter from disease.

Thirdly, Mr. Hunter enumerates the absorption of the fat. No doubt can exist respecting the continual change which is taking place in the quantity of adipose matter in the body, according to the state of the health, the degree of exercise, fatigue, or labour to which the body is exposed, a disturbed or undisturbed condition of the mind, and the effects of different kinds of regimen and diet on the whole system. Perhaps it may be inquired why Mr. Hunter should distinguish this absorption from that of other superfluous matter in the body. The reason does not appear in his writings; unless we receive as such the observation, that he did not consider the fat and earth of bones as true animal substances, as they have no action within themselves and no principle of life. However, this would not be very consistent, because other superfluous matter, comprised in the second classification, especially the fluid secreted by serous membranes, and the fluid of anasarca, are likewise quite destitute of the living principle. At the same time, I admit that the absorption of the fat may be entitled to distinct consideration on other grounds; for sometimes its absorption seems to be retarded in a much greater degree than that of other substances in the body; or at all events its absorption does not keep pace with that of its secretion, so that, although the muscles and other organs remain of their usual bulk, the fat may acquire the thickness of several inches. On the other hand, the absorbents sometimes act upon it with a quickness that does not always extend at the same time to other parts of the body. Thus in fever nearly all the fat may be absorbed in the course of a few days; yet the size of the muscles may have undergone but little reduction.

Fourthly, Mr. Hunter enumerates the species of absorption by which a waste of parts is produced, and in consequence of which the muscles become smaller, the bones lighter, &c. These cases we find exemplified in the ordinary course of nature; for in old age such changes happen in the bones and muscles, and also in other organs like the absorbent glands, which become so diminished, that some writers erroneously assert that they entirely disappear. Whenever the action of a muscle is long prevented by disease of a joint, a fractured bone, or other causes, it always dwindles away in a greater or less degree, and the limb compared with the sound one will be found to be considerably reduced. The absorption of the fat, by which the bulk of parts is also lessened under various circumstances of disease, I believe is not generally restricted to a particular limb or part, like the absorption which affects the muscles in similar cases. Thus, when a patient becomes hectic from disease of the hip-joint, the muscles of the thigh and leg on the same side as the disease undergo a remarkable diminution of their bulk, while those of the sound limb are little or not at all altered; but the fat of the whole body is rapidly absorbed, and the greatest universal emaciation prevails.

Before the period of Mr. Hunter's inquiries, the knowledge of all the different purposes of absorption, by whatever organs it was supposed to be performed, whether by lymphatics or veins, was certainly very limited in comparison with the more extensive in-

formation which now prevails, and which is in a great measure the fruit of his industrious researches. Speaking of the absorbent vessels, which he considered, with the generality of modern physiologists, as the true instruments of absorption, he says: "From a farther knowledge of these vessels we shall find that they are of much more consequence in the body than has been imagined, and that they are often taking down what the arteries have built up; removing whole organs, becoming modellers of the form of the body in its growth; and removing many diseased and dead parts, which are beyond the power of cure."

As these vessels are productive of a great variety of changes in the animal economy, which are very dissimilar in their intention and effect, Mr. Hunter considered them in two general points of view: first, as they absorb matter, which is not any part of the body itself; secondly, as they absorb the body itself. The first of these uses, the absorption of matter which is no part of the machine, he observes, is well known, and of two kinds; first, that of exterior matter, comprising every thing applied to the skin, and also the chyle; the other interior, comprehending that of many of the secretions, the fat, the earth of bone, &c. These kinds of absorption take place principally for the nourishment of the body; but they also answer other purposes, and are very extensive; for, besides their salutary effects, they are frequently the cause of disease in a thousand forms.

In the second of the above-mentioned views, Mr. Hunter considers the absorbents as removing parts of the body itself, and here he again views them in two lights. The first is where only a wasting is produced in the whole body or some particular part of it; to which mode of absorption he applies the epithet *interstitial*, because it consists in the removal of particles of the body out of the insterstices of parts which yet remain, and still form a perfect whole. This kind of absorption, Mr. Hunter says, has always been admitted or supposed, whether performed by the veins or lymphatics. It is often carried farther than the mere wasting of the part; for it may proceed till not a vestige of such part is left, as is sometimes exemplified in the total decay of a testicle. *Interstitial absorption*, therefore, may be understood in two senses.

The second view taken by Mr. Hunter embraces that kind of absorption by which whole parts of the body are removed, and which is sometimes a natural, sometimes a diseased, process. It is a view of which he particularly claims the discovery. In the natural process, he says, the absorbents are to be considered as the modellers of the original construction of the body. No alteration can take place in the original formation of many of the parts, either in the natural growth or the formation arising from disease, without the action of the absorbents, which always have a considerable share in the production of the changes. This he terms *modelling absorption*, the principle of which is as extensive as any in the animal economy. Bones and numerous other parts cannot be formed without it. A part which is of use in one stage of life, but becomes quite useless in another, is thus removed, as is exemplified in the thymus gland, the ductus arteriosus, and the membrana pupillaris. In some cases the absorption of whole parts in consequence of disease leads to dissimilar effects; one is a sore or ulcer; and Mr. Hunter therefore calls the process by which it is produced, *ulcerative absorption*. In other cases no ulcer is caused, although whole parts are removed. Both these forms of absorption, he thinks, might be named *progressive*.

The removal of a whole solid part of the body, or as Mr. Hunter expresses it, "that power which the animal economy has of taking a part of itself into the circulation, by means of the absorbent vessels, whenever it is necessary," is unquestionably one of the most curious facts which can present themselves to the notice of the physiological inquirer. In Mr. Hunter's time the doctrine was a new one; but he informs us, that he had long been able to demonstrate its truth, and that he received the first hints of it from the waste of the sockets of the teeth and of their fangs at the period of their being shed.

"It may be difficult at first to conceive how a part of the body can be removed by itself; but it is just as difficult to conceive how the body can form itself;" yet they are both equally facts. Without dwelling on the exact mode in which such changes happen, he gives it as his belief, that "whenever any solid part of our bodies undergoes a diminution, or is broken in upon, in consequence of any disease, it is the absorbing system which does it.

"When it becomes necessary, that some whole living part should be removed, it is evident that nature, in order to effect this, must not only confer a new activity on the absorbents, but must throw the part to be absorbed into such a state as to yield to this operation."—(See *Hunter on the Blood, &c. p.* 439—442.) For an account of *ulcerative absorption*, vide *Ulceration.*

With regard to the difficulty which there may be in conceiving how such small tubes as the lymphatics can take up solid substances, Bichat points out that the distinction between the solids and the fluids can only be said to prevail when they form a mass; but that when reference is made to their separate particles, they do not differ from each other. This, he says, is so perfectly true, that the very same particle will alternately enter into the composition of a solid and a fluid, just as the elements of water are the same, whether it be in the liquid or frozen state. Now as the absorption of solid substances takes place by the removal of these separate particles or atoms, no greater difficulty can present itself in understanding how this may be effected than in conceiving how fluids may be absorbed. —(See *Anat. Gén. t.* 2, *p.* 92.)

I come now to a very difficult question, and one that has hitherto received no satisfactory answer; not because the subject has not been earnestly, deeply, and ably considered, but because its difficulties and obscurity seem to defy all successful investigation: the question here referred to, is, On what principle and by what power are the lymphatics, *supposing them to be absorbent vessels*, enabled not only to take up the old particles of various organs and different fluids secreted in different textures and cavities, but to convey them frequently with considerable velocity and through a long tract, intercepted also by those complicated organs, the absorbent glands, into the venous system near the heart? In other words, what is their mode of action? As Mr. Hunter has observed, the principle of capillary tubes was at first the most general idea, because it was familiar one; but this is too confined a principle; nor will it account for every kind of absorption. Capillary tubes can only attract fluids; but as solids were often absorbed, such as firm tumours, coagulated blood, the earth of bones, &c., the advocates for this hypothesis were compelled to suppose the existence of a solvent. "This may or may not be true; it is one of those hypotheses that can never be proved or disproved, and may for ever rest upon opinion." But Mr. Hunter's conception of this matter was, that nature leaves as little as possible to chance, and that the whole operation of absorption is performed by an action in the mouths of the absorbents; but even under the idea of capillary tubes, physiologists were still obliged to have recourse to the action of those vessels to carry the lymph along after it had been absorbed; and they might as well therefore have extended this action to the mouths of the vessels.—(*On the Blood, &c. p.* 443.)

The question still continues without satisfactory answer, whether Hunter's language be adopted, and we say that absorption is effected by an action of the lymphatics and their orifices; or whether we employ the language of Bichat, and ascribe the performance of the functions of these vessels, and the circulation of the fluid in them, to what he ingeniously (but not much to the edification of his readers) calls *organic sensibility* and *insensible organic contractility*. This imagined kind of sensibility confers upon every absorbent vessel a power of feeling quite unconnected with the brain, by which it is presumed to be sensible of the presence of matter fit for removal, which is then imbibed and conveyed along the tube by the insensible organic contractility, by which is signified a power of contraction, not admitting of demonstration, not excitable by stimulation or irritation, but inferred to take place in some inexplicable manner, chiefly because the fluid in the absorbents is known to be constantly in motion, and always flowing towards the thoracic duct. In fact, Bichat's explanation is merely a reference to two principles, which are themselves hypothetical, and more calculated to amuse a playful fancy than to satisfy a sound judgment. Organic sensibility, and insensible organic contractility, he observes, are the

more remarkable in the absorbent system, as they survive for a certain time death itself. A fluid, injected while the animal retains some degree of heat, is absorbed both on serous and mucous surfaces, and also in the cellular tissue, though with less freedom. This power of absorption after death, he says, may even be lengthened by keeping up artificial heat by means of a bath, though the plan is less efficacious than he at first supposed, vital heat seeming to be essential.—(*Anat. Gén. t.* 2, *p.* 117.) All these observations, however, merely amount to a recital of the facts, that absorption may proceed for a short time after death (never later than two hours from this event, *p.* 118), and that it is promoted by artificial heat; but how, or by what exact mechanism it is accomplished, is not revealed to us.

The lymphatics are not regarded by Bichat as endued either with what he terms *animal sensibility*, or with *animal contractility*. His proof of the first of these statements is, that when a lacteal vessel, full of chyle, a lymphatic filled with serosity on the surface of the liver, or even the thoracic duct, is punctured, the animal betrays no mark of pain. But the little faith which he himself put in the doctrine, may be conceived from the question to which it leads him, namely, what inference can be drawn from a circumstance where, in consequence of the belly being laid open, the many agonies produced would comparatively annihilate any slight sensation, even were it to exist! He also adverts to the acute sensibility of the absorbent vessels in their inflamed state.—(*P.* 115, *t.* 2.)

Hunter admitted a vital contractile property in the lymphatics, or, as Bichat would express it, sensible organic contractility. The former adopted this belief, because those vessels readily empty themselves of the chyle that is pervading them, and contract when sulphuric acid is applied to them. On the other hand, Bichat argues, that sulphuric acid, like every other concentrated acid, and also heat, produce the same effect upon all animal substances, even after death, namely, a shrinking of them. When the absorbents, and particularly the thoracic duct, are touched with the point of a knife, they do not contract. If they are capable of contraction, Bichat maintains that it is when they cease to be distended, and not when they are irritated; consequently, it appears to him to be by virtue of their contractility of tissue. The opinion at which he finally arrives is, that sensible organic contractility in them is at all events doubtful, and that, if it exist, it is very obscure, and at most not greater than that of the dartos.—(*T.* 2, *p.* 117.)

This last inference, and, indeed, the whole of Bichat's doctrine respecting the non-existence of sensible organic contractility in the absorbent vessels, are very difficult to reconcile with certain observations made by himself, in other parts of his work. Thus, he informs his readers (*t.* 2, *p.* 95), that he had frequently noticed in living animals, especially in dogs, manifest expansions in the course of a lymphatic, and containing a limpid fluid. These appearances were mostly met with on the concave surface of the liver, and on the gall-bladder. When the dilated portions of the vessel were pricked with a lancet, the fluid ran out, and they immediately disappeared. "*On another occasion, I saw two or three of these small dilatations on the gall-bladder, and having then let the liver descend while I examined the bowels, I was much astonished the next instant at not being able to find them again; no doubt* (says he) *the contraction of the vessel had made them disappear.*" He adds, that the liver is the organ on which these vessels can be best seen in living animals; but *its concave surface must be looked at the instant the belly is opened, for the contact of air, by making them contract, soon hinders them from being distinguished.*—(*See Anat. Gén. t.* 2, *p.* 95, 96.) And in another place he says, "in dropsies where the absorbents are full, if the skin be lifted up, they may easily be distinguished by their transparency; but very soon, notwithstanding their valves, they empty themselves, and can no longer be discerned with the eye."—(*P.* 108.)

The fact of the absorbents expelling more or less of their contents, when they have been punctured, might be very well ascribed to what Bichat calls *contractility of tissue*, or even to *elasticity*; but, the propulsion of the fluid from a dilated portion of an unwounded lymphatic into another portion of the same vessel, certainly does not admit of the same explanation. The valves may determine the direction which such fluid must follow, if it move at all; the anastomoses may facilitate the passage of it; and contractility of tissue, or elasticity, may have an auxiliary effect; but its first motion can only be accounted for by supposing either that there is an impelling power in the vessels themselves, or in some organ or organs with which they are connected; or else that their contents are set in motion by external pressure, the swell of muscles in action, or the pulsation of neighbouring arteries. Now, in some of the cases mentioned by Bichat, no doubt can be entertained that the impelling power was in the lymphatics themselves, because he distinctly adverts to the contraction so speedily excited in them by exposure to the air, that the concave surface of the liver must be looked at immediately on the animal's belly being opened, or else they will not be distinguished.

Dr. Bostock conceives, that "an attraction exists between the mouths of the lacteals and the chyle, which seems to be analogous to, or identical with, the elective attraction, which unites different chemical substances;" and "that the lacteals, as well at their extremities as through their whole extent, are possessed of contractility, by which the fluids, when they have once entered, are propelled along them; an effect which is probably promoted by the pressure of the neighbouring parts, while the numerous valves with which they are furnished prevent the retrograde motion of their contents."—(*Elem. Syst. of Physiol. vol.* 2, *p.* 580.) The principle on which the lacteals imbibe the chyle can scarcely be referred to any thing so fixed and determinate as chemical attraction, or so independent of life. On the contrary, the absorption of chyle from the bowels may be looked upon as a process liable to be accelerated, or retarded, by various states of the constitution, habits of life, and different affections of the mind. If it were a chemical operation, and the abundance of chyle happened to exist on the villous coat of the small intestines, at the period of any sudden death, the process would be expected to go on as long as that fluid and the villi remained in contact; yet we have no proof of this being the case: indeed I cannot comprehend any similarity between elective attraction and the absorption of chyle; the former being an operation in which the action of vessels or their orifices, and the influence of life, are considerations totally separated from the subject; whereas, in the latter, they form in reality the main topics of inquiry. Elective attraction, however, may only be intended as a comparison applicable to the disposition which the lacteals have to take up certain substances, but to reject others: though, even in this sense, the comparison would be very imperfect.

Dr. Bostock's opinion is probably true, that an elucidation of the action of the lymphatics must be attended with even greater difficulty, than what presents itself to the inquiry into the principle on which the chyle is taken up and conveyed into the system. The increased difficulty chiefly proceeds from our having no positive information respecting the extremities of the lymphatic vessels, or the mode in which their contents are first received; "for there is reason to suppose that the transmission of the fluids themselves is conducted upon the same plan with that of the lacteals." As the same author remarks, we do not know where the mouths of the lymphatics are situated; with what parts they are connected; how they are brought into contact with the substances which they receive; nor by what power they are enabled to take them up.—(*Vol.* 1, *p.* 582.)

The source of the lymph is also less certain than that of the chyle; for, even at the present day, M. Magendie, influenced by the possibility of injecting the lymphatics from the arteries, and by the uniform nature of the lymph, and its analogy to the blood, professes a belief, which was common many years ago, that it is not formed by the decomposition of the old particles of the body, nor by fluids absorbed from various surfaces; but that it is composed of the thinner parts of the blood, which, instead of returning by the veins to the heart, pass into the lymphatics, and are conveyed to that organ through the thoracic duct. The lacteals certainly have little disposition to take up any thing but chyle; but, as Dr. Bostock has explained, "the lymphatics are capable of absorbing a great variety of substances, differing from each other most

widely in their nature, so that it would almost appear as if, by a certain mode of application, any substance might be forced into them. Nor (says Dr. Bostock) is this conclusion affected by the hypothesis of M. Magendie; for, although we might agree with him in supposing that in the ordinary operations of the system, the veins are the principal, or even the sole instruments in removing the materials of which the body is composed, yet we have unequivocal evidence, that when certain poisonous or medicinal agents are applied to their extremities, they may be received or forced into them, and conveyed into the circulation. The case of metallic or other medicinal substances that are taken up by the lymphatics, may appear to be less difficult to explain, because the absorption is generally produced by friction, or some mechanical process, which may be supposed to force the substance into the mouths of the vessels, or to produce an erosion of the epidermis, which may enable the substances to come into more immediate contact with the mouths of the vessels. We may also imagine that when the component parts of the body are brought into close approximation with their capillary extremities, they are then taken up in the same way that the chyle is absorbed from the intestines."—(*Elem. Syst. of Physiol. vol.* 2, *p.* 583.) For my own part, I believe, that if the modern doctrine of absorption can be effectually defended and retained, the general presence of the orifices of the lymphatics at every point of the variously organized textures of the body must be received as one of its leading principles. Many physiologists have little difficulty in conceiving how fluids can be taken up by the lymphatics, but rather stagger at the notion of this being also the case with the hardest solids. Others, however, accommodate their creed to both hypotheses, reconciling themselves to them by the argument that, if the minute capillary arteries can secrete this dense, hard matter, the small lymphatics can remove it. One example is not more difficult to comprehend than the other. Yet, such reasoning throws little light on the questions, how are the solids prepared for absorption, and in what manner are they taken up? These in fact remain completely unanswered.

"What (inquires a judicious physiologist) are we to conceive of the intimate nature of this operation? If solution of the substance be necessary, we are at a loss to find a proper solvent; many of the substances are insoluble in water, or in the serous fluid which is found in the vessels; while, on the other hand, it is perhaps not easy to conceive how the substances can be absorbed without being previously dissolved, and still more so, how the solids can have their texture broken down, and enter the vessels, particle by particle, as it were, and be suspended in the lymph in a state of extreme communition?" As I have already mentioned, these difficulties some physiologists, including Bichat, endeavour to diminish by arguing that the lymphatics must be supposed to act only upon the elements of every texture, and that, on this principle, the absorption of solids is as readily intelligible as that of fluids, the same elements frequently contributing to the composition of both. However, it must be acknowledged, that all this kind of reasoning is entirely visionary.

It is conjectured, that while parts retain the vital principle, they are capable of resisting the action of the absorbents. According to Dr. Bostock, dead matter is more easily acted upon by the absorbents than living; and, in fact, "no part can be absorbed until its texture is destroyed, and, consequently, until it is deprived of life. No substance can possibly enter the absorbents, while it retains its aggregation, so that it necessarily follows, that the preliminary step to the absorption of the body is its decomposition."—(*Elem. Syst. of Physiol. vol.* 2, *p.* 585.) He afterward explains, that by the death of a part preceding its absorption, is here signified only, "that it is no longer under the influence of arterial action. It therefore ceases to receive the supply of matter which is essential to the support of all vital (living!) parts, and the process of decomposition necessarily commences." To me a better account of the subject appears to be that which, dismissing all metaphysical and chemical reflections upon the supposed death and decomposition of parts, previously to their absorption, represents the absorbents as acting directly upon the individual atoms, particles, or elements of the various textures. We know nothing about the vitality of these atoms, or elements, in their separate capacity; supposing them to possess it, we know nothing of the moment when they part with it previously to their entrance into the absorbent system, just as we are completely ignorant both of the manner in which such elementary materials acquire the vital principle, and of the exact moment when they become thus endued.

With regard to the lymphatic glands, their use is not precisely known, though various conjectures have been offered concerning it. As Dr. Bostock observes, we may presume that they serve an important purpose, from the circumstance of every absorbent vessel, in some part of its course, passing through one or more of these glands, as was first remarked by Nuck.

Mr. Hewson in one subject injected the lymphatic vessels from the groin to the neck, without filling any lymphatic gland, so as to prove a fact which, he says, is contradictory to the received opinion, that such vessels always pass through glands in their way to the blood-vessels. He found, with regard to the abdomen, the observation not strictly true, as, besides the lymphatic vessels which enter glands, there are others which escape them. He declares, that some of the lacteals in the mesentery do not pass into glands.—(*Exp. Inq. vol.* 2, *p.* 44, *vol.* 3, *p.* 54.) On the other hand, Mascagni, in his numerous injections, never met with the circumstance (*Vas. Lymph. Hist. pt.* 1, *sect.* 4, *p.* 25); and Dr. Bostock refers us to Gordon's Anat. p. 74, in confirmation of the rarity of such an arrangement.—(*Elem. Syst. of Physiol. vol.* 2, *p.* 548.)

The fact of every lymphatic vessel commonly entering a gland in some part of its course, seems to Dr. Bostock to warrant the inference, that some important change is effected in the chyle and lymph by means of the lymphatic glands. "But (says he) the same mode of reasoning might lead us to conclude, that although the absorbent glands are necessary to the existence of the higher orders of animals, they are not so for the purposes of nutrition and growth generally, as it appears that there are large classes of animals, which resemble the mammalia in many of their nutritive functions, and in the vascular part of the absorbents, which are without any lymphatic glands, or are very sparingly furnished with them. It is not easy to point out any circumstances that belong exclusively to the mammalia, which can assist us in explaining the necessity for these appendages to their lymphatic system."—(*Vol.* 1, *p.* 554.)

Malpighi fancied that the lymphatic glands had a muscular covering, which enabled them to act as organs for propelling the lymph from their cells into the vasa efferentia, and thence towards the thoracic duct, so that they were, according to his notions, like so many little hearts distributed through the system. This hypothesis, which is contradicted by anatomy, receives no confirmation from observation in the living animal. If it were true, we should expect to find the cells larger, and not so minute as to render even their existence in the human absorbent glands a questionable point; some pulsating movement, gentle or strong, would be perceptible in the situation of every superficial gland; or, if the contraction were of a slower kind, the gland would sometimes be enlarged, and sometimes considerably reduced. Yet none of these circumstances prevail. It is likewise to be remembered, that no jet of fluid takes place from the vasa efferentia when they are cut, as they frequently are in surgical operations.

It is also to be taken into consideration that fishes are destitute of lymphatic glands (*see Blumenbach's Comparative Anat. by Lawrence, p.* 256); yet the fluid in their lymphatic vessels must be presumed to have its due degree of motion. In the mesentery of a turtle, no glands are observable; still, "in this animal, nature does her business as well, though the apparatus is differently constructed."—(*Hewson's Exp. Inq. vol.* 3, *p.* 60.)

Malpighi's hypothesis is, therefore, decidedly untenable; and whatever difficulty we may feel in agreeing with Bichat, that the absorbent vessels are destitute of animal contractility, we can have no hesitation in adopting this conclusion with respect to the absorbent glands, considered as entire organs, without any reference to the nature of the congeries of lymphatics within them.

The existence of a white thick fluid in the lymphatic

glands was noticed by Haller in the following terms: "Succum glandulis conglobatis inesse, album, serosum, lacte tenuiorem, in juniori potissimum animali conspicuum, id quidem certum est. Eum cremori similem dixit Thomas Wharton, cinerum Malpighius, diaphanum Nuckius, album Morgagnius, recte et ad naturam, ut puto omnes.—(*Elem. Physiol. t.* 1, *p.* 184.)

According to Hewson, the fluid formed in the lymphatic glands, if diluted with a solution of Glauber's salts in water, or with the serum of the blood, and viewed with a lens of one twenty-third of an inch focus, presents numberless small white solid particles, resembling in size and shape the central particles found in the vesicles of the blood.—(*Exper. Inq. vol.* 3, *p.* 67.)

The supposition of Ruysch and Nuck (adopted also by Haller) that one use of the lymphatic glands is to produce a fluid for the dilution of the lymph, is destitute of proof, inasmuch as the lymph is not known to be thinner after its egress from, than previously to its entrance into, a gland; and one notion sometimes promulgated is, that it is thicker. The investigations of Dr. Prout certainly show, that it contains a larger quantity of albumen and fibrine in proportion to its vicinity to the subclavian vein.—(See *Thomson's Annals of Philosophy*, 1819.) According to Mr. Wilson, the absorbent glands contain numerous arteries; and, in a horse, this vascularity gives to the inner lining of the cells the usual appearance of a secreting membrane; but whether it does actually secrete, or what it secretes, we have no means of thoroughly knowing.—(*On the Blood and Vascular System*, *p.* 209.) The appearance of the lining of the cells of the lymphatic glands of the whale, is in favour of the opinion, that some secretion takes place from it, as an addition to the lymph.—(See *Abernethy's Obs. in Philos. Trans.* 1796, *pt.* 1.) Other speculators imagined, that the absorbent glands were like so many filters, through which the lymph, or chyle, was strained. Another idea was, that they drew some crude liquid from the nerves and returned it to the blood.—(*Glisson, de Hepate*, *p.* 439.) As to the conglobate glands, they were also sometimes contrasted with the conglomerate, and represented as organs for making good the loss produced in the sanguiferous system by the secretions from the latter. Another suggestion was, that their office was to form the central particles of the globules of the blood. But, as Mr. Wilson justly observed, all these opinions are merely suppositions, without a shadow of proof.

Dr. Bostock considers it most probable either that these glands are proper secreting organs, and intended to prepare a peculiar substance, which is mixed with the chyle and lymph, or that they offer a mechanical obstruction to the progress of these fluids, by which means their elements are allowed to act upon each other, and thus some necessary change in the nature of the chyle and lymph may be produced.—(See *Elem. System of Physiol. vol.* 2, *p.* 554.) Richerand's opinion embraces both these views; for he says it was necessary that the lymph should be retarded in the glands, that it might undergo all the changes which these organs had to communicate to it. Although he confesses his ignorance of what these changes precisely are, he represents the intention of them to be the production of a more intimate mixture, a more perfect combination of the elements of the lymph, and to give it a certain degree of animalization, as, he says, is proved by the greater tendency of the lymph to concrete, taken from the vasa efferentia, or discharged from the glands. He also supposes that another use of the glands is to deprive the lymph of its heterogeneous parts, or, at least, to alter them so that they may do no harm by passing into the circulation. The yellow colour of the glands, in which the lymphatics from the liver ramify; the black colour of the bronchial glands; the redness of the mesenteric glands in animals fed with madder or beet-root; their whiteness at the period when the chyle is pervading them; are circumstances regarded by Richerand as proving that the glands tend to separate the colouring matter from the lymph, though their action in this respect may not always be completely efficient. He adds that, from numerous arteries in the texture of conglobate glands, a serous secretion occurs, which dilutes the lymph, increases its quantity, and at the same time animalizes it.—(*Nouveaux Elém. t.* 1, *p.* 276, *ed.* 5.) These observations, however, are only conjectures, which absurdly enough endeavour to blend together the doctrine of the glands rendering the lymph thinner, yet more disposed to concrete.

Mr. Wilson, and some other anatomists prior to him, affirmed, that they had succeeded in tracing filaments of nerves into the substance of the absorbent glands; the possibility of which, however, is not generally admitted. These contradictory statements are to be reconciled by the consideration, that one anatomist would set down as a minute nervous filament, apparently derived from a large unequivocal nerve, what another would doubt, or deny, to be a real continuation of such nerve; for anatomy, like most other pursuits, cannot be prosecuted to extreme minuteness without leading to conjectures, difference of opinion, doubts, and obscurity. According to Bichat, when the lymphatic glands are irritated in various ways, which is easily done, they do not appear to be endued with animal sensibility; but it may be developed in them, as well as in the absorbent vessels, by inflammation, which raises their organic sensibility to a great height.—(*See Anat. Gén. t.* 2, *p.* 116.)

The changes in the structure and size of the lymphatic glands, brought on by the progress of age, justify the presumption, that the action of the lymphatic system undergoes modifications at different periods of life; but, on this point, as M. Magendie has remarked, no precise information exists.—(*See Précis Elém. de Physiol. t.* 2, *p.* 202.) Haller believed that the absorbent glands were of greater consequence to young than adult animals; and Mascagni, Bichat, and all the best modern anatomists, coincide respecting their greater size and turgidity in children than in grown-up persons. Whatever use may be ascribed to them, it is natural to suppose, as Dr. Bostock remarks, that, during the growth of the body, a larger quantity of nutritive matter will be conveyed into the blood, and must pass through these organs.—(*Elem. Syst. vol.* 2, *p.* 554.)

In the foregoing observations on the functions of the lymphatic system, its vessels have been presumed to be the true instruments of absorption; by which is meant, not merely that they contain lymph, and transmit it into the venous system, a fact of which no doubt is entertained by any class of physiologists; but, that such lymph is really produced by the operation of these vessels upon the various kinds of matter presumed to be taken up by them, and to consist of all the old particles of every texture of the body, the fat, the earth of the bones, and the superfluous quantity of many different secretions, naturally undergoing continual renovation, besides the chyle which is taken up by the lacteals, and conveyed to the thoracic duct, or common trunk of both descriptions of vessels. To this view of the subject, some physiologists of eminent talents do not accede, and even if it should hereafter be decidedly proved that the lymphatics possess the power of absorption, the tendency of numerous experiments performed by M. Magendie, Fodera, and others, is to show that, at all events, they are not the only absorbents, and that the veins are very actively concerned in the function.

As the doctrine of absorption is one that is inseparably interwoven with the theory of disease in general, and always has a powerful influence on practice, and the choice of remedies, I have considered the subject highly deserving of notice in this work; but my thanks are due to Professor M'Kenzie, of Glasgow, for his kindness in having suggested the want of such an article in the book.

ACETIC ACID. *Vinegar. Distilled Vinegar.* Vinegar is of considerable use in surgery; mixed with farinaceous substances it is frequently applied to sprained joints, and, in conjunction with alcohol and water, it makes an eligible lotion for many cases, in which it is desirable to keep up an evaporation from the surface of inflamed parts. Vinegar was once considered useful in quickening exfoliations, which effect was ascribed to its property of dissolving phosphate of lime. Its application to this purpose, however, seems hardly admissible, for reasons which will be well understood from a perusal of what is said on the subject of *Necrosis*. The good effects of vinegar, as an application to burns and scalds, were taken particular notice of by Mr. Cleghorn, a brewer in Edinburgh, whose sentiments were deemed by Mr. Hunter worthy of publication.—(See *Med. Facts and Obs. vol* 2, *and the art. Burns.*)

Diluted vinegar is sometimes applied to the eye.—(See *Collyrium Acidi Acetici.*) In the form of ac ollyrium it is alleged to be the best lotion for clearing the eye of any small particles of lime which happen to have fallen into and become adherent to it on the inside of the eyelids.—(See *A. T. Thomson's Dispensatory, p. 8, ed. 2.*)

Concentrated vinegar is sometimes employed for stopping violent hemorrhage from the nose. With this view it may be used either as an injection or a lotion, in which lint is to be dipped and introduced up the nostril.

Vinegar is sometimes employed for obviating the smell of sick rooms. The strongest acetic acid which can be made is found also to be one of the most certain and convenient applications for the destruction of warts and corns, care being taken not to injure the surrounding skin with it.

Acetic acid has occasionally been recommended as an antidote to the narcotic poisons; but the proofs of this are quite unsatisfactory, and the chemical history of opium and other narcotics by no means sanctions the practice.—(*Brande's Manual of Pharmacy, p. 9, 8vo. Lond.* 1825.)

The pyroligneous acid, which is merely strong acetic acid impregnated with empyreumatic oil and bitumen, is much used by Mr. Buchanan, of Hull, as an ingredient in applications to the ear in certain cases of deafness.—(See *Illustrations of Acoustic Surgery, 8vo. Lond.* 1825.)

ACHILLES, *Tendon of.* See *Tendons.*

ACID. See *Acetic Acid; Muriatic Acid;* and *Nitrous* and *Nitric Acids.*

ACTUAL CAUTERY. A heated iron, formerly much used in surgery for the extirpation and cure of diseases. Its shape was adapted to different cases, and the instrument was of tenapplied through a cannula, in order that no injury might be done to the surrounding parts. *Actual* cauteries were so called in opposition to other applications, which, though they were not really hot, produced the same effect as fire, and consequently were named *virtual* or *potential cauteries.* The actual cautery is still in use upon the continent; and by foreign surgeons we are not unfrequently criticised for our general aversion to what they distinguish by the appellation of an *heroic* remedy. Pouteau, Percy, Dupuytren, Larrey, Roux, Delpech, and Maunoir are all advocates for the practice; and the latter gentleman, when he was in England, took the opportunity of reminding British surgeons of their error, in totally abandoning, as they now do, the employment of heated irons in the business of their profession.—(See *Obs. on the Use of the Actual Cautery, Med. Chir. Trans. vol.* 13, *p.* 364, &c.)

ACUPUNCTURE. (From *acus*, a needle, and *pungo*, to prick.) The operation of making small punctures in certain parts of the body with a needle, for the purpose of relieving diseases, as is practised in Siam, Japan, and other oriental countries, for the cure of headaches, lethargies, convulsions, colics, &c.—(See *Phil. Trans. No.* 148; and *Wilh. Ten. Rhyne, de Arthritide Mantissa Schematica, &c. 8vo. Lond.* 1683.) Dr. Elliotson has tried acupuncture very extensively, and his experience coincides with that of Mr. Churchill, confirming the fact, that as a remedy for chronic rheumatism it answers best where the disorder is seated in fleshy parts. He also finds that one needle, allowed to remain an hour or two in the part, is more efficient than several, used but for a few minutes.—(See *Med. Chir. Trans. vol.* 13, *p.* 467.) Neuralgia is a disease in which the practice may deserve trial. Local paralysis is another. In a modern French work it has been highly commended; but the author sets so rash an example, and is so wild in his expectations of what may be done by the thrust of a needle, that the tenour of his observations will not meet with many approvers. For instance, in one case, he ventured to pierce the epigastric region so deeply, that *the coats of the stomach were supposed to have been perforated: this was done for the cure of an obstinate cough, and is alleged to have effected a cure!* But if this be not enough to excite wonder, I am sure the author's suggestion *to run a long needle into the right ventricle of the heart,* in cases of asphyxia, must create that sensation.—(See *Berlioz, Mém. sur les Maladies Chroniques, et sur l'Acupuncture, p.* 305—309, *8vo. Paris,* 1816. *Churchill on Acupuncture,* 1824; *Dantu, Traité de l'Acupuncture,* 1826.)

ADHESIVE INFLAMMATION. That kind of inflammation which makes parts of the body adhere or grow together. The process by which recent incised wounds are united without any suppuration, and frequently synonymous with union by the first intention.—(See *Union by the First Intention.*)

ÆGYLOPS. (From *αἴξ*, a goat, and *ὤψ*, an eye.) A disease so named from the supposition that goats were very subject to it. The term means a sore just under the inner angle of the eye.

The best modern surgeons seem to consider the ægylops only as a stage of the fistula lachrymalis. Mr. Pott remarks, when the skin covering the lachrymal sac has been for some time inflamed, or subject to frequently returning inflammations, it most commonly happens that the puncta lachrymalia are affected by it, and the fluid, not having an opportunity of passing off by them, distends the inflamed skin, so that at last it becomes sloughy, and bursts externally. This is the state of the disease which is called perfect aigylops or ægylops.

Ægylops was a common term among the old surgical writers, who certainly did not suspect that obstruction in the lachrymal parts of the eye is so frequently the cause of the sore as it really is. The skin over the lachrymal sac must undoubtedly be, like that in every other situation, subject to inflammation and abscesses; but we do not find that sores unconnected with disease of the lachrymal sac are here so frequent as to merit a distinct appellation.

AGARIC. A species of fungus growing on the oak, and formerly much celebrated for its efficacy in stopping bleeding.—(See Hemorrhage.)

ALBUGO. (From albus, white.) A white opacity of the cornea, not of a superficial kind, but affecting the very substance of this membrane. The disease is similar to the leucoma, with which it will be considered.—(See Leucoma.)

ALPHONSIN. The name of an instrument for extracting balls. It is so called from the name of its inventor, Alphonso Ferrier, a Neapolitan physician. It consists of three branches, which separate from each other by their elasticity, but are capable of being closed by means of a tube in which they are included.

ALUM. (An Arabic word.) Alum either in its simple state, or deprived of its water of crystallization by being burnt, has long been used in surgery. The ingenious author of the Pharmacopœia Chirurgica remarks that, except for external use as a dry powder, the virtues of alum are not improved by exposure to fire. Ten grains of alum made into a bolus with conserves of roses are given thrice a day at Guy's Hospital in internal hemorrhages, gleets, and other cases demanding powerful astringent remedies. In a relaxed state of the urinary passages, or want of power of the sphincter vesicæ, small doses of alum have been found of service. Alum is employed as an ingredient in several astringent lotions, gargles, injections, and collyria. Dr. Groshuis, a Dutch physician, first recommended its use in colica pictonum, and Dr. Perceval subsequently joined in the advice. The principle on which it acts is that of decomposing the common preparations of lead, and converting them into sulphates, which are comparatively innoxious. Burnt alum, which is a mild caustic, is a principal ingredient in many styptic powders.

ALVINE CONCRETIONS. Comprehending under this head both gall-stones and intestinal concretions, an interesting subject presents itself, certain parts of which have been chiefly elucidated in modern times, as will be hereafter explained. When the concretions voided are very numerous they are generally gall-stones. Thus Dr. Coe relates an instance in which seventy were discharged in one day. In the same short time Petermann knew of seventy-two being voided from one individual; Birch, one hundred; Barbette, Sloane, and Vögel, two hundred; and Russell, four hundred. A patient under the care of Van Swieten had voided two hundred, and was still continuing to expel others. Riverius speaks of another patient who had voided calculi from the bowels for several years whenever he went to stool.—(Observ. Commun.) Fernelius likewise adverts to cases in which the concretions evacuated were innumerable.—(Pathol. lib. 6, cap. 9.) If we take a view of alvine concretions generally, and include all their different kinds, we shall find that they are of various sizes. Most of them are

not larger than a pea or nut; but others are as large as an orange, and weigh four pounds.—(See Monro's Morbid Anat. of the Human Gullet, &c. and Medico-Chir. Journ. vol. 4, p. 188.) Morgagni saw one which equalled in size a moderate finger, and Gooch, Guettard, Heuermann, Maréschal (Mém. de l'Acad. Royale de Chir. t. 3, p. 55), and others, have seen concretions of this nature which were too bulky to pass out of the rectum without surgical aid. In certain examples, recorded by Heuermann and Maréschal, the passage of the concretion outwards lacerated the sphincter ani. Horstius speaks of one concretion which was as large as an apple (Epist. l. 2, sect. 2, Opp. 2, p. 237), and Marcellus Donatus, Schwind (Schmucker's Verm. Schriften, b. 2, p. 129). Hooke, Venette, and Hecquet give the particulars of other examples in which the concretions discharged were as large as a hen's egg. Mr. C. White extracted two from the rectum, which were nearly as big as the fist (Cases in Surgery, p. 18); and in a boy who had died in an emaciated state, after continued pain in the abdomen, attended with frequent attacks of ileus, Mr. Hey found in the transverse arch of the colon so large a concretion that it could not pass any farther along the bowel, and appeared to have been the sole cause of the boy's death.—(Practical Obs. in Surgery, p. 509, ed. 2.) An analogous case is also reported by White (p. 28). It is stated in the Mém. de l'Acad. de Chir. that Duhamel saw a concretion that had been discharged, which was two inches and a half in length, one inch and a half in diameter, three inches and a half in circumference, and the weight of which was three drachms and a half. But, judging by their weight, how much larger those must have been which were seen by Scroekius and Lettsom, and weighed ten drachms; that reported by Dolæus, which weighed two ounces; that recorded by Orteschi, which, besides weighing two ounces two drachms and a half, is said to have been eight inches in circumference, and to have been taken out by force; that recorded by Schaarschmidt, which weighed four ounces; and lastly, the specimen cited by Plouquet (Literatura Med. Dig. vol. 1, p. 171), the weight of which is alleged to have been half a pound.—(Samml. Med. Wahr. nehm. b. 9, p. 231.) It is observed by Rubini, that although examples of alvine concretions being discharged by vomiting are not so frequent as the foregoing cases, yet they are tolerably numerous. Many of them have been collected by Schenck, and others are collected by Breyn (Phil. Trans. No. 479); by Orteschi in his Journal; by Moreali, (Dell' Uscita di una Pietra, per la Via del Esophago, Modena, 1781); by Borsieri; and by a long list of other writers, whose names and publications are specified by Plouquet.—(Lit. Med. Dig. art. Calculus, Vomitus, &c.)—With this class of substances, says Rubini, may also be arranged those concretions which are found upon dissection either in the intestines or stomach, whence probably in time they might have been expelled. Facts of this description are recorded by Portal, Vicq d'Azyr, Jacquinelle, Chandron, &c. The cases recited by White and Hey, in which the colon was completely obstructed, I have already mentioned; and to these may be added the instance quoted by Rubini, in which Meckel found the jejunum entirely blocked up by a similar substance.—(See Pensieri sulla varia origine e natura de corpi calcolosi, che vengono talvolta espulsi dal tubo gastrico, Memoria, p. 5 and 6, 4to. Verona, 1808.)

Rubini observes that, with respect to the origin of alvine concretions, whether discharged from the alimentary canal upwards or downwards, some of them appear to be formed in that canal itself, while others pass into it from other situations; and they all admit of being distinguished according to the place of their origin and formation into three kinds: 1. hepatic, or biliary; 2. gastric, or intestinal; and 3. (what this author terms) mixed, or hepatico-gastric. Hepatic alvine concretions, as the name implies, are derived from some point of the hepatic system; the gastric, or intestinal, are formed within the alimentary canal; and the mixed commence in the hepatic organs, but afterward get into the bowels, where they acquire an increased size.

On the subject of hepatic concretions, or biliary calculi, or gall-stones (as they are usually named), there is no point of the system where they do not occasionally form. Riedlin found them in the surface of the liver. Sorbait met with a biliary calculus as large as a goose's egg, adhering to the peritoneal covering of the liver, and a similar case is recorded by Benivenio. Tallon, Pomme, Saurau, and Heberden have seen calculi within the substance of the liver; while Blasius, Fallopius, Columbus, Ruysch, Henricus ab Heers, and Morgagni record examples, in which the concretions were in the parenchyma of that organ. Plater, Reverhorst, Glisson, Morgagni, and Walter have seen them in the biliary ducts, as probably were those which Columbus and Camenicus say they found in the vena portæ. Walther and Dietrick found calculi in the ductus hepaticus; Ruysch and Soemmering in the ductus cysticus; and Dietrick, Galeazzi, and Richter, in the ductus choledocus. Greisel, Benivenio, Eller, Morgagni, Dargeat, and D'Hervillay have seen calculi included in morbid cysts, attached either to the liver or the gall-bladder. The place, however, where calculi are found in the greatest number, and with most frequency, is the cavity of the gall-bladder itself. Here they are sometimes single, their size varying up to a magnitude completely filling that cavity, as Saye (Journ. des Savans, Sept. 1697), Halle, and Isenflamm have noticed: while sometimes their number amounts to a hundred, or even a thousand, of different sizes. Rubini possesses a gall-bladder, which contains above a hundred small calculi, and formerly I had a similar number, which I found in the body of a female. Van Swieten met with a hundred; Haller, a hundred and forty; Stieber, two hundred; F. Plater, three hundred; Walther, five hundred; Mentski, seven hundred; Baillie, a thousand; Hunter, eleven hundred; Paré, sixteen hundred; Stork, two thousand; and Meckel, several thousands.—(Handb. der Pathol. Anat. b. 2, p. 460.)

All hepatic concretions, however, are not calculated to pass from the place of their origin into the intestines, but only such as are situated in the ductus hepaticus, or its main branches, in the gall-bladder, the ductus cysticus, or the ductus choledocus. When their size is not disproportionate to the diameter of the ducts, they pass with facility; but, when their dimensions are larger than those ducts can naturally admit, the latter becomes stretched and dilated, whence arise the sharp pains and colic which attend the disorder, analogous to the sufferings produced by the descent of large calculi from the kidneys to the bladder. The reality of these dilatations of the hepatic ducts is proved by dissection. Heister found the orifice of the ductus choledocus, which is usually very small, so much enlarged that it could receive a finger; and Vicq d'Azyr saw this duct enlarged through its whole extent in a similar degree.—(Hist. de la Société Royale de Médecine, an. 1779, p. 220.) Galeazzi, in dissecting a body, found the ductus choledocus so dilated, that it resembled a kind of bag, in which several calculi were included. Mr. Thomas has likewise seen two cases, in which the point of the fore-finger readily passed from the duodenum into the gall-bladder.—(See Med. Chir. Trans. vol. 6, p. 105.) Morgagni saw this duct in one instance large enough to hold a couple of fingers, and he quotes many similar instances from Bezold, Trew, Verney, and others. We may conceive how dilated this tube must have been in a case recorded by Richter, where, though it was not completely obstructed, a calculus weighing three ounces and a half was lodged within it.—(Rubini, op. cit. p. 7—10.)

With regard to those concretions which are distinguished by the epithet gastric, or intestinal, some are formed in the cavity of the stomach; the rest in one or other of the intestines. They remain for a greater or less period in the place of their formation, according as they happen to be lighter or heavier, smoother or rougher, more or less adherent, or as local or general circumstances are more or less favourable to their retention or expulsion. Sometimes, they continue undischarged until they have attained a very considerable size. In particular instances, instead of remaining constantly in one place, they successively pass through the whole intestinal tube, lodging at different points for a greater or less time. In the works of Haller and Conradi may be seen representations of the points of the intestinal canal, where these concretions have been found. The alvine concretion, of which Maréschal has given an account, was some years in traversing all the convolutions of the bowels. These gastric or alvine concretions, which are very common in animals, are less frequent in the human subject, as is proved by the observations of Fourcroy

and Vauquelin, inserted in their valuable essay on this subject in the Annales du Museum Nationale d'Histoire Naturelle de Paris. In the horse they are sometimes of an enormous size, as we may learn from an instance on record, in which the concretion weighed thirteen pounds.—(Voigt, Magazin für das Neueste der Naturkunde, b. 3, p. 578.)

As for the third species, which Rubini names mixed, or hepatico-gastric, they have their beginning in the hepatic organs, and augment in the intestinal tube. Here, if the extraneous body be detained, and the contents of the bowels have a disposition to become thickened and condensed round it, as a nucleus, it may be rendered larger by additional strata of matter, and would increase sine fine, if a stop were not put to the augmentation by the narrowness of the canal, or an effort made for the expulsion of the concretion. Morgagni cites two instances of this sort of concretion; one from Gemma, the other from Bezold; and he gives his opinion that another alvine calculus, spoken of by Vater, must have been of the same nature. Dr. Coe describes another interesting specimen; and others are referred to by Vandermonde, Moreali, Portal, &c. Perhaps, says Rubini, the instances of this kind would have been more numerous if all the concretions discharged from the bowels had been noted with greater attention, and the hepatico-gastric substances not confounded with the hepatic. The lodgement of these concretions in the intestinal canal is of uncertain duration, and depends upon a variety of circumstances. Vandermonde gives the history of a calculus, which, as far as could be judged of by the pain in the right hypochondrium, and the change of symptoms, must have passed into the duodenum in the month of January, and then continued in the bowels until August, when it was discharged from the rectum.

The crystallized appearance of alvine concretions is generally so conspicuous, that it has not escaped the attention of several of the old writers, as we may convince ourselves by referring to the works of Corn, Gemma, Greisel, Baglivi, Scultetus, &c. It was noticed by Haller in his Elementa Physiologiæ, vol. 6, and by Morgagni in his Epist. 37, de Sedibus et Causis, &c. If, says Rubini, these crystallizations are not always plainly visible, distinct, and regular, this depends either upon their imperfection, the heterogeneous nature of the accumulated matter, or particular unfavourable circumstances, which would equally affect the process of crystallization out of the body.

Now, as all crystallizations depend upon the fluids in which they form, and from which they receive their crystallizing elements, it must be evident that, inasmuch as the fluids of the hepatic organs differ in their constituent principles from the fluids contained in the intestinal canal, the concretions produced in the first system must differ from those originating in the second; while the hepatico-gastric calculi will combine the nature and properties of both together.

The fluid from which hepatic concretions are formed is unquestionably the bile, either some or all its ingredients entering into their composition. Indeed, previously to the new chemical doctrines, hepatic calculi were generally considered as being simply condensed indurated bile.

From investigations made in more modern times, however, when the art of analysis has attained a precision of which the old chemistry was not susceptible, it appears, that although human biliary calculi yield the same products as the bile, there is contained in them more or less of a peculiar substance, which was named by the celebrated Fourcroy, adipocere.—(Mém. de l'Acad. des Sciences, 1789, p. 323.) The presence of this substance in the concretion is of such importance, that, when it is abundant and in large proportion, the calculus is regular and the crystallization well finished; and, when it is in small quantity, the crystallization is confused and disordered, the calculus only exhibiting an irregular misshapen concretion, more like a clot than true crystals. The kind of adipocere constituting the base of all human biliary calculi, has some resemblance to spermaceti. Both Fourcroy and Dr. Bostock, who analyzed it, found it composed entirely of carbon, hydrogen, and oxygen. It melts, but requires a heat superior to that of boiling water: in fusion it has a smell like wax, and on cooling, forms a substance, which breaks into crystalline laminæ. It is not soluble in alcohol in the cold; but when the alcohol is boiled on it, it is dissolved in a proportion, according to Fourcroy, of one part in nineteen—according to Dr. Bostock, one in thirty.—(Nicholson's Journal, 8vo. vol. 4, p. 137.) The solution, when it cools, deposites light brilliant scales. It is soluble in ether in the cold, and more abundantly if the ether be heated. Oil of turpentine generally dissolves biliary calculi; and, according to Gren, it dissolves those which consist almost entirely of this peculiar matter; yet Dr. Bostock has remarked, that oil of turpentine acts on it with difficulty, and even when digested with it, at a boiling heat, dissolves it only in a small degree. Pure soda and potassa dissolve it completely, and reduce it to a saponaceous state. Ammonia, as Dr. Bostock has remarked, exerts little action on it, except when boiling. Nitric acid dissolves it, and, according to Fourcroy, converts it into a species of liquid similar to the oil of camphor. This becomes concrete, but without any crystalline structure, and is more soluble in ether and the alkalis than the original matter.

"This substance (Fourcroy has observed) is contained in greater or less quantity in nearly all human biliary calculi, more or less intermixed with other matter, but still so far predominant as to form their basis. Hence, they partake of its properties; are fusible, inflammable, and more or less soluble in the agents which dissolve it."—(See Murray's Syst. of Chemist. vol. 4, p. 594, ed. 2.) Fourcroy, on exposing the above peculiar substance to the action of oxygenated muriatic acid, saw it whitened, and afterward resume its former silvery hue. However, Rubini repeated this experiment, and found that the whiteness which was contracted remained permanent.

While the hepatic system contains a fluid which is always nearly of the same quality, viz. the bile, the alimentary canal, as Rubini observes, contains a hundred different fluids, and is continually occupied by substances of various natures, kinds, and properties, consisting of food, drink, and several secretions. All the principles which are to serve for the formation and renewal of the different species of living solids, and of the many kinds of fluids, at first remain more or less time in the alimentary canal, and there undergo peculiar changes. All the principles which, under different circumstances, may contribute to the production of morbid concretions, either in the gall-bladder, the urinary bladder, the kidneys, or in any other part of the body, where they ever occur, pass at first into the intestinal canal, where they continue for some time. Such a multiplicity of principles, disposed to crystallize, and be converted into calculi, would very often, almost daily, produce these concretions in the bowels, were there not many circumstances which counteract this tendency, as, for instance, exercise, the incessant motion of the matter itself along the intestinal tube, the variety of these elements, whereby their requisite tendency to unite is disturbed, and the decomposing and recomposing influence of the gastric secretions, whereby parts are united, disposed of, dissolved, and analogous matter kept divided, &c. But whenever these circumstances are not actively operating, as may be the case in a noose, or fold of the bowels, or in some preternatural cyst belonging to them; whenever the intestinal fluids undergo such an alteration that the production of these concretions cannot be prevented; or, lastly, whenever some favourable circumstance, such as an extraneous nucleus, forms a centre of reunion for particular elements; then the saline matter, which is most disposed to crystallize, and the earthy and mucilaginous substances, &c., are attracted together, and produce more or less perfect crystallizations. A chemical analysis of some intestinal calculi, first made by Konig, and afterward by Slare (Philosophical Transactions), proves, that when they are exposed to a strong heat in distillation, they yield water, ammonia, and a lixivious salt, a caput mortuum remaining behind. Cadet, in analyzing a similar concretion, found, in addition to the above products, phosphorus. The muriate of ammonia was afterward discovered; and Gioberti, Fourcroy, and Vauquelin, in their histories of the intestinal concretions met with in animals, describe them as composed of the acidulous phospate of lime, phosphate of magnesia, and of the ammoniacal-magnesian phosphate.

Some specimens contained in the Edinburgh museum were very carefully examined by Dr. T. Thomson: they at first swam in water, but afterward sunk;

the specific gravity varying from 1.376 to 1.540. Cold water acquired from them a brownish tinge, and took up albumen, which separated in white flakes by boiling. There was also a peculiar brown substance, at first dissolving in water, but rendered nearly insoluble by slow evaporation; soluble in alcohol; and most nearly resembling vegetable extract. The specimens likewise contained muriate of soda, crystallizing on spontaneous evaporation of the water; phosphate of lime, precipitated by ammonia; sulphate of soda in minute proportion; and, perhaps, sulphate of lime. Alcohol dissolved the peculiar brown matter and some of the salts; caustic potash, the albumen, brown matter, and perhaps some of the salts; and muriatic acid a proportion of phosphate of lime. After all, there remained a peculiar substance, having the colour and texture of the calculus; in very short threads, light, resembling cork, or rather agaric; tasteless, insoluble in water, alcohol, ether, potash-ley, and muriatic acid; being blackened, and partly reduced to charcoal by sulphuric acid; slowly dissolving by heat, without effervescence, in nitric acid; and leaving on evaporation a whitish residue, of bitter taste, and imperfectly soluble in water; burning with a bright flame; but differing from all other animal and vegetable substances hitherto examined, and distinguishable from wood, by its insolubility in potash-ley. The calculi consisted of alternate layers, or intimate mixtures of this substance and phosphate of lime, to which the albumen and brown matter served as a cement, the other substances being in small proportions. Phosphate of lime mixed with a brown animal matter, formed the external crust of some of the specimens. On the surface of a few were noticed crystals of phosphate of ammonia and magnesia. The presence of neither potash, ammonia, carbonate of lime, uric acid, nor urea could be detected.

Varieties have also been found by Dr. Henry and Mr. Brande, exclusively composed of magnesia, of which the patients had been in the habit of taking vast quantities.—(See Thomson's Obs. in Monro's Morbid Anatomy of the Human Gullet, &c. p. 36, or in Medico-Chir. Journ. vol. 4, p. 188, 189.)

From observations made by Dr. Wollaston, it appears probable, that the above fibrous, light, thready substance is derived from oats, which are so commonly taken as food in Scotland.

"If the oat-seed be divested of its husk, minute needles or beards, forming a small brush, are seen planted at one of its ends. Dr. Wollaston, on examining these needles and comparing them with similar ones detached from the calculi, and forming the velvet substance in question, satisfied himself, beyond all doubt, of their perfect identity."—(Marcet on Calculous Disorders, p. 130, 8vo. London, 1817.)

The specimen analyzed by Dr. Ure, he inferred to be a modification of ambergris.—(Dict. of Chemistry, art. Intestinal Concretions.)

As for the mixed or hepatico-gastric calculi, they have for their nucleus a biliary concretion, round which other substances contained in the bowels adhere; hence, it is evident, that as they are formed at two distinct periods in two different situations, and among various fluids, two distinct compositions must be the result. Although, says Rubini, there has hitherto been no scientific analysis of this species of calculus, excepting the very imperfect one by Moreali, reason shows clearly enough, that, if two separate analyses were made, one of the nucleus, the other of the surrounding matter, there would be obtained from the nucleus the same elements as those of an hepatic calculus, and from the rest those of an intestinal concretion.—(See Pensieri sulla Varia Origine, &c. de' Corpi calcolosi che vengono espulsi dal tubo gastrico, p. 15—17.)

As the same author remarks, the foregoing principles will enable us to determine with greater precision than formerly, the characters which appertain to the several classes of calculi liable to be voided from the intestinal canal; characters, by means of which there can be no difficulty in deciding, from the appearance of one of these concretions, the place of its origin, and its peculiar nature. The hepatic calculus being composed of bile, and also of adipocere, its characters will be such as indicate the predominance of a uniform, oleaginous, and (what Rubini terms) a well-animalized principle. The gastric or intestinal calculus, arising from the union of various salts, earths, and other principles, which happen to be in the alimentary canal, will have very different characters, generally indicating its earthy saline composition. Lastly, the hepatico-gastric calculus will present a union of the different characters; viz. in the centre, the characters of the hepatic calculus; more externally, those of the gastric.

The criteria for distinguishing the several kinds of calculi from each other may be divided into such as may be termed external, being derived from accidental circumstances attending the foreign body; and others, which may be called internal, being deduced from the inherent characters belonging to the composition and nature of these concretions.

The first of these external criteria is the age of the patient. C. Stephanus, Hoffmann, Durande, and Morgagni all agree, that biliary calculi seldom occur, except in subjects of advanced age, and never in youth. And Haller writes, "Juniores et pueros, quantum novi, numquam adfligit morbus." Morgagni met with sixty-one old persons who had alvine concretions, but with only eight young persons, not one of whom was a child, the youngest being twelve years of age, and the eldest twenty-nine. To these I may add the instance reported by Saye, in which a stone as large as a hen's egg was found in the gall-bladder of a young female aged only twelve.—(See Journ. des Savans, Sept. 1697.) The cause of this difference is attempted to be explained by Morgagni; but, probably, a more rational explanation than that suggested by him, will be found in the analysis of the bile of old and young subjects, as made by Fourcroy and other modern chemists. From these and other observations, collected by Rubini, it is rational to conclude, that when an alvine concretion is discharged from a young subject, the chances are, that it is not a biliary one; though if the patient be of advanced age, it is not to be inferred, that the foreign substance expelled must certainly be hepatic, because gastric or intestinal concretions are common to individuals of every age.—(Rubini, op. cit. p. 18.) Indeed, with the latter kind of calculi, men of advanced age and women are said to be most frequently afflicted; children and young persons rarely suffering, unless the formation of such bodies has been produced by the presence of fruit-stones, or other indigestible substances, which serve as nuclei.—(Richerand, Nosographie Chir. t. 3, p. 433, ed. 4.) These concretions are also sometimes formed in patients who have been confined by disease a long while in a recumbent posture.

The second criterion is drawn from the symptoms, which precede or accompany the expulsion of the calculus. Sense of heaviness, irritation, and pain in the region of the liver, pain about the ensiform cartilage and navel, bilious vomiting, jaundice, and either looseness of the bowels or constipation, are the symptoms which (especially when they frequently occur) indicate the hepatic origin of the calculus, and proceed from its passing through the narrow ducts of the liver or gall-bladder towards the intestines. The most careful observations have proved, however, that these symptoms are only to be depended upon when taken collectively, and that no single one gives any certain information. Also, if their presence be sufficient to prove the hepatic origin of the calculus, their absence can by no means be regarded as a proof of the concretion being of the intestinal kind.—(Rubini, p. 19.)

Third criterion. A calculus voided may be set down as undoubtedly hepatic, if accompanied by others unequivocally of this nature. In a case recorded by Brunner, and in another by Vater, the absence of certain symptoms in the first, and the magnitude of the calculus in the second, created doubts whether the concretions were not more likely to be of the intestinal kind, than of the hepatic. At length, the bodies having been opened, the presence of other similar calculi in the gall-bladders afforded an adequate criterion.

Morgagni lays down a fourth criterion, deduced from the number of the calculi voided; which, if very numerous, are to be considered as biliary. Rubini points out, however, the fallacy of this test; both hepatic and gastric concretions being sometimes single, sometimes in various numbers even up to a thousand; and he refers to a case where a very large number of concretions of the gastric description were voided, as reported by Konig. The test here suggested, however, may be considered as generally valid; for, the number of in-

testinal concretions is rarely more than two, though sometimes very considerable.—(T. Thomson. See Med. Chir. Journ. vol. 4, p. 189.)

I shall now follow Rubini, and notice those characters of alvine concretions, which he calls internal, and are deduced from their quality and composition, beginning with the criterion furnished by the size of the extraneous substance voided. As the biliary ducts are narrow, it is obvious, that if the calculus be above a certain size, it cannot have passed in this state suddenly through those narrow tubes, and consequently must be either of the gastric description or mixed, having quitted the hepatic system while small, and afterward increased within the alimentary canal. Unquestionably, as Rubini admits, this criterion has considerable weight, especially when the discharge of the calculus has not been preceded by pain, or other symptoms indicating such violent distention, as the above ducts must have suffered from the passage of the foreign body. These are certainly capable of being dilated in a remarkable degree, as some facts, already noticed in this article, sufficiently prove; but such dilatation can never happen without pain, irritation, and a serious train of sympathetic effects. Rubini remarks, this criterion will only apply to large, and not to diminutive concretions. A biliary calculus, of prodigious size, was found by Mr. Brayne, of Banbury, to have passed by ulceration directly from the cavity of the gall-bladder into that of the duodenum, whence it made its way through the rest of the bowels, and was voided from the anus.—(See Med. Chir. Trans. vol. 12.)

A second criterion is the colour of the calculus; a test admitted by Moreau, who asserts, that biliary calculi are yellow or green, and intestinal ones grayish brown or black. But, says Rubini, one need only look at various specimens of alvine concretions, and read the statements of authors who have seen a great many of them, particularly Morgagni and Soemmering, to comprehend, that any criterion deduced from their colour is most fallacious, every species of them presenting great variety in this particular. And it is to be remembered, that the bile and the intestinal fluids, whence these concretions are formed, differ in colour in different individuals, according to a variety of circumstances, in health and disease. One species of hepatic calculus has a white colour, but is sometimes yellow or greenish. Another is of a round or polygonal shape, and often of a gray colour externally, and brown within. A third is of a deep brown or green colour.—(See Ure's Dict. of Chemistry, art. Gallstones.) The smaller intestinal concretions examined by Dr. T. Thomson, destitute of coating, resembled bad yellow ochre; the larger were encrusted with an earthy matter, of a coffee colour, and purple or sometimes white.—(See Monro on the Human Gullet, &c., and Med. Chir. Journ. vol. 4, p. 188.)

Third criterion. The presence or absence of a nucleus will enable one to judge whether a calculus be gastric or hepatic. A biliary concretion has no nucleus, properly so called; that is to say, it has no foreign body in its centre. When a transverse section is made of such a calculus, one finds either a cavity in its middle, or else nothing by which this part of its substance can be distinguished from the rest; or if a nucleus different from the other part of the concretion be apparent there, it consists merely of bile, either grumous, differently coloured, or more or less fluid than the rest of the calculus, but which is nevertheless invariably bile. On the contrary, every gastric concretion has, as it were, an extraneous nucleus, as Fourcroy and Vauquelin have explained in their essay upon the intestinal calculi met with in animals. Ruysch in the Phil. Trans. gives an account of some alvine concretions which were formed round grains of seed. Birch records an example of a crystallized calculus formed round a leaden bullet. Haller met with a calculus in the centre of which was an iron nail. Concretions formed upon fruit-stones are recorded by Clarke, White, and Hey, and also in the Edinb. Med. Essays. Instances in which the nucleus was a small portion of bone are related in the latter work, and also by Hooke and Coe. Homberg and others describe alvine concretions formed round indurated excrementitious matter; and many similar cases are specified by Vallisnieri, Van Swieten, and others. In the hepatico-gastric calculus the biliary concretions serve as a nucleus for the gastric. According to Dr. T. Thomson, the nucleus is commonly a cherry-stone, a small piece of bone, or a biliary calculus.—(See Med. Chir. Journ. vol. 4, p. 188.)

A fourth criterion is deduced from a certain unctuosity which belongs to biliary calculi, but not to those of the gastric class. This character is more palpable when the calculus has been recently voided, or when it is handled with warm fingers. The unctuosity is still more evident when the concretion is cut or sawn, as then the knife, saw, or fingers become smeared with saponaceous particles, which adhere to them. In order to denote an hepatic calculus, however, the unctuosity must pervade its whole substance, and not merely appear towards its outside; for a gastric, earthy, saline concretion may by accident become coated, as it passes through the bowels, with a stratum of bile or saponaceous matter. When the unctuosity is deficient externally, or in the outer laminæ of a calculus, but is found in its interior, it is a clear indication of the hepatico-gastric formation of the concretion.

Fifth criterion. The specific gravity of a calculus, the property which it has of floating or sinking in water, has been long considered as a test of its species. The hepatic calculus is generally specifically lighter than water, as most oily substances are: on the contrary, gastric calculi are specifically heavier than water, like all earthy saline matter, and of course sink in that fluid. This criterion was often employed by Reverhorst, Fernelius, and others, for distinguishing various concretions. But it is by no means regular, as many biliary calculi swim only a little while and then sink. The specific gravity of that analyzed by Dr. Ure, of Glasgow, was 1.0135.—(See Med. Chir. Journ. vol. 4, p. 179.) As Rubini observes, this test will not answer for hepatico-gastric calculi, which are subject to great anomalies.—(Pensieri, &c. p. 22.) Nevertheless, the most correct modern examinations prove, that gastric concretions have a specific gravity varying from 1.376 to 1.540 (Dr. T. Thomson in Monro's Morb. Anat. &c.), and consequently their general character is to be heavier than biliary calculi.

A sixth criterion is that proposed by Vicq d'Azyr in the Mém. de l'Acad. Royale de Méd., and deduced from the figure of the crystallization. According to this writer, intestinal concretions crystallize in concentric laminæ, shaped like a cock's comb, while the crystallizations of biliary calculi are radiated and needle-shaped. Although this criterion is ingeniously founded upon the known laws by which every crystallized substance assumes a peculiar and determinate shape, yet it may be generally observed with respect to the mark of distinction here proposed, that the concretions of which we are now speaking are usually too compound, and too much disturbed in their crystallization to exhibit a regularity, for which simplicity and quietude are indispensable. Hence many of these concretions do not present the slightest vestige of crystallization, while others scarcely show a trace of it, in the midst of a large misshapen mass. The white-coloured hepatic calculus when broken is said to present crystalline plates or striæ, brilliant and white like mica. The round or polygonal one which is often of a gray colour externally, and brown within, is described as consisting of concentric layers of inspissated bile, usually with a nucleus of the white crystalline matter in the centre. Lastly, the hepatic calculi, of a deep brown or green colour, when broken, are said to exhibit a number of crystals of the substance resembling spermaceti, mixed with inspissated bile.—(See Ure's Dict. art. Gall-stones.) With respect to the special shape assigned by Vicq d'Azyr to the two classes of alvine concretions, it may be observed that his specimens were taken from animals, and that consequently the inferences made from them are not applicable to substances of an analogous nature discharged from the human body; because, as the bile varies in different animals, so must the formative principles of the calculous crystallizations. It is farther remarked by Rubini that the substance termed adipocire, which is the basis of biliary concretions, was not found by Poulletier in hepatic calculi taken from horned cattle.

A seventh criterion is founded upon the inflammability of an alvine calculus. A biliary concretion being commonly made up altogether of unctuous matter, liquefies when subjected to heat, smokes, emits a flame, and burns. When this experiment is made in close vessels, the products are hydrogen, carbonic acid gas, oil, and ammonia: some carbon and earth remaining

behind. An intestinal concretion, on the other hand, decrepitates or turns black, but generally does not burn. One specimen examined by Dr. Ure, when heated to the temperature of 400° F., fused into a black mass, and exhaled a copious white smoke, in the odour of which was recognised that of ambergris, mixed with the smell of burning fat. Exposed in a platina capsule to a dull red heat, it burned with much flame and smoke, leaving no appreciable residuum.—(See Ure's Dict. of Chemistry, art. Intestinal Concretions.)

The eighth criterion depends upon the solubility of calculi in an oily menstruum. Haller dissolved biliary calculi in oil of turpentine; Dietrick found them soluble in oil of sweet almonds; and Gren in oils in general. But intestinal calculi are not so readily dissolved by any of these menstrua.

The ninth criterion is founded upon the solubility of the calculus in alcohol. In biliary calculi this solubility is not always the same; but as this point has been already spoken of, it is unnecessary to dwell upon it; and I shall merely add, that while hepatic concretions are almost always more or less dissolved by alcohol, those of the gastric kind resist this menstruum.

Though the above criteria are interesting, as tending to establish distinctions between the different species of alvine concretions, it merits attention that not one of them taken separately is at all certain and pathognomonic. It may happen, says Rubini, that some peculiarity in the biliary secretion, and an irregularity in the crystallization and accumulation of the matter, may cause salts and earths to predominate in hepatic concretions, in which circumstance their usual oily quality will be defective. On the other hand, in the formation of an intestinal concretion, oily adipose matter may accidentally adhere to it, so as to disguise its wonted character. If uniformity of characters and physical properties depend upon uniformity of elementary constituent principles, it can hardly happen even in the natural healthy state of the secretions, because age, sex, and other particular circumstances of the individual will always make a difference in the proportions of those principles. How then can identity of results be expected in a diseased state of the process of secretion?—Such reflections may explain how Morgagni among others met with many biliary calculi which were not inflammable; with others which did not give a yellow tinge to water; and with some which floated or sunk in water, according as they had been recently or long discharged; while Gren found some of these calculi insoluble in alcohol, &c.—(Rubini, p. 24, 25.)

Moreali put a piece of the outer part of an alvine concretion into nitrous acid, when a considerable effervescence took place, and the substance afterward completely dissolved. Now as this calculus had a nucleus, it must have been of the hepatico-gastric kind, and the experiment was therefore made only with the intestinal part of it. Should the experiment be often repeated with the same result, says Rubini, it would furnish another criterion for distinguishing the two species of calculi; those being intestinal which effervesce, and others being hepatic which do not effervesce, but yield globules of wax-like, oily matter.—(P. 28.)

For additional chemical observations on biliary and other alvine concretions, the reader is particularly referred to Rubini's interesting memoir, Vicq d'Azyr's essay in the Hist. de la Société Royale de Médecine, an 1779; the writings of Fourcroy, Vauquelin, and Thenard; Thomson's account of the subject in Monro's Morbid Anatomy of the Human Gullet, &c.; Marcet on Calculous Disorders; and some interesting experiments by Dr. Ure, related in a paper by Mr. Kennedy, in Medico-Chir. Journ. vol. 4, p. 177, &c. Also Ure's valuable Dict. of Chemistry.

With respect to the treatment of cases of biliary calculi, the subject not being generally one for which any surgical proceeding is advisable, I may be very brief. The medicine which is alleged by Durande, a physician at Dijon, to be the best solvent for them, consists of three parts of sulphuric ether and two parts of oil of turpentine. It is to be given in the dose of ℈ij. every morning; purgatives being previously exhibited for a few days. The efficacy of this medicine is also corroborated by Soemmering and Richter. To these statements, however, some doubts must be attached; because what symptoms and circumstances will ever unequivocally prove, that there were biliary calculi in the bowels, and that they have been dissolved by this medicine? And how can the product of such solution be got at and examined? But admitting the authenticity of the cases, doubts must exist of the solvent action of the remedy; since at a temperature below that of the human body, the ether separates from the turpentine and is volatilized.—(See Dict. des Sciences Méd. t. 3, p. 464, 465.)

A calculus in the gall-bladder or one of the biliary ducts sometimes produces so much irritation, that inflammation and suppuration take place, and if the abscess point outwardly, the stone may escape externally, and a termination be put to the patient's sufferings. Heberden records a case of this description; and another is given by Mr. Blagden.—(See Med. Trans. of the College of Physicians, vol. 5, and Thomas in Med. Chir. Trans. vol. 6, p. 106. And for other instances, the following works referred to by Ploucquet: Acrel, Diss. de Cholelithis, Upsal, 1788, p. 204; Act. Natur. Cur. vol. 6, Obs. 69; Bartholinus, Act. Hafn. 4, Obs. 46; Block, Med. Bemerk, p. 27; Gooch's Works, vol. 2, 157—161; Johnston in Phil. Trans. vol. 50, p. 2, 548; Petit, Mém. de l'Acad. de Chir. 1, p. 182—185; Sandifort, Tab. Anat. Fasc. 3; Schlichting in Bald. N. Magas, b. 9, p. 210; Vogler in Museum der Heilkunde, b. 4, p. 91; Haller, Collect. Diss. Pract. 3, No. 107.)

It was J. L. Petit who first suggested the bold practice of making, under certain circumstances, an incision into the gall-bladder, in order to extract biliary calculi. This proceeding, however, is liable to serious objections, arising not only from the usual difficulty of knowing positively whether there is a calculus in the gall-bladder, but also from the difficulty of ascertaining whether this viscus is adherent to the peritoneum, without which state of things, the operation would cause an extravasation of bile, enteritis, and death. Petit himself, indeed, mentions three cases in which distention of the gall-bladder was mistaken for an abscess, and punctured. In two of these examples the consequences were fatal, there having been no adhesion between that organ and the peritoneum to prevent the bile from getting among the bowels: the other patient was saved by this fortunate circumstance.—(See Traité des Mal. Chir. t. 1, p. 262, &c.) However, if a case were to present itself in which an abscess had formed and broken, leaving an aperture in which the calculus could be plainly felt, the surgeon would be justified in attempting to make a sufficient opening for its extraction.

The symptoms induced by the lodgement of large concretions in the bowels are of a formidable description: severe pains in the stomach and bowels, diarrhœa, violent vomitings of blood and mucus, a discharge of thin fetid matter from the rectum, a difficulty of voiding the excrement, an afflicting tenesmus, extreme emaciation, and debility.

That the foregoing account is not exaggerated, may be seen by a perusal of the cases, and remarks published by Mr. C. White, and the late Mr. Hey.

In cases like that reported by Mr. Hey (Pract. Obs. p. 509, ed. 2), where the colon was completely obstructed, surgeons have been advised to cut into that bowel, and extract the foreign body. Let the inexperienced admirer of curious feats with the scalpel, however, pause a little, before he ventures to make up his mind upon this matter; and at all events let him know, that some serious mistakes have nearly been made: "upon the very bold operation of cutting out these concretions when lodged in the colon, proposed by Dr. Monro, senior (See Monro's Morbid Anatomy of the Human Gullet, &c. p. 63), we think it our duty to state that the diagnosis is so difficult, that in one case where the operation was strongly advised, it turned out upon dissection that the disease was a scirrhous pylorus."—(See Edinb. Med. and Surg. Journ. No. 33, p. 112.)

Sometimes patients ultimately get well by voiding the concretions either by vomiting or stool. Mr. C. White gives us an account of some instances of this kind: in one, fourteen concretions on plumb-stones were discharged from the anus; in another, twenty-one similar bodies were ejected from the stomach.

When such concretions are not particularly large and indurated, they sometimes admit of expulsion by doses of castor oil, oleaginous clysters, &c. But in other instances their extraction must be attempted if their situation in the rectum will permit. It may be done with a pair of lithotomy forceps or with the sort of scoop used for taking fragments of stone out of the bladder. In this manner Mr. C. White succeeded in

removing two alvine concretions from the rectum nearly as big as his fist. When the spincter ani will not allow the concretion to be taken out, the muscle should be divided at its posterior angle. According to Richerand, such a division does not permanently weaken its fibres in a perceptible degree, and its paralysis never originates from this cause.—(Nosogr. Chir. t. 3, p. 434. edit. 4.) Maréschal, after a proper dilatation with a scalpel, extracted from the rectum an alvine concretion which weighed two ounces and a half, and was of an oval form, its greatest diameter being two inches eight lines, and its smaller one inch seven lines.—(See Mém. de l'Acad. de Chir.)

AMAUROSIS. (From ἀμαυρόω, to darken or obscure.) Gutta serena. Suffusio nigra. Fr. L'Amaurose; Germ. Schwarzer Staar. According to Beer, the term amaurosis properly means that diminution or total loss of sight which immediately depends upon a morbid state of the retina and optic nerve, whether this morbid state exist as the only defect, or be complicated with other mischief; whether it be a primary affection, or a secondary one induced by previous disease of other parts of the eye. Or we may say, with a critical writer, that the term amaurosis designates all affections of the nerves of vision, which produce either complete or partial loss of sight, whether this arise from obvious or inferred organic disease, or from a diminution or loss of sensibility in the eye, which cannot be traced to change of structure or any other evident cause.—(See Journ. of Foreign Med. and Surgery, vol. 4, p. 166.)

The definition given by Mr. Lawrence in his Lectures appears to be correct and comprehensive. Amaurosis and gutta serena, he remarks, are names applied indifferently to those forms of blindness which result from an affection of the nervous structure of the eye, whether it be seated in the retina, optic nerve, or sensorium; or whether this affection be produced immediately by vascular congestion, inflammation, or organic change; or indirectly by sympathy with other organs.

From these definitions, which comprehend every form of amaurosis, it is evident that this affection does not uniformly take place as a single independent disorder; but not unfrequently presents itself as a symptomatic effect of some other disease of the eye; a fact exemplified in cases of hydrophthalmia, cirsophthalmia, glaucoma, &c. And, as Mr. Wardrop observes, amaurosis in its usual acceptation signifies a symptom of disease as well as a distinct affection.—(Essays on the Morbid Anatomy of the Human Eye, vol. 2, p. 165, 8vo. Lond. 1818.) With respect to the mere name of the kind of disease here implied by amaurosis, its correctness will remain the same, whether the iris be moveable or immoveable; whether the pupil be preternaturally enlarged or contracted; and whether it be perfectly clear and transparent, or more or less turbid; for the name only refers to the morbid state of the retina and optic nerve, and not to the condition of the sight in general. When the long-established name of amaurosis is received with this precise meaning, there will not be the slightest danger of confounding the disease with other affections of the eye. However, when it is wished to make out the very different forms and kinds of amaurosis, the foregoing appearances of the iris and pupil are considerations of great importance.—(See Beer's Lehre von den Augenkrankheiten, b. 2, p. 420, &c. Wien. 1817.)

I think it also of importance that surgeons should well understand what Mr. Travers has particularly mentioned, that the term "amaurosis" comprehends all those imperfections of vision which depend upon a morbid condition, whether affecting structure or function of the sentient apparatus proper to the organ.—(See his Synopsis of the Diseases of the Eye, p. 293.)

Beer reckons four species of amaurosis.

The first is a genuine uncomplicated amaurosis, the characteristic symptom of which consists peculiarly and entirely in an impairment or loss of vision, without any morbid change in the organic matter of the eye. To this case the epithet "proper functional," used by Mr. Travers, would be applicable.

Secondly, there is an amaurosis, which, besides being attended with a diminution or total loss of vision, is also accompanied with appearances of disease in the organic matter of the eye.

Thirdly, there is another amaurosis, in which, together with the above principal symptom, viz. weakness or loss of sight, there are also morbid phenomena exhibited in the form of the eye in general, or its particular textures, and especially in the action of its irritable parts.

Lastly, Beer says, he can often point out an amaurosis in which all the characteristic symptoms of the three preceding cases are more or less combined.—(See Lehre von den Augenkr. b. 2, p. 478.)

The genuine uncomplicated amaurosis, consisting of a mere diminution or loss of sight, without the appearance of any other defect, is one of the most uncommon forms of complaint, not only because singly operating causes are few, but because they can rarely operate directly upon the optic nerves.

In the true uncomplicated amaurosis, merely the vital qualities of the optic nerve and retina are affected, and after death nothing preternatural can be traced in those parts either within or on the outside of the eyeball. It is, in short, the case in which the functions of the retina have become imperfect or destroyed, the eye appearing in other respects sound.

According to Beer, this simple unmixed form of amaurosis is subdivisible into that amaurotic weakness of sight or blindness, which depends upon the vitality or rather sensibility of the optic nerve and retina being too highly raised, and into another case, the proximate cause of which is peculiarly and entirely referable to depression of such vitality or sensibility. The first example is much less common than the second.

Amaurosis does not constantly attack both eyes at the same time; frequently one is attacked some time after the other, and it is not unusual even for one eye to remain sound during life, while the other is completely blind. This depends, in part, upon the disposi-

tion to the disease in one eye being quite local, and in part upon the causes giving rise to the complaint extending their operation only to the eye affected. Where also the origin of amaurosis seems to depend altogether upon constitutional causes, one eye is not unfrequently attacked much sooner than the other; though in these examples, it is more rare to find the eye which does not suffer at first continue perfectly unaffected.—(Beer, b. 2, p. 422.) As a general observation, Mr. Wardrop thinks it may be remarked, that when only one eye becomes at first amaurotic from a sympathetic affection, there is little danger of the other eye becoming blind; but that when amaurosis is produced by any organic change in one eye, the other is very liable to be sympathetically affected.—(Essays on the Morbid Anatomy of the Human Eye, vol. 2, p. 190.) Amaurosis may not completely hinder vision, a diminished power of seeing often remaining during life. Hence the division of cases into perfect and imperfect; which latter, however, sometimes attain a degree in which the patient is only just able to distinguish light, the direction of its rays, and its degree.

Imperfect amaurosis, besides being characterized by a considerable weakness of sight, approaching to real blindness (Amblyopia Amaurotica), is mostly complicated with a greater or less number of other morbid appearances, which merit serious attention.

Among the most important of these symptomatic appearances of imperfect amaurosis is a defective interrupted vision (visus interruptus). For instance, when the patient is reading, single syllables, words, or lines cannot be seen, unless the eye be first directed to them by a movement of the whole head, and greater or less portions of other objects are, in the same manner, indistinguishable. Sometimes, amaurotic patients can see only the upper or lower, or the left or the right half of objects (Visus dimidiatus; Amaurosis dimidiata; Hemiopia; Hemiopsia.)

Sometimes, when the patient shuts one eye, he can only distinguish the halves of objects; but if he open both eyes, he sees every thing in its natural form. In this case, according to Schmucker, one eye is sound, and only some fibres of the nerve of sight are injured in the other.—(Vermischte Chir. Schrift. b. 2, p. 12.)

There are likewise some not very uncommon cases of imperfect amaurosis, in which the patient cannot see an object, unless it be held in a particular direction before the eye; but when the eye or head is moved in the least, he loses all view of the thing, and cannot easily get sight of it again.—(Beer, Lehre von den Augenkrankheiten, b. 2, p. 424.) On this part of the subject, it is remarked by Richter, that patients who may be said to be entirely blind, sometimes have a small part of the retina which is still susceptible of the impression of light, and is usually situated towards one side of the eye. This obliquity of sight was long ago pointed out by the late Mr. Hey, as common in the present disease.—(See Med. Obs. and Inquiries, vol. 5.) Richter mentions, that in one man, who was, in other respects, entirely bereft of vision, this sensible point of the retina was situated obliquely over the nose, and so small, that it was always a considerable time before its situation could be discovered; he adds, that it was so sensible, as not only to discern the light, but even the spire of a distant steeple. According to this author, it is the centre of the eye that seems to be the first and most seriously affected. Hence, the generality of patients, who have a beginning imperfect amaurosis, see objects, which are latterally situated, better than such as are immediately before them.—(Anfangsgr. der Wundarzn. b. 3, kap. 14.)

One of the most common symptoms of a beginning amaurosis, is an appearance in the patient's fancy, as if gnats or flies were flying about before his eyes (Visus Muscarum, Myodesopsia). Sometimes, transparent, dark-streaked, circular, or serpentine diminutive bodies appear as if flying in greater or less numbers before the eyes, often suddenly ascending, and as quickly falling down again, and chiefly annoying the patient and confusing his sight when he looks at strongly illuminated or white objects. The substances thus appearing to fly about before the patient's eyes, are termed Muscæ volitantes; Mouches volantes.—(Beer, Lehre, &c. b. 2, p. 424.) If what obstructs the sight be a single black speck, it receives the name of scotoma.

This illusive perception of various substances being in rapid motion before the eye, gradually increases; the substances themselves become less and less transparent, and, at length, are so connected together, that they form a kind of net-work or gauze, by which all objects are more or less obscured. This is another symptom of amaurosis, technically called visus reticulatus. The net-work commonly has the peculiarity of being black in very light situations, or when white substances are before the eye; while, in dark places, it is quite shining, and, as it were, of a bluish white hue, like silver, though sometimes of a red-yellow golden colour.

A not uncommon symptom of imperfect amaurosis is the patient's seeing every object indistinctly in a rainbow-like, sometimes tremulous, and generally very dazzling light; while, in the dark especially, blue or yellow flashes, or fiery balls seem suddenly to pass before his eyes when the eyelids are shut, and excite considerable alarm (Visus lucidus; Marmoryge Hippocratis; Photopsia.)

In imperfect amaurosis, the sensibility of the retina may be so augmented, that the patient shuns all very light places, particularly those in which the light is strongly reflected into the eye, and, in order yet to discern in some measure large objects, he feels himself obliged always to seek shady, darkish situations, or to screen his eyes, out of doors, with a green shade, or green glasses. This state is termed by Beer, Lichtscheue (Photophobia). Under these circumstances, it sometimes happens, that the patient for a very short time, for example a few moments, or (what is very uncommon) for a more considerable period, is able of himself to discern the smallest objects in a weak light, more plainly and accurately than the best eye can hardly do in a good light. Yet, excepting at such period, the patient with the above degree of light is not capable of seeing even larger objects. This infirmity of sight receives the name of oxyopia.

Sometimes, in the early stage of amaurosis, all objects seem covered with a dense mist; while, in other instances, this mist first presents itself as a simple, continually-increasing scotoma, and rarely in the form of a net-work or gauze; but to the patient, when his blindness commences with the visus nebulosus, the mist usually appears for a day or two of a light gray colour, and then for another day or two very black, every thing appearing as if looked at through a dense sooty smoke.—(Beer, Lehre von den Augenkrankheiten, b. 2, p. 422—426.)

To an eye affected with imperfect amaurosis, all objects frequently appear indistinct, but double (Visus duplicatus; Diplopia). It is remarked by Schmucker, that in the gutta serena, which comes on gradually, the patient sometimes sees double, with both eyes. He once cured a major of hussars, who saw the three lines of his squadron double; and he attended another gentleman similarly afflicted. Such cases, he conceives, are brought on by a violent distention of the vessels of the choroides, where, he thinks, varices may easily arise, in consequence of the weak resistance of that membrane. In this manner, the filaments of the retina suffer pressure, and the rays of light are broken. Under these circumstances, if prompt assistance be not afforded, total and frequently incurable blindness may be the consequence. Schmucker met with an irremediable amaurosis of this kind, in a young man, twenty-six years of age. When the patient made application for advice he had been blind a year. Before he lost his sight, he remarked, that after any violent emotion, his sight at first grew weak, and that objects afterward appeared double. When his circulation was at all hurried, he saw black spots before his eyes, and at length was quite blind. The vessels of the choroides were as large as if they had been injected with wax, and every kind of surgical assistance proved ineffectual.—(Vermischte Chir. Schriften, b. 2, p. 12, &c. 8vo. Berlin, 1786.) In some cases, according to Beer, double vision only occurs when the patient looks at objects with both eyes, and it ceases as soon as he shuts either the diseased or the sound eye. In the last of these circumstances, double vision only originates from the deviation of the unsound eye from the axis of sight; but, in the first instance, it arises from the morbid state of the retina itself of the diseased eye. For the purpose of distinguishing both these examples of diplopia from every other species of symptomatic double vision, Beer applies to them the name of diplopia nervosa. A degree of squinting (strabismus), there-

fore, is a very common symptom of incipient amaurosis, particularly when only one eye is affected; for this always deviates more or less from the axis of vision. It is owing to this loss of correspondence, that persons affected with an imperfect amaurosis of one eye often mistake the relative distance of objects, and frequently see them reflected.—(Traver's Synopsis, p. 170.) It is less usual for imperfect amaurosis to be accompanied with what Beer terms obliquity of the eye (Luscitas); either a paralysis, or a ceaseless, irregular action of one or more of the muscles of the organ, being evidently a condition of this symptomatic appearance.—(See Beer's Lehre von den Augenkrankheiten, b. 2, p. 427.)

Beer has often met with patients labouring under imperfect amaurosis, who could plainly distinguish all objects which were not very small; but saw them of a different colour from their real one; for instance, yellow, green, purple, &c. (Visus coloratus; crupsia.) He had under his care an amaurotic woman, who at midday could discern even the smallest objects in a strong light; but they all appeared yellow, though no marks of jaundice were perceptible.

Sometimes, in the early stage of amaurosis, all objects appear quite distorted, bent, shortened, and, in rarer instances, inverted (Visus defiguratis; Metamorphosia). Thus the flame of a candle appears very long, but all awry. This is said by Beer to be constantly an unfavourable omen, as the cause of it lies in the brain itself.

Imperfect amaurosis is sometimes attended with considerable short-sightedness (Myopia); and sometimes with the opposite affection (Presbyopia); an infallible proof that essential changes have happened either in the transparent media or in the muscles of the eye.

Many patients, when first attacked with amaurosis, every where testify a partiality to a great quantity of light, employing several candles at night, and sitting in the daytime with their backs against a sunshiny window, in order to let whatever they are reading have a very strong light upon it. This symptomatic appearance of incipient amaurosis is termed by Beer, Lichthunger.

Amaurosis may either take place in an instant, even so as to be attended with entire blindness; or it may come on quickly, that is, it may be complete in a few days or weeks; or lastly, what is most frequently the case, it may be produced gradually, and several years elapse before it attains its utmost degree; circumstances of great moment in the diagnosis and treatment.

The type which the disease assumes in its course and developement, is also subject to great variety, and claims the utmost attention; for amaurosis may either be permanent or temporary. It is sometimes an intermittent disorder, making its appearance at regular or irregular intervals. In certain examples it prevails at particular times, commonly all day, till a certain hour; or from one day till the next; or at a stated time every month. The attacks sometimes take place at indeterminate periods. In particular cases, another morbid affection is associated with the impairment of sight. Richter mentions a man who became blind at twelve o'clock in the day, when the upper eyelid used to hang down paralytic. The attack always lasted twenty-four hours. On the following day at twelve o'clock, the sight used to return, and the patient then suddenly regained the power of raising the upper eyelid. He would continue thus able to see for the next twenty-four hours. Whenever he took bark, the disease was regularly doubled; that is to say, the man then alternately remained blind forty-eight hours, and recovered the power of seeing for only twenty-four. In another patient, cited by the same writer, the aqueous humour, during the blindness, always became discoloured, whitish, and turbid; but its transparency regularly returned on the cessation of the attack. According to Richter, the periodical amaurosis commonly depends upon irritation affecting the digestive organs, the stimulus of worms, or irregularity in the menstrual discharge. Sometimes it is plainly a symptom of a confirmed ague, the patient being attacked with an ordinary intermittent, and blind during each paroxysm, but always regaining his sight as soon as each fit is over.—(Anfangsgr. der Wundarzn. b. 3, kap. 14.) Beer believes that periodical amaurosis is chiefly observed in chlorotic, hemorrhoidal, hysterical, and hypochondriacal subjects. Day-blindness (Cæcitas Diurna; Nyctalopia) and night-blindness (Cæcitas Crepuscularis; Hemeralopia) are nothing more than cases of periodical amaurosis. But sometimes the frequently recurring form of the disease confines itself to no determinate type; and, on account of its irregularity, it is then termed by Beer "amaurosis vaga," which, he says, is often of spasmodic origin, and therefore principally met with in persons liable to hysteria, hypochondriasis, convulsions, or epilepsy. Periodical amaurosis, after remaining uncured a certain time, often becomes permanent.—(Beer, Lehre, &c. b. 2, p. 429.)

In amaurosis in general, but particularly when no material knowledge can be acquired of causes, and the treatment must of necessity be conducted on empirical principles, it is of the highest importance to recollect what Richter has pointed out; namely, that amaurosis sometimes commences with several symptoms, betraying an increase of sensibility in the eye, or some irritation affecting this organ. In moderately light places, the patient can discern things very well; but in a great light, he is not able to see at all. The eye is sometimes so sensible, that a strong light will make it weep and become painful. Patients of this description ought always to wear a shade, however bad their sight may be.

This form of amaurosis is described by Beer as having two stages; in the first, the patient never becomes blind; the eyesight not being lost till the end of the second stage. The disease always forms with great quickness, so that the limits between the two stages are frequently very indistinct.

The first stage commences with a peculiar sensation of fulness in the eyeball, joined with continually increasing, violent, and annoying, luminous appearances, and a remarkable weakness of sight. These symptoms are soon followed by a stupifying, constantly increasing headache, during which the power of vision manifestly diminishes, without the slightest defect being perceptible either in the eye itself, or its surrounding parts. The patient, however, is always marked by an athletic constitution, or, at all events, by such symptoms of general and local plethora, and of a phlogistic diathesis, as cannot be mistaken.

Upon the advance of the disorder into its second stage the headache becomes irregular, being less violent at some periods than others; the patient feels as if there were before his eyes a thick net or gauze, which, in a bright light, appears quite black, but in the shade, fiery and shining. This net or gauze, when there is any temporary determination of blood to the head and eyes, as in straining at stool, is immediately rendered considerably more dense; and when such determination of blood is often repeated, or long maintained, the density at length remains much greater than before, and, consequently, the patient suddenly grows more blind, and is very quickly entirely bereft of vision. This complete loss of sight, in the second stage, if efficient assistance be not given, is ultimately produced by the progress of the disease, even without any accidental determination of blood, though never quite suddenly. At last, all power of discerning the light is abolished under incessant stupifying headaches, which are sometimes weaker, sometimes stronger, and attended with a sensation, as if the dimensions of the eye were increased, and, indeed, it really feels harder than in the healthy state.

Sometimes amaurosis originates with symptoms of weakness and diminished irritability. The sight is cloudy, and the patient finds that he can see better in a light than a dark situation. He feels as if some dirt or dust were upon his eyes, and is in the habit of frequently wiping them. His power of vision is greater after meals than at the time of fasting. His sight is always plainer, for a short time, after the external use of tonic remedies, such as hartshorn, cold water, &c. Richter informs us of a person, who was nearly quite blind, but was constantly able to see very well for the space of an hour, after drinking champaign wine. He also mentions a woman entirely bereft of sight, who was in the habit of having it restored again, for half an hour, whenever she walked a quick pace up and down her garden. He likewise acquaints us with the case of a lady, who had been blind for years, but experienced a short recovery of her sight, on having a tooth extracted.—(Anfangsgr. &c. b. 3, kap. 14.)

Whether the benefit arose from the stimulus of the operation, as Richter seems to imply, or from the

removal of an irritating cause, doubts may rationally be entertained. A similar fact is recorded by Mr. Travers, who says, that he has seen an incipient functional amaurosis distinctly arrested by the extraction of a diseased tooth, when the delay of a similar operation had occasioned gutta serena on the opposite side two years before.—(Synopsis, p. 299.)

When the disorder is accompanied with diminished sensibility in the eye in general, Beer joins Richter, with respect to the temporary improvement of the sight after a nourishing meal, or drinking spirituous liquors; or when the patient's mind is elated with joy, or anger, though such melioration of sight, it is true, is but of very short duration.—(See also Vetch's Treatise on the Diseases of the Eye, p. 137.)

On the other hand, it may be remarked, that every thing which tends to depress the passions and spirits, augments the imperfection of sight. Where marks of increased sensibility prevail, the above-mentioned circumstances exercise a transient disadvantageous operation; the patient carefully retires from every strong light, and frequently shelters his eye with his hand, &c.—(Lehre von den Augenkr. b. 2, p. 430.)

Mr. Travers also knows patients, whose vision is benefited in a high degree, and others, in whom it is much deteriorated, by the quickened circulation of a full meal, and a few glasses of wine. The former, he says, are persons of spare and meagre habits; the latter plethoric.—(Synopsis of the Diseases of the Eye, p. 157.)

According to Beer, this amaurosis differs from the preceding, by its formation being usually very slow, and its not exhibiting any traces of those two very different stages which are peculiar to the other case. It also invariably commences with the visus reticulatus, or nebulosus, without any alternation with a blinding glare of light; and the eyesight is sometimes considerably better, and sometimes weaker, which always depends upon the accidental operation of the above internal or external circumstances. The melioration of the eyesight never continues long, while the diminution of it not only remains, but gets worse and worse. It is not at all uncommon for this species of amaurosis to make its appearance as a night-blindness, because common artificial light is much too feeble to make due impression upon the diminished sensibility of the optic nerve, and consequently these patients always show a partiality to a very strong light. To such weak-sighted individuals, the flame of a candle, or the moon, appears as if covered by a dense veil, with an expanded halo round it of various colours. There is no complaint made of pain in the head or eyes; and no sensation of fulness or weight is experienced in the eyeball; much less are there any signs of the disease in the structure and form of the eye, or in the action of its irritable textures; but when it has been long complete, it is usually conjoined with a debilitated habit.

Amaurosis either presents itself as a genuine uncomplicated affection, or, at least, with the appearance of such a form of disease of the eye, depending solely upon a morbid state of the optic nerve, and cognizable by a diminution, or complete abolition, of the power of vision; or the disease is co-existent with other diseased appearances, either in the eye, its vicinity, or some other organs at a distance from the eye, or in the general constitution. These appearances merit the most earnest consideration, because they are for the most part connected with the cause of amaurosis. According to this statement then, there is a genuine local amaurosis, and a complicated amaurosis, which last may be either local, or general, or of both descriptions together, and therefore named by Beer, "perfectly complicated."—(Vol. cit. p. 431.)

The general symptoms of the simple uncomplicated species of amaurosis, putting out of consideration the morbid increase, or diminution of the sensibility of the optic nerve, are thus described by Beer. In the first place, all morbid appearances are absent, which might be produced in the amaurotic eye by any one preternatural change in the texture, form, or state of that organ. Hence we are obliged to trust almost exclusively to the patient's assertion that his sight is bad, or quite gone; and not unfrequently it is necessary, especially in judicial cases, to employ political artifices in order to determine whether such assertion be true, particularly when the patient affirms that the blindness is restricted to one eye. Secondly, when the amaurosis is indeed nearly or quite formed in one eye, a slight degree of strabismus is at most perceptible, arising from the circumstance of the patient's not fixing the eye affected upon any object. This degree of strabismus is noticed by Ackerman and Fischer as the surest sign of amaurosis.—(See Klinische Annalen von Jena, st. 1, p. 144.) And it is particularly pointed out by Richter as an invariable attendant upon amaurosis. The patient, says he, not only does not turn either eye towards any object, in such a manner, that the object looked at is in the axis of vision, but he does not turn both his eyes towards the same thing. This was regarded by Richter as the only symptom which we can trust, where implicit confidence should not be put in the mere assurance of the patient that he cannot see, while all the coats and humours of the eyes present their natural appearance.—(See Anfangsgr. der Wundarzn. b. 3, kap. 14.) Provided this observation be correct, it must be highly interesting to the military surgeon, amaurosis being a common affliction of soldiers, many of whom, however, endeavour to avoid service by pretending to labour under a disqualification which they well know does not necessarily produce any very considerable alteration in the natural appearance of the part affected. Thirdly, while the disorder is only in the stage of amblyopia, the patient always complains of continually multiplying muscæ volitantes, or of the visus reticulatus, or nebulosus. Fourthly, luminous forms appear before the eyes, especially in the dark, even when the patient is entirely blind. Fifthly, the decrease of vision goes on to complete blindness, without any material interruption, or retrogression. Sixthly, when only one eye is quite blind, and the eyesight on the other side is perfectly undisturbed, there is one infallible symptom of this amaurosis; namely, if the sound eye be very carefully covered, the pupil of the blind one immediately expands, and the iris becomes quite motionless, notwithstanding the diseased eye be exposed to the strongest light possible. However, this criterion is mostly wanting, because the amaurosis, unattended with any perceptible effect, except loss of vision, is seldom confined to one eye, but usually affects both.—(See Lehre von den Augenkr. b. 2, p. 481, 482.)

Mr. Travers divides amaurotic affections into two classes, the organic and the functional. The first comprehends alterations, however induced, in the texture or position of the retina, optic nerve, or thalamus. The second includes suspension, or loss of function of the retina and optic organ, depending upon a change, either in the action of the vessels, or in the tone of the sentient apparatus.

As causes of organic amaurosis, Mr. Travers enumerates; 1. Lesion, extravasation of blood, inflammatory deposition upon either of its surfaces, and loss of transparency of the retina. 2. Morbid growths within the eyeball, dropsy, atrophy, and all such disorganizations as directly oppress or derange the texture of the retina. 3. Apoplexy, hydrocephalus, tumours or abscesses in the brain, or in or upon the optic nerve or its sheath, and thickening, extenuation, absorption, or ossification of the latter. As causes of functional amaurosis, Mr. Travers specifies; 1. Temporary determination; vascular congestion, or vacuity, as from visceral or cerebral irritation; suppressed or deranged or excessive secretions, as of the liver, kidneys, uterus, mammæ, and testes; various forms of injury and disease; and hidden translations of remote morbid actions. 2. Paralysis idiopathica, suspension or exhaustion of sensorial power from various constitutional and local causes; from undue excitement or exertion of the visual faculty; and from the deleterious action of poisons on the nervous system, as lead, mercury, &c.

From this description, says Mr. Travers, it will be understood that organic, and many forms of functional amaurosis are incurable; and the functional, by continuance, lapses into the organic disease.

Functional amaurosis is subdivided by Mr. Travers into, 1st, the Symptomatic, or that which is only a symptom of some general disease, or disorder of the system; as, for example, general plethora, general debility: 2dly, the Metastatic, or that produced by the sudden translation of the morbid action from another organ of the body; as, for example, from the skin, the testicle, &c.: 3dly, the Proper, or that which depends upon a peculiar condition of the retina; as, for example, the visus nebulosus, muscæ volitantes.—(Synopsis, p. 139—155.)

On the whole, genuine local amaurosis, that is to say, a diminution or total loss of the eyesight, unattended with any other apparent local or constitutional defect, may be said to be a very rare case, the disorder being usually more or less complicated.

To the local complications, says Beer, belong the cataract; glaucoma; a general varicose state of the eyeball (cirsophthalmia); exophthalmia; atrophy of the eye; spasms in the organ and surrounding parts; paralysis of one or more muscles of the eye (ophthalmoplegia); paralysis of the eyelids; ophthalmia in general, and internal ophthalmia in particular; a scorbutic blood-shot appearance of the eye (hypoema scorbuticum); and finally, wounds or contusions of the eye or adjacent parts. With these cases should also be mentioned that important case, fungus hæmatodes of the eye. From this simple enumeration of local complications one may see how frequently amaurosis is only a symptomatic effect of another disorder of the eye, with which it is conjoined, and how often it is connected with the same common causes which pertain to another or several other diseases of the eye.

Among the general complications Beer enumerates those which are purely nervous: impairment of the health in various forms by infection, contagion, or miasmata; a bad habit of body; typhoid fevers, the amaurotic effects of which upon the eye the author of this work has frequently noticed; asthma; internal and external hydrocephalus; organic defects of the abdominal viscera; worms; chlorosis; consumption; old ulcers of the legs; organic disease of the brain and skull; complaints arising from pregnancy; hemorrhage, &c. In these general complications Beer remarks that the casual connexion between amaurosis and some remote disease of another organ, or of the whole constitution, cannot be mistaken; and in these cases we often see the disease of some other distant part from the eye suddenly or gradually diminish, and immediately appear again as a sympathetic action in the form of amaurosis, of which the most remarkable instance is seen after the sudden healing of old ulcers of the legs.—(Beer, Lehre von den Augenkr. b. 2, p. 433.)

From the above general remarks upon amaurosis it is quite manifest that the symptoms of the disease vary considerably according to the violence of its causes, and of the local and general complications, though the seat of the disease and what is particularly the proximate cause of the loss of vision be in the optic nerve; and it depends especially on the nature of the causes, whether this or that morbid appearance take place in the eye.

One may consider as the only really inseparable symptom of amaurosis that weakness of sight (amblyopia), or that complete blindness, in which neither with the unassisted or assisted eye the least defect can be perceived in the structure and shape of the affected organ. Hence Beer names such impairment of vision, or blindness, amaurotic. But how rarely this essential symptom is met with alone, and how frequently it is obscured by some other defect in the structure and form of the eye, is proved by daily experience.

The incidental symptoms of amaurosis have hitherto been set down as merely consisting of a considerable dilatation of the pupil, and immobility of the iris, because these appearances are indeed the most frequent; but, as Beer observes, this is another proof what ignorance has prevailed respecting the true nature of that disease of the eye and its modifications, which are usually termed amaurosis.

The incidental symptoms of amaurosis may consist in the faulty size and shape of the pupil. In many cases the pupil is very much dilated, immoveable, and possesses its natural black colour and usual transparency. It cannot be denied that this is the state of numerous cases, but it is equally true that there are many exceptions. Sometimes, according to Richter, in the most complete and incurable cases the pupil is of its proper size, and even capable of free motion (Turbès, Recueil Périodique, &c. t. 2, p. 319); and occasionally, it is actually smaller and more contracted than natural. This aperture often continues extraordinarily large in the strongest light; but in some instances it is unusually small in every kind of light.—(Arrachard, Recueil Period. &c. t. 1, p. 273. Richter, Anfangsgr. &c. b. 3, p. 424. Beer, Lehre, &c. b. 2, p. 435.) According to the latter writer, the pupillary edge of the iris rarely has its primitive shape, being generally more or less angular; either at some indeterminate point, or above and below, so as to resemble in some measure the pupil of the cat race; or towards the nose or temple, so as to have some similitude in its form to the pupil of ruminating animals. These appearances are highly important, having great influence over the diagnosis.

Frequently not only the size and shape of the pupil are faulty, but the position of that opening is quite unnatural, being inclined either upwards or downwards, or outwards or inwards; but most commonly in a diagonal line between inwards and upwards, and in these cases the pupillary margin of the iris never describes a regular circle, but is always more or less angular.—(Beer, vol. cit. p. 436.)

The pupil of an eye affected with amaurosis frequently does not exhibit the clear shining blackness which is seen in a healthy eye. In general it is of a dull, glassy, horn-like blackness, which symptom alone is frequently enough to apprize a well-informed practitioner of the nature of the disease. It is, in the words of Mr. Travers, "little more than the healthy appearance of the humours in the eye of a horse."—(Synopsis, p. 146.) Sometimes the colour of the pupil has an inclination to green; while in other examples this aperture seems to be dense, white, and cloudy, so that the complaint might easily be mistaken for the beginning of a cataract. This error, into which inexperienced surgeons are liable to fall, may generally be avoided by attention to the following circumstances:—The misty appearance is not situated close behind the pupil in the place of the crystalline lens, but more deeply in the eye. Nor is it in proportion to the impairment of sight, the patient being quite blind, while the misty appearance is so trivial, that if it arose from the opacity of the crystalline lens, it could at most only occasion a slight weakness and obscurity of vision; at the same time Richter acknowledges that it must be more difficult to avoid mistake when a beginning amaurosis is accompanied with this cloudiness of the eye, and consequently when the degree of blindness seems to bear some proportion to the degree of mistiness in the pupil. However, in this case he maintains that the true nature of the disease may generally be known by comparing the ordinary symptoms of the two diseases.—(Anfangsgr. b. 3, p. 14.) And, according to Beer, when the pupil is of a true dark-gray, or greenish-gray colour, a lateral inspection of the eye will show plainly enough, that the cloudiness is in the vitreous humour or behind it. Sometimes the pupil appears reddish, quite red, or of a yellowish-white colour (Lehre von den Augenkr. b. 2, p. 436); while in other cases the interior of the eye a good way behind the pupil seems quite white, and a concave light-coloured surface may be observed, upon which the ramifications of blood-vessels can be plainly seen. In particular instances this white surface extends over the whole back part of the eye, while in other cases it only occupies a half or a small portion of it. This peculiar appearance has been ascribed to a loss of transparency in the retina itself, and a consequent reflection of the rays of light.—(Haller, Element. Physiol. tom. 5, p. 409.) Mr. Travers inclines to the opinion, that it arises from a deficient secretion of the choroid pigment, a preternatural adhesion between the choroid coat and the retina, and a discoloration or resplendent appearance of the latter from this cause.—(Synopsis, p. 148.)

One of the strongest characteristics of amaurosis and an incipient cataract, and one most to be depended upon in practice, is reported by Mr. Stevenson to be the difference which the flame of a candle exhibits in the two affections. In incipient cataract it appears as if it were involved in a generally diffused, thin mist or white cloud, which increases with the distance of the light; but in amaurosis a halo or iris appears to encircle or emanate from the mist, the flame seeming to be split, when at a distance.—(On the Nature, &c. of Amaurosis, Lond. 1821.)

There can now be no doubt that the whiteness behind the pupil must sometimes have originated from the diseased mass which, in cases of fungus hæmatodes of the eye, grows from the deeper part of this organ, and gradually makes its way forwards to the iris, being always attended with total loss of sight. Putting out of present consideration the change of colour within the eye, produced by fungus hæmatodes, the other palish changes behind the pupil are not confined, as Kieser supposes, to very old cases of amaurosis, because the alteration is described by Schmucker as taking

place especially in examples the formation of which was quite sudden (Vermischte Chir. Schrift. b. 2); and Langenbeck has recorded cases in which the same appearance happened in the early stage of the disease.—(Neue Bibl. b. 1, p. 64, &c.)

Besides the above appearances in the pupil itself, and in the pupillary margin of the iris, Beer adverts to several important phenomena with respect to the motion of the iris. Sometimes the iris moves but very inertly, and frequently not at all, though the light be strong, and the upper eyelid be rubbed over the eyeball. While in other examples a very moderate light will bring on such a rapid contraction of the iris and closure of the pupil, as are never witnessed in a healthy eye.

We have also the authority of Richter for asserting, that in particular instances the iris not only possesses the power of motion, but is capable of moving with uncommon activity, so that in a very moderate light, it will contract in an unusual degree, and nearly close the pupil.—(Anfangsgr. der Wundarzn. b. 3, p. 424, edit. 1795.)

Two or three remarkable instances of the active state of the iris, in cases of amaurosis, were some years ago shown to me by Dr. Albert, then staff-surgeon at the York Hospital, Chelsea, and I have seen other similar cases in St. Bartholomew's Hospital. Most of the patients in question had not the least power of distinguishing the difference between total darkness and the vivid light of the sun, or a candle placed just before their eyes. Janin sometimes found the pupil capable of motion in this disease, and Schmucker twice noticed the same fact.

Such cases, Mr. Travers thinks, can only be explained by concluding the organ to be sound, and the cause of the amaurosis remote or external to it. Thus, says he, in a case of circumscribed tumour, compressing the left optic nerve, immediately behind the ganglion opticum, although the blindness was complete, the iris was active. In two young ladies, in whom the eyes, as in the former case, were perfect, and the blindness complete, the iris was even vivacious; and there was the strongest presumptive evidence from the symptoms that the amaurosis was in the cerebral portion of the nerve.—(Synopsis, p. 188.)

In some anomalous cases, when the strength of the light is suddenly increased, the pupil expands with more or less celerity.

I have already adverted to the occasional moveableness of the iris, notwithstanding the insensible state of the retina. Let me next take notice of a case which sometimes presents itself, and is quite the reverse of this last. The nerves of the iris may be paralytic, while those of sight continue unimpaired. Schmucker was acquainted with a woman whose pupil was uncommonly distended, and totally incapable of motion. Her sight was very weak, and spectacles were of no use to her. She could scarcely discern any thing by day or in a strong light, but she could see rather better at night and in dark places. This infirmity of sight depended upon the dilated, paralytic state of the pupil, by which too many rays of light were admitted into the eye; and the reason why the patient could see better at night was because the pupil, in its natural state, always becomes widened in a dark situation.—(See Vermischte Chirurgische Schriften, von J. L. Schmucker, band 2, p. 13, 14.)

On this curious part of the subject it is remarked by Mr. Travers, that if the retina be opaque, compressed, or unsupported, the iris mechanically disordered, or the ciliary nerves palsied, the pupil is inactive, independently of the state of vision. In the first of these cases it is evident vision will be lost; but we continually see useful vision combined with the second and third, as after operations in which the iris has been half destroyed or has become preternaturally adherent, or in malformations where it is half wanting; and in paralysis of the ciliary nerves accompanying ptosis.—(Synopsis, p. 188.)

Frequently in amaurosis, when the sight of only one eye is lost, and the other retains its full power of vision, not the slightest defect can be discovered as long as the patient keeps both of them open; but the instant the sound eye is completely covered, the iris becomes perfectly motionless, its pupillary margin assumes an angular shape, and the pupil expands, being sometimes evidently drawn towards the edge of the cornea.—(Beer, Lehre von den Augenkrank. b. 2, p. 438.) This demonstrates the difference between the independent and the associated action of the iris.

Besides the above appearances of the pupil and iris, amaurosis is attended with other characteristic phenomena, which occur under certain circumstances, in the form, texture, and state of other parts of the eye and adjoining organs. Thus the patient often complains of a peculiar troublesome dryness of the eye, or of a sensation as if the eyeball were about to be pressed out of its socket; and indeed, says Beer, one may sometimes hear a grating noise, and distinguish a fluctuation in the orbit behind the eyeball, when this organ is pressed upon by the finger, or moved in various directions, though neither its circumference be enlarged, nor any tendency to exophthalmia be really present. Nor is it very uncommon to find the affected eye preternaturally hard, soft, or even quite flaccid; but it is less common to find the dimensions of the globe of the eye increased, or the organ affected with atrophy.—(Beer, vol. cit. p. 428.)

However, in organic amaurosis, as Mr. Travers notices, a peculiar bluish-gray tint of the sclerotic coat is frequently remarkable; and sometimes even a degree of bulging on one or more sides of the eye, or simply a loss of sphericity, its sides appearing flattened.

A turgescence of the superficial vessels, especially of the long fasciculi of conjunctival veins, is likewise another symptom, frequently observed in cases of organic amaurosis.—(See Travers's Synopsis, p. 146.)

The same gentleman also gives the particulars of a dissection, in which a case of amaurosis was attended with a collapse of the retina from absorption of the vitreous humour.—(Op. cit. p. 150.)

Some of the principal morbid effects of amaurosis have been already described in speaking of the several defects of vision, which accompany an amaurotic weakness of sight. Besides these, however, there are others which merit attention. For instance, the patient feels in the eye and surrounding parts an irksome sensation without any actual pain, and complains of a remarkable sense of fulness or weight in the organ. Amaurotic patients are also frequently attacked with sudden violent giddiness, usually ending in a considerable diminution of the eyesight, and sometimes in severe general headache. Occasionally they fancy that small atoms of dust are lodged under the eyelids, and are fearful of moving these parts of the eye. It is also well known, that many persons become amaurotic while labouring under severe hemicrania, extending from or to the diseased eye; while, on other occasions, the most violent pains are confined particularly to the region of the eyebrow, and have the appearance of being strictly periodical. In certain other cases the pain is wandering, and shoots in every direction about the eyebrow. These painful feelings often precede the amaurotic blindness a considerable time, and often first take place when one or both eyes are already blind; but the pains and loss of sight are not unfrequently produced together. Lastly, some patients are met with, in whom the worst pains only last until the amaurosis is perfectly formed, when they gradually and permanently cease. In all these painful cases of amaurosis, the pain and the blindness chiefly depend upon the same cause, and one is seldom the occasion of the other. Sometimes amaurotic patients experience such violent pain, that they lose their senses and grow delirious; but in these cases, if we can credit the assertion of Beer, important morbid changes in the bones of the skull, or the brain itself, are invariably noticed after death.—(See Lehre von den Augenkr. b. 2, p. 439.) In some amaurotic patients lethargic symptoms may be remarked; in others, restlessness; and more rarely delirium in all its degrees, either as a transient or permanent affection.

According to the observations of Mr. Travers, pain affecting the forehead and temples is a percursory symptom of amaurosis, diminishing in proportion as the dimness increases. When the amaurosis is perfect, it usually ceases altogether, if the disease has its seat in the eyeball. But when the pain is severe, remits imperfectly, and is quickly rendered worse by exercise, it is usually connected with organic disease of the brain. In this case derangement and torpor of the primæ viæ, loss of strength and flesh, disposition to stupor, occasional confusion of intellect, inaptitude to exertion, and paralysis of one or more muscles will be concomitant symptoms.—(Synopsis, &c. p. 167.)

Paralytic appearances may precede amaurosis, either in the vicinity of the eye, or in the muscles of the face, or in a distant situation, as the extremities. Sometimes they accompany the disease, and sometimes closely follow the weakness of sight, being not unfrequently the forerunners of a fatal attack of apoplexy.

In the same way convulsive symptoms may be conjoined with amaurosis, and when they first occur in the complete stage of the latter disease, Beer pronounces them a very unfavourable omen for the patient's life.

But according to the same experienced oculist, when in a cause of perfect amaurosis several of the other external senses are affected; and lastly, when the internal senses begin to suffer, when, for instance, the hearing, and then the smell and taste are lost, and afterward the memory and other intellectual powers fail, the patient's speedy dissolution may be expected.—(See Lehre von den Augenkrankh. b. 2, p. 441, Wien, 1817.)

As Professor Beer correctly observes, age cannot be considered a predisposing cause of amaurosis, as it is of cataract; for there are many more blind persons who have been deprived of their sight by amaurosis in their best days than old persons thus attacked. Amaurosis spares no age—not even the new-born infant. Mr. Lawrence, in his Lectures, concurs in this statement, adding his opinion, however, that amaurosis is very frequent during the active middle period of life, and very common about the cessation of menstruation in females, and the corresponding age in the male.

Four forms of congenital organic amaurosis are noticed by Mr. Travers. One in which the eye is preternaturally small, soft, and even flaccid; the iris tremulous, and not influenced by belladonna; and the globe affected with tremor, and not subject to the control of the will. A second, depending on a deficiency of the pigmentum nigrum; the organ is tremulous, strong light produces uneasiness, and vision is dazzled and confused. The vessels of the choroid give the interior of the eye a deep-red tinge. A third case is that in which the sclerotica so encroaches upon the cornea, that the latter is scarcely wider than the pupil. In the fourth kind of congenital amaurosis, described by Mr. Travers, the eyes move in concert, as if attracted by a faint perception of light: but the infant is blind; no marks of organic derangement can be seen; but Mr. Travers apprehends that the disease must be connected with a morbid state of the thalami or optic nerve.—(Synopsis, p. 153, 154.)

Neither does sex nor race appear to have any influence over the origin of the complaint; but it would seem that dark eyes, especially those which are called black, are more disposed to amaurotic blindness than such as are light-coloured. According to Beer's experience, for every gray or blue eye affected with amaurosis, there are five-and-twent yor thirty brown or black ones thus, diseased. In the peculiar constitution of the eye, then, as well as in a sanguineous and choleric temperament, there exists a tendency to the disorder.

More frequently than cataract, amaurosis is found to be a true hereditary disease:—this is so much the case, that most of the members of a family for more than one generation may lose their sight from amaurosis at a certain period of life. Beer says that he is acquainted with more than one family in which this has happened, and what merits attention, the women of one of these families, down to the third generation, became completely and permanently blind from amaurosis on the cessation of the menses, while all the others who had had children were unaffected. But the males of this unfortunate family, who as well as the females have very dark-brown eyes, all seem to be weak-sighted, though none of them are yet blind.—(Lehre von den Augenkrankheiten, b. 2, p. 443.)

In women, especially those with black eyes, the time when the menses stop is a dangerous period for the commencement of amaurosis.

According to the same writer, patients whose piles used to bleed periodically for a long time, but are now suddenly stopped, and whose eyes are dark, are very liable to amaurosis.

One of the less common causes of amaurosis is an idiosyncrasy, in relation to this or that sort of nutriment or medicine, or this or that particular state of the body. Here is to be reckoned the amaurotic weakness of sight, or the perfect amaurosis, which comes on at the very commencement of pregnancy, and subsides after delivery, but always attended with dyspepsia and insuperable vomiting. This species of amaurosis, however, should be carefully distinguished from that which sometimes first originates in the final months of pregnancy, and chiefly from strong and long-continued determination of blood to the head and eyes, particularly when the bowels are at the same time loaded, and the patient constipated. This latter case usually continues till after delivery; or if the labour be tedious, difficult, and attended with considerable efforts, the blindness may first attain its complete form at the time of delivery, and not afterward subside.

Beer saw a young Jewess, who, at the very beginning of her first three pregnancies, which followed each other quickly, regularly lost her sight, becoming completely amaurotic between the third and fourth months, and on the first two occasions she continued blind till after delivery; but in the third instance the power of vision never returned at all. Beer twice had under his care another woman, who was attacked with amaurosis whenever she drank chocolate; but upon leaving off that drink, she never afterward had any complaint in her eyes.

If we are to believe the generality of writers on this subject, the abuse of bitter substances, as of chicory in coffee, bitter malt liquors, and bitter medicines, especially quassia, is unquestionably a predisposing cause of amaurosis.

The abuse of narcotic poisonous substances may induce amaurosis; immoderate doses of opium; hyoscyamus; belladonna, &c. Lead will do the same thing. Respecting the operation of some of these causes, however, Mr. Lawrence entertains a doubt. The narcotic vegetables used to dilate the pupil, he observes, are supposed to give a tendency to amaurosis. He has never seen such an effect produced by the belladonna; and he adverts to one case in which it was used a great length of time. The effect of bitters seems to him equally problematic.

One not unfrequent and very important cause of amaurosis is hysteria and hypochondriasis, with which must be mentioned infarction, and disease of one or more of the abdominal viscera, especially the liver.—(Beer, Lehre, &c. b. 2, p. 444—446.)

According to Richter, the remote causes of amaurosis may be properly divided into three principal classes, the differences of which indicate three general methods of treatment.

The first class of causes depends upon an extraordinary plethora and turgidity of the blood-vessels of the brain, or of those of the optic nerves and retinæ, upon which last parts a degree of pressure is thereby supposed to be occasioned. A considerable plethora, especially when the patient heats himself, or lets his head hang down, will frequently excite the appearance of black specks before the eyes, and sometimes complete blindness. A plethoric person (says Richter) who held his breath, and looked at a white wall, was conscious of discerning a kind of net-work which alternately appeared and disappeared with the diastole and systole of the arteries.

Richter thinks it likely that the disease is thus produced, when it proceeds from the suppression of some habitual discharge of blood, not being bled according to custom, the stoppage of the menses, and the cessation of hemorrhage from piles. In the same manner the complaint may be brought on by great bodily exertions, which must determine a more rapid current of blood to the head. Richter informs us of a man who became blind all on a sudden, while carrying a heavy burden up stairs. He tells us of another man, who laboured excessively hard for three days in succession, and became blind at the end of the third day. Pregnant women in like manner are sometimes bereft of their sight during the time of labour. Schmucker has recorded a remarkable instance of this in a strong young woman, thirty years old, and of a full habit. Whenever she was pregnant, she was troubled with violent sickness till the time of delivery, so that nothing would stop in her stomach. She was bled three or four times without effect. Towards the ninth month her sight grew weak, and for eight or ten days before parturition, she was quite blind. The pupil of the eye was greatly enlarged, but retained its shining black appearance. She recovered her sight immediately after delivery, and did not suffer any particular complaints. Schmucker assures us that he has been three times a

witness of this extraordinary circumstance.—(Vermischte Chir. Schriften, band 2, p. 6, edit. 1786.) Richter speaks of a person who lost his sight during a violent fit of vomiting. Schmucker acquaints us that it is not uncommon for soldiers, who are performing forced marches in hot weather, to become blind all on a sudden.

Beer also coincides with Schmucker, Richter, and others, in regarding as a frequent cause of amaurosis repeated and long-continued determinations of blood to the head and eyes, produced by various circumstances, viz. by pregnancy; a tedious and difficult labour; lifting and carrying heavy burdens, especially with the arms raised up; all kinds of work, in which the eyesight and intellectual faculties are intensely exerted, with the head bent forwards, and the abdomen compressed, as is the case with shoemakers, tailors, &c.; every sudden stoppage of natural or preternatural long-established discharges of blood, as that of the menses, lochia, or hemorrhoids; the omission of habitual venesection at some particular season of the year; severe and obstinate vomiting; forced marches in hot dry weather; scrofulous and other swellings of considerable size in the neck, pressing upon the jugular veins, and obstructing the return of blood from the head; the use of a pediluvium, or warm bath, the water of which is of high temperature; hard drinking; violent gusts of passion; frequent and obstinate constipation; and hard straining at stool. These causes are more likely to occasion amaurosis in proportion as the individual is young and plethoric. The causes of that amaurosis which is characterized in its first stage by increased sensibility of the eye, and intolerance of light, are referred by Professor Beer to circumstances which produce a long and repeated determination of blood to the head and eyes.—(Beer, Lehre von den Augenkr. b. 2, p. 446 and 483, &c.)

Mr. Lawrence, in his Lectures, regards amaurosis, in its most frequent and important form, that which is seated in the eye itself, as generally the result of inflammation of the nervous structure; including under that phrase, all degrees of increased vascular action, whether designated as fulness, turgescence, determination, congestion, or as inflammation in its more limited sense; and the usual consequence of inflammatory disturbance, that is, organic change permanently destroying the function of the part. When, says Mr. Lawrence, we advert to the structure of the retina, we must suppose that it would be liable to such affections; we find it composed of minute ramifications of the arteria centralis retinæ, and on this net-work of vessels the nervous pulp is expanded. The state of the retina, when examined after death, in amaurotic eyes, accords with these views; it exhibits those changes which long-continued inflammatory disturbance would produce; it has been found thickened, opaque, spotted, buff-coloured, tough, and in some cases even ossified. The preceding doctrine is, however, judiciously qualified by its restriction to the disease as seated in the eye itself. The retina and optic nerve, Mr. Lawrence admits, with other surgeons, may be disordered sympathetically, as the stomach may be disordered without any change visible on dissection.

The second class of causes are supposed to operate by weakening either the whole body or the eye alone, and they indicate the general or topical use of tonic remedies. In the first case, the blindness appears as a symptom of considerable universal debility of the whole system; in the second case it is altogether local. Every great general weakness of body, let it proceed from any cause whatsoever, may be followed by a loss of sight. Amaurosis, if we can give credit to the statement of Richter, is sometimes the consequence of a tedious diarrhœa, a violent cholera morbus, profuse hemorrhage, and immoderate salivations.—(Also Travers's Synopsis, p. 144.) Richter informs us of a dropsical woman, who became blind on the water being let out of her abdomen. According to the same author, no general weakening causes operate upon the eyes, and occasion total blindness, so powerfully and often as premature and excessive indulgence in venereal pleasures. Mr. Lawrence, in his Lectures, does not coincide in some of the foregoing views. "Those," says he, "who have considered amaurosis to arise from debilitating causes, have considered that debility and atony of the nerve may be produced by all those circumstances which debilitate the system generally, such as loss of blood from profuse hemorrhage, diarrhœa, copious salivation, &c. I have never seen amaurosis produced by such causes. That great anxiety and grief may favour the occurrence of amaurosis, I am inclined to allow; for it is not improbable that severe impressions of that kind may produce inflammatory excitement in the brain or eyes; but I think we cannot without more direct proofs, admit the influence of debilitating causes generally in the production of amaurosis. The most clear instance of any directly debilitating cause producing amaurosis, is that of protracted suckling."

The causes which operate locally in weakening the eyes are various. Nothing has a greater tendency to debilitate these organs, than keeping them long and attentively fixed upon minute objects. But however long and assiduously objects are viewed, if they are diversified, the eye suffers much less, than when they are all of the same kind. A frequent change in the objects which are looked at has a material effect in strengthening and refreshing the eye. The sight is particularly injured by looking at objects with only one eye at a time, as is done with telescopes and magnifying glasses; for when one eye remains shut, the pupil of that which is open always becomes dilated beyond its natural diameter, and lets an extraordinary quantity of light into the organ. The eye is generally very much hurt, by being employed in the close inspection of brilliant, light-coloured, shining objects. Among the occupations enumerated by Mr. Travers as particularly exposing persons to amaurosis, are those of needle-workers, writers, draughtsmen, inspectors of linen and scarlet cloths, and of new banknotes; money counters; smiths, stokers in iron-furnaces and glass-houses; tavern-cooks; watchmakers, engravers, philosophical instrument makers, sea officers, &c.—(Synopsis, p. 144.) They are greatly mistaken, says Richter, who think that they save their eyes, when they illuminate the object which they wish to see in the evening with more lights, or with a lamp that intercepts and collects all the rays of light, and reflects them upon the body which is to be looked at. Richter mentions a man, who, in the middle of winter, went a journey on horseback, through a snowy country, while the sun was shining quite bright, and who was attacked with amaurosis. He speaks of another person, who lost his sight in consequence of the chamber in which he lay being suddenly illuminated by a vivid flash of lightning. A man was one night seized with blindness, while his eyes were fixed on the moon in a fit of contemplation. Richter also expresses his belief, that a concussion of the head from external violence, may sometimes operate directly on the nerves, so as to weaken and render them completely paralytic.

Beer corroborates the foregoing statement; for, he says, among the most frequent causes is to be considered every abuse of the eyesight, especially in dark-eyed persons, as a long and close inspection of one object particularly with a microscope, when the thing examined is very brilliant, or reflects back much light into the eye. Hence the view of jewels at night, and long journeys through snowy countries &c., are conducive to the disease. In this respect, every kind of employment which strains the eyes much, and requires a strong reflected light, must be considered injurious.—(See also Travers's Synopsis, p. 144.) Thus, reverberating lamps, like Argand's; the view of a white wall illuminated with the sun's rays; and looking a long while at the moon, or more especially the sun, with the unassisted eye, are circumstances likely to bring on the disease. That a flash of lightning, especially when it suddenly wakes a person in the night-time out of a sound sleep, may produce an amaurotic amblyopia in an irritable eye or even perfect blindness, is a well-known fact, and it is on the same principle that going suddenly out of a dark bedroom, immediately after waking in the morning, into an apartment that commands an open extensive prospect, must be hurtful to an irritable eye, though the bad effects may only be very slow. Here is also to be included every kind of over-irritation of the eye by light, as happens to typhoid patients, when they lie with their eyes open all the day in a large sunny chamber.

Very often the cause of amaurosis consists in local or constitutional debility, proceeding from impairment of the nerves in general, or of the nerves of the head, especially those of the forehead and eyebrow; either

from a concussion of the spinal marrow, falls from a considerable height with the weight of the whole body upon the heels; concussions of the eyeball, sometimes caused by violent sneezing, but more generally by contusions of the eye with blunt weapons, &c. Some of the cases of amaurosis from blows on the temple or the eye, observed by Mr. Travers, were attended with signs of disorganization; some were superficially inflamed; and others presented no external appearance of injury. We learn also from the same authority, that it is not always the eye on the struck side of the head that is affected.—(Synopsis, &c. p. 152.) If we are to believe Beer, and other foreign practitioners, considerable direct weakness may arise from cholera, long-continued diarrhœa, salivation, and the incessant spitting of tobacco smokers; bleedings; injudicious tapping of the abdomen; excessive indulgence in venery, and the misemployment of issues. A general debility, which has the worst effect on the eyes, may also arise from long trouble, especially when the diet is poor and bad; also from a deficiency of proper food; long watching; violent and sudden fright; imprudently washing the eyes with very cold water, especially when they are already weakish and irritable; and keeping them long in a dark place, particularly when they are also exerted a good deal in some particular kinds of labour, a case which, Beer says, is very frequent in Vienna. The amaurosis following typhus, without any unusual irritation of the eye by light, Beer also refers to general debility.—(Lehre von den Augenkr, b. 2, p. 449.)

Like nervous deafness (says Mr. Travers), amaurosis sometimes follows typhus and scarlet fever, and the various forms of acute constitutional disease. He has several times met with it as a consequence of infantile fevers. He observes that it is also sometimes a consequence of chronic wasting diseases, in which organic changes interrupt the nutrition of the system. He has seen a rapid and severe salivation instituted for a remote affection, and where no disease had previously affected the eyes, terminate in gutta serena of both.—(Synopsis, p. 155.)

With regard to the doctrine that certain forms of amaurosis are diseases of debility, Mr. Lawrence expresses his disbelief in its correctness, and asserts, that the only scientific and successful treatment of amaurotic affections is found to be antiphlogistic. Whether the amaurosis resulting from typhoid fevers, of which I have seen several instances, proceed from debility, or from too great a determination of blood to the head, may admit of dispute; but I conceive, that in many of such cases, tonic treatment is clearly indicated, if not for the eye itself, certainly for the generally enfeebled state of the health, with which the amaurosis is connected. Yet Mr. Lawrence's doctrine, that fulness and congestion of the vessels originally lead to the amaurotic affection, may be more correct than the theory which refers the blindness simply to weakness. However, as the amaurosis generally does not show itself till an advanced stage of fever, or that of great debility, and as it only recedes as the patient regains strength, it can hardly be considered as a case in which any other treatment than tonic can be availing. It is right to state that Mr. Lawrence himself, notwithstanding his belief in amaurosis being a kind of inflammation of the retina, modifies the antiphlogistic treatment according to the state of the constitution.

The third class of causes consists of irritations, most of which are asserted to lie in the abdominal viscera, whence they sympathetically operate upon the eyes. The observations of Richter, Scarpa, and Schmucker, all tend to support this doctrine. Many amaurotic patients are found to have suffered much trouble and long grief, or been agitated by repeated vexations, anger, and other passions, which have great effect in disordering the bilious secretion and the digestive functions in general. Richter tells us of a man who lost his sight, a few hours after being in a violent passion, and recovered it again the next day, upon taking an emetic, by which a considerable quantity of bile was evacuated. A woman is also cited, who became blind whenever she was troubled with what are termed acidities in the stomach.—(See Anfangs. der Wundarzn. b. 3, kap. 14.) However, according to Beer, imperfect amaurosis seldom depends upon disorder of the gastric organs, excepting the case from worms. (Lehre von den Augenkr. b. 2, p. 456): a very important difference from the sentiments entertained by Schmucker, Richter, and Scarpa. The close sympathy between the stomach and the eyes is well illustrated by a case recorded in one of the journals, and referred to by Mr. Lawrence in his Lectures. It was an amaurosis, with fixed pain over the eyebrow, in a child. It was not relieved by purging and other depletive measures: an emetic was at last given; and under its action, a bead was rejected from the stomach, and the amaurosis immediately disappeared.

Amaurosis sometimes proceeds from mechanical irritation. A small shot pierced the upper eyelid, and lodged at the upper part of the right orbit, between the eyelid and eyeball, so that it could be felt externally. The patient shortly afterward became blind in the left eye; but recovered his sight after the excision of the shot.—(Anfangsgr. der Wundarzn. band 3, p. 439.)

According to Beer, several constitutional disorders, but more especially gout, are frequently concerned in the production of amaurosis. Whoever reads Beer's history of what he terms gouty amaurosis, will naturally doubt the correctness of the name; and Mr. Lawrence distinctly affirms, in his Lectures, that he has never seen gout or rheumatism occasion any tendency to affections of the nervous structure of the eye. It is not because amaurosis sometimes occurs in gouty or rheumatic constitutions, that the affection of the sight is necessarily of a gouty or rheumatic origin; for the fact merely proves, that such constitutions are not exempt from the risk of being attacked by disorders of the eye. Mr. Lawrence has also never seen any case, in which the origin of amaurosis could be referred to syphilis.

Respecting the causes of amaurosis, the following remarks by Beer claim attention. Various swellings in the orbit, as, for instance, encysted tumours, tophi, hydatids in the sheath of the optic nerve, may and must gradually produce complete amaurosis by their pressure upon the optic nerves and retina. Some of these cases are usually characterized by a protrusion of the eye from its socket.—(See Exophthalmia.) In Mr. Langstaff's museum is a specimen of two amaurotic eyes, in which the optic nerves are shrunk to about one-third of their natural size. Similar instances are recorded by Dr. Monteith.—(See Weller's Manual.) According to Mr. Lawrence, Mr. Langstaff has also some interesting specimens of enlargement in front of the third ventricle, the parietes of which bulge so as to press upon the optic nerves, and thus to account for the amaurosis under which the patients laboured.

In the same manner different morbid changes in the brain itself, and in the bones of the cranium in particular, may be the direct cause of amaurosis: for example, hydrocephalus internus, caries, and exostoses at the basis of the skull.

Just as amaurosis is frequently a pure symptomatic effect of various disordered states of the constitution, so may different morbid changes, occasioned in the eye by those states of the health, become the proximate cause of amaurosis, as hydrophthalmia, cirsophthalmia, fungus hæmatodes, dissolution of the vitreous humour, glaucoma, &c.

From a contagious atmosphere, which is generally injurious to the eyes, an amaurotic blindness may originate, though but very rarely, and, as it would seem, only through the powerful influence of such state of the air over the whole sanguiferous and nervous system. Debilitated, nervous, weak-sighted persons, by remaining long in the atmosphere of a privy (Chomel, Mém. de Paris, 1711, Obs. Anat. 5, and Ramazzini, De Morbis Artificum, c. 13), that of a deep cellar, or exposed to other effluvia, may be suddenly attacked with amaurosis; and Beer assures us, that his experience confirms the truth of these reports.—(Lehre, &c. b. 2, p. 452.) A sympathetic affection of the nerves of the eye, with a carious grinder in the upper jaw-bone, is one of the most uncommon causes of amaurotic blindness.

A case, not yet duly considered, and very like the amblyopia senilis, consists of an incessantly diminishing secretion of the pigmentum nigrum upon the tunica Ruyschiana, choroidea, and uvea, which secretion indeed, in some individuals earlier, and more considerably, in others later and in a slighter degree, recedes with other secretions of a different nature.—(See Beer's Lehre von den Augenkr. b. 2, p. 151, &c.)

As Mr. Travers has correctly explained, the history and concomitant appearances of amaurosis, usually

denote whether the case is organic or functional. "For example, diseased changes in the situation or texture of the eyeball or in the brain, or hemiplegia, or partial paralysis, with other signs of apoplectic or hydrocephalic pressure, whether resulting from an injury of the head or otherwise, or an acute deep-seated inflammation, whether accompanied by a visible opacity or not, point out the organic nature of the affection. I have seen (continues Mr. Travers) such an amaurosis produced by abscess in the cerebral substance, and by the medullary fungus of the cerebrum. On the other hand, I have known the following distinct sources of irritation operating to produce functional amaurosis, viz. a wound of the scalp, caries of the skull, abscess and caries of the antrum maxillare, with excessive œdema of the integuments of the lids and cheek, a large abscess under the masseter and muscles of the cheek, and an abscess at the extremity of a molar tooth, while the crown of the tooth was sound. In all these cases, it is to be understood, that the eye was sound, and the orbit was untouched by the disease of the parts in the vicinity, to which the amaurosis was clearly attributable. In like manner, an excessive use, or rather abuse, of the visual faculty, the disordered functions of the stomach, liver, uterus, &c. sudden and alarming depletion, excessive or obstinately suppressed secretions, difficult dentition, the presence of worms in the intestinal canal, and the deleterious effects of noxious agents upon the organ or the system, are sufficiently obvious causes of the functional amaurosis."—(Synopsis, &c. p. 142.) For a variety of additional facts and observations respecting the causes of amaurosis, I would advise the reader to consult Wardrop's Essays on the Morbid Anatomy of the Human Eye, vol. 2, chap. 45; and Travers's Synopsis: works replete with valuable information.

It is remarked by Beer, that amaurosis, when completely formed, has hitherto been but rarely cured. This (says he) may depend in the first place upon our far too imperfect knowledge of the nerves, and of their genuine and complicated disorders. Secondly, it may equally depend upon the present very defective etiology of amaurosis. Thirdly, the frequent incurability of amaurosis also very materially proceeds from the causes of the disease being, in most instances, not only obscure, but exceedingly complicated.

In amaurosis the difficulty of cure is naturally in proportion to the variety and number of causes of the complaint; and the more readily the surgeon makes himself acquainted with them, and the more certainly he obviates them, the more surely and quickly does the cure follow.

It may be considered as generally true, that every amaurotic weakness of sight, and every completely formed amaurosis, are attended with the greatest probability of cure, where they began suddenly and were quickly developed; for experience proves, that in these cases, the whole of the causes of the disease are much more frequently and earlier comprehended, than when the complaint has been several years in forming.—(Beer, Lehre von den Augenkr. b. 2, p. 454—456.) This observation perfectly coincides with the account given by Schmucker, who says that many of these suddenly formed cases fell under his notice, and were more easy of cure than when the disorder had come on in a more gradual way.—(See Vermischte Chir. Schriften, b. 2.)

It also agrees with what Mr. Travers has stated; namely, that slow and steadily progressive cases of amaurosis are more to be apprehended in the result, that is, are less tractable, than either the sudden or the rapidly advancing disease, supposing all to be alike free from unequivocal signs of organic change.—(Synopsis, p. 298.)

Respecting suddenly produced cases, Mr. Lawrence, in his Lectures, holds out less encouragement than the preceding authorities. The prognosis, he says, is doubtful, and rather unfavourable than otherwise, as to the complete recovery of vision, if the affection, even in its most recent state, should have produced complete insensibility of the retina. He thinks we should speak doubtfully of the result in the case of complete insensibility to strong light, even if it had only lasted twenty-four hours. He considers it difficult to say in what number of days or weeks we should give up all hopes of recovery. In the supposed case of total insensibility, or even of a near approximation to it, there would be more ground for apprehension than hope at the end of a week, though sight is sometimes restored under these circumstances; but the lapse of a few weeks, without improvement, makes the case hopeless.

A case may happen, nay, it happens not unfrequently, says Beer (which, considering the imperfect etiology of amaurosis, cannot be wondered at), that the surgeon, after the most careful investigation, can absolutely detect no particular cause of the existing amaurotic blindness; in which event, the prognosis must in every respect be very uncertain and unfavourable, since only empirical treatment can be tried, which rarely answers; and even when a cure in this manner does follow, it is frequently quite accidental.

As will be seen in the account of each particular species of amaurosis, the affected eye is sometimes so conditioned, that the complete incurability, sooner or later, may be prognosticated with entire certainty, and this even though a degree of vision may now be enjoyed.

There are amaurotic patients to whom every treatment does harm, the disease making uninterrupted advances to perpetual blindness. This observation especially refers to local remedies, of the danger of which, under certain circumstances, the patient should be carefully warned.

In general the more complete the amaurosis is, and the longer the patient has been deprived, not only of vision, but of all sensibility to light, the less hope is there of sight being ever re-established.

If the affection be partial, and the case seen early, Mr. Lawrence says, a complete cure may be expected. He thinks favourably of the event, when amaurosis takes place in conjunction with chronic internal inflammation, or when it is evidently caused by active congestion in the head or eye; for that cause can be removed by suitable treatment.

When one eye has been completely bereft of sight by amaurosis, and the surgeon can find out little or no cause for the infirmity, there is strong reason for apprehending that the other eye will sooner or later become blind. This is a fact amply proved by experience, and the exceptions are very rare.

According to Beer, the idea entertained by some writers is not built upon experience, that amaurotic patients in whom the iris is still moveable, and the pupil not very much dilated, are more easily and frequently cured than others in whom the iris is perfectly motionless, and the pupil exceedingly dilated. For sometimes during the treatment, or even spontaneously, the iris, after being quite immoveable, recovers it power of motion, yet the patient may not, at the same time, regain the slightest degree of vision; and, on the other hand, many cases of perfect amaurosis are cured, without the iris recovering any of its mobility, and the pupil remains dilated during the remainder of the patient's life.—(Lehre, von den Augenkr. b. 2, p. 458.) Richter also thinks, that the moveable or immoveable state of the pupil can neither be considered as a favourable nor unfavourable circumstance. Sometimes, says he, an amaurosis may be cured, which is attended with a pupil extraordinarily dilated, and entirely motionless; and sometimes the disorder proves incurable, notwithstanding the pupil be of its proper size, and capable of motion. There are likewise examples, in which the pupil recovers its moveableness, in the course of the treatment, although nothing will succeed in restoring the eyesight.—(Anfangsgr. der Wundarzn. b. 3, p. 424, 8vo. Gött. 1795.)

In some very rare instances, says Beer, amaurotic blindness has been cured by some apparently accidental or indeed morbid effect, without any assistance from art; by hemorrhage from the nose, an intermittent fever, a blow on the head, &c. The same experienced writer operated successfully upon both eyes of a patient with cataracts, which had been previously depressed too far against the retina, so that their pressure gave rise to amaurosis, which, after continuing eight years, had been suddenly removed by the patient's accidentally falling out of bed, and pitching upon the top of his head.—(Lehre von den Augenkr. b. 2, p. 458.)

The following observations made by Beer, respecting the prognosis, cannot fail to prove interesting. There is a species of amaurosis, which gradually diminishes of itself; for instance, that which arises from hard drinking, or the effect of narcotic poisons, belladonna, opium, hyoscyamus, &c.

Sometimes imperfect amaurosis goes away without

any assistance from art, in consequence of the accession of some other disease, as an eruption, a discharge of matter from the ear, bleeding from piles, the menses, &c.

Also, in most cases, when the surgeon is so fortunate as to cure amaurosis, either by scientific or empirical methods, there still continues for life a considerable degree of amblyopia, more especially if the amaurosis has been complete.

Sometimes, by successful treatment, vision is in a great measure, or even entirely restored in one eye, yet the other remains completely blind; or one eye sees again much sooner than its fellow, although they were both affected together with an equal degree of blindness.

It often happens, that though a material degree of vision returns in the course of the treatment, the faculty is restricted to a circumscribed point of the retina, so that the patient is enabled to see objects plainly only when they are held in a particular direction before him; while in other directions, they are either quite invisible, or very indistinct.—(Beer, Lehre von den Augenkr. b. 2, p. 459, 460.)

Amaurosis following an injury of the supra-orbitary nerve, frequently resists every endeavour made to relieve it, and this, whether it come on directly after the blow or some weeks subsequently to the healing of the wound of the eyebrow; but it is not always absolutely incurable. Scarpa only knows of one such cure, viz. the example recorded by Valsalva.—(Dissert. 2, § 11.) But additional instances are reported by Hey (Med. Obs. and Inq. vol. 5), by Larrey (Mém. de Chir. Militaire, t. 4, p. 181), and Dr. Hennen (Principles of Military Surgery, p. 346, ed. 2). According to Mr. Wardrop, it is only when this nerve is wounded or injured, and not divided, that amaurosis takes place; for the blindness may sometimes be cured by making a complete division of the trunk nearest its origin.—(Essays on the Morbid Anatomy of the Human Eye, vol. 2, p. 180.)

Perfect inveterate amaurosis, attended with organic injury of the substance constituting the immediate organ of sight, says Scarpa, is a disease absolutely incurable. Imperfect recent amaurosis, particularly that which is periodical, is usually curable; for it is mostly dependent upon causes which, though they affect the immediate organ of sight, are capable of being dispersed, without leaving any vestige of impaired organization in the optic nerve or retina.

When amaurosis has prevailed several years, in persons of advanced age, whose eyesight has been weak from their youth; when it has come on slowly, at first with a morbid irritability of the retina, and then with a gradual diminution of sense in this part, till total blindness was the consequence; when the pupil is motionless, not circular, and not much dilated; when it is widened in such a degree that the iris seems as if it were wanting, and the margin of this opening is irregular and jagged; and when the bottom of the eye, independently of any opacity of the crystalline lens, presents an unusual paleness like that of horn, sometimes partaking of green, and reflected from the thickened retina, the disease may be generally set down as incurable. Kieser joins Scarpa in representing this alteration as an unfavourable omen, adding, that it only takes place in examples of long standing, and that when it is considerable, the disease is incurable. Langenbeck differs, however, from both these authors, and particularly from Kieser; assuring us, not only that he has often seen this discoloration of the bottom of the eye in the early stage of amaurosis, but seen patients in this state soon cured. The cases which he has published in proof of this statement, I have read with care, and find them completely satisfactory. Langenbeck agrees with other writers in imputing the appearance to a morbid change of the retina; and the treatment which he prescribes consists in the internal exhibition of the oxymuriate of mercury in small doses, and friction with mercurial ointment on the eyebrow and temple.—(See Langenbeck's Neue Bibl. für de Chirurgie, b. 1, p. 64—69, &c. Göttingen, 1815.)

Cases, says Scarpa, attended with pain all over the head, and a continual sensation of tightness in the eyeball; or preceded by a violent, protracted excitement of the nervous system, and then by general debility, and languor of the constitution, as after masturbation, premature venery, and hard drinking; or connected with epileptic fits, or frequent spasmodic hemicrania; or which are the consequence of violent, long-continued, internal ophthalmia, may be set down as incurable. Nor can any cure be expected when amaurosis proceeds from a direct blow on the eye; foreign bodies in the eyeball; lues venerea, or exostoses about the orbit; or when it is conjoined with a manifest change in the figure and dimensions of the eyeball.

Recent, sudden cases, in which the pupil is not excessively dilated, and its circle remains regular, while the bottom of the eye is of a deep black colour; cases unaccompanied with any acute, continual pain in the head and eyebrow, or any sense of constriction in the globe of the eye itself; cases which originate from violent anger, deep sorrow, fright, gastric disorder, general plethora, or the same partial affection of the head, suppression of the menses, habitual bleedings from the nose, piles, &c., great loss of blood, nervous debility, not too inveterate, and in young subjects, are all, generally speaking, curable. Amaurosis is also mostly remediable, when produced by convulsions or the efforts of difficult parturition; when it arises during the course, or towards the termination of acute or intermittent fevers; and when it is periodical.—(Scarpa, Osservazioni sulle Mallatie degli Occhi, cap. 20, Venez. 1802.)

According to Mr. Travers, it is rather the degree than the nature and origin of the symptomatic functional amaurosis, that should in most cases influence our prognosis; yet the latter circumstances, it is equally clear, afford more or less encouragement, in proportion as the pre-existing states of disease ordinarily admit of relief or not. Thus, says he, the amaurosis from gastric diseases, from plethora, from irritation, are all of them relievable, and if treated at an early period, remediable. Whereas paralysis, the sequel of fever, or of epilepsy, or severe constitutional diseases, whether acute or chronic, or depending upon habitual cerebral congestions combined with organic visceral disease, or induced by the operation of noxious agents on the system, is a hopeless form of the malady.—(Synopsis, p. 296.) I may remark, however, that various examples of recovery from amaurosis induced by fevers have fallen under my own notice.

In general, when the treatment proves successful, the return of the power of vision is accompanied with a regression of the same characteristic effects, which were disclosed in the gradual advance of the disorder, viz. appearances as if there were before the eyes flashes of light, a cobweb, net-work, mist, or flaky substances. —(Beer, Lehre von den Augenkr. b. 2, p. 460. Wien, 1817.)

Upon the commencement of the cure, there is also a return of the obliquity of sight; one of the most constant symptoms of imperfect amaurosis. This is a circumstance which Hey took particular notice of; he says, that it was most remarkable in those persons who had totally lost the sight in either eye; for in them the most oblique rays of light seemed to make the first perceptible impression upon the retina; and, in proportion as that nervous coat regained its sensibility, the sight became more direct and natural.—(See Med. Obs. and Inq. vol. 5.)

TREATMENT OF AMAUROSIS.

When amaurosis is to be fundamentally cured, not upon empirical, but scientific principles, all the causes of the disorder must be ascertained, and, if possible, removed, as in the treatment of every other complaint. How often, however, it is impossible to accomplish either the one or the other of these objects, must be clear enough from the preceding observations, particularly those concerning the etiology of the disease; and hence it is not surprising, that amaurosis should so frequently resist every endeavour to cure it.

The plan of treatment is to be regulated, first by the number and kinds of circumstances, which determine the form of the disorder; secondly, by its presence, degree, and duration. When only the chief causes can be ascertained, a scientific mode of treatment may always be instituted; though here it is very necessary to pay the utmost attention to those morbid effects in the constitution, and in the eye in particular, which appear to have no connexion with the causes of amaurosis, and merely exist as accidental contemporary defects.

If no particular circumstances can be assigned as the cause of amaurosis, the surgeon has no alternative

but the adoption of some empirical method of treatment; but, exclaims Beer, wo to the patient whose surgeon, under these circumstances, draws from a heap of what are considered remedies for amaurosis, as from a lottery, the first as the best!

In order to avoid this erroneous method, and not render a half-blind person completely blind, instead of improving, or at least preserving, whatever remnant of vision there may be, the surgeon should act with great caution, and constantly bear in his mind, first, the constitution, sex, and age of the patient; secondly, his ordinary employments, and general mode of living; and thirdly, the principal morbid appearances under which the amaurosis originated and was developed.—(Beer, Lehre von den Augenkr. b. 2, p. 462.) But what will be the greatest assistance is a correct acquaintance with the remedies for amaurosis in general, and the circumstances under which the use of this or that particular means is likely to be useful or detrimental. I know of no writer who has been so minute on this part of the subject as Beer, whose sentiments (be it also remarked) are here in many respects different from those of Richter and Scarpa; for, like the surgeons of this metropolis, he rarely employs the emetic plan of treatment, which, according to his principles, is not only ineffectual, but hurtful, whenever the blindness is attended with determination of blood to the head and eyes, plethora, an accelerated circulation, or (what is understood by) a phlogistic diathesis. Beer's opinions, respecting the employment of emetics and other means for the cure of amaurosis, may be partly collected from the sequel of this article, but more especially from the fuller statement which will be made at a future opportunity.—(See Gutta Serena.) In the mean time, I shall endeavour to offer a general account of the practice recommended by Schmucker, Richter, Scarpa, Travers, and Lawrence, according to the arrangement of causes adopted by the second of these valuable writers; for I need not repeat, that whenever the method of cure can be directed against the causes of the disease, it is the most proper and scientific. The present article will, then, close with some practical observations, chiefly taken from Professor Beer.

In that species of amaurosis, which arises from the first class of causes, or those which induce the disease, by means of a preternatural fulness and dilatation of the blood-vessels of the brain or eye, the indication is to lessen the quantity of blood, and the determination of it to the head. For this purpose, the patient may be bled in the arm, temporal artery, or, as is often preferred by foreign surgeons, in the foot. This evacuation is to be repeated as often as seems necessary, and it will be better to begin with taking away from twelve to sixteen ounces. The efficacy of bleeding, in the cure of particular cases of gutta serena, is strikingly exemplified by numerous well-authenticated observations. Richter informs us of a woman, who, on leaving off having children, lost her sight; but recovered it again by being only once bled in the foot. A spontaneous hemorrhage from the nose also cured a young woman, who had been blind for several weeks.—(Anfangsgr. der Wundarzn. b. 3, p. 442.)

That bleeding is sometimes hurtfully and wrongly practised in amaurotic cases, is a fact which admits of no doubt. Mr. Travers particularly refers to one description of cases where the lancet does harm: these are cases of undue determination of blood to the organ, which are especially common after deep-seated chronic inflammation or distress from over-excitement, by which its vessels have lost their tone; an effect decidedly increased by depletion. In one interesting case of this kind, a gradual but perfect recovery followed a regulated diet, and a course of the blue pill, with saline aperients.—(Synopsis, p. 159.) All cases of direct debility and proper paralysis of the retina (says Mr. Travers) are aggravated by loss of blood, and the great prevailing mistake in the treatment of amaurosis, is the indiscriminate detraction of blood.—(Synopsis, p. 303.)

When, in addition to general bleeding, topical is also necessary, leeches may be applied to the temples, or cupping-glasses to the back of the neck, or temples. Besides bleeding, purgatives, blisters, bathing the feet in warm water, low diet, repose of the organs, &c. are frequently proper.

In some cases, the foregoing means fail in producing the desired benefit, even when followed up as far as the pulse and strength will allow. Here the continuance of the disease may depend either upon the stoppage of some wonted evacuation of blood, or else upon some other cause of the first class. In the first of these cases (says Richter) experience proves, that the disease will sometimes not give way before the accustomed discharge is re-established. A woman, who (as this author acquaints us) had lost her sight in consequence of a sudden suppression of the menses, did not recover it again till three months after the return of the menstrual discharge, notwithstanding the trial of every sort of evacuation. He also tells us of another woman, who had been blind half a year, and did not menstruate, and to whose external parts of generation leeches were several times applied. As often as the leeches were put on (says Richter) the menses in part recommenced; and as long as they made their appearance, which was seldom above two hours, the woman always enjoyed a degree of vision.—(Anfangsgr. der Wundarzn. b. 3, p. 443.)

For the amaurosis arising from suppression of the menses, Scarpa recommends leeches to the pudenda, bathing the feet in warm water, and afterward exhibiting an emetic, and laxative pills, made of rhubarb and tartrate of antimony, combined with gummy and saponaceous substances. If these means fail in establishing the menstrual discharge, he says, great confidence may be placed in a stream of electricity, conducted from the loins across the pelvis, in every direction, and thence repeatedly to the thighs and feet. He enjoins us not to despair at want of success at first, as the plan frequently succeeds after a trial of several weeks.

For the amaurosis proceeding from the stoppage of an habitual copious bleeding from piles, Scarpa recommends leeches and fomentations to the hemorrhoidal veins, then an emetic, and afterward the same opening pills.—(Osservazioni sulle principali Malattie degli Occhi, cap. 19.)

When the disease does not originate from the stoppage of any natural or habitual discharge of blood, and does not yield to the evacuating plan, Richter thinks the surgeon justified in concluding, that the preternaturally dilated vessels have not regained their proper tone and diameter, and that topical corroborant remedies, particularly cold water, ought to be employed. In this kind of case, he is an advocate for washing and bathing the whole head with cold water, especially the part about the eyes; a method, he says, which may often be practised after evacuations, with singular and remarkable efficacy.

When the return of sight cannot be brought about in this manner, Richter advises us to try such means as seem calculated to stimulate the nerves, and remove the torpid affection of the optic nerves in particular. Of these last remedies, says he, emetics are the principal and most effectual.

The principle on which Mr. Lawrence directs the treatment, is that of putting a stop to vascular excitement, with the view of preventing the permanent injury of altered structure, and impaired function of the retina. Hence he is a zealous advocate for the antiphlogistic treatment, in the early stage of amaurosis. "But," says he, "if this treatment be not found to remove the change which has been produced in the retina, we must have recourse to mercury, which appears to be as decidedly beneficial in these cases as in iritis, or general internal inflammation. The remark which I made respecting the use of mercury in those affections, applies also to the present case; namely, that its good effect mainly depends upon the promptitude with which it is employed. The alterative form is insufficient; we give it with the view of arresting inflammation in the structure, which is the very seat of vision; that structure is easily changed by the inflammatory process; our only remedy is to push the mercury in a decided manner, and if we do so, we shall put a stop to the affection." When the antiphlogistic treatment and a fair trial of mercury have failed, Mr. Lawrence contents himself with recommending such management as is most conducive to general health; as a residence and frequent exercise in a pure air; plain nutritious diet; mild aperients, with the occasional use of an active purgative; and repose of the affected organ. He mentions also a trial of a seton, or repeated blisters behind the ears, or at the side or back

of the neck. As already stated, however, Mr. Lawrence does not wish it to be supposed, that all amaurotic patients require to be bled and salivated. Amaurosis, he says, often comes on in a slow and very insidious manner in persons of enfeebled constitution: the organ suffers from habitual excessive exertion at the same time that the general powers are depressed by residence in confined dwellings, bad air, sedentary occupations, unwholesome diet, costiveness, and the other injurious influences of such causes. If you should see a thin, pallid, and feeble woman, who had destroyed her health by close confinement to needle-work, and whose eyes were beginning to fail, the same active measures would by no means be admissible. You would empty the alimentary canal, perhaps take a little blood by cupping, or by leeches to the temples, and then use mercury in the alterative form, together with mild aperients. A few grains of Plummer's pill may be given every night, or every second night, and the bowels may be kept open with electuary, castor oil, or rhubarb and magnesia, taken occasionally. The blue pill may be taken in combination with aloes or colocynth. It may be necessary, says Mr. Lawrence, to persevere with the mercury, slowly increasing the dose until a slight influence is visible in the mouth. A nutritious diet without stimuli, good air, and exercise, and repose of the affected organ, are important auxiliaries, and a succession of moderate-sized blisters may be advantageously combined with these means. Thus, observes Mr. Lawrence, you see, that the same principles regulate our treatment, but that it is modified in degree according to the violence of the symptoms, and the patient's strength. In the latter description of cases, after mild antiphlogistic means, and clearing the alimentary canal, he admits that it may be expedient to combine tonics with aperients, or rhubarb with bark, columba, or cascarilla: and to allow a little porter and wine.

We come now to the consideration of that species of the gutta serena, which is regarded as the effect of some unnatural irritation. Here, according to the precepts delivered by Richter, we should endeavour to discover what the particular irritation is, and then endeavour to effect its removal. When it cannot be exactly detected, we are recommended generally to employ such remedies as will lessen the sensibility of the nerves, and render them less apt to be affected by any kind of irritation.

Sometimes the irritation is both discoverable and removeable, and still the effect, that is to say, the blindness, continues. In this circumstance, Richter thinks that the surgeon should endeavour to obviate the impression which the irritation has left upon the nerves, by the use of anodynes; or else try to remove the torpor of the nerves by stimulants.

But, according to Schmucker, Richter, and Scarpa, the curable imperfect amaurosis commonly depends on some disease or irritation, existing in the gastric system, occasionally complicated with general nervous debility, in which the eyes participate. Hence, in the majority of cases, we are assured that the chief indications are, to free the alimentary canal from all irritating matter, improve the state of the chylopoietic viscera, and invigorate the nervous system in general, and the nerves of the eye in particular.

For an adult, dissolve three grains of antimonium tartarizatum in four ounces of water, and give a spoonful of this solution every half hour, until nausea and copious vomiting are produced. The next day some opening powders are to be exhibited, consisting of an ounce of the supertartrate of potash, and one grain of antimonium tartarizatum, divided into six equal parts. The patient must take one of these in the morning, another four hours afterward, and a third in the evening, for eight or ten days in succession. They will create a little nausea, rather more evacuations from the bowels than usual, and perhaps, in the course of a few days, vomiting. If the patient, during their use, should make vain efforts to vomit, complain of bitterness in his mouth, loss of appetite, and no renovation of sight, the emetic, as at first directed, is to be prescribed again. This is to be repeated a third and fourth time, should the morbid state of the gastric system, the bitter taste in the mouth, the tension of the hypochondria, the acid eructations, and the inclination to vomit, make it necessary. The first emetic often produces only an evacuation of an aqueous fluid, blended with a little mucus, but, if it be repeated, a few days after the resolvent powders have been administered, it then occasions a discharge of a considerable quantity of a yellow, greenish matter, to the infinite relief of the stomach, head, and eyes.

The stomach having been thus emptied, the following aperient pills are to be ordered:

℞. Gum. sagapen. } an. 3 j.
Galban. }
Sap. venet. }
Rhei optim. 3 iss.
Tart. emet. gr. xvi.
Suc. liquerit. 3 j. fiant pilulæ gran. quinque.

Three are to be taken every morning and evening, for a month or six weeks.

When the state of the stomach has been improved, and the restoration of sight partly effected, such remedies must be employed, as strengthen the digestive organs, and excite the vigour of the nervous system in general, and of the nerves of the eye in particular. With this intention Scarpa prescribes bark and valerian in powder, and recommends a diet of tender succulent meat, and wholesome broths, with a moderate quantity of wine, and proper exercise in a salubrious air. For exciting the action of the nerves of the eye, the vapour of liquor ammoniæ, properly directed against the eye, he says, is of the greatest service. This remedy is applied by holding a small vessel containing it sufficiently near the eye to make this organ feel a smarting, occasioned by the very penetrating vapours with which it is enveloped, and which cause a copious secretion of tears, and a redness, in less than half an hour after the beginning of the application. It is now proper to stop, and repeat the application three or four hours afterward. The plan must be thus followed up till the incomplete amaurosis is quite cured.

The operation of these vapours may be promoted by other external stimulants, applied to such other parts of the body as have a great deal of sympathy with the eyes. Of this kind are blisters to the nape of the neck; friction on the eyebrow with the anodyne liquor; the irritation of the nerves of the nostrils by sternutative powders, like that composed of two grains of turbeth mineral, and a scruple of powdered betony leaves; and, lastly, a stream of electricity.—(See Gutta Serena.)

Bark, which is efficacious in intermittent fevers, and other periodical diseases, far from curing periodical amaurosis, seems to aggravate it, rendering its return more frequent, and of longer duration. On the other hand, this disease is most commonly cured, in a very short time, by exhibiting, first, emetics, then the above laxative pills, and lastly, corroborants, and even bark, which was before useless and hurtful.

Such is Scarpa's statement, which agrees with that of Richter, respecting the effect of bark in periodical amaurosis. As if, however, practitioners were doomed always to differ, and learners to be puzzled, Beer tells us, that he has seen only two cases of periodical intermittent amaurosis, both of which were soon perfectly cured by large doses of bark. Other periodical amaurotic affections he has seen, however, attendant on intermittent fever, but they spontaneously subsided with the febrile paroxysms, without any particular treatment being applied to the eyes. Sometimes, when the paroxysms recurred frequently, a considerable weakness of sight remained after them; but this always went off of itself, except in a single instance, in which the functions of the eyes were perfectly re-established by the exhibition of arnica joined with bitters.—(Lehre, von den Augenkr. b. 2, p. 585.)

In the two cases, which were unaccompanied with fever, the vitreous humour had the appearance of being turbid during the attacks, but regained its natural clearness on each return of vision, the loss of which used to be complete. Here we see another instance, in which a cloudiness behind the pupil in amaurosis did not impede the cure, and went away in the most ready manner. Possibly, the opacity, which, in speaking of the prognosis, I said that Langenbeck had not found to prevent the cure of certain cases, might also have had its seat in the vitreous humour, and not depended upon disease of the retina.

Cases, in the formation of which many other causes operate, demand the employment of particular curative means, in addition to those which have been already described. Such is, for example, the imperfect amau-

rosis, which occurs suddenly in consequence of the body being excessively heated, or exposure to the sun, or violent anger in plethoric subjects. This case requires, in particular, general and topical evacuations of blood, and the application of cold washes to the eyes and whole head. An emetic should next be given, and afterward a purge of potassæ tartras, or small repeated doses of antimonium tartarizatum. By means of bleeding and an emetic, Schmucker often restored the eyesight of soldiers who had lost it in making forced marches, with very heavy burdens. In amaurosis, suddenly occasioned by violent anger, an emetic is the more strongly indicated after bleeding, as the blindness, thus arising, is always attended with a bitter taste in the mouth, tension of the hypochondria, and continual nausea. Richter mentions a clergyman, who became completely blind after being in a violent passion, and whose eyesight was restored the very next day, by means of an emetic, given with the view of relieving some obvious marks of bilious disorder in the stomach.

Scarpa's treatment of the imperfect amaurosis brought on by fevers, deep sorrow, great loss of blood, intense study, and forced exertions of the eyes on very minute or brilliant objects, consists also in removing all irritation from the stomach, and afterward strengthening the nervous system in general, and the nerves of the eye in particular. In the case originating from fevers, the emetic and opening pills are to be given; then bark, steel medicines, and bitters; while the vapour of the liquor ammoniæ is to be applied to the eye itself.

When the disorder has been brought on by grief, or fright, the stomach and intestines are to be emptied by means of antimonium tartarizatum and the opening pills; and the cure is to be completed by giving bark and valerian; applying the vapour of liquor ammoniæ to the eyes; ordering nourishing, easily digestible food; diverting the patient's mind, and fixing it on agreeable objects, and recommending moderate exercise. The amaurosis from fright is said to require a longer perseverance in such treatment, than the case from sorrow.—(Scarpa's Osservaz. cap. 19.)

In this country, the emetic practice, which has proved so decidedly efficacious on the continent, has not been attended with much success; Mr. Travers even states, that he does not recollect an instance of decided benefit from it, though he has often tried it fairly. He agrees, however, in the indication, as he remarks, that the removal of an irritating or oppressing cause, will often effect a sudden and marked relief, as by clearing the intestinal canal of vitiated secretions, restoring the digestive functions, or taking away blood where the necessity is indicated. In gastric cases for which emetics have been particularly recommended, he prefers a long-continued course of the blue pill, with gentle saline purgatives and tonic bitters.—(Synopsis, p. 299—304.)

Beer is also a high authority against the use of emetics, even in the amaurosis from disorder of the gastric organs. When, says he, the saburræ have a tendency to be discharged upwards, as indicated by continual nausea and disposition to vomit, emetics, which never operate without some violence, are to be most carefully avoided in plethoric individuals, or those who have a manifest determination of blood to their heads and eyes, or any acceleration of the circulation. The caution here given must be observed, even though emetics may on other accounts seem advisable; and, according to Beer, the determination of blood and the state of the system here mentioned, are commonly attendant upon this species of amaurosis. Indeed (notwithstanding the testimony of Schmucker, Richter, and Scarpa, in favour of emetics in this case), Beer positively affirms, that the violent operation of an emetic frequently converts this sympathetic amaurotic weakness of sight all on a sudden into blindness. Although I apprehend that Beer may here be somewhat prejudiced against emetics, candour obliges me to add, that in this country, their efficacy in the present disease is by no means equal to the representations of Richter and Scarpa. When there is less tendency to vomiting, but the case is attended with an oppressive sense of weight about the stomach, frequent eructations, as if arising from rotten eggs, an inflated belly, and tense hypochondria, a gentle aperient clyster may be ordered, especially when the bowels have been for some days confined, in which circumstances Beer has found, that tolerably brisk purgatives are always of the greatest service, both in regard to the general complaints, and the amaurotic weakness of sight; the removal of the offensive matter from the alimentary canal being immediately followed by a cessation of the determination of blood already mentioned. Lastly, when this amaurosis originates altogether from the presence of worms in the bowels, common anthelmintics are to be prescribed. In all these cases, says Beer, mere local treatment is quite inapplicable, and may do mischief.—(Beer, Lehre von den Augenkr. b. 2, p. 517—521.)

The third species of gutta serena, or that which arises from debilitating causes, is of two kinds; in one, the disease is the consequence of a general weakness of the body; in the other, it is the effect of debility, which is confined to the eye itself, and does not extend to the whole constitution.

According to Scarpa, the incomplete amaurosis from general nervous debility, copious hemorrhage, convulsions ab inanitione, and long-continued intense study, especially by candle-light, is less a case of real amaurosis, than a weakness of sight from a fatigued state of the nerves, especially of those constituting the immediate organ of sight. When this complaint is recent, in a young subject, it may be cured or diminished, by emptying the alimentary canal with small repeated doses of rhubarb, and then giving tonic cordial remedies. At the same time, the patient must abstain from every thing that has a tendency to weaken the nervous system, and, consequently, the eyesight. After emptying the stomach and bowels, it is proper to prescribe the decoction of bark with valerian, or the infusion of quassia with the addition of a few drops of sulphuric ether to each dose, with nourishing easily-digestible food. The aromatic spirituous vapours (mentioned in the article Ophthalmy) may then be topically applied; or, if these prove ineffectual, the vapour of liquor ammoniæ. The patient must take exercise on foot, horseback, or in a carriage, in a wholesome dry air, in warm weather, and avail himself of sea-bathing. He must avoid all thoughts of care, and refrain from fixing his eyes on minute shining objects. The impression of vivid light on the retina is always to be moderated by means of flat green glasses.—(Saggio di Osservaz. cap. 19.)

One case of temporary palsy of the retina from over-excitement, mentioned by Mr. Travers, yielded to blistering the forehead, and a gentle salivation excited by calomel joined with opium.—(Synopsis, p. 164.) Another case, brought on by the use of telescopes and sextants, gave way to a copious bleeding, brisk purging with jalap and calomel, blisters to the temples, and a course of mercury.—(Op. cit. p. 166.)

Mr. Travers remarks, that the amaurosis from depletion is sometimes mistaken for the opposite case, viz. that from plethoric congestion: this is owing to the coincidence of a dilated and immoveable pupil, muscæ, and a deep-seated pain in the head, with occasional vertigo; and its frequent occurrence in a corpulent habit. By a cautious use of tonics (says Mr. Travers) it is relieved; by whatever lowers or stimulates, whether diet or medicine, it is decidedly aggravated. In this form of amaurosis, vision is farther enfeebled by the loss of as much blood as flows from two or three leech-bites.—(Synopsis, &c. p. 160.)

When the weakness is confined to the eye, Richter thinks corroborant applications alone necessary. Bathing the eye with cold water, says he, is one of the most powerful means of strengthening the eye. The patient should dip in cold water a compress, doubled into eight folds, and sufficiently large to cover the whole face and forehead, and this he should keep applied, as long as it continues cold. Or else he should frequently apply cold water to his eyes and face with his hand, on a piece of rag.

The eye may also be strengthened by repeatedly applying blisters of a semilunar shape above the eyebrows, just long enough to excite redness. Richter likewise speaks favourably of rubbing the upper eyelid, several times a day, with a mixture of the tinctura lyttæ and spiritus serpilli.—(Anfangsgr. der Wundarzn. b. 3, p. 452.)

When no probable cause whatsoever can be assigned for the disease, the surgeon is justified in employing such remedies, as have been proved by experience to be sometimes capable of relieving the affection, although upon what principle is utterly unknown.—(See Gutta Serena.) To this article I would refer the reader,

before he makes up his mind about any empirical method of treatment, because he will there find many cautions and instructions given by Beer, respecting the remedies for amaurosis in general. To his remarks, I have also annexed such others, on the same topic, as appeared to me interesting.

Cat-eye amaurosis.

This species of the disorder, of which Beer met with but one form, rarely increases to complete blindness; it occurs chiefly in very old persons, and it is perhaps this affection to which some oculists have given the unmeaning name of "amblyopia senilis." Sometimes, however, this kind of amaurosis takes place in young persons and children: and one circumstance that demands particular notice in its nosology is, that it always takes place either in thin, dwindled, old, gray-headed subjects, nearly in the state of marasmus senilis, in whom consequently the exchange of organic matter is carried on but tardily, or else in young subjects, who are unhealthy, and disposed to consumption, hectical adults, emaciated children, and as a consequence of severe injuries of the eye. While this amaurosis is not perfectly formed, the iris retains its mobility, and the pupil is neither preternaturally dilated nor contracted; but when once the patient is quite bereft of vision, the motions of the iris are slow, and the pupil larger than in a healthy eye in an equal degree of light. At the bottom of the eye, very far behind the pupil, a concave pale-gray, bright-yellowish, or variegated reddish opacity is developed. By this the eyesight is not merely weakened, but rendered quite confused, since all objects, but especially smallish ones, appear to be confounded together, particularly when the patient tries to inspect closely any determinate body. The farther the disease advances, the brighter and more visible is the bottom of the eye, the paler is the colour of the iris (a thing very conspicuous in dark-eyed persons); and when once the amaurosis is complete, so that no susceptibility of the impression of light is left, then, upon an attentive examination of the eye, one can mostly perceive, at the troubled deeper part of the eye, a very slender vascular plexus, which merely consists of the ordinary ramifications of the central artery and vein, which are now visible at the pale-coloured bottom of the eye. In a half-darkened place, such an eye presents a shining yellowish or reddish appearance, but only in certain positions of the eyeball; and, in this respect, it is somewhat similar to the eye of a cat, whence Beer chooses to term the complaint cat-eye amaurosis. The disorder is also not accompanied with any other essential morbid appearances, except the decline of vision or complete blindness.—(Lehre von den Augenkr. b. 2, p. 496.) Beer, in fig. 1, tab. 4 of his second vol., has given from nature an admirable representation of this very remarkable species of amaurosis. The differences in the appearances at the bottom of the eye, in this case, from those presented in the early stage of fungus hæmatodes of that organ, will be best understood by referring to the article Fungus Hæmatodes. On this point, however, I may here briefly state, that in the cat-eye amaurosis, there is no projection, but, on the contrary, a concave depression in the axis of vision. Cat-eye amaurosis may be known from incipient cataract, by the opacity being more deeply situated, and having a shining, pearly lustre.—(See Journ. of Foreign Med. vol. 4, p. 168.)

Beer observes that the causes of this species of amaurosis are so obscure, that whatever is offered upon the subject can be received only as conjecture. After what has been said in the foregoing paragraph is considered, about the particular individuals who are liable to be affected, and the change of the iris to a pale colour, as a constant symptom of this case, a suspicion may be entertained that a deficiency of the pigmentum nigrum and of the tapetum of the uvea, in consequence of the stoppage of this secretion, may be the cause of the disease. Beer justly remarks that much might be learned on this point from the dissection of eyes thus affected; but he has never met with the opportunity.

The prognosis cannot but be very unfavourable; for, as the surgeon is ignorant of causes, he cannot know what means ought to be adopted for their removal. It is fortunate, however, that this amaurosis rarely attains its highest degree, but almost constantly remains in the form of a more or less considerable amblyopia.

Just as little is yet known respecting any well-regulated mode of treatment; but the disease may sometimes be kept from getting worse by the careful employment of such general remedies, regimen, and diet, as are calculated to improve the health. However, in the most fortunately managed cases, Beer never knew a step made towards the removal of the disease.—(Lehre von den Augenkr. b. 2, p. 497, 498.)

Amaurosis produced by bitters, certain articles of food in particular constitutions, or the poison of lead.

The reality of the first alleged cause is sometimes doubted in this country. The following treatment is recommended by Beer. In the first stage he advises gentle antiphlogistic means. When plethora exists, a few ounces of blood may be taken away by venesection, or leeches applied behind the ears, when after bleeding a determination of blood to the head and eyes still continues in full habits, or there is any tendency to inflammation. The same topical bleeding without venesection, but with lukewarm pediluvia, containing salt or mustard, is proper when no general plethora exists; and merely a determination of blood to the head and eyes and some acceleration of the circulation prevail. Internally, lemon-juice or the liquor ammoniæ acet. has excellent effects; and externally, poultices composed of bread-crumb and vinegar, or fomentations containing oxycrat, are the means which Beer has found most successful in the first stage of this form of amaurosis.

As in the first stage, a moderate antiphlogistic general or local treatment is the only one which can be adopted, and which in urgent cases may yet save the patient from blindness, so in the second stage the internal and external employment of fluid stimulants is of great service; for example, naphtha combined with camphor inwardly, liniments to the eyebrow, and the vapours of ether to the eye. The amaurosis produced altogether by the poison of lead, and complicated with lead-colic and ileus, will require, in addition to the foregoing means, such remedies as are known to be of service in these latter disorders.—(Beer, Lehre von den Augenkr. b. 2, p. 499—503.)

Symptomatic amaurosis in individuals affected with hysteria, hypochondriasis, epilepsy, and convulsions.

This amaurosis is rarely permanent, and usually subsides as soon as the spasmodic, epileptic, or convulsive attack is over. However, the complaint may begin at two periods, viz. either during such an attack, or (what is more uncommon) afterward, and it never loses its symptomatic character. The pupil always remains perfectly clear, and of a shining blackness, even when the disease has induced entire blindness; but a slight dull pain in the forehead, especially about the eyebrow, constantly preceding and accompanying the blindness, generally lasts a good while after the amaurosis has completely subsided.

Besides the foregoing general symptoms, the following characteristic appearances present themselves in hysterical and hypochondriacal patients, who suffer frequent attacks of violent spasm. The pupil is much dilated, and the iris, which is immoveable, seems evidently to project in a convexity forwards, when the eye is inspected sidewise; consequently, the anterior chamber is lessened. The eye itself does not move freely in its socket, the patient experiencing an annoying and sometimes a truly painful sensation, as if the eyeball were forcibly compressed (Ophthalmodynia). Every attempt which the patient himself makes to move the eye, or the surgeon to push it out of the position which it has assumed, is unavailing and excessively painful. The eyelids are either painfully shut, or incapable of being shut at all; the eyesight is very weak, but seldom quite impeded; and at the termination of each attack vision returns, though every paroxysm leaves it more and more debilitated, until at length the spasmodic attacks of blindness frequently occurring, and lasting a long while, it is entirely lost. But when the disorder has acquired its utmost degree, the eye always still retains the power of discerning the light, and it seldom happens that vision is abolished by the first or second attack. It is different with respect to the characteristic phenomena of this amaurosis, in hysterical or hypochondriacal patients, especially when often affected with spasms, before, during, or after which the impairment of sight originates; for though the pupil may continue quite clear, it cannot escape the notice of an attentive observer, that, together with a

pupil of diminished diameter, there exists a peculiar motion of the iris, a constant fluttering of it between expansion and contraction, technically called hippus pupillæ. This convulsive state of the iris is mostly accompanied with a similar affection of the eyelids, namely, with an involuntary blinking (nictitatio), and not unfrequently with an involuntary pendulum-like rolling of the eyeball (nistagmus). In these patients the amaurotic injury of sight hardly ever proceeds directly to complete blindness, but more commonly remains as a weakness of vision, characterized during the rest of life by ceaseless oscillations of the eyeball, aversion to light, and frequent sensations as if there were shining fiery objects before the eyes.

This case of symptomatic amaurosis is distinguished by an untroubled, but very expanded pupil; considerable diminution of the motion of the iris; a dilated state of the pupil, even under the stimulus of the strongest light, and tremulous motions of the eyeball, which continue during life, after the epilepsy and amaurosis are cured; and the case is farther characterized by amblyopia, which rarely increases to complete blindness.

According to Beer, the amaurosis connected with convulsions is most frequent in children. The first and most prominent symptom of this incomplete or complete amaurosis consists in an extremely violent convulsive rotation of the eyeball, especially upwards, not unfrequently attended with the most violent convulsive motions of the eyelids. The pupil is excessively dilated, and scarcely the least movement of the iris is distinguishable on exposing the eye to the strongest light. When the general twitchings are over, and only an amaurotic weakness of sight is left, strabismus occurs in both eyes in various directions, though the eyes very seldom deviate from the axis of vision in the direction towards the inner canthus. When the general convulsions happen frequently, and are violent and of long duration, the amaurotic weakness of sight usually changes into perfect blindness, in which the pupil, though it be regularly clear, and of a shining blackness, is greatly expanded, and the eyes constantly retain their faulty position and pendulum-like motion.

With respect to the prognosis, it is observed by Beer, that even when merely an amaurotic weakness remains, the prognosis is always serious; but it is naturally still more unfavourable, when the blindness is complete, and when the loss of sight has suddenly recurred after violent spasmodic, epileptic, or convulsive attacks, without such attacks themselves ever returning. Under these circumstances, Beer has not hitherto seen more than two instances of such blindness partially cured. Generally some hope of recovery may be entertained, when the amblyopia, or even complete amaurosis, begins with these attacks, but always terminates with them, without leaving any serious impairment of vision. On the contrary, it is a very bad sign, not only in regard to the removal of this symptomatic amaurosis, but likewise to the cure of the original disease, when the amaurosis invariably precedes these attacks, and lasts a considerable time after their cessation. As yet, Beer says, he has not known any such patients cured, either of their spasms, epilepsy, or convulsions, much less of their blindness: on the contrary, after three or four attacks, perfect amaurosis remains, and some of the patients die in one of these paroxysms.

As this amaurosis is merely a symptomatic effect of the above general disorders, its removal must entirely depend upon the success with which their treatment is conducted. Were the blindness to continue, however, after the cure of the original disease, the surgeon could do nothing more than try an empirical mode of treatment, and ascertain what good could be effected with antispasmodic and tonic medicines.—(Beer, Lehre von den Augenkr. b. 2, p. 506—510.)

Rheumatic amaurosis.

According to Beer, rheumatic amaurosis is not very uncommon, and is so plainly denoted by certain symptoms, that it cannot well be mistaken; namely, a perfectly clear pupil wavers in the mid state between contraction and dilatation, the iris seeming to be nearly motionless; the eyes weep from the slightest causes, and constantly betray more or less aversion to light; the case is invariably attended with wandering, irritating pains, sometimes affecting the eyeball itself, sometimes the vicinity of the eye, and in other instances, the teeth or neck. Also when both eyes are affected together, which is not regularly the case, a cast of the eye, which cannot be called actual squinting, may be remarked, and frequently the motion of the eyeball is chiefly obstructed only in one direction, though sometimes a true obliquity of the organ exists (luscitas). In nearly every instance there is considerable weakness of the levator muscle of the upper eyelid, and not unfrequently a complete blepharoplegia; but total blindness is seldom produced.

According to Beer, this amaurosis, which is to be considered as chronic rheumatism, often arises from keeping the head long exposed to the air, and is chiefly met with in individuals who, while sweating profusely from the scalp and brow in warm weather, have taken off their hats, and remained with their heads a long while uncovered. As, however, in warm weather, the generality of persons expose themselves in this manner, and few are attacked by amaurosis, I infer that something more is requisite for the production of the disease.

Under certain circumstances the prognosis is by no means unfavourable, and Beer mostly succeeded in effecting a perfect cure, when the amaurosis was not completely formed, and not of very long standing, the patient had no tendency to gout, and when during the treatment every thing likely to bring on an attack of that disease was avoided.

The treatment consists not simply of local means, which indeed are always needful, but likewise of general remedies. With regard to the latter, Beer assures us that manifold experience has convinced him of the preference which ought to be given to the extract of guaiacum joined with camphor, and given alternately with the compound powder of ipecacuanha; which remedies, as soon as the wandering pains about the eye and eyebrow begin to be milder, and more fixed to one part, are to be succeeded by the extract of aconitum, antimonial preparations, and flowers of sulphur. Externally, the most powerful operating means are not to be omitted, especially blisters applied successively behind the ears, to the temples, and eyebrows; and as soon as the pain has completely subsided in these last parts, and is perhaps more concentrated in the eye, frictions are to be made on the eyebrow with liniments, containing at first a moderate quantity of opium, and afterward of the extractum conii. At length, when the pain in and about the eye is nearly subdued, but some degree of amaurotic weakness of sight is left, frictions with naphtha and a small proportion of tinctura lyttæ and tinctura opii will be found exceedingly beneficial. Afterward, when a considerable time has transpired without the recurrence of the slightest rheumatic pain in the eye, its vicinity, or the head, but the eyesight is not perfectly re-established by perseverance in the above general and local treatment, and especially when the paralytic affection of the levator of one or other of the upper eyelids continues (as often happens), galvanism may be tried, with the cautions elsewhere premised.—(See Gutta Serena.) And in the most desperate cases, Beer approves of making an issue in the depression between the angle of the jaw and the mastoid process, and keeping it open for a fortnight after the recovery seems complete.—(Lehre von den Augenkr. b. 2, p. 526—529.)

Traumatic amaurosis.

Beer applies the epithet "traumatic" to such cases of amaurosis as are the consequence of a considerable wound of the eye itself, its surrounding parts, or the skull. Here, consequently, is first arranged the amaurosis produced by the laceration and stretching of the branches of the frontal nerve from irregular scars about the eyebrow. Secondly, Beer reckons the amaurosis arising from external violence directed in such a degree against the upper or lower side of the orbit, that the retina is torn, and many of the internal softer textures of the eye forced out of their natural situations. Thirdly, Beer includes every weakness of sight or perfect amaurosis, which is the result of such injuries of the eyeball itself as extend to the retina, so as either violently to bruise or lacerate it, or cut or pierce it. For the prognosis and treatment of all these cases, he refers to his observations upon ophthalmy. Nor does he choose here to treat of the perfectly complicated amaurosis, which is a direct consequence of a coup-de-soleil, because it never happens unpreceded by a violent general inflammation of the eyeball, and therefore is to be regarded as an effect both of the injury and the inflam-

mation together; but which, like the symptomatic amaurosis, following common and genuine internal ophthalmy, may be easily known by the total insensibility to light, and the evident changes in the texture and shape of the eye; and is quite as incurable as the other example to which we have alluded.—(Lehre von den Augenkr. b. 2, p. 542.)

Gouty amaurosis.

According to Mr. Travers, gout attacks the eye through the medium of the stomach. Vomiting occurs with pain in that organ, on the subsidence of an inflammation in the extremities, and is succeeded by violent pain in the head. The loss of sight, he adds, is sudden and permanent.—(Synopsis, &c. p. 163.) The gouty amaurosis described by Beer, is perhaps badly named; at all events, there are some circumstances in its history which must create doubts on the subject. Gouty amaurosis, he says, has two forms: the first is characterized by a very considerable dilatation and angular displacement of the pupillary edge of the iris towards the canthi; a continually increasing slowness in the movements of the iris, and final immobility of this organ; an actual change of colour at both its circles; a dull, glassy blackness of the pupil, and even a tarnish in the lustre of the cornea; an alternate appearance of the gray and black cloudy substances described in the account of the general symptoms of amaurosis, which effect lasts while the patient is not totally blind. The disorder is farther indicated by a fleeting, wandering, irritating, yet not very severe pain, all about the vicinity of the eye; a manifest tendency to a varicose enlargement of the blood-vessels of the conjunctiva and sclerotica; a transient melioration of sight after meals, or any accidental excitement or stimulus; a considerable temporary decrease of it after the operation of any causes which depress the spirits; the excessively slow formation of the disease, for which several years are usually required; and lastly, by the nature of the patient's constitution. For, in general, this amaurosis (if we are to believe Beer) always attacks both eyes at once, and is confined to dark-eyed and very irritable, slender, weak, maiden females, who either have suffered from scrofula in their childhood, or from severe acute or chronic diseases at a later period of their lives; who are not yet far advanced in years; and whose menses have never been very irregular though profuse.

It is remarked by Beer, that although the second form of gouty amaurosis makes its attack upon males as well as females, the latter, on the whole, are most frequently affected, particularly about the period when the menses cease. This amaurosis, which is seldom formed quickly, that is to say, in a few weeks or months, but mostly requires years for its production, begins with cloudy, indistinct vision; an appearance of different colours before the eyes; and a peculiar sensation, as if insects were crawling over the skin around the eye. The pupil becomes manifestly dilated, and presents a dull greenish-gray colour, which, however, is easily distinguished from the colour seen behind the pupil in the amaurotic cat-eye, and plainly depends upon some defect in the vitreous humour (glaucoma). Also the iris, the pupillary edge of which is drawn towards both angles of the eye, as in the first form of the disorder, undergoes an obvious change of colour, first at its less circle, which becomes of an uncommonly dark hue, and then at its greater circle. The alteration of colour here spoken of certainly proceeds from a general varicose state of the blood-vessels of the eye, which affection daily augments, and is attended with vehement pain in the organ and surrounding parts, or even in the whole head, or one side of it, whether the blindness attack one or both eyes together. This violent pain, however, which is such as often to distract the patient, is unsteady and irregular, being immediately aggravated by every violent mental emotion, whether of the exalting or depressing kind, every sudden and considerable change of temperature, every quick accession of wet cold weather, or when the patient stays only for a short time near a very heated fireplace, lies on feather pillows with the affected eye resting upon them, or covered with flannel, or he has been eating any indigestible food. These attacks of pain subside without any medical assistance, in the dry, warm season of the year, and in a mild, not too hot, climate are often kept off for several years. Upon every such attack the glaucoma becomes more evident, the pupil larger and more angular, and the eyesight perceptibly weaker. At length, during one of these painful exacerbations, vision is completely abolished, not the least sensibility to light remaining; and the pupillary edge of the iris, together with the less circle of the same organ, then entirely disappears, being inverted towards the lens. The cirsophthalmia also gets so much worse, that the sclerotica acquires a smutty, grayish-blue colour; and at length the bluish windings of vessels may be noticed at various points, particularly about the place where the tendons of the muscles are affixed. Afterward the green, or what may be more properly called the glaucomatous cataract, is manifestly developed, and the eye then generally wastes under the most violent attacks of pain. The light which the patient always thinks he sees, but which, according to Beer, is produced of a reddish or bluish colour in the interior of the eye, like galvanism, keeps up the hope of recovery; but all consciousness of this luminous appearance ceases as soon as the eye begins to waste. The first degree of gouty amaurosis readily changes to the second, especially in persons who are getting into years, or are near the period of life when menstruation terminates.

According to Beer, the apothecary's magazines contain no remedies which are adequate to the cure of the first form of this amaurosis. A total change of the whole constitution would be requisite, ere success could be expected, and such change it is not in the power of physic to accomplish. In one single example Beer succeeded in checking the disease, by persuading the patient to observe a strict regimen, not a grain of medicine being given; but the patient still remains weak-sighted, though various medicines have latterly been tried.

With respect to the treatment of the second form of gouty amaurosis, Beer observes that it should be like that of gouty iritis. In particular, attention must be paid to the attacks of pain, and palliative means adopted. The patient should not lie upon feather beds, nor especially feather pillows, but only employ articles of this kind which are stuffed with horse-hair. Neither must he expose himself to an atmosphere which is at the same time both cold and damp; and if he cannot altogether take care of himself in this respect, at all events let him keep his head and feet warm and dry; shun every thing which tends to impede the functions of the skin; and avoid pork-meat, every thing cooked with hogs' lard, and all acid and salt dishes, like herrings. With what are usually considered as gout medicines, the practitioners should act very circumspectly; and, as in gouty iritis, he should pay close attention to the state of the constitution, rather seeking to afford relief by means of a well-regulated diet, than by the employment of much physic.

Of the amaurosis occasioned by the sudden cure of cutaneous diseases, and of old ulcers of the leg.

When this amaurosis assumes its ordinary form, Beer has not yet been able to remark in it any peculiar characteristic symptoms by which it can be effectually distinguished from the second form of gouty amaurosis, excepting, first, that it originates and increases very suddenly, while the true arthritic amaurosis is a long time, and for the most part several years, in forming. Secondly, that at its commencement it is never attended with violent pain in the eyes or head. Hence, the diagnosis will depend very materially upon a correct recollection of circumstances. But, according to Beer, there are some cases in which, besides the complete blindness, unattended with the slightest power of perceiving light, there is no characteristic symptom, but extraordinary enlargement of the pupil, total immobility of the iris, and an inanimate projection of the eye.

Respecting the causes of this amaurosis, Beer says that he has nothing important to offer. He owns that, after the sudden cure of certain cutaneous diseases, and of old ulcers of the legs, an amaurotic blindness does not always ensue; and he believes that the reason why the bad effects take place in other organs, sometimes the brain, the lungs, or the bowels, &c., may probably depend upon this or that organ happening to be most predisposed to disease. Here the discerning reader will not require me to point out to him that such a mode of accounting for things is entirely hypothetical,

and destitute of proof: it is indeed so convenient a sort of explanation that it admits of being extended to all diseases without exception. If we are to believe Beer, the prognosis is very uncertain, and in many cases highly unfavourable; first, because an organic part, namely, the optic nerve, is directly affected, which, by the operation of external and internal causes, is soon rendered unfit for the performance of its functions. Secondly, because in the majority of examples important changes immediately take place in the organization of the whole eye, which are particularly difficult of removal when the nervous textures are affected. Thirdly, because it is impossible to know whether morbid changes may not already exist in the retina or course of the optic nerve.

In the treatment, Beer, who places implicit reliance upon the above statement of causes, is an advocate for reproducing as quickly as possible the original disease; and if that cannot be done, he thinks some artificial disease should be formed in lieu of it. For these purposes, he often employs blisters and friction with antimonial ointment. His treatment, where amaurosis happens to follow the cure of itch, seems very objectionable, as it consists in inoculating the poor patient again with psoric infection, as if it were not more tolerable to remain blind than live perpetually scourged with the other disorder; for the professor's theory leaves us uninformed of the circumstances under which the patient whose sight is restored by this expedient could ever venture to have a sound skin again without the risk of a fresh attack upon his eyes. But it seems, even from Beer's account, that the patient's subjecting himself to the itch will not always cure his eyes; for, says he, when this method fails, friction with antimonial ointment should be tried.

When amaurosis follows the healing of old sores, Beer recommends the formation of them again, by applying to the cicatrix strong mustard cataplasms, and the muriate of soda; and if the new ulcers cannot be made to discharge properly, he praises the application of issues to the calves of the legs, and, in urgent cases, to the thighs. These plans are to be aided by such medicines as act specifically upon the skin, like antimonials, especially the sulphur auratum antimonii. Beer also speaks favourably of sulphur baths; and in cases complicated with debility, administers tonics, particularly the calamus aromaticus and bark.—(See Lehre von den Augenkr. b. 2, p. 556—563.)

Of the sympathetic amaurosis in lying-in women, from suppression of the secretion of milk.

This case is set down by Beer as one of the most uncommon varieties of amaurosis. It comes on rapidly, after sudden stoppage of the secretion and excretion of the milk, with violent headache, concentrated about the forehead and eyebrows; troublesome luminous appearances; an inconsiderable dilatation of the pupil; and scarcely any perceptible irregularity in the pupillary edge of the iris, which is quite motionless, somewhat altered in colour, and swollen. The disease is also accompanied with great aversion to light; a palpable turgescence of all the blood-vessels of the conjunctiva; a slight turbidness of the transparent media of the eye; and, at first, with a mere weakness of sight, which, in the end, suddenly changes into complete amaurotic blindness. The breasts, which before the attack were full of milk, are now empty, and hang down like bags, but are quite free from pain.

From the few cases which Beer had seen, he inferred, that the prognosis is always unfavourable when the blindness is complete, and particularly when there is a manifest diseased change in the transparent parts of the eye; for, in the latter case, he has known patients remain perfectly blind, though the secretion of milk had been most successfully and expeditiously re-established. In one instance, the remedies applied to the breast, instead of reproducing the secretion of milk, excited in the part a painful inflammation and abscess, during which the weakness of sight subsided, though it was very considerable.

In considering other analogous cases of amaurosis, enough has already been said concerning the first and most important indication, namely, the re-establishment of the action which is obstructed; and here the only question is, about the manner in which that object can be most expeditiously and safely effected. For, says Beer, it should be distinctly understood, that the prevention of a complete amaurotic blindness essentially depends, not only upon the renewal of the secretion from the breasts, but upon this change being made without delay. The remedies which Beer has found most effectual for this purpose are warm poultices applied to the breasts, and at first composed of simple emollients, and afterward of more stimulating ingredients, such as hemlock, chamomile flowers, &c. When the breasts have more of a leucophlegmatic appearance, than that indicative of a fulness of the mammary gland, and disposition to a renewal of the milk secretion, Beer strengthens these poultices with aromatic herbs, and applies them alternately with well-warmed bags, full of dry aromatic plants, and sprinkled with camphor. These last means are very useful at night, or when the patient is asleep, and fresh warm poultices cannot be put on sufficiently often. In the daytime, the breasts should be frequently and gently rubbed with warm flannels, medicated with olibanum and mastic. This plan is to be followed up until the secretion and excretion of milk are renewed, and the amaurotic amblyopia has subsided. When the secretion either cannot be restored by the foregoing means, or the eyesight does not return with the re-established secretion, internal remedies must be tried, especially arnica, joined with calomel and camphor. Issues or setons should also be formed, and kept open for a considerable time.—(Lehre von den Augenkr. b. 2, p. 572—575.)

Of the symptomatic amaurosis from morbid changes, either in the optic nerves and their sheaths, or in the bones of the cranium, or the brain itself.

Beer says, a very considerable number of cases of this form of amaurosis, which have fallen under his notice, have enabled him, as it were, not only to know it at once, but to describe its exact symptoms.—1st. Its formation is constantly very slow, and in all cases the patient is not only completely deprived of vision, but, for more or less time previously to his death, rendered quite incapable of distinguishing light. 2dly. A second peculiar symptom of this amaurosis consists in morbid changes in the structure of the eye, which are at first scarcely perceptible, and increase very slowly. 3dly. The amaurosis either originates during an attack of violent headache, which continues almost uninterruptedly until death, or the headache does not come on until complete blindness has taken place; or the patient may have no pain whatever either in his eyes or head. 4thly. In the progress of this amaurosis, objects invariably seem to the patient to be perverted, disfigured, &c.

Symptoms when the disorder proceeds from disease of the optic nerves or their sheaths.

This case comes on slowly, and rarely attacks both eyes together. It always commences with a black cloud, which grows more and more dense, and with a troublesome, alarming perversion and disfigurement of every object, without the least painful sensation in the eye or head. The patient merely complains of a slight sensation of dull pressure at the bottom of the orbit, as if the eyeball were about to be forced from its socket, of which displacement, however, there is not yet the smallest appearance. In the very beginning of the disease, the pupil is already considerably dilated, and the pupillary edge of the motionless iris presents angles at several points, the pupil sometimes representing an irregular pentagon or hexagon. By degrees, though very slowly, a glaucomatous change of the vitreous humour ensues, and afterward of the lens itself; the only species of glaucoma which Beer has ever noticed quite unattended with a varicose affection of the blood-vessels of the eye. At last, the globe of the eye becomes perceptibly smaller than natural; but a complete atrophy does not ensue.

Symptoms when the case proceeds from disease of the skull or brain.

In this form of amaurosis, which usually attacks both eyes together, or at least one very soon after the other, the blindness also commences very slowly, with appearances as if every object looked at were perverted or disfigured. However, there is no black cloud, but rather an obscurity or confusion of every object. The disease in this stage is also accompanied with frequent giddiness, ugly luminous spectra, and, for the most part,

with aversion to light, uncommonly lively motions of the iris, a contracted pupil, angles in the upper and lower portions of the pupillary margin of the iris; an evident turgescence of the blood-vessels of the eye, gradually augmenting with most violent headache into actual cirsophthalmia; frequent convulsive motions of the eyes and eyelids, and strabismus of one or both eyes, ending in a true deviation of one or both of these organs from their natural positions. Under these symptoms, vision is afterward entirely abolished; and the headache, though subject to remissions, grows so much worse, extending back to the spine, that the patient is often nearly frantic, and, indeed, after a time, a destruction of the external senses happens, followed by that of the intellectual faculties. The first of the external senses which is lost is always the hearing, which infirmity is next followed by loss of the smell, or taste, or both these senses together; and then the memory and other intellectual powers decline. In this stage of the disorder, the eyeball not unfrequently protrudes from the orbit, a pathognomonic symptom, to which Beer attaches great importance, because it is an infallible criterion of a diseased state of the bones of the orbit, of the parts which invest this cavity, and of the optic nerve and dura mater, in the sella turcica. In such cases, complete mania now usually follows, and this sometimes in its most violent form, unless the patient happen to be first carried off by paralytic symptoms; life, under these circumstances, never lasting any considerable time.

As far as our external senses can discover, the cause of both these forms of amaurosis, as the title of this section specifies, lies in certain morbid changes in the structure of the optic nerve and its investments, or in diseased alterations of the bones of the cranium, the dura mater, and the brain. But how these changes arise, is not so easy of explanation. The morbid changes in the structures above mentioned, which Beer had himself ascertained by dissection, consist in a real induration of the optic nerves, and an adhesion of them to their sheaths, while within the skull these ash-coloured, gray, very much diminished nerves presented no vestige of medullary structure even as far as their origin from the brain. On the contrary, the optic thalamus presented externally its natural appearance. The retina seemed to have lost its pulpy matter, was tough, not easily torn, and appeared to consist but of a vascular membrane. In one example, although both eyes had been completely deprived of sight together, Beer found only the retina and optic nerve of the left side in this state of atrophy as far forwards as the point of union in the sella turcica. On the other hand, the optic nerve of the right eye was hard, without being in the least dwindled, and was closely adherent to its external coverings. Anteriorly to their decussation, nothing at all preternatural in either nerve could be discerned. But the left corpus striatum was so indurated, that a very sharp, strong scalpel was required for its division, though in colour and shape it was perfectly natural. On this side, also, the plexus choroides was entirely wanting. In three amaurotic patients of this kind, Beer found hydatids between the coverings of the optic nerve, and where such hydatids lay, the medullary matter seemed to have been displaced by their pressure. With the utmost care, he could not trace the ophthalmic ganglion.

Paw also found in the optic nerve a large hydatid, which had produced amaurosis.—(Obs. Anat. Rarior. Obs. 2.) In Mr. Heaviside's museum, there is a preparation of the optic nerve of an amaurotic eye, where a tumour of considerable bulk has grown from the neurilema.—(See Wardrop's Essays on the Morbid Anatomy of the Human Eye, vol. 2, p. 157.) In this work are specified examples of various other morbid changes of the optic nerve, especially calculous concretions within it, the presence of a viscid, muddy, gray fluid in the thickened neurilema, instead of pulp, a dwindling of the nerve, &c.

To the present description of cases, Beer refers the instance recorded by Haller (Opusc. Pathol. Obs. 65, p. 172), in which a calcareous mass was found between the membrane of Ruysch and the vitreous humour. According to Beer, there is preserved in the pathological and anatomical museum of the general hospital at Vienna, an eye, distended with a similar osseous mass, without the capsule of the lens being at all affected. Examples, in which the amaurotic blindness arose from abscesses in the brain, are reported by Ballonius (Paradigmata Hist. 7), by Pelargus (Med. Jahrg. 3, p. 198), Peyronie (Mém. de l'Acad. Royale de Chir. 1, p. 212), Schaarschmid (Berlin Nachrichte, 1740. No. 26), Langenbeck (Neue Bibl. 1, p. 61), and Mr. Travers (Synopsis, p. 143). The latter author has recorded an instance in which a firm lardaceous tumour, of the size of a garden bean, situated on the same side as the blindness, compressed the optic ganglion and nerve at its origin from it.—(Synopsis, p. 151.) I have seen a case of amaurosis, in which a tumour as large as a middling-sized apple was found in the anterior lobe of the brain, attended with protrusion of the eye, and vast destruction of the bones. Mr. Travers has seen amaurosis produced by a medullary fungus of the brain. A case, occasioned by disease of the thalamus, is related by Villeneuve (Journ. de Méd. continué, 1811, Févr. p. 98); another, of a tumour of the thalamus on the same side as the blindness, is recorded by Ford (Med. Commun. vol. 1, No. 4); and other swellings in various parts of the brain are described in Ephem. Nat. Cur. Dec. 3, Ann. 9, and 10, Obs. 253; De Haen's Ratio Medendi, P. 6, p. 271; Journ. des Savans, 1697; Muzell's Wahrnehm. 2, No. 13; Plater, Obs. lib. 1, p. 108; Thomann, Annalen für 1800, p. 400, &c. On this part of the subject, I beg leave to refer also particularly to my friend Mr. Wardrop's valuable Essays on the Morbid Anatomy of the Human Eye, vol. 2, p. 174, &c.

The morbid alterations of the bones of the cavity of the skull mostly happen at its basis, and not only may caries take place, but still more frequently exostoses of various forms, which are sometimes so small that they are first detected by the bone giving the feel of a rough grater. At the same time they are so sharp, that if the finger be passed rudely over them, it will be painfully hurt. In these cases the bones of the cavity of the skull are always found extremely thin; the diploe is almost entirely wanting, and the parietes of the orbit are preternaturally diaphanous, and in some places imperfect. Beer speaks of a lady's skull who had been completely blind, and for some weeks previously to her death insensible, in which instance scarcely any part of the cavity of the skull could be carelessly touched without risk of scratching the fingers with spiculæ. Once in an amaurotic boy, who for a short time before his death was so insane that he used to devour his own excrement, Beer found at the side of the sella turcica a long considerable spicula, which passed directly through the optic nerves at the place of their decussation. A case of amaurosis produced by a spicula of bone injuring the opposite side of the brain is related by Anderson.—(See Trans. of the Society of Edinb. vol. 2.) Sometimes the ethmoid bone has been found carious (Ballonius, Paradigmata, No. 7); sometimes other parts of the cranium.—(Mursinna, Beobacht. 1, No. 6; Schmucker, Vermischte Schrift. 2, p. 12.) Nor is it unfrequent to find the medullary substance of the brain itself as soft as pap, while the cortical substance is full of blood-vessels, and unusually firm, the convolutions being hardly distinguishable.

Many of the causes of amaurosis are of such a nature as to render the disease totally incurable. Of this description is fungus hæmatodes, in which the structure of the retina and optic nerve is changed in a remarkable manner, the whole cavity of the eyeball becoming filled with a substance resembling medullary matter, and the optic nerve changed in its form, colour, and structure.—(See Wardrop's Essays on the Morbid Anatomy of the Human Eye, vol. 2, p. 156, 8vo. Lond. 1818.)

On the authority of Ecker, one case is upon record, where the cause of amaurosis depended upon an aneurism of the central artery of the retina.—(Pinel, Nosographie Philos. vol. 2, p. 122.)

In another instance the macula lutea, which is naturally a yellow spot near the centre of the retina, was found black.—(Mém. de la Société Méd. d'Emulation, an 1798.)

Bonetus, in his Sepulchretum Anatomicum, lib. 1, sect. 18, describes various cases which were quite incurable: after death the blindness in one instance was found to be occasioned by an encysted tumour, weighing fourteen drachms, situated in the substance of the cerebrum, and pressing on the optic nerves near their origin. In the second, the blindness was produced by a cyst containing water and lodged on the optic nerves

where they unite. In the third, it arose from a caries of the os frontis, and a consequent alteration in the figure of the optic foramina. In a fourth, the cause of the disease was a malformation of the optic nerves themselves. In some of the instances in which no apparent alteration can be discovered in the optic nerve, the late Mr. Ware conjectured that a dilatation of the anterior portion of the circulus arteriosus may be the cause of the affection. The circulus arteriosus is an arterial circle, surrounding the sella turcica, formed by the carotid arteries on each side, branches passing from them to meet each other before, and other branches passing backwards to meet branches from the basilary artery behind. The anterior part of the circulus arteriosus lies directly over, crosses, and is in contact with the optic nerves, and just in the same way as the anterior branches lie over the optic nerves, the posterior ones lie over the nervi motores oculorum. Hence Mr. Ware attempted to refer the amaurosis itself, and the paralytic affection of the eyelids and muscles of the eye, sometimes attendant on the complaint, to a dilatation of the anterior and posterior branches of the circulus arteriosus. The frequently diseased state of the trunk or small branches of the carotid arteries at the side of the sella turcica is noticed by Dr. Baillie in his useful work on Morbid Anatomy, and, he says, the same sort of diseased structure is also found in the basilary artery and its branches.—(See Ware's Chir. Obs. on the Eye.)

In 1826, M. Magendie related to the French Academy of Sciences various facts exemplifying the remarkable influence of the fifth nerves over all the senses; and with respect to the sense of sight, he finds that the action of the eyeball and optic nerve cease immediately they are completely deprived of the influence of those nerves. Thus a state of the eye is produced that has the greatest analogy to amaurosis. Indeed, when the fifth nerves are divided in an animal, it is instantly bereft of sight on the side on which the nerve has been cut, notwithstanding the eye retains at the moment all the physical conditions necessary for vision. It is not to be supposed, however, that the fifth nerves perform the function usually referred to the optic ones. To perceive the light, and to see, as Magendie remarks, are, experimentally speaking, two different things. An animal whose fifth nerves have been divided does not see, neither is it conscious of the daylight or of the strongest artificial light; yet it decidedly perceives the impression of the rays of the sun when they fall directly on the eye. Hence a healthy, sound condition of the optic nerve on the one part, and of the fifth nerve on the other, is essential to perfect vision; and M. Magendie therefore deems it highly probable that there are two kinds of amaurosis, one depending on a particular affection of the optic nerve and retina; the other on disease of the fifth nerve, and the defect of its influence on the organ of vision. These reflections led him to make trial of a combination of acupuncture and galvanism for the cure of certain cases of amaurosis. Thus in one case, having introduced one needle into the frontal nerve, and another into the upper maxillary, he brought the needles into repeated contact with the two poles of a Voltaic pile. In a fortnight the patient had received considerable benefit from the plan. Other facts are also recorded in favour of this treatment.—(See Journ. Expér. de Physiol. t. 6, p. 156 et seq.)

Many additional observations, connected with the subject of amaurosis, will be found in the articles Cataract, Diplopia, Fungus Hæmatodes, Gutta Serena, Hemeralopia, Hemiopia, Nyctalopia, Sight, Defects of, &c.

AMBE. (From ἄμβη, the projecting edge of a rock.) An old chirurgical machine for reducing dislocations of the shoulder, and so called because its extremity projects like the prominence of a rock. Its invention is referred to Hippocrates. The ambe is the most ancient mechanical contrivance for the above purpose; but it is not at present employed. Indeed, it is scarcely to be met with in the richest cabinets of surgical apparatus. It is composed of a piece of wood, rising vertically from a pedestal. With the vertical piece is articulated, after the manner of a hinge, a horizontal piece, with a gutter formed in it, in which the luxated limb is laid and secured with straps. The patient places himself on one side of the machine; his arm is extended in the gutter and secured; the angle formed by the union of the ascending piece and by the horizontal branch is lodged in the armpit, and then the horizontal branch is depressed. In this way extension is made, while the vertical part makes counter-extension, and its superior part tends to force the head of the humerus into the articular cavity. But there is nothing to fix the scapula, and the compression made by the superior portion of the vertical piece of the machine tends to force the head of the humerus into the glenoid cavity, before it is well disengaged by the extension.—(See Boyer on Diseases of the Bones, vol. 2.)

AMBLYOPIA. (From ἀμβλὺς, dull, and ὤψ, the eye.) Hippocrates means by this word, in his Aph. 31, Sect. 3, the dimness of sight to which old people are subject. Modern writers generally understand by amblyopia incomplete amaurosis, or the weakness of sight attending certain stages and forms of this disorder.

AMMONIÆ MURIAS. AMMONIA MURIATA. Sal ammoniac. Its chief use in surgery is as an external discutient application.—(See Lotio Ammon. Muriatæ cum Aceto.)

Mr. Justamond recommends the following application to milk abscesses: ℞. Ammoniæ muriatæ ʒj. Spiritus roris marini ℔j. Misce. Linen rags are to be wet with the remedy, and kept continually applied to the part affected.

There can be little doubt of the utility of this lotion in dispersing the induration left after mammary abscesses; but while these cases are accompanied with much pain, tension, and inflammation, emollient fomentations and poultices are to be preferred.

If muriate of ammonia be mixed with its weight of powdered nitre, and dissolved in six or eight parts of water, it produces a very cold lotion, which may be used as a substitute for ice in cases of strangulated hernia.

AMPUTATION. The operation of cutting off a limb, or other part of the body, as the breast, penis, &c.

Such an operation frequently becomes indispensably proper, on the principle of sacrificing a branch, as it were, for the sake of taking the only rational chance of saving the trunk itself. Indeed the suggestion of this measure, in cases of mortification, where there is no chance of the parts recovering, may be said to be derived from nature herself, who, by a process to which I shall advert in speaking of mortification, detaches

the dead from the living parts; this separation is followed by cicatrization, and the patient recovers.

The necessity for amputation has always existed, and ever will continue, as long as the destructive effects of injuries and diseases of the limbs cannot be obviated in any other manner. As Graefe observes, there was once a period (I should say, about forty years ago) when the operation was more frequently practised than at present, and this fact is to be imputed less to the caprice of surgeons than to the imperfection of the means which used to be employed for the relief of local diseases. For then aneurisms of the limbs, and some other cases, at present treated with success, were always deemed incurable without amputation. Boucher, Gervaise, Faure, and Bilguer inveighed against the frequent performance of amputation on the field of battle; yet their arguments must prove of little value; unless a path were at the same time traced which would conduct us to the method of remedying the circumstances which form the necessity for the operation. When this condition is fulfill d, and more effectual modes of treatment are devised, as for instance with respect to the gun-shot wounds specified by Bilguer, then the necessity for amputation in such cases would cease of itself.—(Normen für die Ablösung grösserer Gliedmassen, p. 13, 4to. Berlin, 1812.)

As the author of another valuable modern work has said, it is an excellent observation, founded on the purest humanity, and justified by the soundest professional principles, that to save one limb is infinitely more honourable to the surgeon, than to have performed numerous amputations, however successful; but it is a remark, notwithstanding its quaintness, fully as true, that it is much better for a man "to live with three limbs, than to die with four."—(Hennen on Military Surgery, p. 251, ed. 2.)

To this saying should be added the reflection, that some unfortunate beings, influenced by a relish for life, have been known to submit to the loss of all their legs and arms, and yet recover. In the Hôtel des Invalides at Paris, mutilated objects are in recollection, who had lost all their thighs and arms, so that, unless assisted, they could not stir, and it was necessary to feed and wait upon them like new-born infants.—(Morand, Opusc. de Chir. p. 183, and Graefe, op. cit. p. 23.)

The amputation of the large limbs was anciently practised under many disadvantages. The best way of making the incisions was unknown; the ignorance of the old surgeons about the right method of stopping hemorrhage was the death of a large proportion of the patients who had courage to submit to the operation; the mode of healing the wound by the first intention was not understood, or not duly appreciated; and the instruments were as awkward and clumsy, as the dressings were irritating and improper.

Modern practitioners have materially simplified all the chief operations in surgery; an object which has been accomplished not merely by letting anatomical science be the main guide of their proceedings; not simply by devising more judicious and less painful methods; not only by diminishing the number, and improving the construction, of instruments; but also, in a very essential degree, by abandoning the use of a multitude of external applications, most of which were useless or hurtful.

The Greek, Roman, and Arabian practitioners amputated limbs with feelings of alarm, and, in general, with the most melancholy results; while modern surgeons proceed to the operation completely fearless, well knowing that it mostly proves successful: hence, as Graefe justly remarks, nothing can be more evident, than that the patient's safety must depend very much upon the kind of practice.—(See Normen für die Ablösung grösserer Gliedmassen, p. 1.) By practice is here implied the mode in which the operation is performed, the way in which the wound is dressed, and the whole of the after-treatment.

But, much improved as amputation has been, it cannot be dissembled, that it is an operation at once terrible to bear, dreadful to behold, and sometimes severe and fatal in the consequences which it itself produces, while the patient, if saved, is left for ever afterward in a crippled, mutilated state. Hence it is the surgeon's duty never to have recourse to so serious a proceeding without a perfect and well-grounded conviction of its necessity. Amputation should be generally regarded as the last expedient to which a surgeon ought to resort; an expedient justifiable, as a late writer says, only when the part is either already gangrenous, or the seat of so much injury or disease, that the attempt to preserve it any longer, would expose the patient's life to the greatest danger.—(Dict. des Sciences Méd. t. 1, p. 472.)

Although, says a distinguished modern surgeon, this amounts to a confession, that the cure of some local disorders is not within the limits of our art, yet, on the other hand, it furnishes a proof, that surgery may be the means of saving life under circumstances which, without its assistance, would infallibly have a fatal termination. The operation is adopted as the safest measure: the cause is removed for the prevention of consequences.—(Graefe, op. cit. p. 14.)

Nothing can be more absurd or more misapplied, than the censures sometimes passed upon amputation, because the body is mutilated by it, &c. Although, as a modern writer remarks, the objection proves the limitation of human knowledge and ability, it must be very unfair on this account to throw blame on surgery, or the practitioner who thus saves the patient's life. For, without dwelling upon the fact, that a humane surgeon would never amputate through a mere love of operating, and without urgent cause, one may simply ask, are all diseases in their nature curable? Does not the surgeon cure such as are curable without mutilation? And are not cases, which were in the beginning remediable, often first brought to the surgeon when, from neglect, they have become totally incurable? Is it not his duty then to employ the only means left for saving the patient? And is not the preservation of a long and healthy life a compensation for the sacrifice? Would it not be just as reasonable to blame an architect, when the irresistible force of lightning or a bomb destroys his building? Indeed, is it not rather a greater honour to surgery, that even when death has already taken possession as it were, of a part, and is threatening inevitable destruction to the whole, a means is yet furnished, not only of saving the patient's life, but of bringing him into a state in which he may recover his former good health?—(Brünninghausen, Erfahrungen und Bemerkungen über die Amputation, p. 11, 12mo. Bamberg, 1818.)

Though amputation is in every respect much better than in former times, and its right performance is by no means difficult, I would not wish to be thought to say, that it is always, or even usually done secundum artem, because long opportunities of observation have convinced me of the contrary; and the reason of the knife being yet so badly handled in this part of surgery, may generally be imputed to carelessness, slovenly habits, or, what is as bad, a want of ordinary dexterity. There are several egregious faults in the method of amputating, which even many hospital surgeons in this metropolis are guilty of; but these we shall find, when we criticise them, are for the most part easily avoidable, without any particular share of skill being required. A greater difficulty is to ascertain with precision the cases which demand the operation, those in which it may be dispensed with, and the exact periods at which it should be practised. These are considerations requiring profound attention, and the brightest talents. The most expert operator (as Mr. O'Halloran observes) may not always be the best surgeon. To do justice to the sick and ourselves, we must, in many cases, rather avoid than perform capital operations; and with respect to amputation, if we consider the many cases in which it has been unnecessarily undertaken, or done at unseasonable periods, it may be suspected, that this operation, upon the whole, may have done more mischief than good. At all events, it is not enough for a surgeon to know how to operate; he must also know when to do it.—(See O'Halloran on Gangrene and Sphacelus: preface.)

For such reasons I shall first take a view of the circumstances under which the best surgeons deem amputation necessary; though it may be proper to observe, that in each of the articles relative to the particular diseases and injuries which ever call for the operation, additional information will be offered.

1. *Compound fractures.*

In a compound fracture the necessity for amputation is not altogether proportioned to the seriousness of the accident, but also frequently depends in part upon other circumstances. For example, in the field, and

on board of a crowded ship, it is not constantly in the surgeon's power to pay such attention as the cases demand, nor to procure for the patient the proper degree of rest and good accommodation. In the field, there is often a necessity for transporting the wounded from one place to another. Under these circumstances it is proper to have immediate recourse to amputation, in numerous cases of bad compound fractures, some of which, perhaps, might not absolutely demand the operation, were the patients so situated, as to be capable of receiving all the advantages of the best and most scientific treatment in a well-ventilated quiet house or hospital, furnished with every desirable convenience. At the same time, daily experience proves, that there are many other cases, in which it would be improper to have recourse to the knife, even under the most unfavourable circumstances of the above description. So, when a compound fracture occurs, in which the soft parts have not been considerably injured; in which the bones have been broken in such a direction that they can be easily set and kept in their proper position, or in which there is only one bone broken, amputation would be unnecessary and cruel. But when the soft parts have been more extensively hurt, and the bones have been so badly broken, that perfect quietude and incessant care are required to afford any chance of recovery, it is a good general rule to amputate whenever these advantages cannot be obtained.

The bad air in crowded hospitals and large cities, a circumstance so detrimental to wounds in general, is another consideration which may seriously lessen the chances of saving a badly broken limb, and should be remembered in weighing the reasons for and against amputation.

On this part of the subject, I find the sentiments of Graefe interesting: besides an absolute, says he, there is a relative, necessity for amputation: it is the most mournful, and proceeds altogether from unfavourable external circumstances, though, alas! in many cases nearly unavoidable, when life is to be preserved. In war, every bloody action furnishes proof of what has been stated. The number of the wounded is immense; the number of surgeons for the duty too limited. The supplies most needed are at a distance. In these emergencies, though the military surgeon may, from routine and genius, be able to suggest the quickest method of obtaining what is wanted, know how to avail himself of every advantage which circumstances permit, and contrive tolerable substitutes for such things as are deficient, yet this will not always do. Were we (says Graefe) here to complain of the government not providing due assistance for the defenders of our native soil, to many the remonstrance would only appear reasonable. Yet they who manage the medical affairs of the Prussian army may not constantly have it in their power to avert the inconvenience. The general cannot foretel the number and nature of the wounds which may happen, so as to enable the medical department to take with them exactly the apparatus required, without encumbering the army with a redundance of useless articles. The enemy, perhaps, captures the medical stores, or the rapid movements of particular corps cut us off from the principal depôts. Detachments often skirmish at remote points. The hospitals may lie several miles in the rear of the line; and, for want of means, the transport of the imperfectly-dressed wounded may continue night and day. Hardly are the sufferers brought into the nearest hospital, in the most pitiful state from pain, anxiety, and cold, when an order is given to break up, and they must be conveyed still farther towards their grave; and a thousand other circumstances, as Graefe observes, which deprive the wounded of the requisite attendance, and essential number of surgeons, together with the most necessary stores, make it desirable to simplify every wound as much as possible; which, indeed, is the only means of shunning the reproach, that, while we are endeavouring to save one man's limb, we let another die.

Who doubts, says Graefe, that a soldier with a gun-shot wound, complicated with a smashed state of the bones, may sometimes be saved, without loss of his limb, by employing all the means which the resources of surgery offer? But these very resources are often wanting in a campaign; and the business of dressing the patient would occupy the surgeon several hours daily, during which his useful assistance could not be extended to other sufferers. Notwithstanding the utmost care, the removal of patients from one place to another frequently makes their wounds extremely dangerous, or fatal; and we now lose many a man, who, had he undergone amputation, would have been able to bear the journey.—(See Normen für die Ablösung grösserer Gliedmassen, p. 15, 16.)

From what I have seen of the ill effects of moving patients with bad compound fractures of the lower extremity, produced by gun-shot violence, I am convinced that, as a general rule, it is better to perform amputation; but if this be not done, and an attempt is to be made to save the member, it will be more humane, when the army is retreating, and the enemy are not savages, to leave such wounded behind, than subject them to all the fatal mischief of hastily and roughly transporting them in such a condition. It gives me particular pleasure to find the preceding sentiment confirmed by Dr. Hennen, whose knowledge and experience in military surgery entitle all his opinions to the greatest attention: in noticing what ought to be done with the wounded, when the army is compelled to retreat, he says, "it then becomes the duty of a certain proportion of the hospital staff to devote themselves for their wounded, and become prisoners of war along with them; and it may be an encouragement to the inexperienced, while it is grateful to me, to observe, that I have never witnessed, nor traced, on inquiry, an act of unnecessary severity practised either by the French or English armies on their wounded prisoners."

Compound fractures of the thigh, produced by gun-shot violence, too often have an unfavourable termination, especially when the accident has been caused by grape-shot or even a musket-ball, fired from a moderate distance, and the patient is moved from one place to another after the receipt of the injury. In the military hospital at Oudenbosch, in the spring of 1814, I had charge of about eight bad compound fractures of the thigh, of which cases only one escaped a fatal termination. This was an instance in which the femur was broken a little way above the knee. Another patient was extricated by amputation from the perils immediately arising from the splintered displaced state of the bone, the serious injury of the muscles, and enormous abscesses, but was unfortunately lost by secondary hemorrhage. All these patients had not merely been struck by grape-shot, or else by balls fired from a short distance, but they had been moved from Bergen-op-Zoom into my hospital five or six days after the receipt of the injury, the very worst period possible on account of the inflammation being then most violent. From the ill success of these cases, many a surgeon who saw them might be inclined to think that immediate amputation ought generally to be performed for all compound fractures of the thigh as soon after the receipt of the injury as possible. And such is my own sentiment, whenever the accident has been caused in the violent manner above specified, or whenever the patient must be moved any distance in a wagon after the occurrence of the injury. It may be right to state, however, that I have known more than one compound fracture of the thigh cured, where the accident had not been occasioned by gun-shot violence, and I have been informed of one or two successful cases where the bone was broken by a pistol-ball. In St. Bartholomew's hospital, two compound fractures of the thigh were pointed out to me some time ago, as cases likely to end favourably. However, these may only have been lucky escapes, deviations from what is common, and not entitled to any stress, with the view of affecting the general excellent rule of amputating where the thigh-bone is broken by gun-shot violence.

As Mr. Guthrie has accurately observed, one circumstance which increases the danger of fractures of the femur from gun-shot violence is, that the bone is very often broken obliquely, the fracture extending far above and below the point immediately struck by the ball.—(On Gun-shot Wounds, p. 189, 190.) This disposition of the thigh-bone to be splintered for several inches when hit by a ball, and the increased danger arising from the occurrence, are also very particularly commented upon by the experienced Schmucker, who was surgeon-general to the Prussian armies in the campaigns of Frederick the Great.—(See his Vermischte Chirurgische Schriften, b. 1, p. 39, 8vo. Berlin, 1785.) In several of the cases under the care of Dr. Cole and myself in Holland, the bone was split longitudinally to the extent of seven or eight inches.

According to Schmucker, all fractures of the middle or upper part of the femur are attended with great danger. "But (says he) if the fracture be situated at the lowest part of the bone, the risk is considerably less, the muscles here not being so powerful; in such a case, therefore, amputation should not be performed before every other means has been fairly tried; and very frequently I have treated fractures of this kind with success, though the limb sometimes continued stiff. But (says Schmucker) if the bone be completely fractured or splintered by a ball at its middle, or above that point, I never wait for the bad symptoms to commence, but amputate ere they originate; and when the operation has been done early enough, most of my patients have been saved. However, when some days had transpired, and inflammation, swelling, and fever had come on, I must candidly confess that the issue was not always fortunate. Yet the operation should not on this account be dispensed with; for if only a few can thus be saved out of many, some benefit is obtained, as, without this step, such few would also perish."—(Vermischte Chir. Schriften, b. 1, p. 42.) What I saw of compound fractures of the thigh, after the assault on Bergen-op-Zoom, we may remark, coincides with the results of Schmucker's ample experience; for the only two patients who survived the bad symptoms proceeding directly from the fracture were, one whose femur was broken near the knee, and another whose limb I took off on account of a fracture of the middle of the bone, accompanied with abscesses of surprising extent. The latter was a case, however, in which the limb ought to have been removed earlier. The following remarks, by Mr. Guthrie, I consider judicious and correct.

"The danger and difficulty of cure attendant on fractures of the femur from gun-shot wounds, depend much on the part of the bone injured; and in the consideration of these circumstances it will be useful to divide it into five parts. Of these, the head and neck included in the capsular ligament, may be considered the first; the body of the bone, which may be divided into three parts, and the spongy portion of the lower end of the bone exterior to the capsular ligament, forming the fifth part. Of these, the fractures of the first kind are, I believe, always ultimately fatal, although life may be prolonged for some time. The upper third of the body of the bone, if badly fractured, generally causes death at the end of six or eight weeks of acute suffering. I have seen few escape, and then not with a useful limb that had been badly fractured in the middle part. Fractures of the lower or fifth division are in the next degree dangerous, as they generally affect the joint; and the least dangerous are fractures of the lower third of the body of the bone. Of these even I do not mean to conceal, that when there is much shattered bone the danger is great, so that a fractured thigh by gun-shot, even without particular injury of the soft parts, is one of the most dangerous kinds of wounds that can occur."—(See Guthrie on Gun-shot Wounds, p. 190.)

In compound fractures, as Mr. Pott has correctly pointed out, there are three points of time when amputation may be proper. The first of these is immediately or as soon as possible after the receipt of the injury. The second is, when the bones continue for a great length of time without any disposition to unite, and the discharge from the wound has been so long and is so large that the patient's strength fails, and general symptoms foreboding dissolution come on. The third is, when a mortification has taken such complete possession of the soft parts of the inferior portion of the limb quite down to the bone, that upon the separation of such parts the bone or bones shall be left bare in the interspace,

The first and second of these are matters of very serious consideration. The third hardly requires any.

When a compound fracture is caused by the passage of a very heavy body over a limb, such, for instance, as the broad wheel of a wagon or loaded cart, or by the fall of a very ponderous body on it, or by a cannon-shot, or by any other means so violent as to break the bones into many fragments, and so to tear, bruise, and wound the soft parts, that there shall be good reason to fear that there will not be vessels sufficient to carry on the circulation with the parts below the fracture, it becomes, as Mr. Pott observes, a matter of the most serious consideration, whether an attempt to save such a limb will not occasion loss of life. This consideration must be before any degree of inflammation has seized the part, and therefore must be immediately after the accident. When inflammation, tension, and a disposition to gangrene in the limb have arisen, the period is highly disadvantageous for operating, and the patient's chances of being saved by amputation under these circumstances are much smaller than before the changes here spoken of had taken place. At the same time, there are certain examples of mortification from external causes, where, as far as one can judge from the results of later experience than that of Mr. Pott, the surgeon should not defer amputation, even though the disorder be yet in a spreading state, attended with considerable swelling and tension reaching far up the limb. This is a subject, however, which will require more explanation hereafter.—(See what is presently said on Mortification.) Nor are the cases to which reference is made meant to affect the general truth of the observation delivered by the most experienced surgeons of every age, that when a limb is extensively swelled and inflamed, with a part of it either in a state of spreading mortification or ready to become gangrenous, the period is so unfavourable for amputation that very few patients so circumstanced ever recover after the operation. Nor is it meant to be insinuated, that in the very cases which form exceptions to the general rule of not amputating before the tendency to gangrene has ceased, the patient might not have had an infinitely better chance of his life, had the operation been done immediately after the first receipt of the injury, before any disposition to gangrene had had time to be produced.

The necessity of immediate or very early decision in this case makes it a very delicate part of practice; for however pressing the case may seem to the surgeon, it will not, in general, appear in the same light to the patient, to the relations, or to bystanders. They will be inclined to regard the proposition as arising from ignorance, or an inclination to save trouble, or a desire to operate; and it will often require more firmness on the part of the practitioner, and more resignation and confidence on the part of the patient, than is generally met with, to submit to such a severe operation in such a seeming hurry, and upon so little apparent deliberation; and yet it often happens, that the suffering this point of time to pass decides the patient's fate.

This necessity of early decision arises from the quick tendency to mortification which ensues in the injured limb, and too often ends in the patient's death. That this is no exaggeration, says Pott, melancholy and frequent experience evinces, even in those whose constitutions previous to the accident were in good order; but much more in those who have been heated by violent exercise, or labour, or liquor, or who have led very debauched and intemperate lives, or who have habits naturally inflammable and irritable. This is often the case when the fracture happens to the middle part of the bones, but is much more likely to happen when any of the large joints are concerned. In many of these cases a determination for or against amputation is really a determination for or against the patient's existence.

That it would have been impossible to have saved some limbs which have been cut off, no man will pretend to say; but this does not render the practice injudicious. Do not the majority of those who get into the above hazardous condition, and on whom amputation is not performed, perish in consequence of their wounds? Have not many lives been preserved by amputation which, from the same circumstances, would otherwise most probably have been lost?

Pressing and urgent as the state of a compound fracture may be at this first point of time, still it will be a matter of choice whether the limb shall be removed or not; but at the second period the operation must be submitted to, or the patient must die.

The most unpromising appearances at first do not necessarily or constantly end unfortunately. Sometimes, after the most threatening first symptoms, after considerable length of time, great discharges of matter and large exfoliations of bone, success shall ultimately be obtained, and the patient shall recover his health and the use of his limb.

But sometimes, after the most judicious treatment through every stage of the disease; after the united efforts of physic and surgery; the sore, instead of granulating kindly, and contracting daily to a smaller

size, shall remain as large as at first, with a tawny, spongy surface, discharging a large quantity of thin sanies, instead of a small one of good matter; the fractured ends of the bones, instead of tending to exfoliate or to unite, will remain as perfectly loose and disunited as at first, while the patient shall loose his sleep, his appetite, and his strength; a hectic fever, with a quick, small, hard pulse, profuse sweats, and colliquative purging, contributing at the same time to bring him to the brink of the grave, notwithstanding every kind of assistance: in these circumstances, if amputation be not performed, Mr. Pott asks, what else can rescue the patient from destruction?

The third and last period is a matter which does not require much consideration. Too often the inflammation consequent upon the injury, instead of producing abscess and suppuration, tends to gangrene and mortification, the progress of which is often so rapid, as to destroy the patient in a very short space of time, constituting that very sort of case in which amputation should have been immediately performed. But sometimes even this dreadful malady is, by the help of art, put a stop to, but not until it has totally destroyed all the surrounding muscles, tendons, and membranes quite down to the bone, which, upon the separation of the mortified parts, is left quite bare, and all circulation between the parts above and those below is by this totally cut off. In this instance, whether the surgeon saw through the bare bone, or leave the separation to be effected by nature, the patient must lose his limb. —(See Pott's Remarks on the Necessity, &c. of Amputation in certain Cases, &c. Chir. Works, vol. 3.)

For the consideration of a variety of complicated cases which affect the question of amputation in compound fractures, I must refer to the article Gun-shot Wounds.

2. *Extensive contused and lacerated wounds.*

These form the second class of general cases requiring amputation. Wounds without fracture are not often so bad as to require this operation. When a limb, however, is extensively contused and lacerated, and its principal blood-vessels are injured, so that there is no hope of a continuance of the circulation, the immediate removal of the member should be recommended, whether the bones be injured or not. Also, since no effort on the part of the surgeon can preserve a limb so injured, and such wounds are more likely to mortify than any others, the sooner the operation is undertaken the better.

In these cases, as in those of compound fractures, though amputation may not always be necessary at first, it may become so afterward. The foregoing observations, relative to the second period of compound fractures, are equally applicable to badly lacerated wounds, unattended with injury of the bones. Sometimes a rapid mortification comes on; or a profuse suppuration, which the system can no longer endure.—(Encyclopédie Méthodique; partie Chir. t. 1, p. 80.)

3. *Cases in which part of a limb has been carried away by a cannon-ball.*

When part of a limb has been torn off by a cannon-ball, or any other cause capable of producing a similar effect, the formation of a good and serviceable stump, the greater facility of healing the clean, regular wound of amputation, and the benefit of a far more expeditious, as well as of a sounder cure, are the principal reasons which here make the operation advisable.

This was an instance, in which some former surgeons disputed the necessity of amputation. They urged as a reason for their opinion, that the limb being already removed, it is better to endeavour to cure the wound as speedily as possible, than increase the patient's sufferings and danger, by making him submit to amputation. It must be remembered, however, that the bones are generally shattered, and reduced into numerous fragments; the muscles and tendons are unequally divided, and their ends torn and contused. Now, none of the old surgeons questioned the absolute necessity of extracting the splinters of bone, and cutting away the irregular extremities of the tendons and muscles, which operations would require a longer time than amputation itself. Besides, we should recollect that, by making the incision above the injured part, so as to be enabled to cover the bone with flesh and integuments perfectly free from injury, the extent of the wound is so diminished, that the healing can be accomplished in one-third of the time which would otherwise be requisite, and a much firmer cicatrix is also obtained. Such reflections must convince us, that amputation here holds forth very great advantages. It cannot increase the patient's danger, and as for the momentary augmentation of pain which he suffers, he is amply compensated by all the benefits resulting from the operation.—(See Gun-shot Wounds.)

4. *Mortification.*

Mortification is another cause, which, when advanced to a certain degree, renders amputation indispensably proper. We have noticed, that bad compound fractures and wounds often terminate in the death of the injured limb. Such surgeons as have been determined, at all events, to oppose the performance of amputation, have pretended, that the operation is here totally useless. They assert, that when the mortification is only in a slight degree, it may be cured, and that when it has spread to a considerable extent, the patient will perish, whether amputation be performed or not. But this way of viewing things is so contrary to facts, and the experience of every impartial practitioner, that I shall make no attempt to refute the assertion. While it is allowed that it would be very bad practice, to amputate on every slight appearance of gangrene, it is equally a fact, that when the disorder affects the substance of a member, the operation is generally the safest and most advantageous measure. Nay, there are, as we shall presently see, certain forms of mortification, in which the early performance of amputation is the only chance of saving the patient.

Practitioners have entertained very opposite opinions, concerning the period when one should operate in cases of mortification. Some pretend, that whenever the disorder presents itself, and especially when it is the effect of external violence, we should amputate immediately the mortification has decidedly begun to form, and while the mischief is in a spreading state. Others believe, that the operation should never be undertaken before the progress of the disorder has stopped, even not till the dead parts have begun to separate from the living ones.

The advocates for the speedy performance of amputation declare, that the farther progress of the mortification may be stopped, and the life of the patient preserved, by cutting above the parts affected. However, according to the reports of the greater number of eminent surgical writers, this practice is highly dangerous, and undeserving of confidence. Whatever pains may be taken, in the operation, only to divide sound parts, there is no certainty of succeeding in this object, and the most skilful practitioner may be deceived. The skin may appear to be perfectly sound and free from inflammation, while the muscles which it covers, and the parts immediately surrounding the bone, may actually be in a gangrenous state. But even when the soft parts are found free from apparent distemper, on making the incision, still, if the operator should not have waited till the mortification has ceased to spread, the stump will almost always be attacked by gangrene. Surgeons who have had opportunities of frequently seeing wounds which have a tendency to mortify, entertain the latter opinion. Such was the sentiment of Pott, who says that he has often seen the experiment made, of amputating a limb in which gangrene had begun to show itself, but never saw it succeed, and it invariably hastened the patient's death.

The operation may be postponed, however, too long. Mr. S. Sharp, in particular, recommended too much delay, advising the operation never to be done, till the natural separation of the mortified parts had considerably advanced. Mr. Sharp was a surgeon of immense experience, and his authority carries with it the greatest weight. But, perhaps, he was too zealous in his opposition to a practice, the peril of which he had so often beheld. When the mortification has ceased to spread, there is no occasion for farther delay. We now obtain, just as certainly, all the benefits of the operation, and get rid of a mass of putridity, the exhalations from which poison the atmosphere which the patient breathes, and are highly detrimental to his health. Nay, according to the reports of writers, patients in these circumstances may actually fall victims to the absorption of the putrid matter which is suffered to remain too long. However, this danger would not be

so considerable as that which would arise from too precipitate an operation; and it is better to defer amputation a little more than is absolutely requisite, than run any risk of doing the operation before it is certain that the parts have lost their tendency to gangrene.

In the article Mortification, we have noticed particular cases of gangrene, where, according to Larrey's experience, the surgeon is not to wait for the line of separation being formed, but have recourse to the immediate performance of amputation. The experience of Mr. Lawrence tends also to confirm the propriety of such practice.—(See Medico-Chir. Trans. vol. 6, p. 156, &c.)

In an example, where a large part of the arm was deeply affected with gangrene from external violence, and the disorder was yet making rapid progress, I once recommended the performance of amputation at the shoulder-joint. On the whole this instance was favourable to the practice; for, though the patient died at the end of a fortnight, probably he would not have lived twenty-four hours, had the operation not been done; nor was the stump attacked with mortification, a circumstance worthy of attention, because it is a danger particularly insisted upon by the opponents of amputation, under the preceding circumstances; and, had it not been for a large abscess, which formed in the back, as was supposed, from a violent blow received in the fall which produced the original injury, there were well-grounded hopes of recovery. The patient, here spoken of, was attended by Dr. Blicke, of Walthamstow.

There is likewise a species of gangrene, which is pointed out by Mr. Guthrie as requiring early amputation. "A soldier (says he) shall receive a flesh-wound from a musket-ball in the middle of the thigh, which passed through the limb apparently, on a superficial inspection, without injuring the main artery; or it shall pass close behind the femur, where the artery turns to the back part of the bone; or it may go through the middle of the bone, from behind forwards, between the condyles of the femur, into the knee-joint, and the patient shall walk to the surgeon with little assistance, be superficially dressed, and, in many cases be considered slightly wounded; yet the femoral artery and vein of the whole of these cases, and, indeed, in many others, shall be wounded, or cut across, and the local inflammation be so slight as to obtain little attention. On the third or fourth day, the patient shows his toes discoloured, and complains of pain and coldness in the limb below the wound, the constitution begins to sympathize with the injury, and the surgeon probably thinks the case extraordinary. Perhaps he suspects the real state of the injury; but is surprised that a wound of the femoral or popliteal artery, with so little attendant injury, could cause mortification, &c. He is anxious to do something; but mortification, or at least gangrene, having commenced, he must, according to general rule, await the formation of the line of separation. The temperature of the leg, a little above the gangrene, is good, perhaps higher than natural; he hopes it will not extend farther, and it probably does remain stationary for a little time. At last, the parts originally affected, the toes, become sphacelated, and gangrene quickly spreads up the leg as far as the wounded artery, by which time the patient dies."

For the purpose of preventing such a disaster, where the artery, or artery and vein, have been divided, Mr. Guthrie recommends the performance of amputation as soon as the gangrene is perceived to extend beyond the toes; and the swelling and slight attendant inflammation, which is marked more by the tumefaction, than the redness of the part, has passed higher up than the ankle.—(See Guthrie on Gun-shot Wounds, p. 60, 61.)

5. *White swellings.*

Scrofulous joints, with diseased bones, and distempered ligaments and cartilages, is another case, in which amputation may become absolutely necessary. As Mr. Pott remarks, there is one circumstance attending this complaint, often rendering it particularly unpleasant, which is, that the subjects are most frequently young children, so as to be incapable of determining for themselves, which inflicts a very distressing task on their nearest relations. All the efforts of physic and surgery often prove absolutely ineffectual, not only to cure, but even to retard, the disease in question. Notwithstanding many cases admit of cure, there are numerous others which do not so. The disease often begins in the very inmost recesses of the cellular texture of the heads of the bones forming the large articulations, such as the hip, knee, ankle, and elbow; the bones become diseased, in a manner which we shall explain in the article Joints, sometimes with great pain and symptomatic fever; sometimes with very little of either, at least in the beginning. The cartilages covering the ends of these bones, and designed for the mobility of the joints, are totally destroyed; the epiphyses in young subjects are either partially or totally separated from the said bones; the ligaments of the joints are so thickened and spoiled by the distemper, as to lose all natural appearance, and become quite unfit for all the purposes for which they were intended: the parts appointed for the secretion of the synovia become distempered in like manner; all these together furnish a large quantity of stinking sanious matter, which is discharged either through artificial openings, made for the purpose, or through small ulcerated ones. These openings commonly lead to bones which are diseased through their whole texture. When the disease has got into this state, the constant pain, irritation, and discharge bring on hectic symptoms of the most destructive kind, such as total loss of appetite, rest, and strength, profuse night-sweats, and as profuse purgings, which foil all the efforts of medicine, and bring the patient to the brink of destruction.

It is an incontestable truth, that unless amputation be performed, a patient thus situated must perish; and it is equally true, that numbers, in the same circumstances, by submitting to the operation, have recovered vigorous health.—(See Pott on Amputation.)

It is a fact, highly important to be known, that in these cases amputation is attended with more success, when performed late, than when undertaken at an early period, before the disease has made great advances. This is particularly fortunate, as it affords time for giving a fair trial to such remedies as are best calculated to check the progress of the disorder, and obviate all necessity for the operation.—(Encyclopédie Méthodique, tom. 1, p. 83. See Joints, White Swelling.)

6. *Exostoses.*

Here it will be sufficient merely to mention, that this disease may render amputation necessary, when the tumour becomes hurtful to the health, or insupportable, on account of its weight or other circumstances, and cannot be removed by any of the plans specified in the article Exostoses.

7. *Necrosis.*

Another distemper, sometimes producing a necessity for amputation, is necrosis, or the death of the whole, or of a very considerable part, of the bones of the extremities, accompanied with such extensive abscesses, such disease of the soft parts, such disorder of the constitution and prostration of strength, that every hope of a cure being effected by a natural process must be renounced. By necrosis, is here meant, not merely some disease which destroys the surface of a bone, but one which extends its depredations to the whole of the internal substance, and that from end to end. Portions of the bones die from a variety of causes, such as struma, lues venerea, deep-seated abscesses, pressure, &c.; and bones in this state, when properly treated, often exfoliate and cast off their dead parts. But when the whole substance of a bone becomes diseased from end to end, frequently no means will avail. In the words of Mr. Pott, the use of the scalpel, the raspatory, and the rugine, for the removal of the diseased surface of bones; of the trephine, for perforating into the internal texture of the diseased bone, and of exfoliating applications (if there be any such which merit the name), will prove in many instances unavailing, and, unless the whole bone be removed by amputation, the patient will die. Mr. Pott's refutation of Bilguer, who asserts that amputation is not requisite in these instances, is a masterly and most convincing production; but I would not exactly do as the former of these writers has done, and positively affirm, that every extensive necrosis, affecting a bone nearly its whole length, must inevitably require amputation. The power of nature in restoring the bones is sometimes wonderful, as will be hereafter explained.—(See Necrosis.)

The very late period at which an extensive necro-

sis may follow the injury of a bone, and make amputation necessary, is sometimes almost incredible. Schmucker details the case of a captain who received a musket-ball through the left arm, four or five inches above the elbow. The bone was violently struck, but not broken; several exfoliations followed, and after more than a year's treatment, the patient appeared perfectly cured. For nine years this officer remained well; but at the end of this time, being on a journey, he was attacked with pain and inflammation in the wounded part, and febrile symptoms. He hastened to Berlin, and put himself under the care of Theden and Schmucker, who found an abscess in the situation of the former wound, and as an opening had been already made, the bone could be felt stripped of its periosteum. At length a piece of bone exfoliated, and became loose, precisely under the brachial artery, which interfered with its removal. Notwithstanding the discharge, the elbow-joint continued swelled, and there were red points observable, not only above that joint, but also over the heads of the ulna and radius, indicating disease of those bones. Amputation was therefore performed by Theden, and the patient got quite well. On examining the os brachii, a splinter was found, three inches in length, and one in breadth, its edges being thin and sharp, while its centre was more than three lines thick. The bone, every where about the place where it had been struck by the ball, seemed to consist of callus without any medullary cavity, and the whole of it down to the elbow had no periosteum. The cartilage appeared also disposed to separate, and the periosteum was detached from the radius and ulna, which were likewise affected with necrosis.—(See Schmucker's Vermischte Chir. Schriften, b. 1, p. 23, ed. 2.)

8. *Cancerous and other inveterate diseases, such as fungus hæmatodes.*

Cancerous, inveterate diseases, and malignant incurable ulcers on the limbs, sometimes render amputation a matter of necessity. In treating of cancer, we shall remark that little or no confidence can be placed either in internal or any kind of topical remedies, and that there is nothing, except the total separation of the part affected, upon which any rational hopes of cure can be built. Cancer is not frequently seen on the extremities. Every man of experience, however, must occasionally have seen, in this situation, if not actually cancer, diseases quite as intractable, and which cannot be cured except by removing the affected part. This may often be accomplished without cutting off the whole limb. But when the disease has spread beyond certain bounds, amputation above the part affected is the only thing to which recourse can be had with any hope of success. Sometimes, when the operation has been delayed too long, even amputation itself will not effect a cure. In a few cases of fungus hæmatodes, the operation has succeeded, however, after the disease had reappeared, and a cure had been seemingly achieved by the excision of the diseased parts. Yet, from what I have seen of fungus hæmatodes, I should much doubt whether the benefit obtained by amputation would be lasting; as when this disease shows itself only externally, internal organs are mostly at the same time similarly affected.—(See Fungus Hæmatodes.)

Besides cancerous, there are other ulcers, which may render amputation indispensable. Thus, when an extensive ulcer, of any sort whatsoever, is evidently impairing the health; when, instead of yielding to remedies, it becomes larger and more inveterate; when, in short, it puts life in imminent danger; amputation should be advised.

9. *Various tumours.*

That there are numerous swellings, which destroy the texture of the limbs, rendering them useless; causing dreadful sufferings, and bringing the patients into the most debilitated state, no man of observation can fail to have seen. When such tumours can neither be dispersed nor cut out with safety, amputation of the limb is the only resource.

Mr. Pott has particularly described a tumour affecting the leg, for which the operation is sometimes requisite. It has its seat in the middle of the calf of the leg, or rather more towards its upper part, under the gastrocnemius and soleus muscles. It begins by a small, hard, deep-seated swelling, sometimes very painful, sometimes but little so, and only hindering the patient's exercises. It does not alter the natural colour of the skin, at least until it has attained a considerable size. It enlarges gradually, does not soften as it enlarges, but continues through the greatest part of it incompressibly hard, and when it is got to a large size, it seems to contain a fluid, which may be felt towards the bottom, or resting, as it were, on the back part of the bones. If an opening be made for the discharge of this fluid, it must be made very deep, and through a strangely distempered mass. This fluid is generally small in quantity, and consists of a sanies mixed with grumous blood; the discharge of it produces very little diminution of the tumour, and very high symptoms of irritation and inflammation come on, and, advancing with great rapidity, and most exquisite pain, very soon destroy the patient, either by the fever, which is high and unremitting, or by a mortification of the whole leg. If amputation has not been performed, and the patient dies after the tumour has been freely opened, the mortified and putrid state of the parts prevents all satisfactory examination; but if the limb was removed, without any previous operation (and which Mr. Pott, in his experience, found to be the only way of preserving the patient's life), the posterior tibial artery will be found to be enlarged, distempered, and burst; the muscles of the calf to have been converted into a strangely morbid mass; and the posterior part of both the tibia and fibula more or less carious.—(Pott on Amputation.)

It seems only necessary to adduce another species of tumour to illustrate the necessity of amputation. The following case is related by Mr. Abernethy. A woman was admitted into St. Bartholomew's Hospital with a hard tumour in the ham. It was about four inches in length, and three in breadth. She had also a tumour in front of the thigh, a little above the patella, of less size and hardness. The tumour in the ham, by its pressure on the nerves and vessels, had greatly lessened the sensibility, and obstructed the circulation of the leg, so that the limb was very œdematous. As it appeared impossible to remove this tumour, and its origin and connexions were unknown, amputation was performed. On examining the amputated limb, the tumour in the ham could only be divided with a saw. Several slices were taken out of it by this means, and appeared to consist of a coagulable and vascular substance, in the interstices of which a great deal of bony matter was deposited. The remainder of the tumour was macerated and dried, and it appeared to be formed of an irregular and compact deposition of the earth of bone. The tumour on the front of the thigh was of the same nature as that of the ham, but contained so little lime, that it could be cut with a knife. The thigh-bone was not at all diseased, which is mentioned, because, when bony matter is deposited in a limb, it generally arises from the disease of a bone.—(Surgical Observations, 1804.)

Before the late facts and improvements relative to the treatment of aneurisms, these cases, on the extremities, were generally set down as requiring amputation. Even Mr. Pott, and J. L. Petit, wrote in recommendation of such practice, and their observations on this subject are among the few parts of their writings which the enlargement of surgical knowledge, since their time, has rendered objectionable. The surgeon to whom the honour of first correcting this erroneous doctrine belongs is A. N. Guenault, who opposed the advice delivered on this subject by Petit.—(Haller, Disp. Chir. vol. 5, p. 155.)

I shall conclude these remarks on the cases requiring amputation, with advising surgeons never to undertake this serious operation, without consulting the opinions of other professional men, whenever their advice can be obtained. The best operators are often deficient in that invaluable kind of judgment by which the cases absolutely demanding amputation are discriminated from others, in which the operation may be wisely postponed, and a chance taken of preserving the limb.

Historical remarks on Amputation.

The history of amputation evinces that the steps of surgery to perfection are slow, and that they even sometimes deviate from the straight path, though upon all essential points no retrogration has ever taken place. Here nature has acted as the guide, and the surgeon's chief merit has consisted in obeying the

hints which she herself has thrown out. As already mentioned, the following natural occurrence, no doubt, was one of the circumstances which first led to the bold practice of amputation: in consequence of disease and grievous local injuries, whole limbs were sometimes seized with mortification. In the majority of cases, this was attended with so much constitutional disturbance that the patients died; but in other less numerous instances, the mortification was confined to the part; suppuration was established between the dead and living parts; the whole of the mortified limb fell off; the suppurating surfaces healed up; and thus, by the powers of nature, the patients were restored to health. Here was clearly proved the possibility of recovery, notwithstanding the loss of a limb. The surgeon, as Brünninghausen remarks, viewed with surprise this course of nature, and hardly ventured to promote it by the feeble means formerly employed, which, however, were not really needed. But as the mortified parts, previously to their detachment, caused great annoyance by their fetor, a surgical attempt was at length made to get rid of them; in doing which the knife was always kept from touching the living flesh, on account of a well-grounded fear of bleeding, for the suppression of which no effectual methods were known. Such was the practice that prevailed from Hippocrates down to Celsus.—(Erfahr. &c. über die Amp. p. 14.) "Partes autem corporis, quæ infra terminos denigrationis fuerint, ubi jam prorsus emortuæ fuerint et dolorem non senserint, ad articulos auferendæ ea cautione ut ne vulnus inferatur," &c.—(De Articulis, sect. 6.) Here we find that the earliest mode of amputation was that done at the joints.

A. C. Celsus, who lived in the reign of Tiberius, and whose book, De Re Medicâ, should be read by every surgeon, has left us a short description of the mode of amputating gangrenous limbs.—(Lib. 7, c. 33.) It has been often remarked, that Celsus has left no instructions for securing the divided blood-vessels; but it has not been commonly noticed, that in his chapter on wounds he directs us to stop hemorrhage by taking hold of the vessels, then tying them in two places and dividing the intermediate portion. If this measure cannot be adopted, he advises the use of a cauterizing iron. Several hints are to be met with in the writings of Celsus, from which it may be inferred that the ligature of bleeding vessels was sometimes practised at the early age in which he lived; and this supposition is strengthened by a fragment of Archigenes preserved by Cocchius, on the subject of amputation, where he speaks of tying or sewing the blood-vessels. We are not, however, in possession of all the writings of medical authors prior to the time of Galen, and must therefore remain in doubt upon this point.—(Rees's Cyclopædia, art. Amputation.)

This anonymous writer argues, therefore, with some appearance of reason, that if amputation often proved fatal in the days of Celsus, "sæpe in ipso opere," as the expression is, it was owing to the want of some efficacious method of compressing the blood-vessels during the operation itself; for whether the use of the ligature were known to the ancients or not, no doubt exists about their ignorance of the tourniquet.

But admitting that the ancients were not altogether uninformed of the plan of tying arteries, it cannot be credited that they adopted the practice to any extent; for if they had, they would not have continued so partial to the cautery, boiling oils, and a farrago of astringent applications. They would also never have had recourse to the barbarous method of cutting the flesh with a red-hot knife, with the view of stopping the hemorrhage by converting the whole surface of the stump into an eschar. Painful in its execution and horrid in its consequence as this burning operation was, it seldom proved a lasting antidote to the bleeding, which generally came on in a fatal manner, as soon as the sloughs were loose. On this part of the subject my own ideas fully agree with those of a distinguished foreign surgeon, who says, that although the document left us may prove that the ligature was known to the ancients, and employed in cases of aneurisms and wounded blood-vessels, nay, that the arteries were secured with a needle and ligature; yet the practice could not have been extended to the operation of amputation, since, with the custom of making the incisions in the dead parts, the method scarcely admitted of being put in execution.—(Brünninghausen, Erfahr. über die Amput. p. 29.) Ambrose Paré, therefore, seems to me to deserve as much praise for the introduction of the ligature into common use, as if no allusion to this method whatsoever had existed in the writings of Celsus and other ancients.

The different parts of the operation meriting particular attention are, the choice of the part of the limb where the incisions are to begin; the measures for guarding against bleeding during the operation; the division of the integuments, muscles, and bones, which is to be accomplished in such a manner that the whole surface of the stump will afterward be covered with skin; tying the arteries, which should be done without including the nerves or any other adjacent part; placing the integuments in a proper position after the operation; and, finally, the subsequent treatment of the wound.

At the period of making the incision, the ancients contented themselves with having the skin forcibly drawn upwards by an assistant; they next divided, with one sweep of the knife, the integuments and flesh down to the bone, and afterward sawed the bone on a level with the soft parts, which were drawn upwards. Celsus considered it better to let the incision encroach upon the living flesh than leave any of the diseased parts behind. "Et potius ex sanâ parte aliquid excidatur, quam ex ægrâ relinquatur."—(De Medicinâ, lib. 7, c. 33.)

It appears, however, that his views extended farther than those of most of his contemporaries, and even his followers, almost downto modern times. After cutting the muscles down to the bone, he says that the flesh should be reflected and detached underneath with a scalpel, in order to denude a portion of the bone, which is then to be sawn as near as possible to the healthy flesh which remains adherent. He states, that when this plan is pursued, the skin around the wound will be so loose that it can almost be made to cover the extremity of the bone. It is to be lamented that this advice, inculcated by Celsus, should not have been comprehended, or that it should have been so neglected as to stand in need, as it were, of a new discoverer, and that a suggestion of such importance should have remained so long useless. But the fact is, hemorrhage formerly rendered amputation so dangerous, that the ancient surgeons could not devote much attention to any thing else in the operation, and practitioners amputated so seldom, that we read in Albucasis that he positively refused to cut off a person's hand, lest a fatal hemorrhage should ensue, and the patient did it himself and recovered. Over that part of the stump which the small quantity of preserved skin would not cover, Celsus recommended compresses, and a sponge dipped in vinegar to be laid.—(De Re Medicâ, lib. 7, c. 33.)

Archigenes, who was born at Apamia, in Syria, was the disciple of Agathinus, and physician to Philip, king of that country. He repaired to Rome, where he practised physic and surgery in the reign of the emperor Trajan, about 108 years after the birth of Christ.—(Portal, Hist. de l'Anatomie et de la Chirurgie, vol. 1, p. 61.) In the history of amputation the name of Archigenes is conspicuous, not only because he is supposed to have been acquainted with the use of the needle and ligature for the stoppage of bleeding, but because his description of the operation is in some respects more minute than that of Celsus. For the hindrance of loss of blood in the operation, says Sprengel (Geschichte der Chir. b. 1, p. 404, Halle, 1805), he first of all tied up the vessels, and often the whole limb, over which he also sprinkled cold water. The integuments were then drawn upwards from the wound, and confined there with a band; and after the limb was off, he cauterized the stump, and applied folded compresses. The band was now loosened and a mixture of leeks and salt laid on the stump, to which were also applied oil and cerate.—(Nicet, Coll. Chir. p. 155.) Such was likewise the practice of Heliodorus, who thus early made objections to the plan of cutting off a limb by a single stroke, a proposal that was renewed in far later days. The same author has also spoken of amputating at the joints; a method of which he disapproves.—(Nicet, Coll. Chir. p. 155.) However, Galen entertained a favourable opinion of it, on account of its safety and expedition.—(Comm. 4, in lib. de artic. p. 650.) Galen's precepts concerning amputation are, upon the whole, very like those given by Hippocrates; for he directs only dead parts to be cut, and the stump to be caute-

rized.—(De Arte Curativâ ad Glauconem, lib. 2.) By all the old writers, amputation was entirely restricted to cases of mortification; farther they were afraid to go; and this precept, and all the other doctrines of Galen, may be said to have been the guide of the whole surgical profession for full fourteen centuries.

The timid Arabians were not partial to amputation, and even in cases of mortification generally preferred a farrago of useless applications, like Armenian bole, &c. Paulus Ægineta, like Galen, deviated from Celsus's good rule of making the incisions in the healthy parts, and only approved of making the requisite division near them.—Lib. 4, c. 19, p. 140.) Avicenna, however, repeated the directions left by the Greek writers (Can. lib. 4. Fen. 3, tr. 1, p. 454), and Abu'l Kasem proposed doing the operation with a red-hot knife.—(Chirurg. lib. 1, sect. 52, p. 99.) In the middle ages, little was done for the improvement of amputation. In the 14th century gunpowder was invented, and soon applied to the purposes of war, so that an abundance of cases must have presented themselves in which the wise maxim of not deferring amputation until mortification had come on, but of preventing the mischief by the operation, ought to have struck an intelligent surgeon. One might also expect that practitioners would now have been led to make the incisions in the sound flesh. Unfortunately, the invention of gunpowder and its immediate consequences in surgery, happened at a period when practitioners were ill qualified to profit by the new lessons of experience set before them. The writings of their predecessors furnished them with no directions how they ought to act, and they were themselves too much confounded at the sight of the mischief for which they were consulted, to be able to form any correct opinion about causes and effects. Their first idea was, that the terrible symptoms proceeded from the parts being actually burned, and they afterward inclined to the belief that gun-shot wounds were poisoned. Hence the most absurd modes of treatment were instituted, and, as Brünninghausen expresses himself, human nature groaned under a new evil, for which there were for some time no true plans of relief.—(Erfahr. &c. über die Amp. c. 19.) This deplorable state was the natural result of the depression of science in general, and of the healing art in particular, in the days to which I now refer. In these middle ages, as they are called, the population of all Europe was plunged in the deepest ignorance; and whatever little knowledge remained, either of the arts or languages, was monopolized by the priesthood, the physicians of those times, who, instead of studying the volume of nature, wasted most of their time in discussing the doctrines of Galen. Surgery itself sunk to the lowest ebb, as may be well conceived from the decrees issued at Rheims by Pope Boniface the Eighth, forbidding any of the clergy to do any thing themselves which drew blood; and of course all the operative part of surgery, that which required the most skill and science, was transferred to a set of illiterate, low-bred mechanics, far inferior to the worst country farriers of modern times. Yet the clergy, who were here scrupulously averse to soiling their own hands with blood, or hurting their own tender feelings by viewing the agony of their fellow-creatures submitted to operations, had no hesitation in taking the chief emoluments and honours of the profession, or in turning over these poor sufferers to men more qualified to torture and murder than to give relief; and, what nearly staggers all credulity, the same professors of Christianity, who shuddered to spill a drop of blood themselves on a proper occasion, as Haller observes, eagerly had a hand, and acted an important part, in every sanguinary war, where it was possible for them to interfere. In these dismal days of surgery, the advice delivered by Celsus was renewed by Theodoricus, who used to administer opium and hemlock previously to the operation, for the purpose of rendering the patient less sensible to pain, and afterward vinegar and fennel were given, with the view of dispersing the intoxicating effects of the preceding medicines.—(Chirurg. lib. 3, c. 10.)

The renowned Guido di Cauliaco was the inventor of the plan of taking off limbs without any bloodshed. It is better, says he, for the limb to drop off than be cut off; as in the latter circumstance the conduct of the surgeon is viewed with spite, because it is supposed that the part might have been saved. Guido's practice consisted in covering the whole membrane with pitch-plaster, and applying round one of the joints so tight a band, that the parts below the constriction ultimately dropped off.—(Chirurg. tr. 6, Doctr. 1, cap. 8.) As Sprengel next observes, the method of amputating suggested by Celsus was again revived by Gersdorf, who after the operation not only drew down over the stump the skin which had been retracted, but applied a hog's or bullock's bladder over the stump, so as to render all burning and stitching of the parts needless.—(Feldbuch der Wundarzn. fol. 63.) Bartholomew Maggi also endeavoured to preserve a considerable flap of integuments for covering the stump.—(De Vulner. bombard. et sclopet. 4to. Bonon. 1552; see Sprengel's Geschichte der Chirurgie, p. 404. 406, 8vo. Halle, 1805.)

At length, in the 15th century, the revival of learning occurred first in Italy. Men now began to think for themselves again, and physicians turned from compilations and scholastic nonsense to the consideration of nature. Anatomy was cultivated with great ardour, and made brilliant progress under the eminent characters of the time: De la Torre, Berengarius Carpi, Vesalius, Fallopius, Eustachius, and others, who were also for the most part very distinguished surgeons. "In Italia scientiarum matre medici se nunquam chirurgia abdicarunt. Seculo 15 et 16, professores medici academiæ Bononiensis, Patavinæ, et aliarum in Italia illustrium scholarum et manu curaverunt, et consilio, et inter istos viros summi chirurgi exstiterunt.'—(Haller, Bibl. Chir. b. 1, p. 161.) Practitioners now ventured to amputate limbs in the sound part for other incurable diseases besides mortifications; but the art of stopping hemorrhage after the operation continued imperfect. Though the method of applying the ligature in cases of wounded arteries and aneurisms was understood, yet from some unaccountable causes the practice was never thought of in amputations. Even Fallopius knew of no other means for stopping the bleeding but the cautery.—(De Tum. prætern. p. 665.) On the whole, the stoppage of bleeding was not attended with a degree of success proportionate to the advances of the healing art in general. Straps, bands, and compresses were indeed put round the member; but as the circulation of the blood was not yet correctly known, they were not applied in the proper places, being arranged either close to the wound, or several of them put at random round the limb. The effects of such immoderately tight, long-continued constriction could be nothing less than gangrene; and hence the actual cautery was still chiefly employed. The other means for suppressing hemorrhage scarcely merit the name. Terrified at the insecurity and ill consequences of such expedients, J. de Vigo (Practica in Chirurgia Copiosa, 491, Romæ, 1514), and Fabricius ab Aquapendente (Op. Chir. Venet. 1619), disapproved of amputating in the sound flesh, and returned to the principle inculcated by the ancients, of making the incision in the mortified parts. Others endeavoured to lessen the peril of the bleeding by the rapidity with which the limb was removed, and the instantaneous application of the cautery. For this purpose L. Botalli invented a sort of guillotine, by means of which a member was severed from the body in an instant (De Curandis vulneribus sclopetorum, Lugd. 1560), while others laid a sharp axe upon the limb, and effected the dismemberment by the blow of a wooden mallet. An example of this barbarous practice is recorded by Fabricius Hildanus, called by his countrymen the patriarch and ornament of the German surgery. In consequence of this fear of bleeding, before he knew of the use of the ligature, he was himself accustomed to amputate with a red-hot knife, the representation of which is given in his work.—(De Gangræna et Sphacelo, Op.) Hildanus became a better surgeon, however, as he grew older, and in the end partly contributed to the improvement of amputation, inasmuch as he made the incisions completely in the sound parts, and adopted the method of tying the arteries, as then recently proposed by Paré; but, unfortunately, in weak persons he still preferred the actual cautery to the ligature.—(Op. p. 814.) One of his inventions was a linen bag or cap for the stump; and a sort of retractor for holding back the muscles. According to Sprengel (Geschichte der Chir. b. 1, p. 407), his observations on the pain following the operation are interesting.—(Op. p. 807. 814.)

Ambrose Paré, a French surgeon, who flourished in the 16th century (Opera, Parisiis, 1582), and to whom I have already alluded, made some beneficial innova-

tions with regard to the operation of amputation. It is to his industry, good sense, and skill that we are chiefly indebted for the abolition of cauterizing instruments, and the general use of a needle and ligature for the suppression of the bleeding.—(Lib. 6, c. 28, p. 224.)

An anonymous writer has given the following account of the practice and opinions of this distinguished surgeon in relation to amputation. "Paré recommended to cut off the whole of the gangrenous part if the limb be mortified, but to encroach as little as possible upon the living flesh. At the same time, he laid it down as a rule not to leave a very long stump to an amputated leg; because the patient could more conveniently make use of a wooden leg, with the stump only five finger-breadths long below the knee, than if much more of the flesh were to be preserved. In the arm, however, he left the whole of the living and healthy portion of the member, only separating the diseased part from the sound.

In preparing for amputation, he directs the skin and muscles to be drawn upwards, and bound tight with a broad bandage a little above the part where the incision is to be made. This fillet was intended to answer a threefold purpose:—1st, to afford a quantity of flesh for covering the bone, and facilitating the cure; 2dly, to close the extremities of the divided blood-vessels; 3dly, to dull the patient's feelings by pressure on the subjacent nerves. When this firm ligature has been applied, Paré directs an incision to be made down to the bone, either with a common large scalpel or a curved knife. Then with a smaller curved knife we are carefully to divide the muscle or ligament remaining between the bones of the forearm or leg; after which we may proceed to saw off the bone as high as possible, and to remove the asperities occasioned by the saw.

With the assistance of a curved pair of forceps he drew out the extremities of the bleeding arteries, either by themselves alone, or with some portion of the surrounding flesh, to be firmly tied with a strong double thread. He now loosened his bandage, brought together the lips of the wound over the face of the stump, and kept them as close as he could without actual stretching, by means of four stitches or sutures. If the larger tied vessels should accidently become loose, he desires the ligature or bandage to be again passed round the limb; or else, what is better, to let an assistant grasp the limb firm with both hands, and press with his fingers over the course of the bleeding vessel, so as to stop the hemorrhage; then with a square edged needle, about four inches long, and a thread four times doubled, the surgeon must secure the artery in the following manner. Thrust the armed needle into the outside of the flesh, half a finger's breath from the vessel which bleeds, and bring it out at the same distance from the bleeding orifice; then surround the vessel with the ligature, pass it back again to within one finger's breadth of the place where it first entered, and tie a fast knot upon a folded slip of linen rag to prevent its hurting the flesh. By this means, says Paré, the orifice of the artery will be agglutinated to the adjoining flesh so firmly, as not to yield one drop of blood; but if the hemorrhage were not considerable, he contented himself with the application of astringent powders, &c.

Thus did this famous surgeon endeavour, by his single example and precepts, to exclude the barbarous use of hot irons in amputation. He says, he knew not of any such practice among the old surgeons; except that Galen recommended us to tie bleeding vessels towards their origin in accidental wounds: and he thought proper to do the same in cases of amputation. But in an apology at the end of his book, Paré has quoted in his own defence a dozen authors who employed or recommended the ligature before him; and he might have cited many more.

From the statement we have here given, it may be seen how far the best writers of almost every country have erred in ascribing the original invention of tying arteries to Ambrose Paré. Great merit, indeed, was due to him for the part he took in extending, and even reviving, this incomparable practice: nay, it is not certain whether any one before him had ever applied the needle and ligature in similar cases, that is, after amputation; but how very wide of the truth Mr. John Bell's recent account of this matter is, will appear to every person who will inquire into the facts themselves; for not only were ligatures and needles in use among the ancients, but likewise the tenaculum or hook to lay hold of the bleeding vessels, when they had buried themselves in the muscles. We refer our inquisitive readers to Avicenna, Ætius Albucacis, Brunus, Theodoric, Guido di Cauliaco, John de Vigo, L. Bertapaelia, Tagaultius, Petrus Argillata, Andreas a Cruce, &c. &c., where they will find enough to satisfy them on this head."—(Rees's Cyclopædia, art. Amputation.)

I shall not here expatiate upon the ill-treatment which Paré experienced from the base and ignorant Gourmelin; nor upon the slowness and reluctance with which the generality of surgeons renounced the cautery for the ligature. These circumstances may be conceived, from what has been already stated. Suffice it to add, upon the authority of Dionis, that almost 100 years after Paré, a button of vitriol was ordinarily employed in the Hôtel-Dieu at Paris for the stoppage of hemorrhage after amputations. And Dionis was the first Frenchman who openly taught and recommended Paré's method. This happened towards the close of the 17th century, while Paré lived towards the end of the 16th.—(Dionis, Cours d'Opérat. Paris, 1707.)

As Paré, like the rest of the old surgeons, used to cut directly down to the bone, many of the stumps which he made must have been badly covered with flesh, and ill-fitted for bearing pressure. But all that I have read on the subject of amputation impresses me with a strong conviction, that in former times the projection of the end of the bone, the sugar-loaf form of the stump, the frequent exfoliations, and the difficulty in healing the part and keeping it healed, were as much owing to the mischief done with the cautery, the rude way of dressing the stump, and ignorance of the right method of promoting union by the first intention, as to the mode of operating or any other circumstance.

By many surgeons, however, the tying of arteries continued to be deemed too troublesome, and hence they persisted in the barbarous use of the actual cautery: of this number were Pigrai (Epitome des Preceptes de Med. et de Chir. 8vo. Rouen, 1642), F. Plazzoni (De Vuln. Sclopet. 4to. Venet. 1618), and P. M. Rossi (Consult. et Observ. 8vo. Francof. 1616). Nay, so difficult was it to eradicate the blind attachment to the ancients, that Theodorus Baronius, a professor at Cremona, publicly declared, in 1609, that he would rather err with Galen than follow the advice of any other person; and Van Hoorne seems even to have countenanced the detestable machine of Botalli.—(Μικροτέχνη, p. 75.)

What, asks Brünninghausen, was the reason why the ligature of the arteries, which is now regarded by the surgeons of all civilized nations as the best, easiest, and safest method of stopping hemorrhage after amputation, should so long have remained unadopted? Besides the prejudice for the opinions of the ancients, already mentioned, another cause was undoubtedly the imperfect knowledge of the circulation of the blood, a correct description of which was first delivered by the immortal Harvey early in the 17th century.—(Exercitatio Anat. de Motu Cordis et Sanguinis in Animalibus. Francof. 1628.) For some time this grand discovery met with violent opposition; but after it had been acknowledged as an eternal truth, a happy application of it was made to surgery by a French surgeon, named Morell, who, at the siege of Besançon, in 1674, invented the field tourniquet, by means of which more certain pressure was made on the trunk of the artery. By this simple invention, founded, however, on a knowledge of the circulation, the surgeon could at option let the blood of the stump spirt out, or stop its jet entirely; and now both during and after the operation, he was first enabled to command the hemorrhage, and coolly and judiciously employ whatever measures were indicated; for the most powerful bandages and pressure previously in use either stopped the circulation in the whole limb, or could not be made to have the right effect with sufficient quickness.—(Brünninghausen, Erfahr. &c. über die Amp. p. 36.) Morell's tourniquet, however, was very imperfect, and it was not till the year 1718, that J. L. Petit, whose name shines so brightly in the history of surgery, invented the kind of tourniquet now employed.

Richard Wiseman, who is justly considered as the father of good English surgery, saw the necessity of making the incision in the sound parts, because gangrene does not always spread evenly, but frequently extends much higher up one side of the limb than the other. He deemed the actual cautery objectionable, as

the sloughs were so long in being thrown off. He applied a ligature round the limb, two inches above the limits of the mortification, and, drawing up the muscles, made the incision with a large curved knife, with the back of which he scraped off the periosteum. The bag, or sort of retractor, employed by Fabricius Hildanus, Wiseman thought unnecessary, as the muscles spontaneously drew themselves up as soon as divided. He tied the blood-vessels after the manner of Paré, and deprecated all burning of the stump. After the operation, he drew the flaps over the bone, and either fastened them in this position with stiches or a tight bandage, though he generally preferred the former, as the surest means of keeping the end of the bone from protruding. Across the stump he laid a pledget of wax-cerate, and over this a thick layer of Armenian bole and other styptics, and the whole was covered with a bullock's bladder and a roller, applied spirally from the upper part of the remaining portion of the limb down to the extremity of the stump. On the third day, the dressings were taken off, and a digestive ointment applied. —(Chirurg. Treatises, vol. 2, p. 220, 8vo. Lond. 1690.)

From this time, amputation may be considered as being an infinitely safer proceeding than what it used to be; for, as we have explained, the ligature of the arteries was now practised and commended in Germany by F. Hildanus, in England by Wiseman, and in France by Dionis. Much, however, remained to be done. The wound was large, and suppurated long and profusely; the healing was slow; the ends of the bones perished, and, projecting far beyond the soft parts, retarded the cure so long, that the patient was not unfrequently worn out. Hence the best surgeons began seriously to consider what farther could be done, with a view of lessening the exposed surface of the wound, and making a better covering of flesh for the ends of the bones.

According to Sprengel, most of the old surgeons preserved a flap of flesh, and he is therefore by no means disposed to regard our countryman, Lowdham, as the inventor of this method, though it is acknowledged that the latter surgeon's practice was novel, inasmuch as the flap was formed by making an oblique incision through the integuments from below upwards. —(See James Yonge's Currus Triumphalis e Terebintho, 8vo. Lond. 1679; and Sprengel's Geschichte der Chirurgie, b. 1, p. 408.) Here, if Sprengel means that many of the old surgeons endeavoured to preserve a partial covering of flesh for the bone, there can be no doubt of his correctness; because we find, that they drew back the flesh before they divided it, and Celsus and some others even did more, for, after cutting down to the bone, they detached the flesh farther from it upwards, previously to taking the saw: but, on the contrary, if Sprengel wishes us to believe, that there were practitioners who, previously to Lowdham, in the operation of amputation formed what in England is usually understood by a flap, that is, a portion of flesh, generally of a semilunar shape, and saved particularly from one side of the member for covering the bone, I cannot see any reason for coinciding with Sprengel's observation. Upon the merit of Lowdham's suggestions, and the practice and principles inculcated by J. Yonge, some reflections lately sent me by Mr. Carwardine I insert with great pleasure, as perhaps he is right in thinking that the third edition of this work did not do justice to the memory of the latter writer.

"At the time Yonge wrote (1679)," says Mr. Carwardine, "it was supposed impossible to heal a stump before the bone had exfoliated, and therefore no surgeon would venture upon an attempt at uniting the surface by the first intention. Now this union by the first intention was the chief object of Mr. Yonge in proposing the flap-operation, and it is to him, and not to Mr. Alanson, who wrote precisely 100 years after him, that we must attribute the honour of this improvement. It is related in a letter addressed to his friend Thomas Hobs, chirurgeon, in London, dated Plymouth, August 3, 1678, and published, 1679, at the end of his Currus Triumphalis e Terebintho. It begins thus:

'Sir, I find by yours that you are surprised with the intimation I gave you, of a way of amputating large members, so as to be able to cure them per symphysin in three weeks; and without fouling or scaling the bone. It is a paradox which I will now evince to you to be a truth, after I have first taken notice of what you affirm, that there is a necessity of scaling the ends of those bones left bare after the usual manner of dismembering, before the stump can be soundly cured; that you never yet found it otherwise, but that where it hath been attempted, the stumps have apostumated, and the caries come off thereby.'

Yonge then acknowledges, that it was from an ingenious brother, Mr. C. Lowdham of Exeter, that he had the first hint thereof. He then describes the operation—the laying down the flap over the face of the stump, and sewing it by four or five stitches, &c. After this, Yonge proceeds with a methodical enumeration of the advantages of this mode of operating over all others then in use, viz. that it is more speedy—the cure not occupying a fourth of the usual time—no suppuration—no exfoliation—less danger of hemorrhage—not liable to break open again from slight injury—and lastly, much better adapted to the pressure from an artificial leg, &c.

The foregoing abstract will show (says Mr. Carwardine) how far Mr. O'Halloran's method, presently to be described, in which he dresses the flap and the stump as distinct surfaces, can be regarded as a revival of Lowdham's operation, or whether it has been superseded or improved upon by the mechanical ingenuity of the Dutch and French surgeons:—the apparatus of M. de la Faye and Verduin appear to have been merely clumsy and unscientific contrivances for the suppression of hemorrhage. Garengeot's operation had also for its object to supersede the use of the ligature, which, however, after twelve years' practice, he was obliged to give up, and tie the vessel before he laid down the flap (the particulars of all these methods the reader will presently meet with). Opinions, therefore, founded upon the practice of these gentlemen, I conceive, cannot fairly be admitted as evidence against the flap-operation of Lowdham, which nevertheless appears sinking in the estimation of the best modern surgeons; perhaps no material advantage is gained by it over the common mode of operating in the lower extremities, as now practised—but even here cases may occur where we are glad to resort to it: a few years since, I attended a patient in consultation with a friend at Dunmow, in Essex, where we thought it necessary to remove a man's leg for a caries of the tibia. An ulceration in front extended so high, that no integument could be saved, and the limb would have been removed above the knee, if I had not suggested the propriety of making a flap from the calf of the leg. The tibia was obliged to be sawed as high as possible, but the flap was left sufficiently long to cover the surface, and that most important object, the bend of the knee, was preserved, to bear the pressure of a wooden leg. In the removal of the arm at the shoulder-joint, doubtless the advantages of making a flap from the deltoid, &c. are sufficiently established; but in the mode of dressing, I presume that no English surgeon will admit, that the practice of M. Larrey (perhaps the most eminent surgeon that has been formed by the wars of Buonaparte, and whose practice will be hereafter noticed) can supersede the method of Yonge (or Lowdham), who wrote 140 years before him! Larrey introduces charpie beneath the flap to prevent union by the first intention! Lowdham's object is simply to lay the flap over the wound to prevent exfoliation, and to heal the surface 'per symphysin' in three weeks."—To the correctness of these sentiments of Mr. Carwardine, I believe that every impartial surgeon will bear witness; and it merely remains for me to thank him for his obliging communication, and say, that I have recently looked over the copy of the Currus Triumphalis e Terebintho, preserved in the valuable library of the Medical and Chirurgical Society, and find, that what he had stated is fully confirmed by the contents of that ancient work. At the same time, I retain the belief, that the example set by Mr. Alanson, with respect to the proper method of dressing stumps and obtaining a speedy union of the wound, is entitled to the praise of posterity; because his advice was so well enforced that it soon produced a revolution in practice, while the correct suggestions of Lowdham and Yonge, like the hint in Celsus, of the double incision, had sunk into oblivion, or were only known to a few admirers of surgical antiquities.

As Sprengel remarks, Purmann, Dionis (Cours d'Opér. de Chir. p. 611), De la Vauguyon (Traité Compel. des Opér. de Chir. p. 531), and most other surgeons of the seventeenth century, continued the method of first drawing up the integuments, and then

applying a band round the member. Dionis also took particular pains to recommend the ligature of the vessels, and expresses a strong aversion to the actual cautery. Neither did he approve of amputation at the knee-joint, because he thought that the patella, which must be left behind, would impede the healing of the stump, and he was apprehensive of the articular surface of the femur becoming diseased. De la Vauguyon relied upon the styptic properties of vitriol, and he praised drawing back the muscles by means of the kind of bag invented by Fabricius Hildanus.

Taking off the limbs at the joints was first commended again in modern times by J. Munnicks, who was more partial to styptics than the ligature; and for dressing the wound employed compresses and sticking-plaster.—(Chirurgia, p. 101.)

Mauquest de la Mothe adopted the plan of operating recommended by Dionis; he was also one of the first who made common use of the tourniquet in amputations, afterward drawing out the vessels with the forceps and tying them.—(Traité Compl. de Chir. vol. 3, p. 171.) Lowdham's original suggestion of amputating with a flap has been briefly noticed. About eighteen years after Yonge's publication, Peter Verduin, an eminent surgeon at Amsterdam, submitted to the judgment of the profession a new kind of flap-amputation, which he had put in practice.—(See Dis. Epistolica de Novâ Artuum decurtandorum ratione, 8vo. Amst. 1696.) The following are the chief particulars of Verduin's flap-operation.

Two compresses were applied, one under the ham, and the other on the course of the large vessels. The thigh was wrapped in a fine linen cloth, which was sustained by some turns of a roller. This apparatus was covered with a piece of leather, six inches broad, furnished with three straps with buckles, to secure it round the part. The tourniquet was placed in the usual manner. The part above the place intended to be amputated was surrounded with a leather strap. The point of a crooked knife, which was made to pass as near to the back part of the bones as possible, was thrust in on one side of the leg, and made to come out on the other. The knife was then carried down nearly to the tendo achillis, and thus it separated almost the whole calf of the leg. The flap being formed, the operation was finished in the ordinary manner. The wound was then washed with a wet sponge, in order to clear it from the fragments of sawed bone. The leather strap, which served to secure the flesh, was next loosened, and the flap laid over the stump. The wound was dressed with lycoperdon, lint, and tow, over which was put a bladder, sustained by strips of sticking-plaster. Upon this bladder was placed an instrument called a retinaculum, consisting of a compress, and a concave plate, which were made to press upon the stump, by means of two straps, which crossed each other and were attached to the broad leather strap surrounding the thigh.

In 1702, Sabourin, an able surgeon at Geneva, gave an account of Verduin's practice to the Royal Academy of Sciences, which, however, declined to pronounce any judgment about it, without farther experience.

Though this method of amputation was objected to by Cönerding, in a tract published at Amsterdam in 1705, it was afterward highly extolled by P. Massuet, on account of the quickness with which the stump healed, the safety with which the flap served for the stoppage of the hemorrhage, and the avoidance of exfoliation by the non-exposure of the bone. He also dwelt upon the excellency of the stump for the application of an artificial foot.—(De l'Amputation à lambeau, 8vo. Paris, 1756.) Heister disapproved of the flap-amputation, because it appeared to him, that the irritation of the flesh by the projecting bones was apt to cause pain and inflammation: he operated himself after the manner of Dionis, and was strongly in favour of the use of ligatures.

Some excellent precepts were delivered by J. L. Petit concerning amputation. He improved the tourniquet; and, instead of the large crooked amputating knife formerly employed, first brought into use the straight more moderate-sized knives with sharp backs, now seen in the hands of the best surgeons, because much better calculated than crooked knives for dividing the flesh by a sawing movement, which is the only right and surgical way of attempting to cut any part of the human body. He proved that making the division in the mortified parts was frequently followed by hemorrhage; and for the suppression of bleeding he thought it the best principle to promote the formation of a coagulum.—(Mém. de l'Acad. des Sciences, an 1732, p. 285. See Hemorrhage.) For compressing the vessels, he employed an instrument which covered the stump, like Verduin's retinaculum, and made pressure by means of a screw. His only objection to Verduin's method was, that the extension of gangrene up the limb frequently hindered the formation of so large a flap. He laid down the valuable general maxim of always removing as much bone, and as little flesh, as possible; for which purpose he invented what is termed the double incision, or dividing the business of cutting through the soft parts into two stages. About an inch higher than the place where he meant to saw through the bones, he first made the circular cut through the integuments down to the muscles; the skin was then pulled up so as to leave the flesh uncovered to the extent of an inch, and the muscles were now divided at the highest point of their exposure. Lastly, the flesh was held out of the way with a retractor, and the bone was sawed through high enough up to allow of its extremity being well covered with flesh and integuments. The greatest defect in the doctrine of Petit, relative to amputation, was the confidence he put in pressure, instead of the ligature.—(Traité des Malad. Chir. vol. 3, p. 126.) The first performance of amputation at the shoulder-joint, by Le Dran, and the improvements and alterations of that operation suggested by Garengeot, De la Faye, Desault, &c. I shall notice in a future section.

In chronological order, the next event claiming notice in the history of amputation, was the promulgation of an opinion by T. R. Gagnier, that Verduin's flap-amputation might be traced back to times of great antiquity, the method described by Celsus being very similar.—(Haller, Diss. Chir. vol. 6, p. 161.) On this point, with reference to Lowdham, the true inventor of the flap-operation, I have already delivered my own sentiments.

The flap-amputation of the leg, after Verduin's manner, was tried by De la Faye, who found that the pressure of the flap was not enough to check bleeding from all the vessels, as it only operated on the anterior tibial artery, and by pressing the flesh more firmly against the end of the bones, he thought the risk of mortification would be occasioned.

Verduin and Sabourin, as we have seen, made only one flap. Two French surgeons, Ravaton and Vermale, afterward thought that it would be better to save a flap from each side of the limb. They were also advocates for tying the vessels, and bringing the two flaps into contact, so as to procure their speedy union, and hinder exfoliations and profuse suppuration.

However, there is some difference in their methods of forming the flaps. Ravaton, who submitted his plan to the French Academy in 1739, made three deep incisions down to the bone; first, a circular one, with a crooked knife, within four finger-breadths of the bone intended to be sawed; and then with a somewhat larger knife, the two others perpendicularly to the first, one at the fore part, and the other at the back of the limb; and, taking care not to touch the principal vessels, he detached the two flaps from the bone.

Vermale formed the separate flaps by two incisions. After applying the tourniquet, he surrounded the part with two red threads, at the distance of four finger-breadths from each other; one at the place where the bone was to be sawed, the other at the place where the incision of the flaps was to terminate. He afterward thrust a long bistoury down to the bone, at the fore part of the limb; turned it round the circumference, so that it might come out at the opposite part; then, directing the edge of the knife along the bone, he cut down to the inferior thread, where he separated the first flap, which, as the author says, was of a round or conical figure at its extremity. The second flap was made in a similar way on the interior side of the member.—(Traité des Playes d'Armes à feu, par Ravaton, 8vo. Paris, 1750. De la Faye, in Mém. de l'Acad. de Chir. t. 5, ed. 12mo. Vermale, Obs. de Chir. 8vo. Manheim, 1767.)

In presence of M. Quesnay, Garengeot performed the flap-amputation according to the method of Verduin and Sabourin. We know that they made no ligature on the vessels, and that their intention was, that the

flap, when applied to the stump, and sustained by a particular apparatus, should reunite, and stop all bleeding.

Garengeot's patient died on the third day after the operation; hemorrhage having had a considerable share in producing death.

The multiplicity of machines described by Verduin, La Faye, &c. had no other end but that of keeping the flap near the orifices of the vessels, so as to compress and close them. In consequence of the difficulty of making this compression precisely as required, the most considerable vessels being situated between the two bones, and when cut, generally becoming retracted, Garengeot determined in future to employ ligatures.

With these views, twelve years after the foregoing case, Garengeot performed a flap-amputation of the arm, preserving two flaps, according to the method communicated to the Academy by Ravaton. The brachial artery was tied, and the patient was cured, without any exfoliations.

Garengeot made a third trial of this operation on a soldier dangerously wounded in the right foot by the bursting of a bomb, which fractured the interior part of the two bones of the leg, and several of the foot: the patient recovered in twenty-seven days.

In this operation one single flap was made. Garengeot was fearful, however, that the quick union might create some difficulty in withdrawing the ligatures, and he therefore took a means of hindering adhesion where they were situated; but of this objectionable plan I shall not speak. He rightly preferred dressing and bandaging the stump to the use of the compressing machines invented by Verduin and La Faye; and his choice of a straight knife, instead of a crooked one, was equally judicious.

The preceding case dictated a truth, which will last as long as surgery itself, viz. that it is advantageous to apply the ligatures in such manner as to embrace no more than the vessel, so that they may fall off the sooner, and the parts more quickly unite.—(M. de Garengeot, in Mémoires de l'Acad. de Chir. t. 5, 12mo.)

At one time, an objection frequently urged against the foregoing methods was, that when the fresh cut flap was immediately laid over the stump, inflammation and abscesses were apt to ensue. Hence, in 1765, Sylvester O'Halloran, a surgeon at Limerick, was led to make the experiment of deferring laying down the flap till the end of the first eight or twelve days after the operation, when it was conjectured that the risk of inflammation and abscesses would be diminished. The tenor of O'Halloran's book is apparently corroborated by the facts brought forward. Here we see one of the grand points, insisted upon by our worthy countryman James Yonge, viz. the chance of an immediate union of the wound from laying down the flap without delay, suddenly given up, and because the wound could not always be healed without suppuration, it was determined that it never should do so. However, it is consolatory to find, that O'Halloran's suggestion now exists only in the history, and not in the practice, of surgery.

Alexander Monro, senior, was a great opposer of certain methods which originated among the French surgeons, and, in particular, he disapproved of the tourniquet: he secured the vessels with needles and ligatures; and was the inventor of a bandage, which has been extensively approved of under the name of Monro's roller.—(Medical Essays of Edinb. vol. 4, p. 257.)

Bromfield, like Le Dran, restricted amputation to a few cases; and he did not acknowledge its necessity, as a matter of course, in every case of gangrene, much less in every instance of white swelling or caries. From a passage which I have cited from Dr. Rees's Cyclopædia, it would seem that the tenaculum was known to the ancients; yet, according to general opinion (and I cannot affirm that it is incorrect from any passage in my recollection), Bromfield is allowed to be the first modern surgeon who employed this very useful instrument.—(Chir. Cases and Obs. vol. 1, p. 41, 8vo. Lond. 1773.)

About the year 1742, the removal of thighs without bloodshed was a subject a good deal broached. A single case recorded by Schaarschmid, where a mortified thigh separated without hemorrhage, was the foundation of the scheme. The arteries were completely blocked up, and the parts insensible.—(Haller, Diss. Chir. vol. 5, p. 155.) A similar occurrence was related by Acrel (Chir. händels. p. 557); and Lalouette professed himself a believer in the security from hemorrhage, on account of the vessels being filled with coagula, and therefore he also approved of letting dead parts be removed, or rather fall off, without bloodshed.—(Haller, Diss. Chir. vol. 5, p. 273.)

In cases where the projecting bone of the stump was affected with necrosis, Bagieu, an experienced military surgeon, ventured to amputate a second time, and urged a variety of arguments in defence of the practice.—(Mém. de l'Acad. de Chir. t. 2, p. 274.) He coincided with Le Dran and Bromfield, however, about the propriety of restricting amputation to few cases, and has related numerous examples of limbs being saved, which, according to the doctrines then in vogue, ought to have been cut off.—(Deux Lettres d'un Chir. de l'Armée, 12mo. Paris, 1750.)

M. Louis, a French surgeon of extraordinary talents, introduced the plan of dividing the loose muscles first, and lastly those which are closely connected with the bone. He noticed that the muscles of the thigh, after being divided, were retracted in an unequal degree. He observed that the superficial ones extending along the limb, more or less obliquely, without being attached to the bone, were drawn up with greater force, and in a greater degree than others, which are deeply situated, in some measure, parallel to the axis of the femur, and fixed to this bone throughout their whole length. The retraction begins the very instant when the muscles are cut, and is not completed till a short time has elapsed. Hence, the effect should be promoted, and be as perfect as possible, before the bone is sawed. In the amputation of the thigh, Mr. Louis was always desirous of letting the muscles contract as far as they could, and for this reason he was rather averse to using the tourniquet, as the circular pressure of this instrument in some measure counteracted what he wished to take place; and hence, at one time he preferred letting an assistant make pressure on the artery, though he subsequently expressed his approbation of the tourniquet proposed by M. Pipelet for compressing the femoral artery.—(Mem. de l'Acad. de Chir. vol. 4, p. 60, 4to.)

Actuated by such principles, Louis practised a kind of double incision different from that of Cheselden and Petit, and different also from Alanson's method, which I shall hereafter notice. By the first stroke he cut, at the same time, both the integuments and the loose superficial muscles; by the second, he divided those muscles which are deep and closely adherent to the femur. On the first deep circular cut being completed, Louis used to remove a band which was placed round the limb, above the track of the knife. This was taken off in order to allow the divided muscles to become retracted without any impediment. He next cut the deep adherent muscles on a level with the surfaces of those loose ones which had been divided in the first incision, and which had now attained their utmost state of retraction. In this way he could evidently saw the bone very high up, and the painful dissection of the skin from the muscles was avoided. Louis was conscious that there was more necessity for saving muscle than skin; and he knew that when an incision was made at once down to the bone, the retraction of the divided muscles always left the edge of the skin projecting a considerable way beyond them. Hence he deemed the plan of first saving a portion of skin by dissecting it from the muscles and turning it up, quite unnecessary. As the bone should always be sawed rather higher than the division of the soft parts, Louis, like J. L. Petit, and most other judicious surgeons, highly approved of the employment of a retractor. He was likewise the author of some valuable instructions for preventing the protrusion of the bone after the operation.—(See Mém. de l'Acad. de Chir. t. 2, p. 268—410, &c. 4to.) The impartial reader, who takes the trouble to read the remarks on amputation published by this greatest of all the French surgeons of the last century, with the exception perhaps of J. L. Petit and Desault, will be impressed at once with the force and perspicuity of his matter, and with the evident propriety of a good deal of the practice inculcated.

In England, Cheselden, and not J. L. Petit, is regarded as the surgeon who revived Celsus's method, by proposing to divide the soft parts by a double incision, that is, by cutting the skin and cellular substance first, and then, by dividing the muscles down to the bone, on a level with the edge of the skin, so that the bone might be sawed higher up, and its end be more com-

pletely covered with skin. Whether Cheselden had the priority in this improvement, I cannot presume to say; but he gave an account of it in Gataker's translation of Le Dran's treatise on the operations, as early as 1749, which was long prior to the appearance of Petit's posthumous writings; and Mr. Cheselden farther mentions, that during his apprenticeship to Mr. Fern he had communicated to that gentleman his sentiments about the double incision.

In order to hinder the stump from assuming a pyramidal or sugar-loaf shape, which sometimes happened notwithstanding every improvement hitherto mentioned, a circular bandage was employed, which acted by supporting the skin and muscles, and preventing their retraction. This bandage, when properly applied, from the upper part of the limb downward, fulfilled in a certain measure the end proposed, though many stumps yet turned out very badly. Mr. Sharp was induced, therefore, to revive the ancient plan of bringing the edges of the skin together with sutures; but the pain and other inconveniences of this method were such that it was never extensively adopted, and Mr. Sharp himself ultimately abandoned it. The cross-bandage, however, which he used to put over the end of the stump, remains in fashion even at the present day.—(Treatise on the Oper. p. 216; Critical Inquiry, p. 268.) It is to be regretted that an excellent modern surgeon, the late Mr. Hey, should have commended so much as he has done the use of sutures, in bringing together the edges of the wound after amputation.—(Practical Observations in Surgery, p. 534, edit. 2.)

In opposition to Louis, the inefficiency of his method for hindering the protrusion of the bone was asserted by Valentin, who thought the object might be better attained by dividing the parts while they were in a state of tension; for which purpose he recommended changing the posture of the limb, according to the parts which he was about to cut.—(Recherches Critiques sur la Chirurgie Moderne, 8vo. Amst. 1772.) Valentin's proposal seems never to have made much impression on the profession; whether on account of its inconvenience or inefficacy, I know not; certain it is, many cases present themselves, in which the posture of a limb absolutely cannot be changed during the operation, owing to the nature of the disease, or cannot be altered without extreme agony.

At this period arose the celebrated controversy about the propriety of amputation in general. As Sprengel remarks, several French surgeons now began to be convinced, with Le Dran and Bagieu, that the operation was undertaken on too slight grounds, and in particular that many bad complicated fractures might be cured without amputation. Such was the doctrine of Boucher (Mem. de l'Acad. de Chir. t. 2, p. 304), Gervaise (Anfangsgr. der Wundarzn. 8vo. Strasb. 1755), and Faure (Mem. qui ont concourn pour le Prix de l'Ac. de Chir. vol. 1, p. 100). The latter especially urged the prudence of delay in gun-shot wounds, and comminuted injuries of the bones. But the writer who at this time made the most noise in the world by his general condemnation of amputation, was Bilguer (Diss. de Membrorum Amputatione, 8vo. Hal. 1761), whose sentiments received a complete refutation from his own contemporaries, Pott (Chir. Works, vol. 2), Morand (Opusc. de Chir. t. 1, p. 232), and de La Martinière (Mem. de l'Acad. de Chir. vol. 4, p. 1), and also from later writers, to whom reference will be made in speaking of Gun-shot Wounds. Even Bilguer himself was compelled to admit the necessity of amputation in cases of gangrene.—(Anweis. für die Feldwundärzie, s. 170.)

Bilguer's colleague, the celebrated Schmucker, inclined to the same doctrines, and has detailed several cases, where limbs were not only shattered, but actually carried away by balls, yet where a cure followed without amputation. One of his maxims was, that it was better for the member to be taken off by gun-shot than by the surgeon's knife, as the ball operated on a healthy subject, and the knife on a person debilitated by an hospital.—(Chir. Wahrn. th. 2, s. 493.) In a later valuable essay on this subject, he restricts amputation to shattered limbs affected with gangrene. His mode of operating was that of M. Louis. He sanctioned joint-operations on the hip and shoulder; but condemned those of the knee and elbow as never answering.—(Verm. Schrift. th. 1, s. 3.)

Soon after the middle of the last century, the practice of amputating at the joints began to excite increased attention; but as this is a topic to which I must presently return, it is unnecessary now to dwell upon it. The writings of Puthod, Wohler, Brasdor, Barbet, Sabatier, Park, Moreau, and Vermandois, in relation to this subject, deserve particular notice.

I now come to Mr. Alanson, whose name is as conspicuous in the history of amputation as that of any surgeon yet mentioned. His chief objects were to hinder a protrusion of the bone, and to promote union by the first intention. He rejected the band which was formerly put round the limb for the guidance of the knife, as altogether useless, and an impediment to the quick performance of the circular incision through the skin. When the tourniquet had been applied, an assistant grasped the integuments with both hands, and drew them and the muscles firmly upwards. The operator then fixed his eye upon the proper part where he was to begin the incision, which was made with considerable facility and despatch, the knife passing with greater quickness in consequence of the tense state of the integuments.

After the incision through the skin had been made, the assistant still continued a steady support of the parts, while Mr. Alanson separated the cellular and ligamentous attachments with the point of his knife till as much skin had been drawn up as would, with the muscles divided in the particular way hereafter recommended, fully cover the whole surface of the wound. Then, instead of applying the knife close to the edge of the integuments, and dividing the muscles in a circular perpendicular manner down to the bone, Mr. Alanson proceeded as follows: when operating upon the thigh, and standing on the outside of the limb, he applied the edge of his knife under the edge of the supported integuments, upon the inner margin of the vastus internus muscle, and cut obliquely through that and the adjacent muscles upwards as to the limb, and down to the bone, so as to lay it bare about three or four finger-breadths higher than is usually done by the common perpendicular circular incision. He now drew the knife towards himself; then keeping its point upon the bone, and the edge in the same oblique line already pointed out for the former incision, he divided the rest of the muscles in that direction all round the limb; the point of the knife being in contact with and revolving round the bone through the whole of the division.

According to Mr. Alanson, the speedy execution of the above-directed incision will be much expedited by one assistant continuing a firm and steady elevation of the parts, and another taking care to keep the skin from being wounded as the knife goes through the muscles, at the under part of the limb. Mr. Alanson censures the old method of depriving the bone of its periosteum to a considerable extent above and below the part where the saw was to pass, not only as creating unnecessary delay, but, since the periosteum serves to support the vessels in their passage to the bone, as apt to produce exfoliations above the part where the bone is to be divided with the saw. Instead of this practice he recommends first the application of the retractor, as advised by Gooch and Bromfield; and then denuding the bone at the part where the saw is to pass, whereby the bone may be sawed off higher than is usually practised; a material object for hindering a projection of the bone and forming a small cicatrix.

If the flesh of a stump formed in the thigh agreeably to the foregoing plan, be gently brought forwards after the operation, and the surface of the wound be then viewed, it may be said to resemble in some degree a conical cavity, the apex of which is the extremity of the bone; and the parts thus divided Mr. Alanson thought the best calculated to prevent a sugar-loaf stump.

The part where the bone is to be laid bare, whether two, three, or four finger-breadths higher than the edge of the retracted integuments; or, in other words, the quantity of muscular substance to be taken out in making the double incision, must be regulated by considering the length of the limb, and the quantity of skin that has been previously saved by dividing the membranous attachments. The quantity of skin saved, and muscular substance taken out, must be in such exact proportion to each other, that the whole surface of the wound will afterward be easily covered, and the limb not more shortened than is necessary to obtain this end.

After the removal of the limb, Mr. Alanson drew each

bleeding artery gently out with the tenaculum, and tied it as nakedly as possible with a common slender ligature. When the large vessels had been tied, the tourniquet was immediately slackened, and the wound well cleaned, in order to detect any vessel that might otherwise have remained concealed with its orifice blocked up with coagulated blood; and before the wound was dressed, its whole surface was examined with the greatest accuracy; by which means Mr. Alanson frequently observed a pulsation where no hemorrhage previously appeared, and turned out a small clot of blood from within the orifice of a considerable artery. He is very particular in recommending every vessel to be secured that is likely to bleed on the attack of the symptomatic fever; for, besides the fatigue and pain to which such an accident immediately exposes the patient, it seriously interrupts the desired union of the wound. He used always to clean the whole surface of the wound well with a sponge and warm water, as he thought that the lodgement of any coagulated blood would be a considerable obstruction to the quick union of the parts.

The skin and muscles were now gently brought forwards; a flannel roller was put around the body, and carried two or three times rather tightly round the upper part of the thigh, as at this point it was intended to form what Mr. Alanson called a sufficient basis, which materially added to the support of the skin and muscles. The roller was then carried down in a circular direction to the extremity of the stump, not so tight as to press rudely or forcibly, but so as to give an easy support to the parts.

The skin and muscles were now placed over the bone in such a direction that the wound appeared only as a line across the face of the stump, with the angles at each side, from which points the ligatures were left out, as their vicinity to either angle might direct. The skin was easily secured in this posture by long slips of linen or lint of the breadth of about two fingers, spread with cerate or any cooling ointment. If the skin did not easily meet, strips of sticking-plaster were preferred. These were applied from below upwards, across the face of the stump, and over them a soft tow-pledget and compress of linen; the whole being retained with the many-tailed bandage, and two tails placed perpendicularly, in order to retain the dressings upon the face of the stump.

Mr. Alanson censured the plan of raising the end of the stump far from the surface of the bed with pillows, as the posterior muscles were retracted by it; and he considered it best to raise the stump only about half a hand's breadth from the surface of the bed, by which means the muscles were put in an easy relaxed position. The many-tailed bandage Mr. Alanson found much more convenient than the woollen cap, frequently used in former times to support the dressings; and he observes, that though this seems well calculated to answer that purpose, yet if it be not put on with particular care, the skin is liable to be drawn backwards from the face of the stump; nor can the wound be dressed without first lifting up the stump to remove the cap.—(See Alanson's Pract. Obs. on Amputation, 8vo. Lond. 1779.)

The chief peculiarity of Alanson's method of operating, namely, the mode in which he recommended the oblique division of the muscles to be performed, did not, however, meet with universal approbation, and his extensive dissection of the skin from the muscles was complained of as excessively painful. The formation of a conical wound by following Alanson's directions, was regarded by several as impracticable.—(See Marten's Paradoxieen, b. 1, s. 88; Loeffler, Beytrage 1, No. 7; Wardenburg, Briefe eines Arztes, b. 2, p. 20; Richter, Anfangsgr. vol. 7; Graefe, Normen, &c. p. 8; Hey, Pract. Obs.) In my opinion there can be no doubt of the truth of some of the criticisms made by these and some other writers on the impossibility of making a wound with a regular conical cavity, by observing the directions given by Alanson; for if the knife be carried round the member with its edge turned obliquely upwards towards the bone, it will pass spirally, and of course the end of the incision will be considerably higher than the beginning. But though Alanson probably never did himself exactly what he has stated, I am sure that his proposition of making an oblique division of the muscles all round the member has been the source of great improvement in amputations in general, and is what is usually aimed at by all the best modern surgeons. It is true they do not actually perform the oblique incision all round the limb by one stroke or revolution of the knife round the bone, as Alanson says that he did; but they accomplish their purpose by repeated, distinct, and suitable applications of the edge of the instrument turned obliquely upwards towards the bone or bones.

Among others, Mynors found fault with some of Alanson's instructions, and thought every desideratum might be more certainly attained by saving skin enough, and then cutting through the muscles. The first incision, however, he directed obliquely upwards through the integuments, while they were drawn up by an assistant, and he then cut down to the bone.—(Pract. Thoughts on Amputation, 8vo. Birming. 1783.) Sprengel considers Mynors's plan merely as a revival of Celsus's method, as it had in view only the preservation of skin, and not the formation of a fleshy cushion.—(Geschichte der Chir. b. 1, p. 426.)

Kirkland endeavoured to improve Mynors's plan by cutting off a piece of skin at each angle of the stump, so as to keep the integuments from being thrown into folds; and in opposition to Pott, he defended the sentiments of Bilguer concerning the successful management of desperate cases without amputation.—(On the present State of Surgery, p. 273, and Thoughts on Amputation, 8vo. Lond. 1780.)

B. Bell used to operate very much in the same way as Mynors; and when it seemed advantageous to make a flap, he did not disapprove of the plans suggested by Ravaton, Verduin, and Alanson.—(Syst. of Surgery.)

An interesting paper on amputation was some years ago published by Loder; its chief purport was to defend Alanson's method with some slight modifications.—(Chir. und Medic. Beobacht. b. 1, p. 20, 8vo. 1794.) However, the alterations suggested by Loder do not seem to Graefe at all adequate to the removal of the difficulties with which the mode of cutting the flesh exactly after Alanson's directions is complicated.—(Normen für die Abl. grösserer Gliedmassen, p. 8, 4to. Berlin, 1812.)

The removal of limbs, without bloodshed, proposed by Guido di Cauliaco in the 14th century, has met with modern defenders in J. Wrabetz and W. G. Plouquet. J. Wrabetz, with a ligature, which was daily made tighter, took off an arm above the elbow. In the fissure he sprinkled a styptic powder. On the fourth day, the flesh was severed down to the bone, which was sawed through.—(Geschichte eines ohne Messer abgesetzten Oberarms, 8vo. Freyb. 1782.) Plouquet thought the plan suited to emaciated timid subjects, but not well adapted to the leg or forearm.—(Von der Unblutigen Abnehmung der Glieder, 8vo. Tub. 1786.)

Some other modes of doing flap-amputations, and in particular the suggestions and improvements made by Hey, Chopart, Dupuytren, Larrey, Lisfranc, and other modern practitioners, will be noticed in the description of the amputation of particular members. In the mean time, I shall conclude this section with mentioning the laudable attempts made at different periods to render the patient less sensible of the agony produced by the removal of a limb. Theodoricus, as we have said, administered for this purpose opium and hemlock, and though he was imitated by many of the ancient surgeons, few moderns have deemed the practice worthy of being continued. Guido made the experiment of benumbing the parts with a tight ligature; but a machine devised a few years ago in England expressly for the object of stupifying the nerves of a limb previously to amputation, is perhaps not undeserving of farther consideration.—(See J. Moore's Method of preventing or diminishing Pain in several Operations of Surgery, 8vo. Lond. 1784.) The great reason of the latter plan being given up is, that some patients have made more complaint of the sufferings occasioned by the process of dulling the sensibility of the nerves than of the agony of amputation itself without any such expedient. Yet daily experience proves that the pressure caused on the sciatic nerve by sitting with the pelvis in a certain position, will completely benumb the foot and leg, and this with such an absence of pain, that the person so affected is actually unaware of his foot being asleep, as it is termed, until he tries to walk. On the little good done by warming and oiling the cutting instruments, a method once much commended (Faust und Hunold über die Anwendung des Oehls und der Warme, p. 3—23, Leipsic, 1806), I am sure it is unnecessary for me to comment.

AMPUTATION OF THE THIGH.

The thigh ought always to be amputated as low as the disease will allow, so that as little of the limb may be cut off as possible, the pain may not be greater than necessary, and the surface of the wound have less extent than would otherwise happen.—(Sabatier, Med. Obs. p. 350, t. 3, ed. 2.) The patient is to be placed on a firm table, with his back properly supported by pillows and assistants, who are also to hold his hands, and keep him from moving too much during the operation. The ankle of the sound limb is to be fastened by means of a strong band or garter to the nearest leg of the table.

Here, however, through an imprudent solicitude to obtain the above advantages, let not the surgeon ever be unmindful of the great axiom in surgical operations, that all the diseased parts should be removed; but let him be assured of the truth of what Graefe inculcates, that it is more pardonable to cut away too much than too little.—(Normen für die Ablösung grösserer Gliedm. p. 60.) At the same time, I do not agree with some modern writers, who deem it necessary to amputate beyond the limits of every abscess and sinus, which may extend very far above a diseased joint or compound fracture. Many of these suppurations are only like ordinary abscesses, and finally get well after the main disease or injury is removed, as I have often seen. Were it an invariable rule to cut off a limb above every collection of matter, sometimes five or six inches more of the thigh would be sacrificed than circumstances absolutely demanded, and the greater danger of a high than a low amputation would be encountered. However, in all cases where the bone is suspected to be unsound, or the muscles are affected with the morbid changes peculiar to fungus hæmatodes or other incurable diseases, the operation should be practised sufficiently high to take away all the distempered parts. In secondary amputations, where there has been much suppuration in the limb, and a sinus runs up, Mr. Guthrie says, that if the sinus extend only a short way between the muscles, the membrane lining it may be dissected out; but if the matter has lain upon the bone, this will have become diseased, and amputation should be done high enough to remove the affected part of it.—(On Gun-shot Wounds, p. 87.)

Many writers disapprove of amputating too close to the knee (Graefe, Op. cit. p. 60); and Langenbeck urges one objection to it not specified by any other author, viz. that if the operation be done lower down than two hand-breadths above the knee, the femoral artery shrinks into the aponeurotic sheath, which it here receives from the vastus internus and triceps, and cannot be drawn out with the forceps, so as to be separately tied, without first slitting up that sheath. Hence, he recommends cutting through the muscles at the distance above the knee already mentioned.—(Bibl. für die Chir. b. 1, p. 571, 12mo. Gött. 1806.) But when I come to look at the breadth of two adult hands, and see how much of the limb would be sacrificed at all events, only to save a little trouble, I cannot bring my mind to concur with Langenbeck—the remedy being worse than the alleged evil.

The next thing is the application of the tourniquet.—(See Tourniquet.) The pad should be placed exactly over the femoral artery in as high a situation as can be conveniently done. When the thigh is to be amputated high up, it is better to let an assistant compress the femoral artery in the groin with any commodious instrument, furnished with a round blunt end, calculated for making direct pressure on the vessel without injuring the integuments. Some authors indeed give a general preference to this method, whether the thigh be amputated high up or low down.—(Paroisse, Opuscules de Chir. p. 188. Brünninghausen, Erfahr. über die Amp. p. 273. Langenbeck, Bibl. Chir. p. 564. See also Liston's Obs. in Ed. Med. and Surg. Journ. vol. 20, p. 43.) Were the patient, however, in a debilitated state, and unable to bear loss of blood, as there might, in this way, be some considerable bleeding, by reason of the anastomoses with the branches of the internal iliac artery, I should feel disposed to employ the tourniquet whenever circumstances would admit of its application. In amputations of the thigh, the great objection to the use of this instrument is, that it impedes the free and immediate retraction of the loose muscles after they have been cut; the consequence of which is, that the surgeon cannot divide so high as he otherwise could do, the deeper muscles which are more fixed and attached to the bone. Yet in order to have the bone well covered with flesh, and no danger of a sugar-loaf stump, the latter object is one of vast importance. Perhaps the best general rule is to abandon the application of the tourniquet in amputations done as high as the middle of the thigh, except where the patient is remarkably weak, so that he cannot bear the smallest loss of blood, and no steady intelligent assistant is at hand, to whom the compression of the artery in the groin can be prudently confided. When, however, the operation is to be done much higher up, of course the employment of a tourniquet is wholly inadmissible.

Whether the right or left thigh is to be removed, it is customary for the operator to stand on the patient's right side. The great advantage of this situation seems to be, that the surgeon's left hand can be thus more conveniently and quickly brought into use than if he were always to stand on the same side as the limb he is about to amputate. This seems to be the only assignable reason for this habit; for when the left thigh is to be amputated, it is certainly some inconvenience to have the right limb between the operator and the one that is to be removed. But this is found less inconvenient than not having the left hand next the wound.

Mr. Guthrie, in speaking of amputations on the two lower thirds of the thigh, observes, that "in these cases the tourniquet should be used;" but in operations high up the thigh, he joins all other surgeons in recommending the inguinal artery to be compressed against the os pubis.—(On Gun-shot Wounds, p. 202.) The utility of slackening the tourniquet completely, however, as soon as the principal vessels are secured, a piece of advice delivered by this excellent surgeon, I presume, cannot be right on the ground which he specifies, viz. the impediment made by the strap of the instrument to the retraction of the muscles, and the consequent difficulty in high operations of sawing the bone, because in common practice the bone is always sawed before any of the vessels are secured; and loosening the tourniquet entirely, while any arterial branches still require the ligature, must generally be objectionable, if loss of blood be a disadvantage. In flap-amputations high up the limb, indeed, where the arteries are sometimes tied, before the division of the bone, the employment of a tourniquet at all is quite out of the question.

We know that it was an opinion of the late Mr. J. Bell, that the flow of blood through a large artery could not be completely stopped by pressure; and the late Mr. Hey adopted a similar notion, in consequence of seeing a case in which the application of two tourniquets to the thigh did not restrain the hemorrhage from a fungus hæmatodes of the limb. He says, the pressure of the tourniquet does not completely obstruct the passage of blood in the arteries; it only diminishes so much of the force of the current as to enable the vessels, in a sound state, to exert their natural contractile power so effectually as to prevent hemorrhage. (See Hey's Pract. Obs. p. 257, 258, ed. 2.) Of the inaccuracy of this doctrine no man can doubt, who sees the femoral artery with its open mouth on the face of a stump not bleeding, while the tourniquet is tight, or skilful pressure is kept up, but throwing out its blood to a great distance the instant the pressure is discontinued. Nor, I apprehend, can any surgeon, who has amputated at the shoulder, and seen how completely pressure commands the flow of blood through the open-mouthed axillary artery, join in the sentiment of John Bell and Hey upon this particular point. Here I can speak with confidence, because I have myself amputated at the shoulder, and assisted at this operation several times, and found the statements of the preceding writers perfectly and clearly contradicted. Were any farther testimony required, I might cite that of Dr Hennen, who mentions, among other facts, that in a shoulder-joint case, operated upon by Mr. Dease, the amount of blood lost from the principal artery was no more than the quantity contained between the point of pressure and the point of incision through the vessels.—(Principles of Military Surgery, p. 257, ed. 2.) The same fact presented itself in the example, where I recently assisted Dr. Blicke in private practice.

Mr. Liston, of Edinburgh, confirms the preceding statement, observing that pressure complete enough not only to stop the pulsation of an artery in a limb,

but also to arrest completely the flow of blood, can be easily applied by means of the fingers only. And, in order to prove the correctness of this remark, he has repeatedly, when no proper assistant was at hand, compressed both the femoral and humeral arteries with the fingers of one hand, while with the other hand he removed the limb, and this, as he affirms, with the loss of much less blood than if he had followed the ordinary mode. His common practice, however, is to let the pressure be made by an assistant, and to employ no tourniquet.—(See Ed. Med. and Surg. Journ. vol. 20, p. 44.)

If, then, the flow of blood through an artery can easily be commanded by pressure, how are we to explain the occasional continuance of bleeding, notwithstanding the pressure of one, or even two, tourniquets? Without doubt, by the fact that the pads of these instruments, when not duly arranged, do more harm than good, by raising the band off the vessel, and perhaps also, in Mr. Hey's example, by the additional consideration, that tumours of the fungus hæmatodes kind include a large quantity of blood, and will bleed profusely, and for a considerable time, after the main supply of blood to them is cut off. The same thing happens in the disease called aneurism by anastomosis, as I have had several opportunities of witnessing, but in no instance more strikingly than in one, where, some time after Mr. Hodgson had tied the radial and ulnar arteries, Mr. Lawrence divided every part of the finger, excepting the tendons and bone, and yet a considerable bleeding went on from the farther side of the wound.—(See Med. Chir. Trans. vol. 9, p. 216.)

The application of the tourniquet is generally left too much to assistants; but, as far as my judgment extends, no operator is justified in commencing his incisions before he has examined, and fully satisfied himself that the instrument is correctly applied. Mr. Guthrie candidly tells us, that he once lost an officer, in consequence of hemorrhage during the operation, although the tourniquet was in the charge of a surgeon of ability; and the advice with which he follows this statement is worth recollecting: "In a case of this kind, where it (the tourniquet) is found of little benefit, the surgeon should not continue twisting and turning it, while his patient is bleeding, but quit it altogether, and compress the artery against the pubes." This maxim, I think, cannot be too highly commended.

The shape and size of the pad of the tourniquet are matters of importance. At St. Bartholomew's, the pads employed are very firm, being composed of wood, or cork covered with leather, and rather thicker than the thumb, the upper surface being flat, and the lower, which is put against the thigh, being convex. They are about an inch and a half in length. Such pads answer extremely well, as I can affirm from the observation of some hundreds of amputations in that hospital. A common fault formerly was the employment of pads which were too large and soft, and not judiciously shaped. As Mr. C. Hutchison remarks, the principal objection to a large pad is, that the band of the tourniquet is so much raised by it, that a considerable space is left on each side of it, where no compression is made on the limb, however closely the instrument may be screwed, and thus there will be a risk of hemorrhage from such vessels as happen to be in these situations. The same gentleman uses a pad which is not thicker than a finger, and places it obliquely over the artery, so as to preclude the possibility of displacement.—(Pract. Obs. in Surgery, p. 21—23.) Mr. Guthrie says, "the pad should be firm and rather narrow, and carefully held directly over the artery, while the ends of the bandage in which it is contained, are pinned on the thigh. The strap of the tourniquet is then to be put round the limb, the instrument itself being directly over the pad, with the screw entirely free. The strap is then to be drawn tight, and buckled on the outside, so as to prevent its slipping, and not interfere with the screw, which is to be turned until the pressure is sufficiently forcible to stop the circulation. If the screw require to be turned for more than half its number of turns to effect this, the strap is not sufficiently tight, or the pad has not been well applied, and they must be replaced."—(On Gun-shot Wounds, p. 204.)

In two amputations at St. Bartholomew's Hospital, I saw the tourniquet break after the soft parts had been divided, and as in one of these cases a good deal of blood was lost, because another tourniquet happened not to be in the room, and pressure on the artery in the groin was not immediately adopted, I coincide with such writers as recommend the rule of always having two tourniquets ready. Graefe even goes so far as to advise putting both of them round the limb before the operation commences (Normen für die Ablösung grösserer Gliedmassen, p. 48); but the frequency of a tourniquet breaking is not so great, I believe, as to demand such precaution, and the plan would be very objectionable in thigh-amputations, where it is a material advantage to have plenty of room between the place of the incision and the band which goes round the limb.

An assistant, firmly grasping the thigh with both hands, is to draw up the skin and muscles, while the surgeon, beginning with that part of the edge of the knife which is towards the handle, makes a circular incision as quickly as possible, through the integuments down to the fascia, or, as Mr. Guthrie and Dr. Hennen recommend, even completely through it. According to Mr. Guthrie, the skin cannot be sufficiently retracted, unless the fascia be divided, which he appears to think ought rather to be drawn up with the integuments than dissected from them.—(On Gun-shot Wounds, p. 205. Also, Hennen's Military Surgery, p. 263.) On the contrary, Professor Langenbeck is very particular in enjoining surgeons to avoid cutting through the fascia by the first sweep of the knife, because he finds that the muscles are better held together, and can be more regularly divided, by cutting them and the fascia at the same time.—(Bibl. für die Chir. b. 1, p. 564.) Nor does M. Roux divide the fascia by the first incision.—(Mem. sur la Réunion immédiate de la Plaie après l'Amputation circulaire, p. 9, 8vo. Paris, 1814.) At St. Bartholomew's, the surgeons rarely or never cut through the fascia with the integuments, but aim at carrying the knife perfectly down to it all round the limb. This at least ought to be done without fear of doing rather more; for, as Graefe observes, if the outer layers of the muscles be here and there a little touched, this occasions less pain than the additional strokes of the knife for dividing any portion of the skin and cellular substance not completely cut through in the first instance. Graefe also dissents from Mynors and others, who are advocates for cutting the skin obliquely instead of perpendicularly, because he finds the thin edge of the integuments thus separated from the subjacent cellular membrane, very apt to slough.—(Normen für die Abl. grösserer Gliedmassen, p. 102.) In a thigh of ordinary dimensions, the first incision should be made four inches below where it is intended to saw the bone. When the thigh is bulky, the large amputation knife will be found the best. Before beginning this first cut, the arm is to be carried under the limb, till the knife reaches almost round to the side on which the operator stands. With one sweep penetrating at least to the fascia, the knife is then to be brought round to the point where it first touched the skin. Thus, the wound is more likely to be regularly made, than by cutting first on one side, and then on the other, while the patient is saved some degree of pain, in consequence of the uninterrupted quickness with which the incision is made. At the same time, I ought to confess, that the late Sir C. Blicke, and some other surgeons, whom I have seen operate, used to complete the circle by two strokes of the knife, so well and expeditiously, that their capricious attachment to this plan could hardly be found fault with.

The next object is the preservation of as much skin as will afterward, conjointly with the muscles, cut in an oblique direction, cover the end of the stump with the utmost facility. It is rather difficult to lay down any other general principles for the guidance of the surgeon in saving integuments. I am disposed to agree with several modern writers, that the painful dissection of the skin from the muscles has been recommended and practised to a very unnecessary extent, that is to say, unnecessary if the division of the muscles be performed in the most advantageous manner. Graefe, one of the best surgeons at Berlin, does not dissect the skin from the muscles at all in amputating the thigh, but takes care, after making the cutaneous incision, to have the integuments and subjacent flesh very firmly drawn up before commencing the oblique division of the muscles. This retraction he also strongly advises to be done uniformly and smoothly all round

the member, lest in dividing the muscles any irregular projection of the skin interfere with the requisite movements of the knife.—(Normen für die Abl. grösserer Gliedmassen, p. 103.) Instead of dissecting back the skin, Dupuytren cuts all the soft parts at once to the bone, which he next removes, after retracting the muscles.—(Syme, in Edinb. Med. and Surg. Journal, vol. 14, p. 32.) However, Langenbeck, another of the most skilful operators on the continent, prefers detaching the integuments from the fascia for about two finger-breadths (Bibl. für die Chir. b. 1, p. 567), as is perhaps the most common practice in the London hospitals. Some late writers, particularly Mr. Syme, in expressing their preference to muscle as a covering for the end of the bone, seem to forget one fact which I have often noticed, viz. that the muscular cushion, though at first thick and good, soon shrinks to a comparatively small mass. This is consonant to a general law in the animal economy, prevailing whenever the natural action of a muscle is lost or prevented. Sir Astley Cooper states, that the covering for the end of the bone must be integuments and not muscles; for if muscular fibres are preserved with the integuments they will contract, and retraction of the skin covering the stump will be the result.—(Lancet, vol. 1, p. 148.) Brünninghausen also thinks skin a better and more durable covering for the end of the bone than muscular fibres, which after a time dwindle away; and hence he computes the quantity of integuments which ought to be saved, by the measure of the circumference and diameter of the member. Thus, when the limb is nine inches in its circumference, the diameter is about three; therefore, one inch and a half of skin on each side is to be saved.—(Erfahr. &c. über die Amp. p. 75.) But this author cuts the muscles perpendicularly, so that he is obliged to separate much more skin from the flesh than is necessary when the incision through the muscles is carried obliquely upwards. Mr. Hey's method of calculation, which I shall presently notice, appears more adapted to ordinary practice; and he says, "the division of the posterior muscles may be begun at half an inch, and that of the anterior at three quarters, above the place where the integuments were divided."—(Pract. Obs. in Surgery, p. 528, ed. 2.) With the view of preventing the necessity of dissecting the skin from the fascia, Mr. Guthrie, as already noticed, commends the plan of cutting through the fascia, together with the integuments, by the first stroke of the knife, and retracting these parts at the same time, instead of detaching them from each other. If this method be found perfectly efficient, and it be not objectionable, as exposing the muscles to be cut unnecessarily, I think the reason specified against it by Langenbeck, and explained in a preceding page, not weighty enough to form a just ground for rejecting a practice which comes with the alleged advantage of superseding the necessity for all painful dissection of the skin from the muscles. However, in secondary amputations of the thigh, if the integuments be unsound and will not retract, Mr. Guthrie approves of their being dissected back to an equal distance all round.—(On Gun-shot Wounds, p. 205—208.) Dr. Hennen, by giving an oblique direction to all the incisions through the muscles, obviates the necessity for much dissection of the integuments, and he says that in a small limb he has repeatedly performed the operation with one sweep of the knife, cutting obliquely inwards and upwards at once to the bone.—(Principles of Military Surgery, p. 265, ed. 2.) This author, like Mr. Guthrie, also recommends carrying the knife through the fascia in the first circular incision; and so does Mr. C. Hutchison, who makes no mention of dissecting back the skin, but simply states, that the "integuments and fascia being divided by a circular incision, and retracted upwards as high as is judged necessary, the superficial muscles should next be divided," &c.—(Pract. Obs. in Surgery, p. 23, 8vo. Lond. 1816.) We are therefore to conclude, that he joins Graefe and others in thinking the separation of the skin from the fascia unnecessary. My own observations in practice lead me to believe, that the dissection of the integuments from the subjacent parts used formerly to be carried to an extent beyond all moderation and necessity, and that, as it is a most painful proceeding, and hurtful by forming a large loose pouch for the lodgement of matter, it ought to be abandoned by every surgeon who follows the method of sawing the bone considerably higher than the first cut through the superficial muscles. I am not, however, prepared to assert, that no dissection at all is generally requisite, but am rather disposed to believe the moderate adoption of it, as recommended by Mr. Hey, the most prudent. This gentleman, like Desault (Œuvres Chir. t. 21, p. 515), is an advocate for amputating with a triple incision, and for preserving such a quantity of muscular flesh and integuments as are proportionate to the diameter of the limb. By a triple incision, he means first an incision through the integuments alone; secondly, an incision through all the muscles, made somewhat higher than that through the integuments; and thirdly, another incision through that part of the muscular flesh which adheres to the bone, made round that point of the bone where the saw is to be applied. The proper distance of these incisions from each other, he says, must be determined by the thickness of the limb upon which the operation is to be performed, making allowance for the retraction of the integuments, and of those muscles which are not adherent to the bone. Supposing the circumference of the limb to be twelve inches where the bone is to be divided, the diameter is about four inches, and if no retraction of the integuments were to take place, a sufficient covering of the stump would be afforded by making the first incision at the distance of two inches from the place where the bone is to be sawed, that is, at the distance of the semi-diameter of the limb on each side. But as the integuments, when in a sound state, always recede after they are divided, it is useful to make some allowance for this recession; and to make the first incision in this case at least two inches and a half or three inches below the place where the bone is to be sawed. As the posterior muscles of the thigh retract a great deal in the process of healing, Mr. Hey advises their division to be begun half an inch above the place where the integuments were cut, and the anterior muscles three quarters of an inch. The integuments, says he, will retract a little both above and below the place where they were divided; but the distance from that place must be computed from the mark left upon the surface of the muscles in dividing the integuments. Thus, in fact, in a common thigh-amputation, Mr. Hey deemed it necessary to detach the skin from the muscles merely to the extent of half an inch at the back part of the limb, and of three quarters in front; a very different practice from the old custom of making quite a bag of integuments, and turning them back as the upper piece of a glove is turned down, or rather as the sleeves of a coat are turned up.

In common amputations of the thigh, Roux strongly disapproves of separating the skin far from the muscles, as a circumstance highly unfavourable to the healing of the wound by adhesion; he divides only a few of the cellular bands between the integuments and fascia; and occasionally he has imitated M. Louis in cutting through the skin and superficial muscles together.—(Mém. sur la Réunion de la Plaie après l'Amputation, &c. p. 9.)

I believe the generality of the best modern operators are now convinced of the impropriety of dividing the muscles exactly in the manner directed by Mr. Alanson, viz. by letting the knife revolve uninterruptedly all round the bone, with its edge turned obliquely upwards towards the point where it is intended to apply the saw. It is a topic, indeed, to which I have already called the reader's attention in the foregoing columns. Langenbeck says, that he is perfectly convinced of the impossibility of forming a conical wound with one stroke of a large amputating knife, and joins Mr. Hey in approving of the triple incision.—(Bibl. für die Chir. b. 1, p. 564.) The objections first urged by Wardenburgh against Alanson's method are mathematically correct, inasmuch as the course of the edge of the knife, in this gentleman's method, must be spiral, and the end of the incision be considerably higher than the beginning of it. Such must be the result of performing the division of the muscles all round the limb by one continued stroke of the knife, with its edge directed obliquely upwards; for the idea of making the knife revolve in this manner while its point is confined to an imaginary, regular, determinate circle on the bone, I believe, is now abandoned as not really practicable. Yet with the exception of Desault, who confined himself to the triple incision conducted on the principles of M Louis (Œuvres Chir. t. 2, p. 547), few experienced surgeons refuse to acknowledge, that in this operation im-

mense advantage does proceed from the oblique division of the muscles, the honour of bringing which method into practice Mr. Alanson still unquestionably merits, however he may have erred in recommending the conical wound to be made with one sweep of the knife. Nor are there many living surgeons who entertain a doubt of the excellence of the principle inculcated by M. Louis respecting the utility of dividing the loose superficial muscles first, and then such as are deeper and adherent to the bone. In fact, a combination of this last method with the oblique division of the muscles, not exactly by one but several strokes of the knife, constitutes the mode of amputating at present most extensively adopted, and sometimes termed, as already mentioned, amputation by a triple incision. Thus, after the skin is cut, and as much of it retracted and saved as is deemed necessary, the operater cuts through the loose muscles of the thigh at the edge of the retracted skin, first those on the fore part of the limb, and then such as are situated behind. For this purpose he makes two or more sweeps of the knife, as may be found necessary, carefully directing them obliquely upwards towards the point where he means to saw the bone. The oblique division of the muscles does not merely enable the operator to saw the bone higher up than he could otherwise do, and leaves at the same time more muscle for covering its extremity, but it is a preservation of sound, undetached integuments, which assuredly form the most efficient and durable covering to the stump. I say this without precisely coinciding with Brünninghausen, who, trusting entirely to skin for covering his stumps, makes an extensive detachment of it from the muscles, and then cuts straight down to the bone. The loose muscles actually cut through now retract considerably, leaving those which are deeper and attached to the bone in a condition to be cut higher up than could have been previously done. Lastly, these are also to be divided with the edge of the knife directed obliquely upwards towards the place where the saw is to be applied. Some operators do more than this; for, after cutting down to the bone, they follow the plan of Celsus, and detach the flesh from its whole circumference upwards with a scalpel, to the extent of about another inch, in order to be enabled to saw the bone still higher up. "Inter sanam vitiatamque partem incidenda scalpello, caro usque ad os, reducenda ab eo sana caro, et circa os subsecanda est, ut eâ quoque parte aliquid ossis nudetur." This method, I think, deserves commendation, because it may have considerable effect in hindering a protrusion of the bone, if it does not, in conjunction with the foregoing method of operating and judicious dressings, render this disagreeable event quite impossible. As long as I live, however, I shall never forget a poor soldier, whose thigh had been amputated in Bergen-op-Zoom, and who was brought about ten days after the operation into the military hospital at Oudenbosch, under my care. Not the slightest union of any part of the wound had taken place; abscesses had formed under the fascia on every side of the stump; the loose skin was literally a large bag of purulent matter; the muscles were wasted to almost nothing, and their remains retracted and shrinking still farther away from the extremity of the bone, which protruded at least three inches beyond the soft parts. This unfortunate man had been attacked with chronic tetanus soon after the operation, and probably it was to the disturbance of the stump by the effects of that disease, and to the strong and continual tendency of the muscles to retract themselves, induced by this state of the system, the deplorable state of the stump was to be attributed. He lingered nearly a fortnight in the hospital before he died; previously to which event large abscesses, communicating with the hollow of the stump, surrounded the greater part of the pelvis. As I had every reason to believe that the operation had been skilfully done, perhaps when I say that the above mode of amputating will make a protrusion of the bone impossible, it is not exactly correct, as the occurrence may sometimes originate from causes which are quite independent of the particular way in which the operation has been executed.

The practice of detaching the bone from the circumjacent flesh to the extent of about an inch, after the other principal incisions are completed, as advised by Celsus and Louis, I have sometimes seen done at St. Bartholomew's Hospital, and have practised myself on other occasions, with the decided advantage of letting the bone be sawed higher up than could otherwise have been effected. Mr. Guthrie, after the incisions down to the bone, even recommends dissecting back the muscles from it "for the space of two or three inches, as the size of the limb or other circumstances may require;" but I should be reluctant myself to imitate the practice to this extent, though inclined to think most favourably of it within more moderate limits. If we reckon that three inches of the member lie between the first circular cut in the skin and the place where the knife arrives at the bone, and then take away two or three inches more of the femur, it is clear that in many examples we should be getting very high up the limb, and if a detachment of the muscles from the bone to the extent of two or three inches were thus made, it would at all events be of no service unless the bone would admit of being sawed at this great distance from the termination of the oblique division of the muscles. However, if this were truly practicable (a point which I leave for others to discuss), it would certainly be consonant to the excellent general maxim laid down by J. L. Petit, that in amputation as much of the bone and as little of the flesh should be taken away as possible.—(See Traité des Mal. Chir. t. 3, p. 150.) When this final detachment of the deep muscles from the bone is adopted, particular care, as Roux observes, should be taken always to divide the thick aponeurosis connecting the triceps to the linea aspera.—(Mem. sur la Réunion de la Plaie aprés l'Amputation, p. 10.)

With respect to Desault's method of amputating the thigh by a circular incision, already mentioned, he considered turning the knife obliquely upwards quite unnecessary: his plan was, to cut through the muscles, layer after layer, with the precaution of retracting the first stratum before he divided the second; the latter was then cut through on a level with the flesh that had been previously divided and retracted, and so on down to the bone. This, says he, is the right way of forming a true hollow cone, of which the integuments, which were drawn up before the muscles were cut, form the base, from which are gradually continued the various layers of muscles, and the highest point of which is the bone itself. Desault owns, that this method is somewhat tedious and painful, but in his opinion, these disadvantages are more than counterbalanced by the benefits procured for the patient.—(Œuvres Chir. de Desault par Bichat, t. 2, p. 547.)

All the muscular fibres, on every side, having been cut down to the bone, a piece of linen, somewhat broader than the diameter of the wound, should be torn at one end, along its middle part, to the extent of about eight or ten inches. This is called a retractor, and is applied by placing the exposed part of the bone in the slit, and drawing the ends of the linen upwards on each side of the stump. In this manner, the retractor will obviously keep every part of the surface of the wound out of the way of the saw. Graefe thinks, that in amputations of parts, where there is only one bone, the unslit portion of the linen should always be applied over the anterior muscles, as these ought constantly to be most evenly kept back, so that no projection of them may interfere with the action of the saw.—(Normen für die Ablösung grösserer Gliedm. p. 105.) This is a preference, however, which may not be of great importance, though I confess that there appears some reason in what Graefe has stated. That meritorious surgeon, J. L. Petit, whose name I always mention with pleasure, strongly commends the use of the retractor, the ends of which he drew over the anterior muscles: he says that he has employed this simple and natural means, but that it did not suit the taste of every body, especially of those who consider all the merit of an operation to consist in the quickness of its performance, or who think it satisfactory reasoning to say, this is not their way.—(Traité des Mal. Chir. t. 3, p. 152.) I have seen the saw do so much mischief, in consequence of the operator neglecting to use the retractor, that my conscience obliges me to censure such surgeons as neglect to defend the soft parts by this simple contrivance. There are some who have rejected the use of the retractor, because they have seen it get under the teeth of the saw, and obstruct the action of the instrument; but this very circumstance adduced against the retractor is, when considered, the strongest one that could possibly be brought forward in its favour, as the surface of the wound itself, and particularly the edges

of the skin, would, in all probability, suffer the same fate as the linen, by getting under the teeth of the saw, if no retractor were employed, in attempting to saw the bone high up, as closely as possible to the soft parts. I think no one can urge any but the most frivolous objections to the use of the retractor, and I know that many who have been with myself eye-witnesses of the mischief frequently done by the saw in amputations, are deeply impressed with an aversion to the neglect of this bandage. I have often seen the soft parts skilfully divided, and I have, in these same instances, seen the operators directly afterward lose all the praise which every one was ready to bestow, by their actually sawing through one-half of the ends of the muscles together with the bone. Men who have had fortitude not to utter a sigh, nor to let a groan be heard, in their previous sufferings, have now had their involuntary cries extorted from them by unnecessary, unjustifiable torture. But besides defending the surface of the stump from the teeth of the saw, the retractor will undoubtedly enable the operator to saw the bone higher up than he could otherwise do.

Mr. Liston, of Edinburgh, endeavours to show, that the saw is the only necessary thing in the case of amputating instruments; and he adds (alluding, as I suppose, to operations at the joints), that it was seldomer required than might be supposed; and he particularly declares all kinds of retractors superfluous. Here it should be remembered, that this gentleman's practice is that of flap-amputation, to which he gives the universal preference; a method in which unquestionably the retractor may be dispensed with, as, while the saw is acting, one or both of the flaps can be effectually held out of the way by an assistant. The same preference also explains, in some measure, this surgeon's rejection of the tourniquet, the application of which is inconvenient in certain flap-amputations.—(See Edinburgh Med. and Surg. Journ. vol. 20, p. 43—45.) Here, however, I am treating of amputation by the circular incision, in which practice I consider both the tourniquet and the retractor too useful to be commonly relinquished.

Another proceeding, which seems fit for reprobation, and which, indeed, Mr. Alanson very properly condemned, is the practice of scraping up the periosteum with the knife, as far as the muscles will allow. Nothing seems more probable, than that this may be the cause of the exfoliations which occasionally happen after amputations. At all events, it is a superfluous, useless measure, as a sharp saw, such as ought to be employed, will never be impeded by so slender a membrane as the periosteum. All that the operator ought to do is, to take care to cut completely down to the bone all round its circumference. Thus a circular division of the periosteum will be made, and upon this precise situation the saw should be placed. This is the method which was approved of by J. L. Petit.—(Traité des Mal. Chir. t. 3, p. 159.) It is what I have always done and recommended; yet it must be confessed, that differences of opinion prevail about the necessity and modes of dividing the periosteum. Graefe, in common with several others, entertains considerable apprehension of the effects of the periosteum being torn and lacerated by the saw, exfoliations of the bone and abscesses up to the joint being possible consequences of the rude separation and inflammation of this membrane. Hence he is an advocate for making a circular cut through at the place where the saw is to be applied, and then scraping away all below this point in the direction downwards.—(Normen für die Abl. grösserer Gliedm. p. 105 and 165.) Perhaps no very great objection may lie against this mode, which is not uncommonly followed, though I have some doubts of its real utility, as it scarcely seems practicable in the midst of the oozing of blood to hit with the saw the precise line at which the remains of the periosteum terminate; and in confirmation of the safety of Petit's practice, Mr. Guthrie's experience may be adduced, who says, "I have often sawed through the bone, without previously touching the periosteum, and the stumps have been as soon healed, and with as little inconvenience as any others."—(On Gun-shot Wounds, p. 88.) A very modern author, impressed, like many others, with the fear of tearing the periosteum with the saw, differs from them, in thinking it best to scrape the periosteum upwards; by which means, he says, that at least half an inch of this membrane, and a proportionate quantity of muscular fibres, may be preserved for covering the end of the bone, inasmuch as the muscular fibres adherent to the periosteum will remain connected with it; an advantage which this author deems very important while the edges of the bone are sharp. In amputation below the knee, he considers the method highly useful, as the sharp edge of the tibia may be not merely covered with skin, but periosteum and the cellular membrane connected with it. Since his adoption of this practice, he assures us that he has not for a very long time seen any exfoliation of the tibia, and never any protrusion of the bone of a stump.—(Brünninghausen Erfahr. &c., über die Amp. p. 65, 66, 8vo. Bamb. 1818.) Such are the sentiments of a gentleman who has published a valuable tract on amputation, as well as some other works of deserved reputation. His opinion is unquestionably the reverse of what is most prevalent in England; and I think his practice liable to the objection, that the disadvantages of scraping the bone at all, and denuding it, may exceed the benefit supposed to proceed from afterward bringing down the detached membrane over its sharp margin, even admitting this to be always practicable.

But in no part of the operation of amputation do operators in general display more awkwardness, than in sawing the bone; though, if we except directing the saw against the flesh, the faults are here less pernicious in their consequences than the errors already noticed. At the time of sawing the bone, much depends upon the assistant who holds the limb. If he elevate the lower portion of the thigh bone too much, the saw becomes so pinched that it cannot work. On the other hand, if he allow the weight of the leg to operate too much, the thigh bone breaks before it is nearly sawn through, and its extremity is splintered. It is one of the most common remarks of such persons as are in the habit of frequently seeing amputations, that the part of these operations, which a plain carpenter would do well, foils the skill of a consummate surgeon, and few operators acquit themselves well in the management of the saw. Many of them begin the action of this instrument by moving it in a direction contrary to the inclination of its teeth. Many, seemingly through confusion, endeavour to shorten this part of the operation, by making short, very rapid, and almost convulsive strokes with the saw. Almost all operators fall into the error of bearing too heavily on the instrument. That operator will saw best, who makes the first stroke of the saw by applying its heel to the bone, and drawing the instrument across the part towards himself, so as to make a slight groove in the bone, which serves very materially to steady the future operations of the instrument; and who makes long regular sweeps with the saw, rather slowly than quickly, rather lightly than heavily. But there is often a fault in the construction of the saw itself, which impedes its action, quite independently of any fault on the part of the surgeon. I allude to the edge of the instrument not being a little broader than its blade. When the saw is well made, the teeth always make plenty of space for the movement of the rest of the instrument. The instrument, as Mr. Guthrie recommends, should cut with both edges, backwards and forwards, which expedites the operation, and (what is of more consequence) helps to prevent splintering when the bone is nearly divided, because the division can be finished by the backward motions, which are the most gentle.—(On Gun-shot Wounds, p. 89.)

Graefe commends the plan of oiling the saw, for the purpose of facilitating its action (Normen für die Abl. grösserer Gliedmassen, p. 65); and though the method is innocent enough, the best operators in this metropolis do not consider it sufficiently important for adoption.

If the bone should happen to break before the sawing is finished, the sharp-pointed, projecting spiculæ, thus occasioned, must be removed by means of a strong, cutting sort of forceps, termed bone-nippers. The perpendicular division of the bone, leaves a sharp edge at the extremity of its circumference. It is not the common practice to take any measures for the removal of such sharpness; yet Graefe recommends filing it away (Op. cit. p. 66), and Mr. C. Hutchison makes it an invariable rule, whether there be any occasion to use the bone-nippers or not, "to take off the asperities, and scrape or endeavour somewhat to round the sharp cut edge of the bone with a strong blunt scalpel, in order to prevent the soft parts from being injured,

when brought over the end of the bone in forming the stump."—(Pract. Obs. in Surgery, p. 24.) Though I have not followed this practice, or rather the part of it which relates to cutting off the edge of the bone, nor seen it adopted in London in amputation of the thigh, I know of no objection to it, unless it be on the score of its inutility, and the delay which it occasions. All projecting points of bone, it is the ordinary custom to remove.

After the removal of the limb, the femoral artery is to be immediately taken hold of with a pair of forceps, and tied with a firm round small ligature, the best being that kind which is recommended and used by my friend Mr. Lawrence.—(See Ligature.) Care is to be taken to leave the accompanying branches of the anterior crural nerve out of the noose. None of the surrounding flesh ought to be tied, though the ligature should undoubtedly be placed round the artery, just where it emerges from its lateral connexions. The late Mr. Hey was accustomed to tie the femoral artery twice, leaving a small space between the ligatures. Some reasons against this plan will be found in the article Hemorrhage. The other arteries are usually taken up with a tenaculum. After tying as many vessels as require it, one-half of each ligature is to be cut off near the knot on the surface of the stump. One portion is quite sufficient for withdrawing the ligature when this becomes loose, and the other being only an extraneous body, and productive of irritation and suppuration, should never be allowed to remain.

My friend, the late Dr. Hennen, in his excellent publication, ascribes the improvement of removing one half of the ligature to Mr. James Veitch, a naval surgeon, who, in April, 1806, published some valuable precepts relative to the mode of tying the arteries in amputation.—(See Edinb. Med. and Surgical Journal, vol. 2, p. 176.) But highly as I approve of the tenor of the anonymous paper here referred to, it is impossible for me to suppose Mr. Veitch could be the first, or nearly the first, who suggested such improvement. When I went as an apprentice to St. Bartholomew's Hospital, in 1797, no surgeon of that hospital ever followed any other mode, and the practice was then so far from being new there, that gentlemen who were at the hospital seven years before myself, had seen one-half of each ligature regularly cut off the first time they went into the operating theatre of that munificent institution. The use of very broad ligatures, and the inclusion of a considerable quantity of flesh in the noose, together with the vessel, were also practices quite exploded at St. Bartholomew's at the very beginning of my apprenticeship. Mr. Veitch, however, seems to merit the honour of having been perhaps the first to set the example of tying every vessel, the femoral, as well as the smaller arteries, with a single silk thread, taking care to include, as far as was possible, nothing but the artery; and when this had been done, he took off one-half of each ligature, as near as possible to the knot, "so that the foreign matter introduced was a mere trifle, compared with what I had been accustomed to see."—(Edinb. Med. and Surg. Journ. vol. 2, p. 178.) The use of a single silk thread, therefore, was the part of these improvements, probably originating with Mr. Veitch, though the principles which led to this innovation were unquestionably first established by Dr. Jones.

Mr. Alanson directs the ends of the ligatures to be left hanging out at the two extremities of the wound, according as their nearness may point out as best. But when a ligature is situated in the centre of the wound, it is best to bring it out between the strips of adhesive plaster, at the nearest part of the surface; otherwise its running across one-half the wound to get at either angle, would create a great deal of unnecessary irritation and suppuration. The advantages of this method of placing the ends of the ligatures were well explained by Mr. Veitch; but his practice, like the innovation of cutting off the half of each ligature, has been common in the London hospitals, and at St. Bartholomew's in particular, many years earlier, I presume, than the case referred to by this gentleman; since it has been familiarly adopted in those institutions ever since 1797, as I can testify from my own personal observation. These remarks are offered without the slightest intention of detracting from the merits of the abovementioned paper, which is replete with valuable advice; nor am I influenced by any design of throwing honour on the memory or character of any other individual at the expense of Mr. Veitch, being at this time unacquainted with the exact periods when either this improvement, or that of removing the half of each ligature, commenced. M. Roux is one of the few remaining modern surgeons who declare their preference to the method of bringing out all the ligatures at the lower angle of the wound; the benefit of having them brought out thus low, so as to keep up a drain for any pus that may form, being in his opinion greater than that of arranging them at the points of the wound nearest to them.—(Mém. sur la Réunion de la Plaie après l'Amp. p. 12.)

As Dr. Hennen observes, the reducing the immoderate size of ligatures, the separating the threads of which they were composed, and placing them at convenient points along the face of the stump or wound, and the actual removal of one-half of each ligature, were amendments very slowly made; "but," says he, "an improvement which appears to me of great consequence, was the last of introduction, and is now the slowest of adoption, although the artery once secured, and the value of adhesion duly acknowledged, it is the most obvious of all. I allude to the plan of removing the ends of the ligature altogether, and thus leaving to an extensive wound the greatest possible chance of immediate union." The first printed mention of this practice, as far as Dr. Hennen's investigations have discovered, was in a letter written by Mr. Haire, dated Southminster, Essex, Nov. 1786. "The ligatures," says this gentleman, "sometimes became troublesome and retarded the cure. An intimate friend of mine, a surgeon of great abilities, proposed to cut the ends of them off close to the knot, and thus leave them to themselves. By following this plan we have seen stumps healed in the course of ten days. The short ligature thus left in commonly made its way out by a small opening in a short time without any trouble, or the patient being sensible of pain."—(See Lond. Med. Journ. vol. 7.) Certainly, considering the thickness of the ligatures in use at the above period, this testimony of the success of the method, as Dr. Hennen remarks, is very satisfactory.—(Principles of Military Surgery, p. 181, ed. 2.) In a letter received by me from Mr. Dunn, surgeon at Scarborough, and dated June 3, 1819, he tells me, "My predecessor, Mr. J. Wilson, the late partner of Mr. Travis, amputated a limb in 1792 or 1793, and cut off the ligatures close to the arteries, and no trouble ensued. He did this at the recommendation of Dr. Balcombe, of York, who had seen the method practised on the continent." In September, 1813, Dr. Hennen, who was serving with the army in Spain, began the adoption of this plan, which, he expected, would not only prove useful in promoting immediate union, but in obviating any accidental violence to the ligatures, and the wrong interference of the younger dressers in trying to pull them away. Between September and January, thirty-four cases were treated in this way without any inconvenience following, or the small particles of silk left behind giving rise to any apparent irritation. Dr. Hennen also presented to Sir J. M'Grigor some of the small circles of silk, a part of which had come away with the dressings, while others had floated out on opening the little pustules, which formed over the face of the stump at the points where the arteries had been tied. Some few of the ligatures never made their appearance, and the patients complained of no uneasiness whatever. Convinced of the utility of the method, Dr. Hennen afterward published an account of it.—(See Lond. Med. Repository, vol. 3, p. 177, and vol. 5, p. 221.) This gentleman subsequently found that Dr. Maxwell of Dumfries had adopted the plan as far back as 1798; and Dr. Ferguson, who was at Stockholm during the peace of Amiens, saw it also then followed by some of the surgeons of that city, without any ill effects.—(Hennen's Military Surgery, p. 175—178, ed. 2.) In July, 1814, Mr. Lawrence communicated to the Medical and Chirurgical Society of London, some cases and observations highly in favour of the practice, and the particularity which he lays much stress upon is, using for the purpose minute firm ligatures, composed of what is called dentist's silk.—(See Med. Chir. Trans. vol. 6, p. 156.) And in a paper of later date, he says, his farther experience had confirmed the usefulness of the method, "that this plan, by diminishing irritation and inflammation, and simplifying the process of dressing, very mate-

rially promotes the comfort of the patient, and the convenience of the surgeon, while it has not produced ill consequences or any unpleasant effect, in the cases which have come under his own observation." According to Mr. Lawrence, the small knots of silk generally separate early, and come away with the discharge; that where the integuments have united by the first intention, the ligatures often come out rather later, with very trifling suppuration, and that, in some instances, they remain quietly in the part.—(Op. cit. vol. 8, p. 490.)

After the battle of Waterloo, it was tried in many cases by Mr. Collier and by myself, though our ligatures were certainly not so minute and eligible as those employed by my friend Mr. Lawrence, whose plan essentially requires the use of minute ligatures made of dentist's silk. As I joined the army in the field after nine days, and was therefore obliged to leave my patients at Brussels to the care of others, I lost the opportunity of witnessing the effects of this method. But from Mr. Collier I afterward learned, that the new plan and the common one appeared in his judgment to answer about equally well; which report, considering hat we did not use the smallest ligatures, must be regarded as favourable. When the plan is tried, single strong threads and silks, or rather the kind of ligature which will be described in another place (see Ligature), should be employed; for otherwise, the knots would be large, and likely to create suppuration and future trouble. The practice has likewise been tried by Delpech at Montpellier; but it is not explained whether he used single threads or silks, or whether any inconveniences resulted from the method.—(See Relation d'un Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Anglaise avec la Chirurgie Francaise par P. J. Roux, 8vo. 1815.) Yet candour requires me to state, that the method is not generally adopted, and that one well-informed writer, as I shall hereafter notice (see Hemorrhage), has recited a case and some experiments, which are unfavourable to the practice.—(Cross, in Lond. Med. Repository, vol. 7, p. 355.) By Sir Astley Cooper, the practice has been found to occasion suppuration, and he has therefore given it up.—(Lancet, vol. 1, p. 149.) Mr. Guthrie, in two or three instances, has also seen some ill-looking abscesses arise from the presence of the bits of ligature, though he approves of the plan where the wound will not unite by the first intention, which, however, can rarely be known beforehand.—(On Gun-shot Wounds, p. 941.) On this subject, it merits particular attention, that no cases can be regarded as fair trials of Mr. Lawrence's method, unless precisely such ligatures as he himself employs be used.

[Dr. Koch, Professor of Chemical Surgery at the Hospital of Munich, Bavaria, after performing the flap-operation on the thigh, contents himself with approximating the flaps without securing any vessel; thus dispensing with ligatures altogether, as he finds that keeping the cut surfaces in perfect co-aptation is sufficient to prevent hemorrhage; and his success has been truly surprising. Dr. Wagner has long since proved in this country, that ligatures may be dispensed with in cases of surgical wounds, in which they are not only applied by most surgeons, but thought indispensable. See the report of his operation for removing the lower jaw, in which he used no ligatures. Many surgeons in this country are satisfied with securing the larger arteries only, and incur the risk of unimportant hemorrhages from the smaller vessels rather than multiply their ligatures. Professor Davidge, of Maryland, fell into the opposite extreme; from having encountered terrible secondary hemorrhages in the early part of his practice, he would never leave a single artery without a ligature, if he could distinguish it, and would often wait half an hour after amputation before closing the stump. He operated with singular success; but if he had used animal ligatures, his cases would not have been retarded for the sloughing of their pendent extremities. He used to say in his lectures, that arteries were like felons and murderers; there is no safety for us without we rope them.—*Reese.*]

Sometimes the sawed surface of the bone itself bleeds rather profusely. When this happens, it is an excellent plan, which I have often seen my late master Mr. Ramsden and others adopt with the greatest success, to hold a compress of lint over the end of the bone during the time requisite for securing the rest of the vessels. At the end of this period, the compress may generally be taken away, the bleeding from the bone having entirely ceased. As Monro remarks, the surgeon ought not to content himself with tying only such vessels as he observes throwing out blood, while the patient is faint with pain; he should endeavour to rouse him from that faintish state by a cordial, and then wiping off the coagulated blood with a sponge wet in warm water, he should examine narrowly all the surface of the stump, for otherwise he may expect to be obliged by a fresh hemorrhage to undo all the dressings.—(On Amputation of the larger Extremities, p. 475, Monro's Works.)

When there is merely an oozing from small vessels, Bromfield's advice to loosen the tourniquet completely is highly proper, as this measure, and washing the stump with a little cold water, will put an entire stop to such bleeding, without any occasion for more ligatures. A good deal of blood is sometimes lost from the mouths of the larger veins, and where they bleed much in debilitated subjects, I think Dr. Hennen is right in recommending them to be tied.—(On Military Surgery, p. 264.) There is no necessity for doing so, however, in ordinary cases, nor should I be disposed to imitate Mr. Hey, who, in consequence of having seen a few instances of bleeding from the femoral vein, generally enclosed that vessel in the ligature along with the artery.—(Practical Obs. in Surgery, p. 530, ed. 2.) This method was sanctioned by the eminent Desault, who says, that if the vein be left open, and the bandage at the upper part of the limb be too tight, the flood regurgitates downwards, and hemorrhage takes place, as this surgeon assures us he has often seen. When the vein and artery lie close together, as often happens, one branch of the forceps is to be introduced into the artery, and the other into the vein, which being done, the two vessels are to be drawn out together, and included in one ligature, but if they are not so near together, they must be tied separately.—(Euvres Chir. de Desault par Bichat, t. 2, p. 550, 8vo. Paris, 1801.) At St. Bartholomew's, it is not the usual practice to tie the femoral vein; and except in particular cases, I consider the custom wrong, because a ligature on a large vein sometimes excites a dangerous and fatal inflammation within the vessel, while the intervention of the vein between the one side of the circle of the ligature and the artery, must rather tend to hinder the thread from operating in the most desirable manner upon the latter vessel.

The wound is now to be evenly closed with strips of sticking plaster, so that the edges of the skin may form a straight line across the face of the stump. This was the mode commended by Alanson, and is what is preferred by the generality of surgeons in this country. It is also advised by Graefe.—(Normen für die Abt. grösserer Gliedm. p. 106. Guthrie on Gun-shot Wounds, p. 208.) Over these plasters and the ends of the ligatures it is best to place some pieces of lint, spread with the unguentum cetaceum, in order to keep such lint from sticking, which becomes an exceedingly troublesome circumstance when the dressings are to be removed. I am decidedly averse to the general plan of loading the stump with a large mass of plasters, pledgets, compresses, flannels, &c.; and I see no reason why the strips of adhesive plaster and a pledget of simple ointment should not suffice, when supported by two cross bandages and a common linen roller, applied spirally round the limb from above downwards. The first turn of the roller, indeed, should be fixed round the pelvis, while the lower circles secure the cross bandages, often called the Malta cross, over the end of the stump. It is also an excellent method to leave some little interspaces between the plasters, and in summer to keep the linen bandages constantly wet with cold water. In this way any discharge will readily escape, and the parts, being kept cool, will be less disposed to hemorrhage and inflammation.

Sir Astley Cooper states, that he has seldom succeeded with his stumps above the elbow or knee when a roller was not employed, which, he says, prevents retraction of the muscles and extensive suppuration. After applying the roller, and bringing the integuments together, he merely puts three strips of adhesive plaster over the wound, and one round the stump to keep the ends of the plaster in their place: in hot weather he applies a lotion of spirit of wine and water.—(Lancet, vol. 1, p. 150.)

I am completely of opinion with Mr. Alanson, that the elastic woollen cap, sometimes placed over all the bandages and dressings, if not put on with a great deal of care, has a tendency to push the skin backwards from the extremity of the stump; and as it must also heat the part, its employment should be discontinued.

If possible, the dressings should never be removed before the fourth day, not reckoning the one on which the amputation is performed; and Sir Astley Cooper even prefers the sixth or eighth day, merely removing on the fourth one strip of plaster in order to let out any confined matter.—(See Lancet, vol. 1, p. 150.) Monro also set down the fifth, sixth, or seventh day as generally soon enough for the change of the dressings. He allows, however, that if the smell of the wound should become offensive, the outer dressings may be removed sooner. Even when the dressings are to be taken away, it will frequently be found useful not to remove one strip of plaster; but the stump must be made clean, and any discharge washed away. These and other valuable precepts, derived from the eminent Dr. A. Monro senior, are worthy their great source, and the correctness of them promises to be acknowledged for ever.

The manner of renewing the dressings of stumps is indeed a very important business, which should never be intrusted to mere novices; for in taking off the straps of sticking plaster, if great care be not taken, the slight and newly-formed adhesions may be torn asunder. Thus, as Mr. A. C. Hutchison has remarked, if the strap be pulled off by holding one end of it at nearly a right angle with the adhering part, the flap will be raised up with it, and thus a separation of the newly-united parts will be produced. "My plan," says he, "is to reflect the raised end of the strap close down upon the adhering part, and to bring it gently forwards with one hand, while the removing part of the strap is followed by two fingers of the other placed upon the skin, &c.; and when one end is detached from its adhesion, as far as the line of incision on the face of the stump, in like manner the other end is brought down and wholly removed."—(Pract. Obs. p. 46.)

In order to facilitate the removal of the plasters, and save the patient a great deal of pain, I have always followed the plan of letting warmish water drop over them from a sponge for a few minutes previously to the attempt to remove them. In the early part of the treatment, it is also a valuable rule never to let every strap of plaster be off at once, so as to leave the flesh quite unsupported. Some skill and care are also invariably necessary, to avoid pulling away the ligatures with the dressings.

At the end of five or six days the surgeon may begin to try, in a very gentle manner, whether any of the ligatures are loose; observing rather to twist than suddenly pull them directly outwards. However, he should not use the smallest force, nor persist, if the trial create pain. One would hardly try whether the ligature on the main artery were loose before the eighth or ninth day. If minute ligatures made of dentist's silk be employed, and both their ends cut off close to the knot, of course this delicate business of trying to get rid of the irritation of these foreign bodies is entirely superseded.

Though in the above account I have directed the edges of the wound, after the amputation of the thigh, to be brought together in such a way that the wound shall appear as a line across the face of the stump, yet there are instances in which the bone seems most easily and conveniently covered, by making the line of the wound in a perpendicular direction.

Mr. B. Bell, indeed, generally approved of it, as affording a ready outlet for matter; it is likewise directed by Mr. C. Bell (Op. Surgery, vol. 1), by Roux (Mém. sur la Réunion immédiate de la Plaie, après l'Amp. p. 11), and by Dr. Hennen (On Military Surgery, p. 265, ed. 2).

On the other hand, Mr. C. Hutchison objects to it, because it seems to him, that when a stump thus put up is laid on a pillow, the pressure tends to separate and open the lower part of the wound.—(Pract. Obs. on Surgery, p. 37.)

It is curious to remark, however, that the thing which leads this gentleman to disapprove of the plan, is one which would be urged in its favour by Roux and some other surgeons, who actually take the precaution of never closing the lower angle of the wound, in order that whatever discharge occurs may find a ready outlet.—(Mém. cit. p. 14.)

Mr. Alanson objected to this method, asserting that the cicatrix afterward became situated immediately over the end of the bone, the pressure of which was very likely to make the part ulcerate. However, in St. Bartholomew's Hospital, I have seen the edges of the wound occasionally brought together in the perpendicular direction, and capital stumps made in this manner. In a case in which I assisted Mr. Ramsden at Christ's Hospital, when an attempt was made to put up the wound in a common manner, the bone seemed to make considerable pressure against the skin, which did not happen when the line of the wound was made in the other direction, which of course was immediately adopted. Mr. Hey has noticed this subject as follows: the integuments and muscles may be brought into contact by pressing either the anterior and posterior parts or the sides of the thigh together. The former method, by the gradual retraction of the posterior muscles, causes the integuments of the anterior part of the stump to cover more completely the extremity of the bone. The latter method causes the integuments and muscles to meet each other the more readily, and therefore is to be preferred when the quantity of soft parts preserved is somewhat deficient.—(Pract. Obs. on Surgery, p. 533, edit. 2.)

The plan of bringing the edges of the wound together after amputation, so that they may unite by the first intention, has received, for many years past, the universal approbation of British surgeons. It is their general practice in the treatment of all incised wounds. It may be said to be the pride of English surgery; for in nothing does she display more convincingly her superiority. Baron Larrey, however, in cases of amputation, disapproves of the attempt to unite the wound by the first intention, and merely brings forward its edges somewhat towards each other with a piece of linen, that covers the whole of the wound, and has small holes cut in it for the passage of the discharge.—(Mém. de Chir. Mil. t. 3, p. 379.) This piece of linen is supported with a moderately tight roller.

M. Roux, on his arrival in this country, wondered to see British surgeons so prejudiced in favour of union by the first intention, as to adopt it after all amputations. "C'est pareillement abuser de la réunion immédiate que de l'appliquer en toute circonstance à la plaie qui résulte de l'amputation des membres. J'entends parler de l'amputation dans la continuité des membres, et plus particuliérement encore de l'amputation circulaire."—(P. 128. Parallèle de la Chirurgie Anglaise avec la Chirurgie Française, 8vo. Paris, 1815.) But M. Roux has curiously omitted to explain in his book what are the advantages of not bringing the edges of the wound together, and why he calls prejudice the partiality to a method, the superior efficacy of which is continually demonstrated in every hospital of London. He does not indeed presume to condemn the practice altogether; on the contrary, he allows it to be proper in certain cases; yet he contends that it ought to be confined within particular limits.—(P. 130. See also Mém. et Obs. sur la Réunion immédiate de la Plaie après l'Amputation, &c. 8vo. Paris, 1814.)

In this tract, which is well drawn up, Roux proves most convincingly the benefits of union by the first intention after amputation of the thigh by the circular incision; but, strangely enough, his prejudices hinder him from advising the practice to be extended to other amputations. He does not positively condemn it in the arm, though he thinks the method less necessary, because amputation there is less dangerous than in the thigh, &c.—(P. 45.) To such futile reasoning is this author reduced by the unsoundness of his doctrine. He also deems the attempt at union by the first intention counterindicated where limbs are amputated for injuries which violently contuse and crush the parts (P. 48), and where the limb is much wasted.—(P. 50.) In the latter condition, however, he thinks Desault's flap-amputation may be done, and an effort made to heal the wound by adhesion. In one case he did this with success.—(P. 51.)

Richerand informs us that Dubois at Paris follows the plan with a success equal to that of the London surgeons. For some years past, he has himself also constantly endeavoured to accomplish union by the first intention, after all the amputations which he has had occasion to practise, and he succeeds at least in

three out of four. "The method is preferable," says he, "to the old one, in whatever point of view it is considered. This union is more expeditious; a few days being sufficient for its completion. A woman, whose thigh I took off in 1810, was very well in a week, &c. Besides the advantage of a quick cure, and such quickness is especially of great importance where the patient has been much reduced, so that he would hardly be able to bear a long suppuration, union by the first intention has the recommendation of saving the patient from a great deal of pain, the flap of integuments, with which the bleeding surface of the stump is covered, being much less irritating to the flesh than the softest charpie would be, &c. Three years have elapsed since the publication of the third edition of this book. During this interval I have performed more than a hundred and fifty amputations, and the utility of immediate union has been more and more proved to me."—(Nosographie Chirurg. p. 475. 477, edit. 4.)

But notwithstanding these and other encomiums on the practice, Richerand, like other French surgeons, is not an advocate for it in certain cases; as, for instance, limbs shattered by gun-shot wounds, or affected with hospital gangrene. Here, he maintains, that it hardly ever succeeds.—(P. 478.) But though it be true that amputations after gun-shot wounds do not generally heal so well as many other cases, it cannot be denied that they do sometimes unite more or less by the first intention; and why should not the chance be taken? It is productive of no danger; there is nothing better to be tried; and if it fail, what is the harm? Why, the wound will then heal by suppuration and the granulating process, just as soon as if the hollow of the stump had been filled with charpie or left open; it will in fact heal in a way which is less advantageous than union by the first intention, but which is the best which can now happen.

From what has been said, it appears that the practice of healing the wound by the first intention after amputation is less general in France than it is in England; a circumstance which may perhaps be explained by the fact of its being much newer to the French than to us. Every improvement must encounter for a time the opposition of prejudice; but one so important as that which we are considering, must at length prevail and meet with universal adoption. Our extraordinary partiality to union by the first intention arises from a conviction of its superior efficacy, and is a decisive proof of the goodness of English surgery in respect to wounds. The observations of Roux and Richerand tend to prove, that they are not altogether unaware of its advantages, and they therefore recommend it for certain cases; but their backwardness to extend it to all amputations without exception, is little in favour of the comparison which they are so fond of making of French with English surgery. Even the justly eminent Dupuytren still fills the hollow of the stump with charpie.—(Syme, in Edinb. Med. and Surgical Journ. No. 78, p. 32.)

However, that stumps may fall into a state in which the pressure of all plasters and bandages whatever should be most carefully avoided and emollient poultices used, is a truth of which every surgeon of experience must be fully convinced. This happens whenever the parts are affected with considerable tension, inflammation, and swelling, or painful acute abscesses. There is also no utility in keeping the edges of the wound very closely compressed together when all chance of adhesion is past, and the parts must heal by the granulating process. My friend Mr. Guthrie, after amputations performed from necessity in parts not in a healthy state, as in most secondary amputations after compound fractures of the thigh, does not insist upon the edges of the wound being brought into close contact by sticking plaster, compress, and bandage. In these cases, he also recommends the bone to be sawed an inch shorter than usual, or than would be necessray under other circumstances, in order to prevent its protrusion, and the ligatures to be cut off close to the knots, so as to lessen irritation. The integuments and muscles are to be brought forwards and retained so by a moderately tight roller, but not laid down against the bone. Some fine lint, smeared with cerate or oil, is to be put between the edges of the wound; and a piece of linen and a Malta cross over it, supported by a few light turns of the roller. "In some cases," says Mr. Guthrie, "I have put one and even two straps of plaster over the stump to keep the edges approximated without being in contact; and where the parts are but little diseased, this may be attempted; but if the stump becomes uneasy they should be cut, and a poultice applied. When only a part of the stump has appeared to slough, I have found the spiritus camphoræ, alone or diluted with a watery solution of opium, applied with the lint, very useful."—(On Gun-shot Wounds, p. 104.)

The reasons which led Mr. Guthrie to incline to the plan of not bringing together the edges of the wound in cases of this description, must be learned by reference to his own valuable work. His cases and arguments are entitled to serious consideration; and though they, as well as the observations of Roux (Mém. sur la Réunion immédiate de la Plaie après l'Amputation, 8vo. Paris, 1814), leave me unconvinced of the usefulness of not bringing the edges of the wound together immediately after the amputation of bad compound fractures, there are some of his observations respecting the injurious effects of too much pressure in certain conditions of the stump, perfectly agreeing with my own sentiments. At present, I have never seen any case of amputation in which I should not have thought the surgeon wrong, had he not brought the sides of the wound together directly after the operation, so as to afford the chance of union by the first intention

[A mode of amputating the thigh with two flaps was proposed a few years since by Professor J. B. Davidge, of the University of Maryland, which combines several important advantages.

The first incision is made with the large knife on the outside and inside of the thigh through the integument, so as to surround the limb, with the exception of an inch or more in the centre above and below. The surgeon having calculated the size of the flaps required, which are to be as long as the semi-diameter of the limb, makes with a scalpel a second and third incision through the skin, in form of the letter V, commencing above the centre of the space left vacant on the superior and inferior surface, and continued until its diverging extremities reach the ends of the semicircular cuts first mentioned. The flaps of integument are then dissected back until they equal in length a little more than the semi-diameter of the limb, to allow for the retraction that may occur. A circular incision is then made through the muscles down to the bone with the large knife. The bone is then denuded for an inch or two, the retractor employed, and the bone sawed off at the edge of the divided flesh. The arteries are then secured, the muscles drawn down, the ligatures so arranged as to come out of the superior and inferior angles of the wound, and the flaps are brought together and kept in place by adhesive straps, supported by a cross bandage, roller, &c. By this amputation the bone is cut off an inch or more within the actual face of the stump, and the flaps of integument having the angle cut out above and below do not present that unnecessary and inconvenient lump or puckering, formed at the angles after the common circular amputation. I have seen this operation performed by Dr. Davidge and others with singular success. The stump heals by the first intention, without any of the delays which are often encountered with the common flap-operation, and I prefer it for the arm as well as the thigh, unless the limb be much emaciated.—*Reese.*]

HEMORRHAGE AFTER AMPUTATION.

Bleeding after the operation is of two kinds in regard to the time when it occurs. The first takes place within twenty-four hours after the operation. Hence an assistant should always be left with the patient, with directions carefully and repeatedly to look at the stump; and if any bleeding should arise, to apply the tourniquet until farther aid be obtained. In case no assistant can be spared for this purpose, as must frequently happen in country practice, the tourniquet should be left slackly round the limb, and the nurse or patient himself directed to turn the screw of the instrument, in order to tighten it in case of need. A slack tourniquet left round the limb after amputation cannot do harm, and its not having been ready in this way has cost many patients their lives, as I have known instances of.

This kind of hemorrhage has often been known to arise from the pressure of a tight bandage round the stump. As Monro observes, the circular turns of the bandage, when tight, must stop the return of blood in the cutaneous veins, and thus by making a greater re-

sistance to the blood in the arteries which anastomose with them, occasion the contracting power of the heart and arteries to dilate, and force more blood into their other branches, but these being cut in the amputation will pour out their blood, and so hemorrhage is brought on. Making much pressure round the stump is highly deserving of reprobation; and whenever there is an universal oozing of blood I would recommend the operator to be sure that the circulation in the superficial veins is not impeded by the tightness of any bandage or tourniquet.

If the bleeding should not be from an artery of consequence, the application of linen dipped in cold water will sometimes check it, and the disagreeable necessity for removing the dressings and opening the wound may thus be avoided.

But it often happens that the wound must be opened, and the bleeding vessel tied. This is a very painful proceeding, and when the dressings have been applied some hours, so that the stump has had time to inflame, nothing can exceed the suffering to which the patient is now subjected. Here we see the prudence of being particularly careful at first to tie every suspicious vessel.

The second sort of hemorrhage after amputation arises from ulceration of the large arteries, and may occur a month after the operation, when the ligatures are all away, and the patient seems nearly well.

Two such cases are related by Mr. Bromfield.—(Vol. i, p. 307.) Now that the plan of covering the stump with sound skin is adopted, this kind of bleeding is less common than formerly. When the bleeding vessel is large there is no chance of putting the patient out of danger, except by cutting down to the vessel and tying it. The trunk of the vessel, however, may sometimes be more conveniently tied than the bleeding branch itself.

Mr. Hey makes mention of a particular sort of hemorrhage after the operation: "I have seen," says he, "a few instances of the integuments becoming so contracted after the operation as to compress the veins just above the extremity of the stump, and bring on after some hours a copious hemorrhage. When it has appeared clear to me that the hemorrhage was venous, I have made a division of the integuments on one side of the thigh, sufficient to remove the stricture, and this method has immediately suppressed the hemorrhage." —(P. 530, edit. 2.)

I have never yet met with a case in which a hemorrhage was unequivocally produced by a contraction of the integuments. Dr. Hennen says that he has seen only one example, and it was successfully treated by loosening the bandage and moistening the dressings with cold water.—(On Military Surgery, p. 264, ed. 2.) Doubts may therefore be entertained, whether the cause was the pressure of the integuments or of the roller on the veins.

In Mr. Guthrie's truly practical work there are some excellent remarks on the hemorrhages which, in an irritable and sloughing state of a stump, frequently take place from the small branches, or from the main trunks of the arteries, in consequence of ulceration. It is (says he) not always easy to discover the bleeding vessel, or, when discovered, to secure it on the face of the stump; for, as the ulcerative process has not ceased, and the end of the artery, which is to be secured, is not sound, no healthy action takes place. The ligature very soon cuts its way through, or is thrown off, and the hemorrhage returns; or some other branch is opened, and another ligature is required which is equally uncertain; and under this succession of ligatures and hemorrhages the patient dies. Here cutting down to the principal artery in preference to another amputation has often succeeded; but under certain circumstances it fails, and amputation becomes ultimately necessary. At the same time it is allowed that this operation may also fail. On the whole, Mr. Guthrie professes himself to be an advocate in most cases for tying the artery in the first instance; and if this proceeding should not answer, he would then amputate. However, the practice of taking up the artery, he thinks, should not be adopted indiscriminately, the doctrines of aneurism not being here applicable, because there is a wounded vessel with an external opening. "In the thigh the operation is less certain than in the arm, and especially if it is not the main artery that bleeds; for the branch from which the hemorrhage proceeds may come from the profunda, and tying the artery in the groin on such opinion would be doing a serious operation, and one which probably would not succeed; for the anastomosing branches would restore the circulation in the stump in a short time, and again establish the bleeding. If it is the femoral artery that bleeds, and the ligature is applied high, it is very liable to a return of hemorrhage. To obviate these difficulties, the part from which the bleeding comes should be well studied, and the shortest distance from the stump carefully noted, at which compression on the artery commands the bleeding; and at this spot the ligature should be applied, provided it is not within the sphere of the inflammation of the stump."—(On Gun-shot Wounds, p. 105, 106.) Thus far the advice seems to me correct and valuable; but where the hemorrhage could be restrained by taking up the artery in the groin, though not lower down, I doubt the propriety of preferring amputation to this other less severe operation, provided the efficiency of a ligature above the profunda be proved in the manner judiciously recommended by Mr. Guthrie, viz. by means of pressure.

The following is the counsel offered by Mr. Hey: "When we are under the necessity of amputating a limb that has suffered great contusion, though the operation is performed upon a part apparently sound, the wound sometimes becomes sloughy and ill-conditioned No good granulations arise to cover the extremities of the arteries; but the ligatures cut through these vessels, or becoming loose, cease to make a sufficient pressure upon them, and hence repeated hemorrhages ensue. This is a dangerous state for a patient; for if the vessels are taken up afresh with the needle, the hemorrhage will now and then return in the course of two or three days. In such cases, the application of dry sponge cut transversely, as directed by Mr. White (Cases in Surgery), has been found singularly useful, and has saved the life of the patient. But a constant pressure must be kept upon the pieces of sponge by the fingers of a succession of assistants, till granulations begin to arise upon the stump, and the prospect of future hemorrhage disappears. This method is of the greatest importance after amputation on the thigh or leg, where the great vessels are deeply seated. In the arm, above the elbow, where the vessels are more superficial, the great artery may be taken up with a portion of muscular flesh above the surface of the stump, by making first an incision through the integuments. My colleague, Mr. Logan, has done this twice within the last year with complete success, when repeated ligatures, applied in the usual way, had failed.

"In the morbid sloughy state of the stump above-mentioned, the application of lint, soaked in a liquid composed of equal quantities of lemon-juice and rectified spirit of wine, has been found very advantageous, and has caused it to put on soon a healthy aspect."—(P. 536, 537, edit. 2.)

[When this operation is necessary in crowded hospitals, where hospital gangrene is prevailing, Delpech recommends the practice of cutting off the ligatures close to the knots on the vessels, so that the lips of the wound may be more completely and accurately brought together.

By this means, as his experience has taught him, the risk of the wound being affected is materially lessened. The small particles of the ligatures enclosed in the stump, he says, are discharged at a period when the patient has regained strength enough to be moved into a healthy atmosphere, little openings being produced for their escape, and healing up again within twenty-four hours. He assures us that he has never seen the practice give rise to an abscess. Delpech is led by the view he takes of the consequences of suppuration, and the contraction of cicatrices, to prefer bringing the sides of the wound together after amputation of the thigh, so that the line of the cicatrix may be transverse and not perpendicular. His reason is, that most of the ligatures which unavoidably produce suppuration are placed on branches of the profunda in the posterior part of the limb, consequently here the greatest contraction follows cicatrization, and the anterior flap is thereby drawn over the extremity of the bone in the most advantageous manner.—(Chirurg. Clinique, t. 2, p. 395.) The same author gives an instance of the failure of a seton to unite a broken thigh-bone, where no union had followed a long trial of common means; and he was in the end compelled to

amputate the limb at the hip joint; the second example of his performing this severe operation.—(P. 466.) Under certain circumstances he is an advocate for the excision of diseased joints in preference to amputation; and refers the union of the bones in this case, not to the same process by which fractures are united, but to the production of a fibrous substance analogous to that of a cicatrix. Several successful examples of the practice are recorded.—(P. 472.) With respect to uncured fractures, I have now one under my care in the King's Bench. The accident happened two years and a half ago, and I have recommended the trial of a seton.—Pref.]

ON PROTRUSION OF THE BONE.

It is clearly proved by the observations of M. Louis, that this disagreeable consequence may be generally prevented by taking care to divide the loose muscles first, and (after their complete retraction, which will be favoured by no band or tourniquet being applied round the limb,) by observing to divide with a bistoury the muscles which adhere to the bone; for instance, the crural muscle, and the adhesion of the vasti and triceps to the spine of the femur. By this method, the bone may be sawn three finger-breadths higher than it could be if no attention were paid to beginning with the division of the loose muscles, and concluding with that of others attached to the bone.

The protrusion of the bones will never take place so long as they are immediately encompassed with the fleshy substance of the muscles: this proposition is incontestable. The state of the skin, whether longer or shorter, conduces nothing to this protrusion; nor will the inconvenience be prevented by drawing the skin upwards and preserving as much of it as possible. —(See Mém. sur la Saille de l'Os après l'amputation, in Mém. de l'Acad. de Chirurgie, tom. 5, p. 273, édit. in 12mo.)

As Mr. Guthrie has observed, a protrusion of the bone, after sloughing of the stump, or other accidental circumstances, will sometimes happen without any fault on the part of the operator; but he thinks it may almost always be prevented by attention to the following rules:—1. To leave the integuments attached to the muscles, instead of turning them back. 2. When the muscles are cut through in a slanting direction, upwards and inwards, or even directly downwards, to separate them from the bone, so that it may appear at the bottom of the cone as a depressed point. 3. To cut the bone short, and to keep the thigh constantly bandaged from the trunk during the cure, so as to prevent the retraction of the muscles. If, says Mr. Guthrie, a surgeon find, directly after the operation, that the bone cannot be well covered, he should immediately saw off as much more of it as will reduce it to its proper length. The error may be remedied at this moment with very little inconvenience in comparison with what must afterward be encountered if the opportunity be neglected.—(On Gun-shot Wounds, p. 109.) For some very useful directions how to bandage and support the soft parts with adhesive plasters, with the view of counteracting the tendency of the bone to protrude, I refer to some observations by Mr. Wright.—(See Bromfield's Chir. Cases, &c. vol. 1, p. 177.)

Having explained, that the surest way of preventing the evil is to save a sufficiency of muscle, especially of that muscular substance which is naturally most near and adherent to the bone, we shall next speak of the mode of relief.

When the end of the thigh-bone protrudes, it of course hinders cicatrization and becomes itself affected with necrosis. By the process of exfoliation, the dead portion of bone is sometimes thrown off, and a cure follows. But, in general, this desirable change is extremely tedious, and the result uncertain, because it frequently happens that, after the piece of bone has separated, the rest yet projects too much, and the stump still continues too conical to heal firmly enough to be capable of bearing the pressure of a wooden leg. When, however, the end of the bone forms only a slight projection, and the stump is not too conical, it is always best to leave nature to throw off the redundant exfoliating portion. In the opposite circumstances, the removal of all such part of it as cannot be covered by the integuments is the best practice, and, if well executed, will effect a cure.

This second operation is exceedingly unpleasant to the surgeon, because patients are apt to suspect, and not without reason, that the first was not properly managed. Let me therefore repeat, that the surest way of avoiding the evil is to cut the deep muscles rather higher than the superficial ones, as inculcated by M. Louis, by which means the bone will certainly lie within the level of the surface of the divided flesh. The advice delivered by my friend, Mr. Guthrie, I also consider valuable.

The second performance of amputation is a still more severe and unpleasant operation; yet, as Dr. Hennen has explained, it sometimes becomes necessary for osteosarcoma, extensive necrosis, abscesses of the medulla, unsuspected fissure, phagedena, or great protrusion of bone, with an extensively diseased periosteum, where the powers of nature are inadequate to the cure. "If the general health is not impaired, and the flesh does not peel off from the bone, as if it were boiled, the efforts of nature may be trusted to, aided by proper bandaging, and, in some cases, by the employment of the saw; but when restless nights, intense pain, flushings, and irregular bowels, with great tumefaction and hardness of the stump take place, indicating approaching hectic, and there is evidence of an irregular action of the parts, osseous matter becoming deposited, and forming a distinct tumour around the stump, our best plan will be to operate again near the trunk."—(Principles of Military Surgery, p. 266, ed. 2.) Sometimes amputation has been considered necessary a second time, in consequence of a morbid protuberance of the nerves of the stump, a change noticed by Molinelli, Morgagni, Lower, Arnemann, and Prochaska, and always attended with excruciating pain and great irritability of the part, and sometimes with retraction of the skin, and protrusion of the bone. Sir Astley Cooper, in his Lectures, relates one instance of such a stump high up the arm, where, upon examination of the part near the axilla, a tumour was felt, which, when touched, made the patient jump as if he had been electrified. In this case, as the bone protruded, amputation at the shoulder was performed. In another example, where a leg-stump was in a painful irritable state from a similar cause, Sir Astley Cooper effectually relieved the patient by removing the diseased end of the posterior tibial nerve. In a third instance, amputation was repeated at the patient's desire, and the nerves were found enlarged, forming a ganglion which partly rested upon the extremity of the bone. Such a degree of irritation had been produced by it, that no part of the stump could be touched without exciting a kind of electric shock. In a case that occurred in the Middlesex Hospital, amputation of the thigh was performed a second time, in consequence of the first stump being thus diseased. A complete ganglion, or plexus of nerves, was found closely adhering to the removed portion of bone, having almost the appearance of cartilage. The os femoris was of an unusually small size, but the linea aspera larger than natural. —(See Lancet, vol. 1, p. 115; vol. 2, p. 192.)

The following works may be consulted for information on diseases of the bones of stumps: Bonn, Thesaurus Ossium Morborum, Amst. 1788; Weidmann de Necrosi Ossium, Francof. 1798; Macdonald, de Necrosi ac Callo, Edinb. 1799; the above-mentioned Essays of M. Louis; Lévéillé sur les Mal. des Os après l'Amputation, Mém. de la Société d'Emulation, t. 1, p. 148; Von Hoorn De iis, quæ in partibus membri, præsertim osseis amputatione vulneratis, notanda sunt; Lugd. 1803. Roux, de la resection des Os Malades, Paris, 1812; Mém. de Physiologie, &c. par Scarpa, et Lévéillé, Paris, 1804.)

SPASMS OF THE STUMP.

Spasmodic contractions of the muscles of the stump is another very afflicting occurrence. Such spasms put the patient to the greatest agony, tend to cause a protrusion of the bone or sugar-loaf stump, and in some cases increase, affect the whole body, and ultimately prove fatal. But this unfortunate affection, which was rather frequent after amputations performed in the ancient manner, is infinitely less so after the modern improved plans of operating, tying the vessels, and dressing the wound. When, however, it does occur, the stump must be kept from starting, by fastening it to the pillow and bedding on which it lies, the flesh is to be properly supported with a bandage applied from the pelvis downwards, and

opium and the camphor mixture should be liberally exhibited.—(Encyclopédie Méthodique, Partie Chir. t. 1, p. 93. Latta's Surgery, vol. 3, &c.)

FLAP-AMPUTATION OF THE THIGH.

Although I concur with the majority of surgeons in regarding the operation by a circular incision the most eligible under ordinary circumstances, no doubt can exist about the preference which should be given to amputating with a flap in particular examples. The choice, as Dr. Bushe has well remarked, ought to depend on the state of the limb and nature of the malady requiring amputation. "One surgeon is so devoted to the double circular incision, that he performs no other (method), though his coadjutor in the same hospital is bigoted to the double flap-operation, and never amputates but after this manner. But the unprejudiced practitioner will look to the nature of the case, and adjust means accordingly."—(Lancet, No. 246, p. 204.) Notwithstanding this good doctrine, however, Dr. Bushe is in reality very partial to flap-amputations, affirming, that there is only one part, viz. the upper third of the leg, where he would recommend the double circular incision to be preferred.—(Op. cit. p. 207.) At the same time, he confesses, that when the arm is much emaciated and flaccid, Dupuytren's mode, with a single circular incision, is that to which he has himself given the preference. He admits, also, the frequency of tedious suppuration and sinuses after flap-amputations, which evils, however, he ascribes to the fault of making the flaps too long.—(P. 206.) Flap-amputation of the thigh, I believe, has the important advantage of being least exposed to the danger of a protrusion of the bone, and, hence, I think it may be advisable, whenever any reasons exist in the state of the parts, or the constitution, for apprehending that disagreeable occurrence. An experienced military surgeon informs us, that, in the first years of his practice, he performed several amputations by the double incision, strictly according to the precepts of Sabatier, Desault, Pelletan, and Pott, but had the mortification to have three cases in which the bone protruded, though the greatest circumspection was used in the operation and after-treatment. Hence he was induced to make trial of the flap-amputation, and although he imitates O'Halloran in not attempting to bring the flaps close together for the first six or eight days, he reports that the stump is generally healed in twenty or thirty days, and exfoliations rarely happen, on account of the bone being so well covered. In short, he says, that this method is to be preferred to all others.—(J. B. Paroisse, Opusc. de Chir. p. 185—203. Paris, 1806.)

Mr. Syme also informs us, that though the flap-amputations seen by him have been very numerous, he has never met with an instance of the bone protruding or exfoliating after them.—(Ed. Journ. vol. 14, p. 38.)

A description of Desault's or rather Vermale's mode of operating, being given in the First Lines of the Practice of Surgery, I need not here repeat it, nor say by how many respectable names the practice is sanctioned. In Guy's Hospital, flap-amputation of the thigh seems now to be mostly preferred. The operation is also sometimes adopted by my friend Mr. Vincent in St. Bartholomew's Hospital, who showed me, some time ago, a capital stump which he had made in this manner, and which healed with great expedition.

By Mr. Guthrie the flap-operation is considered preferable to the circular incision at the upper part of the thigh, "as it permits the head of the bone to be removed if found necessary, allows it to be examined and cut shorter with greater ease, and makes a much better covering afterward.—(On Gun-shot Wounds, p. 200.)

In military surgery, flap-amputation of the thigh is often advantageous, because all the flesh on one side of the limb is frequently torn away, or left in so terribly a mangled state as to be unfit for making a covering for the end of the bone. Here a flap, sufficient to cover the whole face of the stump, should be saved from the sound flesh on the other side of the limb. When the surgeon chooses the flap-amputation, not from necessity, as under these last circumstances, and the flesh is sound all round the member, the best way is to save a flap on each side of the limb, by making two semicircular cuts, the convexities of which extend in a parallel manner forwards, and the terminations of which meet at the upper and lower surfaces of the limb. The skin is not to be at all dissected from the muscles, which are to be obliquely divided as high as the base of the flap on each side. However, though this is the best plan, particular cases may require a flap to be made from the anterior, or even the posterior side of the thigh. The latter method should never be followed but from necessity.—(See Hey's Pract. Obs. in Surgery, p. 531. ed. 2.)

According to Mr. Guthrie, the difference between the flap-operation at the upper part of the thigh and that at the hip consists in its being done lower down, and in the flaps being saved more immediately from the external and internal sides of the thigh, the inner flap being the largest, in order to prevent the inconvenience which might arise from the external one being tightly stretched over the end of the bone. For the same reason Mr. Guthrie also recommends the bone to be sawed off close tothe lesser trochanter, even when the nature of the injury would allow of its being left an inch longer.—(On Gun-shot Wounds, p. 200.)

Flap-amputation of the thigh, after the manner of Vermale, is now preferred by Klein, one of the best operating surgeons in Germany, and by Messrs. Liston and Syme, two surgeons of great merit in Edinburgh. —(See Edinb. Med. and Surg. Journ. vol. 14, p. 36—46, &c.) It is also sometimes practised in several of the metropolitan hospitals. Of seven cases in which Klein adopted this method, the greater number were healed in ten days, and the rest in three weeks; and this success determined him in future always to practise it. After this mode he finds there is no danger of the muscles retracting themselves, and leaving the end of the bone protruding, even though the patient be transported from one place to another. With respect to the occasional difficulty of taking up the obliquely cut vessels, Klein admits this objection, but thinks that it equally applies to Alanson's method. He lays great stress on the utility of giving due support to the flaps with compresses and a roller.—(See Practische Ansichten der bedeutendsten chirurgischen Operationen, p. 35—38, 4to. Stuttgart, 1816.)

In one instance, where a ball had broken the upper part of the femur, and mortification had spread so far towards the great trochanter and buttock, that it was impossible to operate except by the flap-operation, or by taking the head of the bone out of the joint, Klein made a broad flap six inches long at the inner and upper part of the thigh, and then he cut the soft parts straight across just below the great trochanter, so as to make this wound meet the termination of the incision by which the inner flap was formed. This patient got perfectly well in three weeks (Op. cit. p. 39); and so did another very similar case, operated upon by the same gentleman.—(P. 43.) Where the bleeding is considerable, the femoral artery and profunda should be tied previously to sawing the bone; but if the vessels are well commanded by the pressure the sawing ought to be first completed.

At the middle of the thigh, Lisfranc also prefers amputating with two lateral flaps; pressure is made on the femoral artery as it passes over the brim of the pelvis; and the vessel is tied immediately the inner flap is formed. Lisfranc makes the flaps with a very long narrow two-edged knife, which he introduces through the limb on each side, and then cuts obliquely outwards, and downwards with it; but I think Mr. Syme is right in recommending the knife used by Mr. Liston, and the back of which is thin and blunt except for an inch from the point.—(Ed. Med. Surg. Journ. vol. 14, p. 37.) Mr. Hey also preferred a knife with a blunt back, lest the vessels should be cut with it in a way that would render the securing of them troublesome.

AMPUTATION BELOW THE KNEE.

In treating of amputation of the thigh I have remarked that as much of the limb as possible should be preserved. The longer it is after the operation, the stronger and more useful will it be found. But when the leg is to be amputated writers commonly advise the operation to be performed a little way below the knee, even though the disease for which the limb is removed may be situated in the foot or ankle, and would allow the operation to be done much farther down. The common practice is to make the incision through the integuments, just low enough to enable the operator to saw the bones, about four inches below the lowest part of the patella.

About six inches below this point is generally an eligible place for the first circular cut through the skin. This degree of lowness is usually deemed necessary, in order not to deprive the stump of that power of motion which arises from the flexor tendons of the leg continuing undivided. It is alleged also as a reason for this mode of proceeding, that it is quite sufficient to preserve a few inches of the leg in order to afford the body a proper surface of support in walking with a wooden leg; whereas, if a larger portion was saved, the superfluous part would be a great inconvenience both in walking and sitting down, without being of the smallest utility in any respect whatever. However, as I shall presently notice, experience proves that where, according to these maxims, an injury or disease would dictate the performance of amputation above the knee, the practice of amputating below this joint, but much higher than is generally sanctioned, may be followed with advantage.

The tourniquet should be applied to the femoral artery about two-thirds of the way down the thigh, just before the vessel perforates the tendon of the triceps muscle. This place is much more convenient than the ham, where it is very difficult to compress the vessel against the bone. The patient is to be placed upon a firm table, as in the amputation of the thigh, and the leg being properly held by one assistant, while the integuments are drawn upwards by another, the surgeon with one quick stroke of the knife is to make a circular incision through the integuments all round the limb. Some recommend the operator to stand on the inside of the leg, in order that he may be able to saw both bones at once. No reflections could ever make me perceive that any real advantage ought strictly to be imputed to this plan. Many suppose that it diminishes the chance of the fibula being splintered, this bone being completely divided rather sooner than the tibia. But splintering the bones generally arises from the assistant depressing the limb too much, or else not supporting it enough. If the assistant were to be guilty of this mismanagement, it would be difficult to explain why the tibia should not be splintered instead of the fibula, when a certain thickness of it had been sawed through. At the same time it must be admitted, that if the surgeon prefer standing on the inside of the limb, there is no objection to it at the time of using the saw; but before this period, in amputating the right leg, there is great convenience in having the left hand next to the wound, as is the case when the surgeon stands on the outside of the right limb. Hence I have seen many hospital surgeons, in amputating the right leg, cut the soft parts while they stood on the outside of the limb, and having done this part of the operation they proceeded to the other side of the member for the purpose of applying the saw. I have only to repeat, that I do not think any particular reason exists against sawing the two bones together, yet in such manner as to let the fibula be divided entirely through the first; and the advantage of fixing this bone against the tibia by the pressure of the hands of the assistants, while the surgeon is sawing it, is another circumstance which influences a great many writers to commend the latter plan. Graefe, who, as already mentioned, prefers the true flap-operation, does not think it advisable for the surgeon to stand on the inside of the limb in his method of operating, because, when the knife is introduced through the muscles of the calf, its point would be apt to go between the two bones.—(Normen für die Abl. grösserer Gliedm. p. 130.)

A circular cut having been made through the integuments, about two inches below the place where it is intended to saw the bones, the next object is to preserve skin enough to cover the front of the tibia and the part of the stump corresponding to the situation of the tibialis anticus, extensor longus pollicis pedis, and other muscles, between the tibia and fibula, and those covering the latter bone. Throughout this extent there are no bulky muscles which can be made very serviceable in covering the end of the stump, and consequently the operator must take care to preserve sufficient skin in this situation by dissecting it from the parts beneath and turning it up.

On the back part of the leg, on the contrary, the skin should never be uselessly detached to a great extent from the large gastrocnemius muscle, which, with the soleus, will here form a sufficient mass for covering the stump. However, the experience which I had in the army taught me the truth of a remark made by Graefe, that in forming the posterior flap of muscle it is a matter of the highest importance to let the integuments be somewhat longer than it; for otherwise, when it is turned forwards, as it must be for the purpose of covering the ends of the bones, its front edge will be left uncovered by integuments which, being the outermost, describe a greater circumference than the deeper muscular flap.—(Normen für die Abl. grösserer Glied. p. 131.) I was fully convinced of the truth of this observation by two amputations which were done by myself one in the neighbourhood of Antwerp, in 1814, and the other at Brussels the day after the battle of Waterloo. Yet Graefe, who performs the flap-amputation, strictly so called (that is to say, the operation in which a flap of skin corresponding in shape to the flap of muscle is preserved), does not himself detach the skin from the muscles of the calf at all, but at the time of making the incision in that situation directs one assistant to pull up the integuments, while another bends the foot as much as possible, which manœuvres have the effect of letting the muscles be cut rather shorter than the skin. Unfortunately, however, in many cases, the very nature of the disease or injury for which the operation is performed, would not admit of these proceedings. Nor, in a very muscular limb, would they be likely to suffice, as Graefe himself confesses, since in such cases he recommends the use of a knife bent laterally for the purpose of excavating, as it were, as the incision is made, the thick muscular flap.—(Op. cit. p. 134.) In the common method with the circular incision, I am disposed to think it best, therefore, to let a small quantity of skin be detached and saved at the back part of the leg, so that there may be a certainty of having enough to cover well the extremity of the divided muscles of the calf. As soon as the skin has been separated in front and on the outside of the leg, the surgeon is to detach the skin from the calf for about an inch, and having reflected or drawn this preserved portion out of the way, he is to place the edge of the knife close to the edge of the retracted or reflected skin at the back of the limb, and cut obliquely upwards through the muscles of the calf, from the inner edge of the tibia quite across the fibula, supposing the operator to be on the outside of the right leg, and that it is this member which is undergoing removal. In performing this last incision, as M. Louis well observes, it is essential to incline the edge of the knife obliquely upwards. In this manner the skin will be longer than the muscles, and the cure considerably accelerated.—(Mém. de l'Acad. de Chir. t. 5, édit. in 12mo.)

In the leg, the necessity of dissecting the skin from the subjacent parts is acknowledged to be greater than in the thigh: thus Mr. Guthrie says, "as the attachment of the skin to the bone will not readily allow of its retraction, it must be dissected back all round, and separated from the fascia, the division of which in the first incision would avail nothing, from its strong attachment to the parts beneath."—(On Gun-shot Wounds, p. 220.) In dissecting the skin, however, a much greater detachment of it should be made at the front and outer part of the limb, than at the opposite points, as already explained.

The flap formed of the integuments and muscles of the calf is then to be held back by one of the assistants, while the surgeon completes the division of the rest of the muscles, together with that of the interosseous ligament, by means of the catling, a kind of long, narrow, double-edged knife.

In amputating below the knee, very particular care must be taken to cut every fasciculus of muscular fibres before the saw is used. Every part except the bones being divided, the soft parts are next to be protected from the teeth of the saw by a linen retractor, made with two slits to receive the two bones, care being taken to let the unslit part be applied to the muscles of the calf, as particularly advised by Graefe.—(Op. cit p. 136.)

In the leg there are only three principal arteries requiring ligatures, viz. the anterior and posterior tibial, and the peroneal or fibular arteries. In addition to these, however, the surgeon is sometimes obliged to tie large muscular branches. The anterior tibial artery will be found in front of the interosseous membrane, and between the extremities of the bones; the fibular artery behind the fibula; and the posterior tibial situated more inwardly than the last, among the fibres of

the soleus, near the tibia.—(C. Bell, Oper. Surgery, vol. 1, p. 385.)

When the soft parts have been cut in the preceding way, the bones sawed, and the arteries tied, the wound is to be closed by bringing the flap of skin over the front and external parts of the stump, so as to meet the flap composed of the gastrocnemius, soleus, and integuments on the opposite side. This should be done without letting any tight strap of plaster press the skin against the sharp edge of the tibia; a serious and hurtful practice, which has often occasioned ulceration and sloughing of the integuments, and protrusion and necrosis of the bone. It is this danger which leads Mr. Guthrie to prefer closing the wound vertically, or nearly so, and applying the adhesive straps from side to side.—(On Gun-shot Wounds, p. 221.) I think, however, the above mode of operating almost necessarily requires the wound to be closed, so as to form a line, extending in a direction from the tibia to the fibula. But where a great deal of skin is saved all round the limb, and the muscles of the calf are not chiefly calculated upon for covering the bones, the perpendicular line of the wound will answer very well.

Many surgeons, however, operate differently. They first make the circular incision through the skin, two inches below where they mean to saw the bones. They next detach the skin from the muscles and bones equally all round the limb to the extent of about a couple of inches. The integuments are then turned up, and a division of the muscles made all round down to the bones, on a level with the line where the detachment of the skin has terminated. The parts between the bones are afterward cut through, &c. The hemorrhage having been stopped, the integuments are drawn down over the stump, and the line of the wound made perpendicular.

In the army, the practice has sometimes been adopted of sawing off the sharp upper ridge of the tibia; but I can offer no exact judgment on the merits of the innovation, which has made but slow progress. It has been done a few times at St. Bartholomew's, and I should have no objection to giving it a fair trial, especially as it has the sanction of Mr. Guthrie, who says, that in thin persons, where the spine of the tibia is very sharp, this part should be removed with the saw. —(P. 222.)

Occasionally surgeons have also removed the small remnant of the fibula, and such was sometimes the practice of Larrey, when he amputated nearer the knee than common.—(Mem. de Chir. Mil. t. 3, p. 389.)

Whether the above plan of amputating the leg so high up, when the foot or ankle is the part diseased or injured, be on the whole most advantageous, I cannot presume to determine. By some clever men the practice has been condemned; and though we see it pursued by the best surgeons in this metropolis, and my own sentiments incline me to believe they are right, I will not say that the matter is so settled as not to require farther consideration.

Mr. White of Manchester, in a paper dated 1769 (Med. Obs. and Inq. vol. 4), informs us that he took the hint to amputate a little above the ankle, from seeing a case in which this had been done by a simple incision, with such success that the patient could walk extremely well, though with a machine that was very badly constructed. After this, Mr. White began to operate above the ankle with the double incision; and he invented a machine much better calculated for the patient to walk upon.

In 1773, Mr. Bromfield published his Chirurgical Cases and Observations, wherein he mentions his having begun about the year 1740 to amputate above the ankle, in a case of gangrene of this part of the leg. The patient walked so well, with the aid of a very simple machine, both along a level surface, and in going up and down stairs, that it was difficult to perceive he had lost his foot. Mr. Bromfield was persuaded, however, to give up this practice, until he learned that in 1754, a Mr. Wright had thrice amputated in this way with success, when he again had recourse to it without the least unpleasant consequences.—(See Chir. Cases and Obs. vol. 1, p. 189, &c.)

The advantage of amputating a little below the knee is, that the pressure in walking with a wooden leg is entirely confined to the front of the limb, the cicatrix itself not being subjected to irritation. After amputating at the ankle, the pressure in walking operates directly on the cicatrix. According to Sabatier, this st plan has been extensively tried in France, but not found to answer, the stump being incapable of bearing pressure, and not continuing healed.—(Médecine Opératoire, t. 3, p. 377, edit. 2.) Baron Larrey also speaks of it as an objectionable operation, not merely because some patients, as for instance soldiers, have not the means of providing themselves with artificial legs of the above description, but because it is almost always followed by bad symptoms, owing to the small quantity of cellular substance and flesh, and the thickness of the bone at this part of the leg, whereby cicatrization is impeded. A nervous irritation is more apt to be produced by this than the common mode of operating, and the suppuration, which is always sanious, takes place with difficulty. "I have (says Larrey) seen many amputations done at this part, but nearly all the patients died of nervous fever or tetanus."—(Mém. de Chir. Mil. t. 3, p. 394.)

In the foregoing columns I have given some account of the flap-amputation of the leg, as done by Lowdham, Verduin, Garengeot, Vermale, and others, and, in particular, the practice of O'Halloran has been touched upon, whose chief peculiarity, viz. that of not laying down the flap until ten or twelve days had elapsed, was unquestionably his greatest error, though the idea may have been admired and followed by a few speculators in modern times.—(See Paroisse, Opusc. de Chir. p. 196, &c. Paris, 1806.) This last author, who is a general approver of flap-amputations, leaves the stump unclosed for some days after the removal of the limb; but it surprised me to hear, that in one of the finest hospitals in this metropolis, three or four trials were made a few years ago, of a modification of this absurd practice, after amputation by the circular incision. Instead of bringing the sides of the wound together, the stumps were only partially closed, and kept for a day or two covered with wet linen. The last patient whom I heard of as having been treated in this manner, died a few days after the operation; and it gives me pleasure to hear, that all farther intention of subjecting more patients to the experiment, in the hospital alluded to, is given up.

In flap-amputations below the knee, Alanson and Lucas conjectured that the cure might be rendered more safe, easy, and expeditious by applying the flap, with the view of uniting it by the first intention.

The following case explains Mr. Alanson's flap-operation. The disease was in the left leg, the patient, therefore, lay on his right side, upon a table of convenient height, so as to turn the part to be first cut fully into view. The intended line, where the knife was to pass in forming the flap, had been previously marked out with ink. A longitudinal incision was made with a common scalpel, about the middle of the side of the leg; first on the outside, then on the inside, and across the tendo Achillis: hence, the intended flap was formed, first by incisions through the skin and adipose membrane, and then completed by pushing a catling through the muscular parts in the upper incised point, and afterward carrying it out below, in the direction of the line already mentioned. The flap was thick, containing the whole substance of the tendo Achillis. The usual double incision was made; the retractor applied to defend the soft parts; and the bone divided as high as possible with the saw.

The flap was placed in contact with the naked stump, and retained there at first by three superficial stitches, between which adhesive plasters were used. Notwithstanding the patient caught an infectious fever a few days afterward, the stump healed in three weeks, except half an inch at the inner angle, where the principal vent had been. In another week, the wound was reduced to a spongy substance, about the size of a split pea. This being touched with caustic healed in a few days. The man was soon able to use an artificial leg, with which he walked remarkably well. He went several voyages to sea, and did his business with great activity. He bore the pressure of the machine totally upon the end of the stump, and was not troubled with the least excoriation or soreness.

In the next instance, in which Mr. Alanson operated, he formed the flap by pushing a double-edged knife through the leg, and passing it downwards and then outwards, in a line first marked out for the direction of the knife. In this way, the flap was more quickly made.

The leg should be completely extended during the operation; and kept in that posture till the wound is perfectly healed.

We shall next notice Mr. Hey's method. He was satisfied, that very near the ankle is not the most proper place for this kind of amputation.

Some cases occurring in which, from a scrofulous habit, the wound at the stump would not heal completely, nor remain healed, Mr. Hey determined to try whether amputation in a more muscular part would not secure a complete healing, and give the patient an opportunity of resting his knee on the common wooden leg, or using a socket, as he might find most convenient. Mr. Hey latterly preferred this method, which he reduced to certain measures.

It had been customary at the Leeds Infirmary, to make the length of the flap equal to one-third of the circumference of the leg. This was determined by the eye of the operator, who usually pushed the catling through the leg near the posterior part of the fibula. Mr. Hey, finding the flap was not always of the proper breadth, began to determine this by measure, and then operated as follows: to ascertain the place where the bones are to be sawed, together with the length and breadth of the flap, he draws upon the limb five lines, three circular and two longitudinal ones. He first measures the length of the leg from the highest part of the tibia to the middle of the inferior protuberance of the fibula. At the mid-point between the knee and ankle, he makes the first or highest circular mark upon the leg. Here the bones are to be sawed. Here Mr. Hey also measures the circumference of the leg, and thence determines the length and breadth of the flap, each of which is to be equal to one-third of the circumference. In measuring the circumference of the limb, Mr. Hey employs a piece of marked tape or riband, and places one end of it on the front edge of the tibia. Supposing the circumference to be twelve inches, he makes a dot in the circular mark on each side of the leg, four inches from the anterior edge of the tibia. These dots must, of course, be four inches apart behind. From each of these dots Mr. Hey draws a straight line downwards, four inches in length, and parallel to the front edge of the tibia. These lines show the direction which the catling is to take in making the flap. At the termination of these lines, Mr. Hey makes a second mark round the limb, to show the place where the flap is to end. Lastly, a third circular mark is to be made an inch below the upper one, first made for the purpose of directing the circular cut through the integuments, in front of the limb. The catling for making the flap should be longer than those commonly employed in amputations. Mr. Hey uses one which is seven inches long in the blade, and blunt at the back, to avoid making any longitudinal wound of the arteries, which is very difficult to close with a ligature; and, for the same reason, he pushes the catling through the leg a little below the place where such muscles are to be divided as are not included in the flap. The limb being nearly horizontal, and the fibula upwards, he pushes the catling through the leg where the dot was made, and carries it downwards along the longitudinal mark, till it approaches the lowest circular mark, a little below which the instrument is brought out. The flap being held back, Mr. Hey divides the integuments on the front of the limb along the course of the second circular mark. The muscles not included in the flap are then divided a little below the place where the bones are to be sawed. No great quantity of these muscles can be saved, nor is it necessary, as the flap contains a sufficient portion of the gastrocnemius and soleus muscles to make a cushion for the ends of the bones. After sawing the bones, Mr. Hey advises a little of the end of the tendon of the gastrocnemius to be cut off, as it is apt to project beyond the skin when the flap is put down; and he recommends the large crural nerve, when found on the inner surface of the flap, to be dissected out, lest it should suffer compression.

As strips of adhesive plaster cause great pressure on the end of the stump, Mr. Hey prefers sutures for keeping the flap applied; small strips of court plaster being put between the ligatures. The sutures may be cut out on the eighth or ninth day, and the flap supported by plasters.

Mr. C. Bell describes another sort of flap-amputation. The operation is not to be done so low, as there will not be a sufficiency of muscle to cover the end of the bones. An oblique cut is to be made with the large amputating knife upwards, through the skin of the back part of the leg. The assistant is to draw up the skin, and the knife is to be again applied to the upper margin of the wound, and carried obliquely upwards till it reaches the bones. The knife, without being withdrawn, is next to be carried in a circular direction over the tibia and fascia, covering the tibialis anticus until it meets the angle of the first incision on the outside of the limb. The surgeon is then to pierce the interosseous membrane, &c. The sawing being completed, and the arteries secured, the flap is to be laid down, and the integuments of the two sides of the wound will be found to meet.—(Operative Surgery, vol. 1.) Langenbeck disapproves of the plan of pushing the knife through the calf of the leg, as practised by Alanson, Hey, Graefe, Liston, Lisfranc, Syme, &c., because an inexperienced surgeon may run the point between the two bones, and in this way the wound is never made evenly. His manner of forming the flap is very similar to Mr. C. Bell's, except that he first makes three cuts in the integuments, two longitudinal and one transverse, by which the shape of the flap of skin is determined.—(Bibl. für die Chir. b. 1, p. 571.)

The regular flap-amputation of the leg, I mean that operation in which the circular incision is abandoned, and a semicircular flap both of skin and muscle preserved, is often considered more painful than the common method. Yet when we come to see what respectable names are recorded in its favour, how soon the stump generally heals, how well the ends of the bones are covered, and how all dissection of the integuments from the fascia is avoided in this mode of operating, at least as far as the flap extends, the method must be allowed to possess weighty recommendations. Indeed, in its present improved state, and with the peculiar fitness of such a stump for adhesion, this operation, I think, is again rather rising in the estimation of the profession. In 1816, Klein had performed flap-amputation of the leg about twenty times. If the flap should happen to be made too large, he particularly dwells on the propriety of removing part of it at once; and when it is too short, he enjoins carrying the incision a little farther upwards without delay. He confesses that the plan is attended with some little trouble in securing the interosseous arteries, which are apt to retract considerably; but such has been the success of his practice, that out of twenty cases seventeen got well, and most of them very soon, without the least exfoliation; and the other three died of typhus.—(Practische Ansichten der bedeutendsten Chir. Op. Iste Heft, p. 47.) In the same work, this experienced surgeon, convinced how much more quickly and certainly the wound heals after amputations with two flaps than those with one, has suggested a plan of amputating below the knee, so as to form two lateral flaps. Mr. Syme, of Edinburgh, recommends an anterior and a posterior flap. On the other hand, as already mentioned, it is only in amputating below the knee that Dr. Bushe conceives the circular incision decidedly preferable to the flap-operation. He distinctly declares, that he "never saw a case where a flap was formed from the calf of the leg, in which considerable retraction of the remaining muscles did not ensue, attended with great induration of the flap, separation of its edge from the skin on the front of the tibia, sometimes exfoliation of the bone, and generally tedious suppuration. Nor (says he) can I speak much in favour of the method recommended by Mr. Syme, viz. that of forming an anterior and posterior flap; for before I saw his paper, I once performed this operation, and regret to say that my success was so indifferent, that I have not since repeated it."—(Lancet, No. 246, p. 208.) I have also tried the same method, and coincide with Dr. Bushe respecting it.

The principal reasons have already been specified which have established the common custom of amputating the leg about four inches below the patella, and if the disease or injury will not admit of the operation being done thus low, of removing the limb above the knee-joint. In the Egyptian campaign, however, Baron Larrey performed two amputations very near the knee-joint, almost on a level with the head of the fibula, which he judged proper to extirpate. The successful result of these operations dispelled the fear which this experienced surgeon previously entertained about am-

putating in the thick part of the upper head of the tibia; for no caries of this spongy portion of the bone, no bad effects on the knee-joint, and no anchylosis of the stump ensued: and, with the difference of a few days, the wound healed as readily as that made in the common place of election, viz. three or four finger-breadths below the tuberosity of the tibia. Since the above-mentioned campaign, Larrey has adopted this practice in many cases where it was impossible to have operated at the usual place, and he assures us, the success fully equalled what attends operations done at the ordinary distance from the knee. In 1806, another French military surgeon, who had tried this method himself, published a dissertation, in which he commended operating, where circumstance required it, much higher than the point allowed by generally-received rules. Larrey differs, however, from Garrigues, in forbidding amputation higher than the level of the tuberosity of the tibia, the thick portion of which may be sawed, but not above the insertion of the tendon of the patella. A transverse line, drawn from this point, usually passes below the articulation of the fibula, and over the lower portion of the uppermost part of the condyles of the tibia; but as the relative positions of the heads of the two bones to each other differ somewhat in different individuals, Larrey makes the tuberosity of the tibia the point above which the bone should never be sawed. By cutting higher, the ligament of the patella is separated from its insertion; the bursa mucosa, situated underneath it, is wounded, and the ligaments at the sides of the joint are injured; whence arise retraction of the patella, effusion of the synovia, and such disease of the knee-joint as may render another amputation indispensable. By making the division on a level with the tuberosity of the tibia, the attachment of the ligament of the patella is preserved as well as that of the flexor tendons of the leg, which are requisite for the motion of the stump. The bursa mucosa is left untouched; and the head of the bone is sawed low enough to avoid creating a risk of caries. But, says Larrey, if this mode of amputating below the knee be compared with amputation of the thigh, as recommended by authors for the cases in which the new method is proposed, the advantages of the latter are considerable. In the first place, life is less endangered, because a smaller portion of the body is removed. The operation is as easy in one situation as the other. The stumps heal with equal facility. Larrey has never seen the spongy part of the tibia become carious, nor perceptibly exfoliate. When the remaining portion of the fibula is very short, as usually happens, it ought to be taken away, as it is a useless body, inconvenient for the employment of a wooden leg. Larrey directs as much skin as possible to be preserved, and making a perpendicular incision through that part of it which covers the tibia, in order to hinder the bone from making its way through it by ulceration.

With a stump thus formed, comprising the knee and one or two finger-breadths of the leg, the patient has a firm point of support, on which he can securely walk without a stick. The stump admits also of an artificial leg of the natural shape being worn, the knee being always bent, provided the length of the stump do not exceed the diameter of the calf of the artificial limb.—(Mém. de Chir. Militaire, t. 3, p. 386—394.) From a passage quoted by Mr. Guthrie, it would seem that Mr. Bromfield (Chir. Obs. and Cases, vol. 1, p. 185) advised amputating as near to the knee as could be done, without risk of cutting the ligament of the patella, so that the stump might not extend beyond the wooden leg. On the whole, Mr. Guthrie's own observations are very favourable to this practice; but he candidly acknowledges his belief, that "it would not succeed when indiscriminately done in the hospitals of large cities," though it may frequently be practised in the army with advantage, provided the surgeon saw through the tibia below its tuberosity.—(On Gun-shot Wounds, p. 223 and 227.) Upon looking over the details of the cases recorded by Larrey in confirmation of the above statement, I was struck with one important fact, which does not justify a part of his commendations; viz. most of the stumps were above four months in healing; and that which healed most quickly was not well before the sixty-eighth day.—(See Mém. de Chir. Mil. t. 3, p. 57. 397, 398, &c.) Hence, unless it be supposed that the wounds produced by amputation below the knee in the ordinary manner are generally thus long in healing, as treated by the French surgeons, the inference is rather unfavourable to the method so highly commended by Larrey, though I am far from wishing to assert that, even if the stumps cannot usually be healed in less time, more than a full compensation for this disadvantage is not obtained by some of the benefits above enumerated. However, in order to be able to pronounce any positive judgment on the merits of this mode of operating, it would be requisite not only to see two or three successful cases just after their cure, but to examine the state of a tolerable number of stumps some time after they had been subjected to the pressure of an artificial leg.

AMPUTATION OF THE ARM.

The structure of the arm is very analogous to that of the thigh: like the latter, it contains only one bone, round which the muscles are arranged. The interior muscles are attached to the os brachii, while the more superficial ones extend along the limb, without being at all adherent. The first consist of the brachialis internus and the two short heads of the triceps; the second of the biceps and long head of the triceps. Hence amputation is here to be done in the same way as in the thigh, unless when we are necessitated to amputate very high up above the insertion of the deltoid muscle. In the arm, says Graefe, the incisions through the muscles should even be made more obliquely upwards than in the thigh, where the muscles are more bulky, by which means two inches of muscle may be saved, besides the retracted integuments; an abundance for covering the stump, were the arm full ten inches in cicumference.—(Normen für die Abl. grösserer Gliedm. p. 109.)

The patient being properly seated, the arm is to be raised from the side, and, if the disease will allow it, into a horizontal position. As I have seen some inconveniences produced by the patient's fainting in the midst of the operation, I join Graefe and some other practitioners in thinking that the patient, if circumstances will allow, should be placed upon a table in the recumbent position.—(Normen für die Ablosung grösserer Gliedm. p. 108.) The surgeon is to stand on the outside of the limb, apply the tourniquet as high as possible, and let the skin and muscles, which he is about to divide, be made tense by the hands of an assistant. The soft parts are next to be divided, as much of the limb being preserved as possible. The retractor is to be applied, the bone sawed with the usual precautions, and the bleeding stopped in the ordinary way, care being taken to leave the radial nerve out of the ligature, which is put round the brachial artery. The wound is then to be closed so as to form a transverse line, the dressings are to be applied, and the patient put to bed with the wound a little elevated from the surface of the bleeding.

In taking off the arm, I entirely coincide with Mr. Guthrie with regard to the uselessness of dissecting back the integuments, a plan long ago renounced by the celebrated Dupuytren, their effectual retraction by an assistant after their complete division being quite enough (On Gun-shot Wounds, p. 354); but, as I have invariably imitated Graefe and others, in making the incisions through the muscles with the edge of the knife turned very obliquely upwards, it has not appeared to me necessary, after cutting down to the bone in this manner, to clear away the muscles from it to the extent of an inch and a half or two inches higher. Instead also of attempting to perform the circular oblique incision through the muscles with one stroke of the knife, the objections to which have been noticed in the description of amputation of the thigh, I have made it a rule to divide the loose biceps muscle as soon as the integuments have been cut and retracted, and of letting it fully recede before the division of the rest of the soft parts is begun.

If the disease should require the arm to be taken off at its upper part, there would be no room for the application of the tourniquet. Here, instead of putting a compress in the axilla, and having it held firmly upon the artery by a bystander, as advised by Sabatier, it is more eligible to make pressure on the artery as it passes over the first rib, of which method I shall speak in treating of amputation at the shoulder-joint. With a straight bistoury the surgeon is now to make a transverse incision down to the bone, a little above the lower extremity of the deltoid muscle. Two other longitudinal incisions,

made along the front and back edge of this muscle, now form a flap, which must be detached, and reflected. Lastly, the rest of the soft parts of the limb are to be divided by a circular cut, made on a level with the base of the flap, and the operation finished like a common amputation.—(Sabatier, Medecine Opératoire, t. 3, p. 375, &c. ed. 2.)

As a matter of choice, and not at all of necessity, the arm may be amputated with two flaps; one anterior, the other posterior. The first should be formed of the skin and biceps, and be three or four inches in length; the other is to be of the same size, and composed of the triceps and integuments. The muscular flesh close to the bone is now to be divided all round, and the saw used. Klein preferred this to the common method, and adopted it in nine cases. So well is the end of the bone always covered, that a protrusion of it is impossible.—(Practische Ansichten der Chirurgischen Operationen, p. 44.)

When the arm is injured very high up, Baron Larrey prefers amputation at the shoulder-joint to preserving a short stump, containing the upper end of the humerus; for, says he, if this bone cannot be divided at least on a level with the tendinous insertion of the deltoid, the stump is retracted towards the armpit by the pectoralis major and latissimus dorsi; the ligatures on the vessels irritate the brachial plexus of nerves; great pain and nervous twitchings, often ending in tetanus, are produced; the stump continues swelled; and, in the end, the humerus is fixed by anchylosis to the shoulder, so that this portion of the arm remains altogether useless, and renders the patient liable to accidents. "I have seen (says Larrey) many officers and soldiers, who, on these accounts, were sorry that they had not undergone amputation at the shoulder."—(Mem. de Chir. Mil. t. 3, p. 53. 400.)

Mr. Guthrie also states, that when amputation by the circular incision is attempted at the insertion of the pectoralis major, the bone will generally protrude after a few dressings. However, he entirely dissents from Larrey respecting the necessity of taking off the limb at the shoulder, and prefers doing it from half an inch to an inch and a half below the tuberosities of the humerus, as the state of the injury may require. Two incisions are to commence one or two finger-breadths below the acromion; and the inner one is to be extended directly across the under side of the limb, till it meets the lower point of the outer wound. Thus the under part of the arm is cut by a circular incision; the upper in the same manner as it sometimes is in removing the limb at the shoulder-joint. Without detaching the skin from the muscles these are cut through; the soft parts are held out of the way of the saw; the bone is sawed; the vessels secured; and the flaps brought together, so as to form a line from the acromion downwards.—(Gun-shot Wounds, p. 337, &c.) I am decidedly of opinion, that, in the description of cases referred to, either this method or Sabatier's operation should be preferred to the removal of the whole limb at the shoulder-joint.

Dupuytren sometimes amputates at the elbow-joint; but as the stump is not more useful than when the operation is done a little higher up, and the wound is frequently long in healing, the method appears hardly to merit a description.

AMPUTATION OF THE FOREARM.

The wisest maxim, with respect to the place for making the incision, is to cut off as little of the limb as possible. This fact is perfectly established, though it is true that Larrey, in consequence of his mode of dressing the stump, has not experienced success in his amputations done in the tendinous part of the forearm. The forearm is to be held by two assistants, one of whom is to take hold of the elbow, the other of the wrist. The tourniquet is to be applied to the lower part of the arm, and the assistant holding the elbow should draw up the integuments, so as to make them tense. The circular incision is then to be made down to the fascia; from this as much skin is to be detached, reflected, and saved, as is necessary for covering the ends of the bones, and the muscles are to be cut on a level with the reflected skin, the knife being at the same time directed obliquely upwards. As many of the muscles are deeply situated between the two bones of the forearm, too much attention cannot be paid to dividing all of them, with a double-edged knife introduced between the radius and ulna.

The soft parts are to be protected from the saw by a linen retractor. It is generally recommended to saw the two bones together, for which purpose the forearm should be placed in the utmost state of pronation. As the radius at the lower part of the forearm is larger than the ulna, it should perhaps be sawed through first, the latter bone, in consequence of its connexion with the humerus, being better adapted to bear the weight of the saw.—(Averill's Op. Surgery, p. 124.)

The ulnar, radial, and two interosseous arteries are those which usually require a ligature.

Graefe removes the forearm by making a flap from the flesh in front of the limb, and then extending the wound quite round the member.—(Normen für die Ablösung grösserer Gliedm. p. 138, &c. 4to. Berlin, 1812.) Mr. Guthrie makes two flaps, one in front, the other on the back of the forearm; but, above the middle of this part of the limb, he prefers the circular incision.—(On Gun-shot Wounds, p. 373, 374.) Dr. Hennen also expresses his approbation of amputating the forearm, so as to make two semilunar flaps (Principles of Military Surgery, p. 265, edit. 2); which is the method recommended and practised by Klein.—(Practische Ansichten bedeutendsten Operationen, Heft 1, p. 45.) Lisfranc also operates in this way at the lower third of the forearm. These flap-operations of the forearm are rather proceedings of choice than of necessity; for I have seen this part of the limb removed in numberless instances by the circular incision, and can hardly remember a case in which the stump turned out badly. In making the inner flap, the radial and ulnar arteries must obviously be in danger of being wounded higher up than the point where they are quite cut through, as Mr. Guthrie candidly acknowledges; an accident which I think might give rise to a great deal of trouble.

With respect to Larrey's preference to amputating in the fleshy part of the forearm, though the case would admit of the operation being done much lower, I need only say, he would find no reason for this choice were he to practise union by the first intention at every opportunity, as is the custom in England.

The hand may be amputated at the joint of the wrist whenever the disease does not extend too high, and a flap can be made of the integuments of the back of the hand. Richerand thinks such an operation sometimes preferable to amputation above the joint.—(Nosogr. Chirurg. t. 4, p. 506, edit. 4.) Lisfranc saves the flap from the palm. The circumstances of the case should of course frequently determine the choice. The amputation may also be done by the circular incision.

AMPUTATION AT THE HIP-JOINT.

The very idea of this formidable operation for a long while checked the hand even of the most ready advocate for the use of the amputating knife, and every mind shuddered at so extensive a mutilation. Still, it could not be denied, that the chance of saving life occasionally depended upon a submission to the greatest temporary suffering, and that, without the most cruel of sacrifices, the preservation of the patient was totally impossible. Dreadful as amputation at the hip appeared, both in respect to the magnitude of the part of the body to be removed, and the extent of the wound caused by such removal, the desperate nature of some cases at length began to incline surgeons to view more dispassionately a scheme, at which the mind at first naturally revolted. Morand is the earliest practitioner who made this severe operation the subject of considerable attention (Opuscules de Chir. t. 1, p. 176, 8vo. 1768); and in the year 1739, two essays on the same topic were communicated to the Royal Academy of Surgery at Paris, by two of his pupils, Volner and Puthod. In 1743, Ravaton wished to have performed amputation at the hip-joint in a case of gun-shot fracture of the trochanter major, and neck of the thigh-bone, but was prevented by the opposition of other surgeons.—(Chir. d'Arm. p. 323, &c.) In 1748, the propriety of attempting the operation was urged by l'Alouette.—(Disp. Chir. Halleri, t. 5, p. 265.) At length, the Royal Academy of Surgery at Paris thought the subject highly deserving of farther investigation, as it appeared to several of its members, that there were circumstances under which its performance might be advisable. In the year 1756, they therefore proposed the following

question, as the grand prize subject: In the case in which amputation of the hip-joint should appear to be the only resource for saving the patient's life, to determine whether this operation ought to be practised, and what would be the best way of performing it? No satisfactory memoirs having been presented, the same subject was proposed in 1759. The approbation of the Academy was now conferred on a paper written by Barbet, in which the propriety of amputating at the hip-joint was defended, and some of the cases demanding the operation specified. If, for instance, a cannon-ball, or any other violently contusing cause, had carried off or crushed the thigh, so as to leave only a few parts to be cut to make the separation complete, he thought a surgeon ought not to hesitate about doing it. The same author conceived that a sphacelus, extending to the circumference of the joint, and destroying the greatest part of the surrounding flesh, might also render the operation equally necessary and easy.—(See Sabatier, Méd. Opératoire, t. 3, p. 271, &c.) Cases were also adduced, where the surgeon completed the separation of the dead parts with a knife. However, this cannot be considered as amputation at the hip-joint. Dividing a few dead fibres was a thing of no importance, in regard to the likelihood of its creating any bad symptoms. The proceeding, in fact, seems to me to have no analogy at all to the bloody operation of taking the thigh-bone out of the socket. It is quite a different thing, when the operator has to cut through parts which bleed profusely, and are endowed with life and sensibility.

In addition to the memoir by Barbet, thirty-three other essays were offered to the academy, the majority of which were filled with arguments in favour of the operation; and, besides these productions, two other memoirs were published at Paris, one by Goursaud in 1758, explaining a new method of operating, and another by Moublet (see Journ. de Médec. an 1759), in which, says Professor Thomson, the operation is very ably considered in all its different relations.—(Obs. made in the Mil. Hospitals in Belgium, p. 260—263.)

Some of the best surgeons of the last and present century condemn the proceeding. The following are Mr. Pott's sentiments: "M. Bilguer and M. Tissot are the only people whom I have met with or heard of in the profession, who speak of an amputation in the joint of the hip as an advisable thing, or as being preferable to the same operation in the thigh." After a quotation or two, he continues; "that amputation in the joint of the hip is not an impracticable operation (although it be a dreadful one) I very well know. I cannot say that I have ever done it, but I have seen it done, and am now very sure I shall never do it, unless it be on a dead body. The parallel which is drawn between this operation and that in the shoulder will not hold. In the latter it sometimes happens, that the caries is confined to the head of the os humeri, and that the scapula is perfectly sound and unaffected. In the case of a carious hip-joint, this never is the fact; the acetabulum ischii, and parts about, are always more or less in the same state, or at least in a distempered one, and so indeed most frequently are the parts within the pelvis, &c.—(Pott on Amputation.) Here it may be remarked, that Pott was right, inasmuch as the operation is totally unjustifiable in disease of the hip-joint, but wrong in not perceiving, that, though unfit for such a case, it might be proper for others. Callisen had difficulty in supposing any circumstances in which the operation could be undertaken with hopes of success.—(Syst. Chir. Hod. p. 418, t. 2, edit. 1800.) And Richerand thinks, that unless the limb be nearly separated by the disease or accident, a prudent surgeon should decline making the attempt.—(Nosogr. Chir. t. 4, p. 519, edit. 4.)

It is a remarkable fact in the history of surgery, that an operation which had been invented in France, and concerning which so much had been written in that country, should have been first actually put in practice in England. "I have been informed (says Professor Thomson), that the operation was performed in London by the late Mr. H. Thomson, surgeon to the London Hospital, and imagine that it must have been his operation to which Mr. Pott alludes."—(Obs. made in the Mil. Hospitals in Belgium, p. 264.) At all events, whether this was the identical case which Mr. Pott saw or not, the example referred to by this distinguished surgeon is the earliest instance of the operation being actually performed. It was even repeated in this country before it was ever practised on the continent, as far as can be made out from the records of the profession; for it was performed by Mr. Kerr, of Northampton, on a girl between eleven and twelve years of age, in a case of diseased hip; a case in which I am now completely satisfied that it ought never to be attempted, for the reason laid down by Mr. Pott. In fact, Mr. Kerr, after removing the limb, found the acetabulum, and all the adjacent parts of the ossa innominata, carious. But the experiment was here rendered still more hopeless by the patient being consumptive. Yet with all these disadvantages, the girl lived till the eighteenth day from the operation, and after death her lungs were found to be a complete mass of disease, one of them being totally reduced to matter.—(See Duncan's Med. Commentaries, vol. 6, p. 337, 8vo. Lond. 1779.) Larrey performed this operation twice in Egypt; and once while he was serving with the French army on the Rhine. He was encouraged to make these attempts to save his patients by the consideration that he had already preserved some lives by amputating either both thighs, both legs, or both arms, or removing the humerus at the shoulder-joint. Larrey has also the true merit of having first done the operation in the only description of cases in which perhaps (with the exception of bad examples of necrosis of the higher part of the femur) it ought ever to be performed; viz. gun-shot injuries of the head, neck, and upper part of the femur, with or without injury of the femoral artery, or where the limb had been carried away by a shell or cannon-ball, too high up to admit of amputation in the ordinary manner. However, he also regards as fit occasions for amputation at the hip-joint circumstances in which, from gun-shot violence, the limb is seized or threatened with gangrene nearly up to the hip.—(Mém. de Chir. Mil. t. 2, p. 185.)

Severe as the operation is, Larrey contends that it is an act of humanity, if it ever is the means of saving lives which are in danger, and he argues that it is justifiable by the old maxim of Hippocrates, "Ad extremos morbos extrema remedia." To the chief objections which have been made to it, he replies, 1st, That the wound is more alarming than dangerous. The Cæsarean operation (says he) has been successfully performed on the living female, and is still recommended by many practitioners. L'Aumonier, principal surgeon of the Rouen Hospital, has successfully removed a scirrhous ovary of considerable size. Examples are recorded of the arm and scapula being torn away, and the patients soon recovering. Besides, the surgeon has it in his power to lessen the wound produced by the operation. 2dly, The dangers of hemorrhage may be obviated by the assistants temporarily placing their fingers on the mouths of the cut vessels, until ligatures can be applied.

In confirmation of his sentiments concerning the propriety of the operation, Larrey adverts to a fact reported by Morand, where a soldier had both his legs amputated very high up, and also both his arms so near the shoulders that he could hold nothing in his armpits. Yet, mutilated as he was, he enjoyed good health.—(Opuscules de Chir. p. 183.) And Larrey, in his own work has recorded several instances in which the whole of a limb was removed, or more than the halves of both the upper or lower extremities of the same subject, without any fatal constitutional disturbance.—(Mém. de Chir. Mil. t. 2, p. 182—184.) One of his patients above alluded to survived the operation a week, at the end of which he was carried off by the plague; and the others died, after being conveyed, in a very uneasy manner, during the precipitate march of the army.—(See Relation de l'Expédition de l'Armée d'Orient en Egypte, &c. p. 319, 8vo. Paris, 1803.) At the battle of Wagram, Larrey operated at the hip-joint on two soldiers of the imperial guard, under very unfavourable circumstances; and the events were fatal in a few hours.—(Mem. de Chir. Mil. t. 3, p. 349.)

Larrey used to operate as follows: he began with making an incision in the track of the inguinal artery in the bend of the groin, and after carefully excluding the nerve, which is more externally situated, he tied this vessel, with the aid of a semicircular curved needle, as closely as possible to Poupart's ligament, in order that the ligature, which was placed above the origin of the circumflex arteries and the profunda, might obviate all inconvenience from the bleeding

which might otherwise happen from their numerous branches. This being done, a straight knife was perpendicularly plunged between the tendons of the muscles attached to the trochanter minor and the base of the neck of the femur, so as to bring out its point at the back part of the limb, or in a diametrically opposite situation to its first entrance; and now, by directing the knife obliquely inwards and downwards, a flap, which was not to be too large, was made of the soft parts at the inner and upper portion of the limb. This flap was now drawn towards the scrotum by an assistant, and the articulation was brought into view. The obturator artery, and some branches of the pudendal, wounded by making the flap, were immediately tied. The thigh was now put into the state of abduction; the inner part of the orbicular ligament made tense by this position, was divided, and the joint opened. The ligamentum teres was then cut, and the bone dislocated. The knife was next brought to the outside of the great trochanter, and an external flap formed of the soft parts, calculated to meet that which had been made at the inside of the limb. In proceeding through the operation, Larrey secured, as soon as they were divided, the obturator arteries, and several branches of the pudendal, gluteal, and ischiatic arteries. The two flaps were brought together and kept in this position with strips of adhesive plaster, and a woollen spica bandage.—(See Mem. de Chir. Mil. t. 2, p. 186—188.)

In the Russian campaign, Larrey had two more opportunities of amputating at the hip-joint. In the first instance he operated upon a Russian at Witepsk, whose thigh-bone was broken to pieces up to the trochanter, and the soft parts of two-thirds of the thickness of the limb destroyed. This man went on as favourably as possible until the 25th day from the operation, the parts being healed except at two points where the ligatures had been brought out; but, unfortunately, a scarcity of provisions now occurred from some neglect or another; and the patient on the 29th or 30th day fell a victim. The second operation was done on a French dragoon, at the battle of Mozaïsk, who was afterward seen perfectly cured by the surgeon-major at Orcha, who received him there, and made a report of the fact to Larrey by letter.—(See Mém. de Chir. Mil. t. 4, p. 26—50, 51, 8vo. Paris, 1817.)

In 1812, M. Baffos, surgeon to the Hôpital des Enfans Malades at Paris, amputated at the hip nearly in the manner of Larrey, except that he only compressed the artery in the groin, and did not begin with tying it, a method to which Larrey himself now gives the preference.—(See Mém de Chir. Mil. t. 4, p. 434.) The patient was a child seven years old, and the case a diseased hip. The patient got well of the wound, but died of scrofula three months afterward. The cotyloid cavity was found full of fungous flesh, and the os innominatum carious. As the latter state always exists in the diseased hip-joint, the whole of the disease does not admit of removal by amputation, and consequently the attempt ought never to be made.—(See Joints, Diseases of.)

The plan of operating adopted by Baffos is considered, I believe, by all surgeons of the present day, better than that formerly advised by Larrey, inasmuch as the objectionable and unnecessary preliminary measure of taking up the artery in the groin, instead of simply compressing it against the os pubis, was rejected. Cutting down to the artery as a precaution against hemorrhage, is doing a double operation and putting the patient to needless suffering: it was the earliest method, having been proposed by Volther and Puthod. Who was the first proposer to press the artery against the os pubis, instead of cutting down to the vessel, I am not at present aware; but I know that it has been publicly recommended by Mr. Abernethy, in his anatomical lectures, for the last thirty years; it is thirty-two years since I began to attend his courses, and in the exhibition of this operation, by the circular incision upon the dead subject, compression of the artery in the groin was then advised, and, as I have stated, not for the first time. Lisfranc is said to complete amputation at the hip-joint upon the dead subject in ten seconds: the following is his method, as described by a modern writer:—The nates of the patient resting on the edge of the table, and the limb being supported by an assistant, the operator draws a line an inch in length, from the anterior and superior spinous process of the ileum, straight down the thigh. From this point he marks another inwards towards the pubes, of half an inch, so as to form a right angle. On the inner extremity of the last he places the point of a long-bladed catling, and pushes it perpendicularly downwards till it strikes against the head of the femur. Then passing it on the outer side of the bone, he thrusts it onwards till it protrudes at about an inch from the margin of the anus. He now cuts outwards, for near an inch, in order to clear the great trochanter, and forms the external flap, four or five inches in length, by cutting down the limb between the muscles and bone. The femoral artery, which may now be seen, is to be compressed between the fingers and thumb of an assistant, while the operator thrusts the knife in and out at the same points as before; but carrying it on the inner side of the head of the bone, he forms a smaller flap on that side of the extremity. He then, with the point of his knife, cuts through the capsular ligament, dislocates the bone, and removes the limb by dividing the round ligament, &c.—(See Averill's Operative Surgery, Lond. 1823, p. 158, &c.; also Maingault, Méd. Opératoire, fol. Paris, 1822.) It is obvious (says Mr. Syme), that as long as the surgeon merely cuts downwards, and keeps close by the bone, he will not injure the femoral artery, which cannot be divided till the knife is carried outwards. This is one great excellence referred by Lisfranc to his operation; for before the surgeon cuts the artery, the assistant can introduce his fingers into the wound and compress the vessel.

The disarticulation is accomplished as follows: the surgeon, seizing the limb with his left hand, while the assistant holds aside the flaps, makes a cut half round margin of the acetabulum at its fore part. The limb is then put in the posture of abduction, the bone starts from its socket, the knife is carried round its head, and the triangular and what remains of the capsular ligament are divided.—(See Ed. Med. Surg. Journ. No. 78, p. 41.)

A very similar method of operating was followed by Professor Von Walther.—(See Graefe and Walther's Journ. Also Anderson's Quarterly Journ. vol. 1, p. 630.)

This method was preferred by Mr. Syme in the very interesting case in which he lately amputated at the hip-joint for an extensive necrosis of the femur, where the neck of the bone was itself diseased. Unfortunately, when the wound was nearly healed, the patient became dropsical, and died at the beginning of the eighth week from the period when his limb was taken off.—(Op. cit. p. 25.)

Langenbeck begins the first incision on the outside of the femoral artery, and forms the external flap by extending the wound towards the tuberosity of the ischium. The knee is then inclined inwards, and the head of the femur dislocated, after which the knife is carried to the inside of the thigh, and the inner flap made.—(Bibl. für die Chir. b. 4, s. 512.)

When serving with the army in Holland in 1814, I assisted the late Dr. Cole in the performance of this operation. The plan adopted by him is the same as that which has been taught by Mr. Abernethy, in his lectures, for more than thirty years. The flow of blood through the femoral artery was stopped by compressing the vessel in the groin with the handle of a key covered with lint. The thigh was then amputated as high as possible, close below the trochanters. The femoral artery was immediately secured, and afterward every other vessel requiring ligature. An incision was now made directly on the acetabulum, and the head of the bone removed with the utmost facility and expedition. The patient lost even less blood than in an ordinary amputation, and the wound admitted of being brought together with adhesive plaster in the best manner possible, so as to represent a transverse line. I am sorry to add, that the patient lived only till the following day. In one dreadful case of fracture of the upper part of the femur by a grape-shot, where the operation had been delayed too long, the whole limb being inundated with matter, and the upper end of the lower portion of the bone projecting through the flesh backwards, I ventured to perform the same operation at Oudenbosch in Holland, a few days after the assault on Bergen-op-Zoom; and here happened what must often occur; immediately the soft parts had been divided, as the bone was broken to pieces, the limb came off, leaving the head of the bone, the trochanters, and

a small piece below them projecting. Had not the man appeared in a very bad way by the time the vessels had been secured, I should now have removed the head of the bone; but the shock of the operation was such, that he survived it but a few minutes, though scarcely any blood was lost. The mode of operating by the circular incision is preferred by Graefe, who unknowingly considers it as a new method.—(Normen für die Abl. grösserer Gliedm. p. 118.) It has also been proposed by Mr. Veitch, with the modification of leaving an inch or two of the bone projecting, which is done without giving any additional pain, by dissecting off the soft parts below the first incisions down to the bone. This projecting piece is intended to serve as a lever, with which the head of the bone is to be got out of the acetabulum.—(Edinb. Med. and Surg. Journ. vol. 3, p. 129.) Ingenious as this suggestion may be, I do not regard it as an important practical improvement; 1st, because in almost all cases, where the operation is necessary, the bone is so fractured that its division is already made by the injury; 2dly, because the scheme is unnecessary; for, in Dr. Cole's case, where I assisted, the head of the femur was removed from the acetabulum with the utmost facility by merely making an incision over that cavity, cutting the ligaments, and availing ourselves of the small piece of bone accidentally projecting. In fact, in all gun-shot injuries, requiring this operation, excepting a few instances of spreading gangrene from wounds, the bone is usually broken too high for Mr. Veitch's method to be practicable. With the same view of facilitating the exit of the head of the bone from the acetabulum, Graefe (p. 123) recommends dividing the transverse ligament which completes the brim of the anterior and inferior side of the socket. From my having once seen one of the first anatomists in London, with a powerful young assistant, and the whole length of the unbroken femur for a lever, baffled for nearly half an hour before he could dislocate the head of the bone, I suppose Graefe's maxim worth recollecting.

Sir Astley Cooper commenced his operation by making an incision just below Poupart's ligament, a little on the outside of the femoral artery. The wound was then carried obliquely downwards and outwards to the back of the thigh, about one-third of the way down it, from which point the knife was carried in the opposite direction, obliquely upwards and inwards to meet the first incision, so as to form an elliptical curve. The femoral artery, being now divided, was immediately tied. The muscles were next cut through, another artery secured, and the bone taken out of its socket. Only about twelve ounces of blood were lost.—(See Lancet, vol. 2, p. 95, &c.)

The following method is recommended by Mr. Scoutteten. The patient is to lie on the opposite side of the body to that on which the operation is to be done. The inguinal artery is to be compressed. The surgeon, standing behind the limb, is to put the thumb or forefinger of his left hand on the great trochanter. With the right he introduces the point of the knife perpendicularly over this process, and then depressing the handle, extends the incision forwards and inwards four finger-breadths below the groin. He then carries the knife round the limb, cutting as deeply as possible, and bringing the knife at length up to the point from which the wound commenced. All the muscular fibres are rarely divided by this first incision, and hence the knife must generally be applied again, ere this first stage of the operation can be completed.

For the purpose of getting at the capsule, the sides of the wound must be kept apart, and any muscular fibres not yet cut, be divided. As soon as it is perceived, it is to be cut through perpendicularly on the head of the femur. The limb is now to be somewhat depressed, and foot turned outwards, whereby the head of the bone is forced nearly out of its socket, and quits it completely as soon as the round ligament is cut, which is the only part by which it is confined. The operator then raises the thigh-bone, so as to make its head project, after which he cuts the rest of the capsule and muscular fibres, and completes the separation of the limb. When the operation is on the left side, the surgeon stands in front of the limb.—(See Scoutteten, Méthode Ovalaire, ou Nouvelle Méthode pour amputer dans les Articulations, Paris, 1827, 4to.)

The variety in the mode of operating is now very considerable. Were I to offer a particular description of every method, my limits would be greatly exceeded. It may suffice, therefore, to refer to Graefe's Journal for an account of the plan which he adopted on the living subject; and though the case had not a fortunate result, the operation itself was very skilfully performed.

Several cases are now recorded, in which amputation at the hip-joint proved successful. The first was that under the care of Mr. Brownrigg, surgeon to the forces, on the twelfth of December, 1812. The upper part of the thigh-bone had been broken by a gun-shot near Merida, in Spain, the 29th of December, 1811. Some time ago, the man was living at Spalding, in Lincolnshire, in perfect health.

The second successful operation was that performed by Larrey, at Witepsk.

The third was done by Mr. Guthrie in the Netherlands on a French prisoner of war, who completely recovered. The fourth is the example in which Sir Astley Cooper amputated at the hip on account of a disease of the higher part of the femur. As the patient had formerly suffered amputation of the thigh, it was certainly not the sudden removal of nearly a quarter of him; but I cannot presume to say, what difference in the chances of success, and whether any, would be connected with the circumstance.

In June, 1824, amputation at the hip was done by Professor Delpech, of Montpellier, on account of a necrosis of the femur, and the patient was completely well in the following September.—(See Revue Medicale.) The operation was also performed by Dr. Mott, of New-York, on the 7th of October, 1824, and the whole of the wound had healed by the 20th of November. This case was a bad fracture of the upper part of the femur, followed by abscesses and disease of the bone.—(See Philadelphia Journal, No. 9, vol. 5, New Series.) The patient's age was favourable, as he was a boy of only ten years of age. At this period of life, the chances of success will always be greater than in adults, not only in consequence of the remedial power of nature being then particularly great, but on account of the smaller dimensions of the wound necessary for the purposes of the operation.

[The following details of this case may prove serviceable to the profession, by showing that the operation may be advantageously attempted in a patient who would otherwise have speedily sunk under his disease. It is moreover interesting from the circumstance of its being the fifth instance in which it was ever successfully performed, and the first amputation at the hip-joint in this country.

"George Byles, a healthy boy, ten years old, broke his thigh about two-thirds of its length from the hip-joint; two days after, splints and bandages were firmly (and injudiciously) applied, which produced great distress, and were removed at the instigation of the boy. Physick's modification of Desault's splint was prepared by the physician then called in, who pointed out to the father, previous to its application, a projecting point on the outside of the thigh, which was the extremity of the superior fragment, which by the improper pressure was nearly forced through the integuments. The bone being properly coaptated, the long splint was then applied.

About three weeks subsequent to this period another physician was called in, who recommended the employment of the inclined plane, which was adopted, the boards forming it having pegs at the side. The boy stated that during his confinement to this inclined plane for several weeks, he had in tossing restlessly about, injured the thigh on the inside just above the condyle, which produced a sinuous opening leading to the fractured bone. It is most probable, however, that the sinus was formed and pointing when it was struck against the peg and opened.

He was brought into the city of New-York on the 7th of September, 1824, at which time we first saw him. His countenance was expressive of much anguish, with a white tongue and feeble pulse; his right limb was much enlarged on the outside, resembling a case of spina ventosa. To the touch it was hard and irregular, was exceedingly tender, and when pressed gave excruciating pain. The swelling extended to the great trochanter, gradually diminishing towards the top of the thigh. Opposite to the greatest enlargement was a sinus, discharging a thin sanious fluid, leading to the middle of the thigh bone, which was perfectly carious.

During two weeks succeeding his arrival in the city, medicines were administered with a view of allaying irritation, and imparting tone to the system, but hectic and night sweats, notwithstanding, supervened. As ulcerations began to occur by the side of the tibia, and all the symptoms became worse, it was resolved to amputate at the hip-joint as the only chance of saving the life of the patient.

On the 7th of October, 1824, the patient, after having passed a comfortable night, was placed upon the table in order to be operated on. An incision was made over the femoral artery as it emerges from under the femoral arch, and the vessel secured by ligature. While feeling on the outside of the artery for the lesser trochanter, the pulsation of a vessel apparently but little smaller than the femoral artery immediately below the ligature, convinced us that in this case the profunda femoris was given off above the femoral arch, as we occasionally find it. This vessel was taken up.

Lisfranc's knife was then introduced between the artery and bone, and carried through close by the neck of the femur towards the tuber ischii, thus forming the inner flap. The external flap was formed by cutting from without inwards. The hemorrhage from the veins and small arteries was considerable when the incisions were made, and numerous vessels were taken up: but comparatively little blood was lost during the operation, and the patient was put to bed shortly after it was completed. After the inner flap was cut, some of the surgical attendants, examining the lesser trochanter, pronounced that the head of the bone was not diseased. In order to satisfy the doubts expressed, the bone was sawed through the lesser trochanter, when it was found to be of the consistence of cheese, being denuded of periosteum on the outer side up towards the joint, and requiring to be removed, which was afterward done, as originally contemplated.

It is scarcely necessary for us to enter into the detail of symptoms and treatment subsequent to the operation, as nothing occurred worthy of note, except various degrees of irritation of the stomach and whole system, previous to the coming away of the ligatures. The treatment consisted in regulating the diet, and administering anodyne and tonic medicines according to circumstances.

On the 15th of October, eight days from the operation, two-thirds of the stump was healed by the first intention. Between the 17th and 31st of October, all the ligatures, seventeen in number, were removed; and by the 20th of November the whole stump was effectually healed, and the boy had become fat and lusty. There can be no doubt but that this limb might have been saved without difficulty, had the proper treatment been instituted when the accident occurred. When it came under our charge, nothing short of the operation above related could have saved this boy's life."—*Reese.*]

Another successful amputation at the hip was performed by Mr. Orten: the disease commenced in the knee; but terminated in extensive disease of the thigh-bone, large abscesses, and dislocation of the knee, the leg being fixed in the bent position, and drawn under the thigh.—(See Med. Chir. Trans. vol. 13, p. 605.)

On the other hand, the failures of this operation are numerous, though undertaken by surgeons of reputation and ability. Mr. Guthrie, Dr. Emery, Mr. Brownrigg, Baron Larrey, Walther, Graefe, Mr. Brodie, Mr. Carmichael (Trans. of the Assoc. Physicians, vol. 3), Drs. Blick and Cole, and many other military practitioners, have had opportunities of amputating at the hip without success.

A calculation has been made, that out of twenty examples of hip-joint amputation, six have had a favourable termination.—(Chelius, Handb. der Chir. b. 2, p. 763.) According to my computations, this account is rather too favourable.

No one can expect, however, this operation not to fail in a large proportion of the cases in which it is attempted; this must always happen, let it be done in the most skilful manner possible. Yet, as there are unquestionably some descriptions of injury, where life must be inevitably lost, if this proceeding be rejected, and experience proves that it sometimes answers, an important consideration is, what cases are most proper for it? Here I am decidedly of opinion with Professor Thomson, that the examples, in which it is particularly called for, and where no delay should be suffered, are those in which the head or neck of the thigh-bone has been fractured by a musket-ball, grape-shot, or small piece of shell. Eight or ten such cases, where amputation ought to have been done in the first instance, were brought in wagons several days after the assault on Bergen-op-Zoom, into the hospital superintended by myself at Oudenbosch, and not one of these patients lived ten days after their removal. In the whole course of my professional life, I have never elsewhere witnessed so much suffering, or suppuration in such profusion. From each limb, I should guess, that at least three or four pints of matter were discharged daily. Had amputation at the hip been performed at first, some of these patients might possibly have been saved; at all events, I am certain that it was their only chance.

Larrey, as I have stated, thinks the operation proper, where the thigh has been shot off high up, or where the femur and soft parts near the hip have been broken, and extensively lacerated by a cannon-ball or pieces of shell. Here the operation (though perhaps the only chance) must almost always fail, because, as Professor Thomson observes, these injuries occasion a shock to the constitution, of which the patient mostly sinks either immediately, or in a few hours.—(Obs. made in the Mil. Hosp. in Belgium, p. 274.) The truth of this observation I saw exemplified at Merxham, near Antwerp, at the bombardment of the French fleet in that port; a shell burst between the thighs of one of the guards; tore and lacerated two-thirds of the thickness of the upper part of the right thigh; broke the ascending ramus of the ischium; lacerated the perinæum and scrotum; and fractured the higher part of the femur. There was no hemorrhage of consequence; but the exposed lacerated surface of the soft parts was immense, and the unfortunate soldier, who lay with his hairs standing erect, and bereft of his intellectual faculties, sunk in the course of a quarter of an hour into a state of insensibility, and was quite dead in twenty minutes. However, there are numerous cases in which the patients, after dreadful injuries of the upper part of the thigh, are less depressed and overcome, and live several weeks; facts clearly proving that the operation ought to be attempted. Many instances of this kind are related by Mr. Guthrie.—(On Gun-shot Wounds, p. 134, &c.) Bad and incurable disease of the upper part of the femur (not the scrofulous hip, nor any other example in which the pelvis is affected) may also require the performance of amputation at the hip-joint, as was recently illustrated in the practice of Mr. Syme, of Edinburgh, and in that of Sir Astley Cooper. The case in which Mr. Carmichael amputated at the hip, was what is termed an osteosarcoma; the patient, a girl 19 years of age, died on the fifth day.—(See Trans. of the King's and Queen's College of Physicians, Ireland, vol. 2, p. 357, &c., and vol. 3, p. 158.) Dr. Mott's case, already referred to, was one of fracture of the upper part of the femur, ending in disease of the bone and extensive abscesses. The disease, for which Delpech operated, was necrosis of the thigh-bone. The propriety of the operation in desperate cases is now perfectly established.

AMPUTATION AT THE SHOULDER-JOINT.

H. F. Le Dran performed the first operation of this kind, of which the particulars are recorded. It was in a case of caries and exostosis, reaching from the middle to the neck of the humerus. Le Dran began with rendering himself master of the bleeding, for which purpose he introduced a straight needle and a strong ligature under the artery. This was passed from the front to the back part of the arm as closely to the axilla and bone as possible. The ligature then, including the vessels, the flesh surrounding them, and the skin covering them, was tightened over a compress. Le Dran, with a straight narrow knife, then made a transverse incision through the skin and deltoid muscle down to the joint, and through the ligament surrounding the head of the humerus. An assistant now raised the arm and dislocated the head of the bone from the cavity of the scapula. This allowed the knife to be passed with ease between the bone and the flesh. Le Dran then carried the knife downwards, keeping its edge always somewhat inclined towards the bone. In this manner he gradually cut through all the parts, as far as a little below the ligature. As there was a large flap, Le Dran made a second ligature with a curved

needle, which ligature included a great deal of flesh, the redundant portion of which was cut off together with the first ligature, which had become useless. The cure was completed in about ten weeks.—(Obs. de Chir. t. 1, p. 315, Paris, 1731; and Traité de Opér. p. 365.) Le Dran (the son), who published this memorable case, does not state that the operation was a new one, and it appears from the Recherches Critiques sur l'Origine, &c. de la Chirurgie en France, and from La Faye's notes on Dionis, that it had been previously practised by Morand, the father.

Garengeot thought that the ligature might be applied by means of a curved needle, with sharp edges; and in order to lessen the wound, he directs the incision to begin two or three finger-breaths below the acromion, across the deltoid muscle, so as to form one flap; then a lower one was made in the axilla; and after the second ligature had been applied, the two flaps were brought into contact.—(Traité des Opér. de Chir. t. 3, p. 350; Mém. de Acad. de Chir. t. 2, p. 261.)

La Faye extended the improvements farther. After placing the patient in a chair, and bringing the arm in a horizontal position, he made, with a common bistoury, a transverse incision into the deltoid muscle down to the bone, four finger-breadths below the acromion. Two other incisions, one in front, the other behind, descended perpendicularly to this first, and made a large flap of the figure of a trapezium, which was detached and turned up towards the top of the shoulder. The two heads of the biceps, the tendons of the supra-spinatus, infra-spinatus, teres minor and subscapularis, and the capsular ligament, were next divided. Now when the assistant who held the lower part of the limb made the bone describe the motion of a lever upwards, the head of the bone was easily dislocated. La Faye next carried his incision downwards, along the inner part of the arm, until he was able to feel the vessels, which he tied as near the axilla as possible. The separation of the limb was then completed a finger's-breadth below the ligature. The flap was then brought down over the glenoid cavity, and the wound dressed. —(See Nouvelle Methode pour faire l'Opération de l'Amputation dans l'Articulation du Bras avec l'Omoplate, par M. La Faye, in Mém de l'Acad. de Chirurgie, tom. 5, p. 195, edit. in 12mo.) With respect to La Faye, it is curious to remark a coincidence between him and Larrey: the latter, though generally averse to the attempt of uniting stumps by the first intention, is an advocate for this practice after hip-joint amputations; so La Faye, who was fearful of laying down the flap after amputation of the leg, had no such apprehension at the shoulder.

La Faye's method is yet regarded as one of the most approved where the state of the soft parts will admit of it. But it is absurd to think of applying any one plan to all the various states in which the injured or diseased limb may present itself. It is advised by Larrey himself, when a wound extends through the upper part of the arm, breaking the bone, and injuring the soft parts. Here, says he, it would be impossible to form an anterior and a posterior flap, for the soft parts in these situations have been destroyed. On the contrary, when the deltoid is shot away, La Faye's plan is inadmissible.—(Mém. de Chir. Mil. t. 2, p. 167.)

The advantages of La Faye's plan are obvious. As only one ligature was applied, the patient was saved a great deal of pain; the flap connected with the acromion was capable of covering the whole surface of the wound, and was more easily applied and kept on the stump than the lowermost of the two flaps which Garengeot recommended; and the discharge found a ready outlet downwards.

Mr. S. Sharp recommended the following plan: "The patient's arm being held horizontally, make an incision through the membrana adiposa, from the upper part of the shoulder across the pectoral muscle down to the armpit; then turning the knife with its edge upwards, divide that muscle and part of the deltoid; all which may be done without danger of wounding the great vessels, which will become exposed by these openings. If they be not, cut still more of the deltoid muscle, and carry the arm backwards. Then, with a strong ligature, having tied the artery and vein, pursue the circular incision through the joint, and carefully divide the vessels at a considerable distance below the ligature; the other small vessels are to be stopped, as in other cases.

"In doing this operation, regard should be had to the saving as much skin as possible, and to the situation of the processus acromion, which, projecting considerably beyond the joint, an unwary operator would be apt to cut upon."—(Operations of Surgery.)

Bromfield used to press the artery against the first rib. His incision began on the inside of the arm, by the edge of the deltoid muscle, as high up as where the pectoralis goes over the axilla to its insertion into the humerus. Cutting through the integuments and muscles, he continued his incision obliquely downwards and outwards, as far as a little below the termination of the deltoid muscle. Then carrying on the incision transversely for a small space in a semicircular direction, the wound was next extended to the external part of the arm, as high up as the fold of the integuments in the axilla. The flap thus shaped, when raised from the humerus, was intended to fill up the axilla, after the removal of the limb. Bromfield's next incision began at the acromion, and being carried through the skin and deltoid down to the bone, terminated in the semicircular incision above described, and it was so guided that it left the outer portion of the divided flap larger than the inner one. Bromfield then passed his knife under the lower edge of the internal half flap, and dissected it up as high as possible. The tendon of the pectoral muscle was thus exposed, under which he now passed his left fore-finger, which served as a conductor to a probe-pointed curved bistoury. With this he now divided the attachment of that muscle to the humerus. If the vessels were not now sufficiently brought into view, he cut through the outer head of the biceps, and tied them (artery and vein) each with two strong ligatures about half an inch apart. The vessels were then cut through in the interspace, and the nerve was divided much higher than the artery. The external flap was now raised sufficiently to expose the joint; and the muscles and capsular ligament having been cut through in the superior and lateral parts, the humerus slipped out of the glenoid cavity immediately the arm was carried a little backwards. Lastly, the ligatures and vessels being held out of the way, the soft parts towards the axilla were divided in a semicircular direction.—(Chir. Obs. and Cases, vol. 1, p. 249—252, 8vo. London, 1773.) The unnecessary tediousness and, I may add, severity of Bromfield's method have long withdrawn from it the approbation of modern operators. The division of the flap into two portions, its extraordinary length, and the painful dissection practised to get at the artery, were serious faults in the operation.

In 1774, Alanson amputated at the shoulder-joint as follows: the subclavian artery was compressed by the fingers of an assistant. An incision was made about a hand's breadth below the acromion, and carried through the integuments all round the limb. The deltoid and posterior muscles were then obliquely divided up to the capsular ligament. The tendon of the biceps and the capsular ligament upon the anterior and posterior part of the joint were now cut through. One of the circumflex arteries, which bled a good deal, was next tied. The great pectoral muscle, the rest of the capsule, and all the other parts except the vessels and nerves were then divided, but previously to cutting the vessels a temporary ligature was put around them. Thus the separation of the limb was completed. The mouths of the vessels were drawn out and tied, and the temporary ligature taken away. Lastly, the sides of the wound were brought together so as to make a transverse line. Graefe, seeming not to recollect that amputation by the circular incision directed obliquely upwards had been practised by Alanson, mentions it as a new proposition. In one case, after operating in this manner, his patient was quite well in three weeks; and with the particular sort of knife which he uses, and which is broadest towards its point, he pretends to be able to make the oblique incision through the muscles all around the limb with one sweep. Of course he is very careful to make pressure on the artery, both with Mohrenheim's compressor applied under the clavicle, and the fingers of an assistant above it.—(See Normen für die Abl. grösserer Gliedm. p. 110, &c.) In proof of the possibility of making the oblique incision quite evenly with one stroke of his particular knife, he injected a female subject, did the operation, and caused the stump to be drawn from nature.—(See Plate ii. of his Work.)

In 1760, P. H. Dahl published at Göttingen a dissertation on amputation at the shoulder. In this tract a

tourniquet was proposed, the pad of which was calculated to press upon the subclavian artery under the clavicle, and enabled the operator to dispense with tying the vessels in the first instance. Camper had observed, that if the scapula were pushed backwards, and the axillary artery pressed with the finger between the clavicle, coracoid process, and great pectoral muscle, the pulse at the wrist might be instantly stopped.

Dahl's tourniquet was obviously constructed in consequence of what Camper had observed. It is made of a curved, elastic plate of steel, to the shortest end of which a pad is attached, capable of projecting farther by means of a screw. The instrument embraces the shoulder from behind forwards, while the pad presses on the hollow under the clavicle, between the margins of the deltoid and pectoral muscles. The long extremity of the steel plate, which descends behind the shoulder, is fixed to the body by a sort of belt. The pad is depressed until the pulsation of the axillary artery is stopped.

Farther experiments have proved, however, that this tourniquet may be dispensed with, and the flow of blood in the axillary artery commanded, by properly compressing this vessel with a pad, or even the fingers alone, as some operators prefer, at the place where it emerges from between the scaleni muscles above the middle part of the clavicle. Thus the artery is pressed between the pad or fingers and the first rib, across which it runs. In certain plans of operation, hereafter to be described, all compression of the artery either above or below the clavicle is dispensed with.

Some practitioners, forgetful of the horizontal posture in which the patient is usually placed after the operation, have feared that in La Faye's method the lower flap may sometimes confine the discharge. In order to avoid this inconvenience, Desault recommended the formation of two flaps, one of which was anterior, the other posterior. The axillary artery was compressed from above the clavicle, at its coming out from between the scaleni muscles, while the integuments and flesh of the upper and internal part of the arm were pushed away from the humerus. A knife was plunged between these and the other soft parts behind, to make the anterior flap. The arm being inclined backwards and outwards, the humeral artery was tied, the articulation opened, and the head of the bone dislocated. The knife was then carried downwards and backwards so as to form the posterior flap, the incisions meeting in the axilla.—(See Sabatier's Médecine Opératoire, t. 3, p. 393—399, ed. 2.)

Larrey, who had frequent opportunities of amputating at the shoulder-joint, aimed at the same object which Desault did; but in his earlier operations, he was in the habit of beginning with the formation of the external or posterior flap, for the following reason: by proceeding in this way, the surgeon can tie the humeral artery more safely, because the ligature is applied after the operation is entirely finished, and consequently at a time when there is nothing to be attended to but the hemorrhage. Thus, the patient being placed on a stool, and well supported, the arm is to be raised from the side, and the axillary artery compressed from above the clavicle. The integuments and other soft parts of the upper and outer parts of the arm are then to be pushed away from the humerus, and the external flap formed. It is now very easy to cut the tendons of the infra-spinatus and teres minor, and open the outside of the joint. The limb is to be carried inwards and luxated backwards. The tendons of the supra-spinatus and biceps are to be divided, and as soon as the head of the bone is out of the glenoid cavity, the knife is to be carried along the internal part of the head and neck of the humerus, with its edge close to the bone. An internal flap, equal to the external one, is to be formed, consisting of a portion of the deltoid, great pectoral, biceps, and coraco-brachialis muscles, and including the brachial vessels and nerves. The artery is to be taken hold of with a pair of forceps, and tied. Any other vessels which require a ligature are also now to be secured. Larrey puts some charpie between the flaps, and brings them towards each other by the usual means.—(See Mém. de Chir. Militaire, t. 2, p. 170.) Of this method of putting charpie to prevent union by the first intention, I entertain the most unfavourable opinion.

When Larrey published his campaign in Egypt, he had operated in this way on nineteen patients, thirteen of whom recovered. But, at a subsequent period, he and his colleagues had amputated at the shoulder, in the above manner, in upwards of a hundred cases, more than ninety of which recovered.—(Mém. de Chir. Mil. t. 4, p. 432, 8vo. Paris, 1817.)

In his latter operations he adopted the innovation of first making a longitudinal incision from the acromion to about an inch below the neck of the humerus down to the bone, so as to divide the fleshy part of the deltoid into two even parts. This cut, he says, facilitates and renders more exact the rest of the operation. From this wound the incisions for the flaps are continued. Having made the foregoing incision, "I direct an assistant to draw up the skin of the arm towards the shoulder, and I form the anterior and posterior flaps by two oblique strokes of the knife made from within outwards and downwards, so as to cut through the tendons of the pectoralis major and latissimus dorsi. There is no risk of injuring the axillary vessels, as they are out of the reach of the point of the knife. The cellular connexions of these two flaps are to be divided, and the flaps themselves raised by an assistant, who, at the same time, is to compress the two divided circumflex arteries. The whole joint is now exposed. By a third sweep of the knife, carried circularly over the head of the humerus, the capsule and tendons running near the articulation are cut; and the head of the bone being inclined a little outwards, the knife is to be carried along its posterior part in order to finish the section of the tendinous and ligamentous attachments in that direction. The assistant now applies his fore-fingers over the brachial plexus, for the purpose of compressing the artery, and commanding the current of blood through it. Lastly, the edge of the knife is turned backwards, and the whole fasciculus of axillary vessels is cut through, on a level with the lower angles of the two flaps, and in front of the assistant's fingers. The patient does not lose a drop of blood; and ere the compression is remitted, the extremity of the axillary artery is readily seen, taken up with a pair of forceps, and tied. The circumflex arteries are next secured, which completes the operation."—(Mém. de Chir. Mil. t. 4, p. 428, Paris, 1817.) In addition to these important deviations from his earlier method, he subsequently preferred bringing the flaps together with two or three straps of adhesive plaster, and interposes no charpie.—(P. 429.) It should be observed also, that he lays no stress on first making the outer flap, though, from the description, it does not exactly appear which flap he now begins with. He has changed likewise, on another point of importance, viz. instead of preferring La Faye's plan in certain examples already specified, he affirms that the above-described way of operating is applicable to almost every case met with in military practice. First, because all gun-shot wounds, generally, which mutilate the arm so as to create the necessity for the operation, partly or entirely destroy the centre of the deltoid, while there is always enough flesh left at the sides for making the two flaps. Secondly, because, in the very rare instances where the lateral parts of the shoulder are destroyed, and the middle untouched, no advantage would be gained by operating in La Faye's manner, as Larrey conceives that the detached flap would slough, or become, as he terms it, disorganized. He now prefers dividing the middle piece of flesh, and giving the flaps the same shape as if they were uninjured. He even asserts, that the operation, done without any flaps at all, answers better than any method in which the surgeon preserves flaps not naturally intended for the part. Thus, when all the flesh of the shoulder has been shot away, he has seen surgeons cover the glenoid cavity with a flap saved from the soft parts of the axilla; but such flaps invariably sloughed, hemorrhages ensued, and the patients died.—(P. 430—431.) Some of these latter observations are, clearly enough, the result of great partiality to a particular method of operating; because who can doubt, when the lateral parts of the shoulder are injured, as they frequently are (and not very rarely, as Larrey asserts), by the passage of a musket-ball through the shoulder, from before backwards, that the right method is that of La Faye; or the same operation, with the slight difference of making the flap of a semicircular shape? It was for cases of this description that Mr. Collier and I operated after La Faye's plan, with perfect success, after the battle of Waterloo; and a poor fellow of the

rifle brigade, who was brought in too late for operation, and died of sloughing, had his shoulder injured in the same way, the middle of the deltoid being untouched, and shot-holes existing behind, and in front of, the articulation. But if it required any farther arguments to prove, that Larrey is wrong in wishing to extend his, or rather Desault's method, to all cases, I might criticise his assertions about the sloughing of the flap, when it is not cut into two portions, and its preservation by the singular expedient of making a division of it, and, of course, injuring it still more than it may have been injured underneath by the bullet. The cases, however, which have fallen under my own personal observation, and numerous others on record, furnish an adequate proof, that excellent as Larrey's method is for many cases, La Faye's answers very well in others. Thus, in an example where a Prussian hussar had had his arm amputated, and a projection of the bone took place, to the extent of three inches, with hospital gangrene commencing in the stump, Klein felt obliged to remove the limb at the shoulder. He operated in La Faye's manner; the separation was finished in one minute; and on the eighteenth day the stump was perfectly healed.—(See Practische Ansichte Chir. op. h. 1, p. 1—10, 4to. Stuttgart, 1816.) The same practitioner had five other secondary amputations of the same kind; but one patient was afterward carried off by hemorrhage, and another by hospital gangrene. Klein, however, in common with the majority of army surgeons, considers the idea of applying any one plan of operating to different cases, totally absurd.—(P. 12.) After the storming of St. Sebastian's, nine shoulder-joint amputations were done with success; seven of them by raising the deltoid as a flap.—(See Guthrie on Gun-shot Wounds, p. 108.)

After the battle of Waterloo, I adopted La Faye's plan; but with this difference, that I did not cut the brachial artery till I made the last stroke of the knife, which separated the limb; and consequently I did not tie that vessel till the time when I had nothing but the hemorrhage to occupy my attention. The circumflex arteries, however, I tied as soon as the external flap was made. The modification of thrusting a knife under the deltoid, quite across the shoulder, and making the flap by cutting downwards, until the instrument comes out again through the skin, is practised by some surgeons of eminence.—(Klein, Lisfranc, &c.) An excellent lithographic plate illustrative of this last method is given by Maingault, pl. 4, fig. 17.—(See Méd. Opérat. p. 24, fol. Paris, 1812.)

When the state of the integuments will permit the choice, Mr. Guthrie thinks their preservation best effected by Larrey's first method; but he particularly insists upon the advantage of raising the shattered arm or stump to nearly a right angle with the body before the operation begins, and even before the assistant makes pressure on the subclavian artery, as some change in the mode of accomplishing the latter object might be rendered necessary by elevating the limb during the operation itself. Mr. Guthrie commences the first incision immediately below the acromion, and, with a gentle curve, extends it downwards and inwards, through the integuments only, a little below the anterior fold of the armpit. The second incision outwards is made after the same manner, but is carried rather farther down, so as to expose the long head of the triceps at the under edge of the deltoid. The third incision, commencing at the same spot as the first, but following the margin of the retracted skin, divides the deltoid on that side down to the bone, and exposes the insertion of the pectoralis major, which must be cut through. This flap is now to be raised, so as to expose the head of the bone. The fourth incision outwards divides the deltoid muscle down to the bone, when the posterior flap is to be well turned back, so as to bring into view the teres minor and infra-spinatus passing from the scapula to the great tuberosity of the humerus. The outer and inner flap being now raised, the head of the bone may be rolled a little outwards, the teres minor and infra-spinatus cut, and an opening made into the joint. The capsular ligament, supra-spinatus, and long head of the biceps are then divided. The inner side of the capsule is now cut through, together with the subscapularis muscle, as it approaches its insertion into the lesser tuberosity of the humerus. The long head of the triceps is next divided, and lastly, with one sweep of the knife, the rest of the soft parts are cut, together with the axillary artery, veins, and nerve.—(On Gun-shot Wounds, p. 274—276.) Larrey, in his latest method, takes no measures in the first stage of the operation for commanding the flow of blood, as the assistant merely presses the axillary artery between his fingers just before it is divided.

Some of the modern French surgeons were earlier than Larrey in dispensing with the compression of the axillary artery, and following a method which renders it unnecessary. Richerand, for instance, describes nearly the same plan as that advised by La Faye; but after making the deltoid flap, cutting the tendons, and dislocating the bone, he dissects down close to the inside of the humerus, so as to enable an intelligent assistant to put his thumb on the cut surface behind the artery, which, with the aid of the fingers applied to the skin of the axilla, can then be grasped and compressed so as to command the flow of blood through the vessel. The operator now, fearless of hemorrhage, completes the internal or inferior flap.—(Richerand, Nosographie Chir. t. 4, p. 509—511, edit. 4.)

Baron Dupuytren amputates at the shoulder, in a manner which seems principally commendable on account of its celerity. The arm being raised and held at a right angle with the trunk, Dupuytren stands at the inside of the limb, with one hand grasps and elevates the mass of the deltoid muscle, and plunges under it a two-edged knife, from before backwards, on a level with the end of the acromion. Cutting in this way close to the head of the humerus, he continues the incision downwards between this bone and the deltoid, and at length, bringing out the knife, completes the external or superior flap. The rest of the operation does not essentially differ from Richerand's, except that Dupuytren takes hold of the lower flap itself, before dividing it, and compresses the artery until he has cut through it and tied it.

Dupuytren's plan would be difficult on the left side, unless the surgeon were an ambidexter; but, in other respects, it cannot be found much fault with. This surgeon has also proposed making one flap in front, and the other behind, in order to prevent the lodgement of matter. Richerand justly observes, however, that frequently a good deal of the wound unites by the first intention, and that as the patient after the operation lies in the recumbent posture on an oblique plane, he cannot see what advantage one way of making the flaps has over another, in regard to affording a ready issue to the discharge.—(Op. cit. p. 515.)

For the sake of celerity, of which the French are rightly admirers in all capital operations, another plan of amputating at the shoulder has been proposed by Lisfranc. Supposing the left extremity is to be removed, the patient is placed on an elevated seat, one assistant pressing the artery against the first rib, while another draws the arm forwards: the operator, standing behind the patient with a long-bladed catling, pierces the integuments on the inner edge of the latissimus dorsi muscle, opposite the middle of the axilla, and pushes it obliquely upwards and forwards, till its point strikes against the under surface of the acromion; then, by raising the handle of the knife, its point is lowered, and protruded just in front of the clavicle at its junction with the acromion. By cutting downwards and outwards, he then forms a flap from the superior and posterior part of the arm, including the whole breadth of the deltoid muscle, and a part of the latissimus dorsi. This being held back by the assistant, the joint is cut through from behind forwards, and a corresponding flap is formed by cutting downwards and outwards, between the muscles and bone, on the inner side of the arm. When the operation is on the right side, the patient should be seated on a low chair, and the catling thrust from above downwards, from the part just in front of the point where the clavicle is connected with the acromion, the surgeon raising his hand as the instrument proceeds downwards and backwards, until its point has come out at the inner edge of the latissimus dorsi, when the flap is to be made, and the operation finished as above directed.—(See Averill's Operative Surgery, p. 135. Also Lisfranc de St. Martin, et Champesme, Nouveau Procedé Opératoire pour l'amputation du bras dans son articulation scapulo-humerale. Paris, 1815.)

Speaking of this mode of operating, Richerand remarks; "en l'employant, on parvient à desarticuler

l'humérus, et à séparer le bras en aussi peu de temps qu'en met un habile découpeur à détacher l'aile d'un perdrix."—(P. 514.)

The last method which I shall describe is that of M. Scoutteten. It is done on the left arm, as follows:—The surgeon first takes hold of the middle of the arm with his left hand, and raises it four or five inches from the side. With his right hand he then applies the point of the scalpel immediately below the acromion, and passes it into the flesh until it touches the head of the humerus. He then depresses the handle, and forms the first incision, which extends downwards four inches from the point of the acromion, and divides the posterior third of the deltoid, and the greater part of the fibres of the long portion of the triceps down to the bone. The second incision is next commenced with the point of the knife directed downwards upon the inner side of the limb, and in front of the biceps, on a level with the place where the first incision ended. The wound is then extended inwards and upwards to the acromion, where it terminates by joining the first. These two wounds form a triangle, which partly consists of relinquished integuments, and has its base downwards.

In order to find the joint with greater ease, the surgeon may now detach a little of the deltoid from the bone. An assistant can also keep the edges of the incision asunder, so that the operator may be enabled to see and divide the capsular ligament, and the tendons of the supra-spinatus, infra-spinatus, and teres minor, which are inserted into the greater tubercle of the humerus, and the tendon of the subscapularis, which is inserted into the lesser tubercle. The operator, who constantly keeps hold of the arm, now communicates to it some rotatory movements, in order to bring the above tendons, one after another, under the knife, and divide them with the capsule. Immediately the capsule and tendons have been cut through, the head of the bone readily quits its socket. The surgeon luxates the bone by pushing it a little upwards, and, at the same moment, inclining the condyles towards the side. The next proceeding is to divide the flesh on the inner side of the limb as closely as possible down to the bone; but when the knife approaches the artery, this vessel is to be taken hold of and compressed by an assistant, before the incision is completed. In this way, no hemorrhage need be apprehended.

When it is the right limb, the only difference is, that the first incision is made at the inner side of the arm, and extended up to the acromion. Scoutteten considers a single assistant sufficient, and compression of the subclavian artery unnecessary.—(H. Scoutteten, La Méthode Ovalaire, ou Nouvelle Methode pour amputer dans les Articulations, Paris, 1827, 4to.)

When the scapula is shattered, of course the loose fragments should be taken away, and if the acromion be broken, and the remnant of it pointed and irregular, this sharp rough portion should be sawed off, as was practised long ago by M. Faure.—(See Mém. de l'Acad. de Chir. t. 6, p. 114.) In one case, indeed, Larrey found it necessary to take away more than two-thirds of the scapula, and the humeral end of the clavicle.—(Mém. de Chir. Mil. t. 4, p. 432.) Sawing off part of the acromion and coracoid process, as a general rule, seems to me quite unnecessary (see Fraser on the Shoulder-joint Operation, 8vo. Lond. 1813) and improper, not only as producing delay, but wounding other parts which should not be at all disturbed.—(See Guthrie on Gun-shot Wounds, p. 285, 286, &c.) The practice of scraping away the cartilage of the glenoid cavity, except when it is diseased, is not of greater value.

Amputation at the shoulder has been partly superseded by a preferable operation, even in cases in which it would formerly have been deemed quite indispensable; such as considerable gun-shot fractures of the head of the humerus, a caries of the substance of this part, &c. Boucher, in 1753, proved that considerable wounds extending into the shoulder-joint might be successfully treated by extracting the fragments and splinters of bone.—(Mem. de l'Acad. de Chir. t. 2, p. 287 et 461.) Instances are also recorded, in which, when the head and neck of the humerus in children had been totally disunited from the body of that bone, a cure was accomplished by making such incisions as allowed the portions of bone, now become extraneous bodies, to be taken away. The earliest case of this kind on record is that in which M. Thomas, a surgeon at Pezenas in Languedoc, removed the separated head of the humerus in 1740, which in a child four years of age presented itself loose in an incision which had been previously made for the extraction of some sequestra. The particulars may be read in Guthrie's valuable work.—(On Gun-shot Wounds, p. 215, &c.) Mr. White of Manchester proceeded farther, for he made a deep incision at the upper part of the arm, dislocated the head of the humerus, which he knew was carious, and pushing it through the wound took it off with a saw. He began an incision at the orifice of a sinus situated just below the processus acromion, and extended the wound down to the middle of the humerus, by which all the subjacent bone was brought into view. He then took hold of the patient's elbow, and easily forcing the upper end of the humerus out of its socket, he brought it so entirely out of the wound that he readily grasped it in his left hand, and held it there till he had sawed it off with a common amputation saw, having first applied a pasteboard card between the bone and the skin. The patient did not lose more than two ounces of blood, only a small artery which partly surrounded the joint being wounded, which was easily secured.

In about five or six weeks, the part from which the bone had been taken had acquired a considerable degree of firmness, and the boy was able to lift a pretty heavy weight. At the end of two months, a large piece of the whole substance of the humerus was ready to separate from the sound bone, and with a pair of forceps it was easily removed. After this exfoliation the wound healed very fast, and in four months after the operation, the boy was discharged perfectly cured. On comparing this arm with the other, it was not quite an inch shorter; the boy had the perfect use of it, and could not only elevate his arm to any height, but perform the rotary motion as well as ever. The figure of the arm was not at all altered. Mr. White did not make use of any splints, machine, or bandage, during the cure, in order to confine the limb strictly in one certain situation, nor was the patient's arm ever dressed in bed, but while he was sitting in a chair, and as soon as he could bear it standing up. To this method, Mr. White attributed the preservation of the motion of the joint.

"As this is the first operation of the kind that has been performed, or at least made public (says Mr. White), I thought the relation of it might possibly conduce to the improvement of the art. That ingenious surgeon Mr. Gooch, has indeed related three instances of the heads of bones being sawed off in compound luxations. In one of these cases the lower heads of the tibia and fibula were sawed off; in another, that of the radius; and in the third, that of the second bone of the thumb; but these were in many respects different from the present case. I believe it will seldom happen, that this operation will not be greatly preferable to amputation of the arm at the scapula, as this last is generally performed for a caries of the upper head of the os humeri, and as the preservation of a limb is always of the utmost consequence, and what every surgeon of the least humanity would at all times wish for, but particularly where, as in this case, the whole limb and its actions are preserved entire, the cure no ways protracted, and the danger of the operation most undoubtedly less. For though amputation is often indispensably necessary, and frequently attended with little danger or inconvenience when only part of a limb is removed, yet when the whole is lost, the danger is greatly increased, and the loss irreparable." Mr. White concludes with suggesting an analogous operation for removing the head of the femur, in lieu of amputation at the hip. Something of this kind is indeed reported to have been actually done on a girl with success.—(See Joannis Mulder Oratio de Meritis P. Camperi, &c. p. 81. Cases in Surgery, by C. White, p. 57; or Phil. Trans. vol. 59, for 1769.)

Here, however, the acetabulum and ossa innominata being always, or generally, more diseased than the head of the femur, neither of these operations, I think, ought to be attempted. Long after the publication of White's case, viz. in 1767, an example, in which Vigaroux adopted the same practice, in 1788, was communicated to the profession: the result, however, was unfortunate, the patient, a lad seventeen years of age, having died soon after the experiment.—(See Œuvres de Chir. Prat. par I. M. I. Vigaroux (fils), Montp. 1812.)

Mr. Bent, of Newcastle, inserted a similar case to Mr. White's in the 64th vol. of the Philosophical Transactions. White made only one incision, from the vicinity of the acromion down to the middle of the arm. Bent, not being able to get at the head of the bone through the wound which he had made, from the clavicle to the attachment of the pectoral muscle, detached a portion of the deltoid where it is connected with the clavicle, and another part where it is adherent to the humerus. A third successful case is also reported in the 69th vol. of the same work, p. 6. Afterward, Bromfield published some directions for the guidance of the surgeon in such operations.—(Chir. Obs. and Cases.) Sabatier proposed making two cuts at the upper part of the arm, which meet below like the letter V, extirpating the flap, dividing the inner head of the biceps and capsular ligament; dislocating the head of the bone, and sawing it off.—(Médecine Opératoire, t. 3.)

I think the cases recorded by White and Bent are truly important, inasmuch as they are the earliest models of a practice which may sometimes supersede all occasion for one of the most formidable and mutilating operations of surgery. To military and naval surgeons, these cases cannot fail to be highly interesting, as they must have frequent opportunities of availing themselves of the instruction which they afford. Larrey, who was surgeon-general to the French army in Egypt, employed the practice with the greatest success, in cases of gun-shot wounds. He thereby saved limbs, which, according to ordinary precepts and opinions, would have been a just ground for amputating at the shoulder; and when it is considered, not only that a most dangerous operation is avoided, but that an upper extremity is saved, for which no substitute can be applied, we must allow that the plan, first suggested and practised by Mr. White, cannot be too highly appreciated. When the arm was fractured near its upper extremity by a musket-ball, most surgeons formerly deemed it necessary to amputate the limb. Here, says Larrey, it would be useless to dilate the entrance and exit of the ball, because a sufficient opening could not be prudently made in this way for the extraction of the head of the bone. Yet this body is now an extraneous substance, having lost its connexion with the shaft of the humerus, and its presence exciting irritation and inflammation of the joint, abscesses, necrosis, &c. Here Larrey seems to imply, that the detached head of the bone cannot unite again; an assertion which, I have no doubt, is quite incorrect, as I have attended several cases in which the humerus was broken very high up, yet united without difficulty. The bad symptoms, which he so emphatically attributes to the detachment of the head from the body of the bone, are in reality the effects of the gun-shot violence itself. If, therefore, the head of the bone were merely broken off, and it and the neighbouring part of the bone not splintered, nor the flesh not more extensively injured than would arise from the passage of a musket-ball, and the joint itself not involved, I should question the propriety of having recourse, at once, either to the extraction of the head of the bone, or amputation at the shoulder. When the bone is shattered the case is often very different, and Larrey's practice is then commendable. In confirmation of these sentiments, I may mention Mr. Guthrie's opinion, who, in reference to the extraction of the head of the bone, says, he does not consider a perfect fracture of the humerus an inch below its head (although there be evident separation) as demanding even this operation, as he has known such cases do well when treated as other compound fractures, except that the motion of the joint was nearly lost.—(On Gun-shot Wounds, p. 329.) However, it is fair to mention that Mr. Guthrie inclines to amputation at the shoulder when the body of the bone is splintered or has long fissures in it, in which sentiment he is probably right. The other operation seems principally calculated for cases in which the damage is restricted to the head and uppermost portion of the bone.

According to Mr. Guthrie, when the ball passes out with little injury to the bone, and the openings already made are not sufficient to admit of a moderate examination with the point of the finger, the wound should be enlarged. However, others might argue, that such dilatation should be made only when the bone is felt to be seriously broken, and the fragments will probably require immediate removal. But whatever course be adopted, the most rigorous antiphlogistic treatment will be proper; and if abscesses form, depending openings should be made for the discharge.

Larrey says, "I have had the good fortune on ten different occasions to supersede the necessity for amputation at the shoulder, by the complete and immediate extraction of the head of the humerus or its splinters without delay. I perform the operation in the following manner: I make an incision in the centre of the deltoid muscle, and parallel to its fibres, carrying the incision as low down as possible. I get the edges of the wound drawn asunder, in order to lay bare the articulation, of which the capsule is generally opened by the first incision, and by means of a probe-pointed bistoury I detach with the greatest ease from their insertions the tendons of the supra and infra-spinati, of the teres minor, of the subscapularis, and of the long head of the biceps; then I disengage the head of the humerus, and remove it through the wound in the deltoid by means of my fingers or of an elevator. I bring the humerus up to the shoulder, and fix it in a proper position with the aid of a sling and a bandage. Such is the operation which I performed on ten patients in extirpating the head of the humerus; one of these died of the hospital fever, two of the scurvy at Alexandria, and the fourth, after he was cured, died of the plague on our return to Syria. The rest returned to France in good health. In some the arm became anchylosed to the shoulder, and in others an artificial joint, allowing of motion, was formed."—(See Mem. de Chir. Militaire, t. 2, p. 175.) Another successful case of the same kind was published by Mr. Morel.—(See Medico-Chirurg. Trans. vol. 7, p. 161.)

Mr. Guthrie thinks it not sufficient to make a simple incision through the deltoid muscle into the capsular ligament, and take away the fragments of bone, but urges the removal at the same time of a considerable part of the capsular ligament, lest disease still go on in the joint. Also, as it is impossible to know beforehand in what state the bone may be below the fracture (that is, with respect to fissures running more or less down it), he advises the incision designed for the extraction of the splintered head of the bone, to be made in a situation where, if amputation at the joint be found indispensable, it will be of advantage. Mr. Guthrie likewise describes the manner of turning out the head of the bone in these cases, and sawing it off; the necessity of which, however, I do not clearly comprehend, unless the taking away of any sharp spicula of the upper end of the body of the bone be implied, which may be right.—(On Gun-shot Wounds, p. 333—335.) My ideas, however, chiefly extend to the removal of loose fragments and splinters; and with respect to sawing off the head of the bone, this is a proceeding, I suppose, necessarily limited to the kind of cases reported by Mr. White and Mr. Syme.—(Edinb. Med. and Surgical Journ. No. 88, p. 49.)

In Mr. Syme's example the head of the humerus was diseased. A perpendicular cut was made from the acromion through the middle of the deltoid, extending nearly to its insertion. A similar incision was then made upwards and backwards from the lower end of the first wound, and a large flap formed from the back portion of the deltoid, "which being held up, exposed the joint so far, that (says Mr. Syme) I was able to insulate the head of the bone by means of my finger, and then to detach the scapular muscles from their connexions with the tuberosities, when, the arm being brought forwards, I easily protruded the head of the humerus, embraced it in my left hand, and sawed it off without any injury to the other parts."—(Op. cit. p. 51.) A portion of the acromion, being diseased, was removed with the cutting plyers. From what has been stated, it may be inferred, that when the object is merely to extract splinters, a single perpendicular incision will suffice; but that when the joint is diseased, and the head of the bone requires to be sawed off, the operation will be much facilitated by following the plan adopted by Mr. Syme. In this gentleman's case the patient recovered, and the shoulder had motion in every direction.

Walther first demonstrated on the dead body the practicableness of amputating the scapula; and in one case, where this bone was inseparably connected with a tumour, the greater part of it was successfully removed by Haymann.—(See Walther in Journ. für Chir. b. 5, p. 274; and Haymann, vol. cit. p. 509.) The par-

neulars are also detailed by Chelius.—(Handb. der Chir. b. 2, p. 759.)

AMPUTATION OF THE HEADS OF BONES.

In a letter to Mr. Pott, dated 1782, Mr. Park, surgeon to the Liverpool Hospital, made the proposal of totally extirpating many diseased joints, by which the limbs might be preserved, with a share of motion that would still allow them to be very useful.

Mr. Park's scheme, in short, was to remove entirely the extremities of all the bones, which form the diseased joint, with the whole or as much as possible of the capsular ligament; and to obtain a cure by means of callus, or by uniting the femur to the tibia, when the operation was done on the knee; and the humerus to the radius and ulna, when it was done on the elbow; so as to have no moveable articulation in those situations.

In order to learn whether the popliteal vessels could be avoided without much difficulty in the excision of the knee, Mr. Park made an experiment on the dead subject. An incision was made, beginning about two inches above the upper end of the patella, and extending about as far below its lower part. Another one was made across this at right angles, immediately above the patella, down to the bone, and nearly half round the limb, the leg being in an extended state. The lower angles formed by these incisions were raised so as to lay bare the capsular ligament; the patella was then taken out; the upper angles were raised, so as fairly to denude the head of the femur, and to allow a small catling to be passed across the posterior flat part of the bone, immediately above the condyles, care being taken to keep one of the flat sides of the point of the instrument quite close to the bone all the way. The catling being withdrawn, an elastic spatula was introduced in its place, to guard the soft parts while the femur was sawed. The head of the bone, thus separated, was carefully dissected out; the head of the tibia was then with ease turned out and sawed off, and as much as possible of the capsular ligament dissected away, leaving only the posterior part covering the vessels, which on examination had been in very little danger of being wounded.

The next attempt was on the elbow: a simple longitudinal incision was made from about two inches above to the same distance below the point of the olecranon. The integuments having been raised, an attempt was made to divide the lateral ligaments, and dislocate the joint; but this being found difficult, the olecranon was sawed off, after which the joint could be easily dislocated without any transverse incision, the lower extremity of the os humeri sawed off, and afterward the heads of the radius and ulna. This appeared an easy work; but Mr. Park conceives the case will be difficult in a diseased state of the parts, and that a crucial incision would be requisite, as well as dividing the humerus above the condyles, in the way done with respect to the thigh-bone.

Mr. Park first operated, July 2, 1781, on a strong, robust sailor, aged 33, who had a diseased knee, of ten years' standing. The man's sufferings were daily increasing, and his health declining. Mr. Park wished to avoid making the transverse incision, thinking that, after removing the patella, he could effect his object by the longitudinal one; but it was found that the difference between a healthy and diseased state of parts deceived him in this expectation. Hence the idea was relinquished, and the transverse incision made. The operation was finished exactly as the one on the dead subject related above. The quantity of bone removed was very little more than two inches of the femur, and rather more than one inch of the tibia. The only artery divided was one on the front of the knee, and it ceased to bleed before the operation was concluded, but the ends of the bones bled very freely. In order to keep the redundant integuments from falling inwards, and the edges of the wounds in tolerable contact, a few sutures were used. The dressings were light and superficial, and the limb was put into a tin case, sufficiently long to receive the whole of it, from the ankle to the insertion of the glutæus muscle.

I shall not follow Mr. Park throughout the treatment. Suffice it to remark, that the case gave him a great deal of trouble, and that it was attended with many embarrassing circumstances, arising chiefly from the difficulty of keeping the limb in a fixed position, the great depth of the wound, and the abscesses and sinuses which formed. On the other hand, however, the first symptoms were not at all dangerous. But the patient was obliged to keep his bed nine or ten weeks, and it was many months more before the cure was complete. The man afterward went to sea, and did his duty very well.

Subsequently to the publication of the letter to Mr. Pott, another excision of the knee was done by Mr. Park, on the 22d of June, but the event was unsuccessful, as the patient lingered till the 13th of October, and then died.

In 1782, P. F. Moreau presented to the French Academy of Surgery a memoir proposing the excision of carious joints. It only seems necessary to notice here the difference in Moreau's plan of operating from that adopted by our countryman. Moreau, the son, who has published the account, observes, that the multiplicity of flaps is unnecessary, as two answer every purpose; and he deems Mr. Park's direction to remove the olecranon, if this be free from caries, at least useless. Moreau junior operated on the elbow as follows: with a dissecting scalpel he cut down to the sharp edge or spine of the inner condyle of the os humeri, about two inches above its tuberosity; and, directed by the spine, he carried the incision down to the joint. He did the same on the other side, and then connected the two wounds by a transverse incision, which divided the skin and the tendon of the triceps immediately above the olecranon. The flap was dissected from the bone, and held out of the way by an assistant.

The flesh which adhered to the front of the bone above the condyles was now separated, care being taken to guide the point of the instrument with the forefinger of the left hand, and when the handle of the scalpel could be passed through between the flesh and the bone, M. Moreau allowed it to remain there, and sawed the bone through upon it. The removal of the piece of bone was next finished, by detaching it from all its adhesions. The removal of the heads of the radius and ulna remaining to be done, was more difficult, and the first flap being insufficient, it became necessary to make another. The lateral incision, at the outer side of the arm, was extended downwards, along the external border of the upper part of the radius. The head of the radius was separated from the surrounding parts; its connexion with the ulna destroyed, and a strap of linen was introduced between the bones, in order to keep the flesh out of the way of the saw. The radius was sawed through, near the insertion of the biceps, which was fortunately preserved. Some remaining medullary cells, filled with pus, were removed with a gouge. The ulna was now exposed, by extending the lateral incision on the inner side of the arm. Thus another flap was made, and detached from the back part of the forearm, and that portion of the bone which it was wished to remove. The bone being separated from every thing that adhered to it, and a strap of linen put round it to protect the flesh, about an inch and a half of it was sawed off, measuring from the tip of the olecranon downwards. A few diseased medullary cells were taken away with the gouge. Two or three vessels were tied, and the flaps were brought together with sutures. In a fortnight this man became so well, that he was allowed to go wherever he pleased, with his arm supported in a case. The arm was at first powerless, but it slowly regained its strength, and the man could ultimately thrash corn and hold the plough with it, &c.

Seven months after another operation, performed in the same way as the preceding one, by Moreau the father, the patient was completely cured, and two years after this period the flexion of the forearm on the arm was very distinct. In another case only one longitudinal incision and a transverse one were made, the flap being of course triangular. The patient got well in six weeks, and in three months more joined his regiment.

In all Moreau's cases, the flexion and extension of the forearm were preserved, which circumstance no doubt depended very much on the insertion of the biceps not being destroyed. After the excision of the knee, however, the bones grew together.

Moreau junior's method of operating differed from his father's, inasmuch as the patient was in a recumbent instead of a sitting posture, and the os humeri sawed before it was dislocated.

In a knee-case, Moreau the father operated as follows:—He made a longitudinal incision on each

side of the thigh, between the vasti and the flexors of the leg, down to the bone. These incisions began about two inches above the condyles of the femur, and were carried down along the sides of the joint till they reached the tibia. They were united by a transverse cut, which passed below the patella, down to the bone.

The flap was raised; but the patella attached to it, being diseased, was dissected out. The limb was then bent, so as to bring the condyles of the femur into view. As it was desired to cut them from the body of the bone before dislocating them, every thing adhering to them behind, where they joined the body of the bone, was separated, and at that place the fore-finger of the left hand was passed through, in order to press back the flesh from the bone while the saw was used. The knee having been bent, Moreau drew the cut piece towards him, and easily detached it from the flesh and ligaments.

The head of the tibia was laid bare by an incision nearly eighteen lines long, made on the spine of that bone. The first lateral incision on the outer side of the knee was extended nearly as far down on the head of the fibula. Thus were obtained one flap which adhered to the flesh filling up the interosseous space, and another triangular flap formed of the skin covering the inner surface of the tibia, which bone was of necessity exposed before the saw could be applied.

Upon raising the outer flap, the head of the fibula came into view, and after being separated from its attachments was cut off with a small saw. The inner flap was then raised, and the head of the tibia having been separated from the muscles behind, was sawed off.—(See Moreau (le fils), Obs. pratiques relatives à la resection des articulations affectées de carie. Paris, an xi.) Some cases and remarks, in favour of the excision of diseased joints, have been published by Mr. Crampton.—(Dublin Hospital Reports, vol. 4, p. 185, &c.) He has removed with success one knee and one elbow. Another knee-operation may be set down as a failure, no union having taken place, and a sinus and discharge having continued in the ham until the patient's death, three years and two months after the operation. Respecting the plan of operating on the knee he concludes thus: "I am satisfied, from repeated trials on the dead subject, that the operation can be most safely and rapidly executed by separating the condyles from all their attachments previously to sawing the bone. As soon, therefore, as the flap containing the patella is turned upwards, the edge of the knife should be carried round the condyles close to the bone, so as to divide all the ligaments which connect the femur with the tibia. The tibia can then with great ease be pushed backwards, and as much of the projecting condyles can be removed as the operator may think necessary."—(Vol. cit. p. 213.)

It does not appear necessary to insert in this work the account of cutting out the ankle-joint, an operation which will never be extensively adopted; nor shall I add any thing more concerning the mode of removing, in a similar way, the shoulder-joint. In treating of amputation in this situation I have already said enough, and whoever wishes for farther information respecting this practice, must refer to Dr. Jeffray's work, entitled "Cases of Excision of Carious Joints." (Glasgow, 1806.) This publication contains all that was then known on the subject. Dr. Jeffray has recommended a particular, and indeed a very ingenious, saw, for facilitating the above operation. The saw alluded to is constructed with joints, like the chain of a watch, so as to allow itself to be drawn through behind a bone, by means of a crooked needle, like a thread, and to cut the bone from behind forwards without injuring the soft parts. An instrument of this kind was executed in London by Mr. Richards, who was assisted in making it by his nephew, the present Mr. Richards, of Brick-lane. In placing the saw under a bone, its cutting edge is to be turned away from the flesh. Handles are afterward hooked on the instrument.

According to my notions of the treatment of diseased joints, as long as the patient's strength is not subdued by the irritation of the local disease, humanity dictates the propriety of persevering in an attempt to save the affected limb, &c. Will a patient, greatly reduced by hectic symptoms, be able to recover from so bold and bloody an operation as the dissection of the whole of the knee-joint out of the limb? If some few should escape with life and limb preserved, would the bulk of persons treated in this manner have the same good fortune? I cannot admit that the extirpation of the whole of so large an articulation as the knee can be compared with the operation of amputation, in point of simplicity and safety. However, it is not on the difficulty of practising the former, that I would found my objections; for I believe that any man possessing a tolerable knowledge of the anatomy of the leg, might contrive to achieve the business. The grounds on which I withhold my approbation from the attempt to cut out large joints are the following:—1. The great length of time which the healing of the wound requires. Whoever peruses the case of Hector M'Caghan, will find that the operation was performed on the 2d of July, 1781, and that it was February 28th of the following year before all the subsequent abscesses and sores were perfectly healed. This space of time is very nearly eight months! Mr. Park describes the patient as a strong, robust sailor, and gives no farther particulars concerning the state of his constitution than that his health was declining. I entertain little doubt, that if the excision of the knee had been performed in that state of the health in which amputation becomes truly indispensable, this man would not have survived the illness arising from the operation. The only other case in which Mr. Park extirpated the knee ended fatally. In the instance related by Moreau there seemed, indeed, to be considerable debility. This patient escaped the first dangers consequent to so severe an operation; and after three months' confinement, the patient was in such a state that Moreau expected he would be able to walk upon crutches in another month or six weeks! The young man, in the mean time, was attacked by an epidemic dysentery and died. On the 21st of October, 1809, Mölder extirpated the knee-joint of a pregnant woman in the hospital at Groningen; but she died of tetanus on the 8th of the following February. He conceives that the operation is much facilitated by removing the ends of the femur and tibia in their connected state.—(See Diss. de Articulis extirpandis auctore G. H. Wachter, 1810.) 2. Even supposing the excision of the knee to be followed by all possible success, is the advantage of having a mutilated, shortened, stiff limb, in lieu of a wooden leg, sufficiently great to induce any man to submit to an operation, beyond a doubt infinitely more dangerous than amputation? I think not. The practice is at present nearly exploded in this country; but I hear every now and then of its being adopted at Paris, and Mr. Crampton has thought it worthy of revival. The difficulties of his operations, however, and tediousness of the after-treatment, and in particular the general course and termination of one of his two knee-cases, as represented by himself, are sufficiently discouraging. No doubt, more limbs might be saved by this practice than by that of amputation, but more lives would be lost. On this principle I see no reason for preferring excision to amputation. Many interesting observations on the extirpation of various diseased joints may be found in the above-mentioned dissertation by Wachter, and in the analysis of it by Langenbeck.—(Bibl. für die Chir. b. 3, Göttingen, 1811.)

In quitting this part of the subject, I may just notice the interesting case recorded by Mr. Dunn of Scarborough, who cut out several of the tarsal bones, including the diseased surface of the astragalus, and also some of the metatarsal bones from a boy's foot, with complete final success. The hemorrhage, however, was profuse, and great difficulty experienced in stopping it. Whether this bold experiment merits imitation, I am not prepared to say; but, be this as it may, the fact merits attention.—(See Med. Chir. Trans. vol. 11, p. 337.) Consult also White's Cases in Surgery; Sabatier, Séances publiques de l'Acad. de Chir. Paris, 1779, p. 73; et Mém. de l'Institut National, vol. 5, 1805; Roux, de la Resection, &c. de portions d'os malades, &c. Paris, 1812; Ph. Crampton, in Dublin Hospital Reports, vol. 4, 1827.

AMPUTATION OF THE FINGERS AND TOES, AND PART OF THE FOOT.

The best surgeons all agree with Mr. Sharp, that the amputation of the fingers and toes is most conveniently performed in their articulations. With a common scalpel, the skin is to be cut through circularly, not exactly upon the joint, but a little towards the extremity of the finger, in order that a sufficient flap may

be preserved for covering the end of the bone. On taking away a finger from a metacarpal bone, Mr. Sharp recommends making two small longitudinal incisions on each side of the joint, as a means of facilitating the separation.

In amputating the fingers and toes, the operation is greatly facilitated by cutting into the joint when it is bent. Having made an opening in the back part of the capsule, one of the lateral ligaments may easily be cut, after which nothing keeps the head of the bone from being turned out, and the surgeon has only to cut through the rest of the exposed ligamentous and tendinous parts.

Some recommend making a small semicircular flap of skin to cover the bone; but this is quite unnecessary if care be taken to draw the skin a little up, and to cut where Mr. Sharp directs. However, as making a small flap gives little pain, I have generally followed this method, though it appears to me nearly a matter of indifference which plan is adopted. In operating at the joints between the phalanges and metacarpal bones, a flap should always be made, either on the upper or under part of the fingers to be removed.

Although it is generally best to remove the fingers at the joints, it is sometimes thought right, where the injury just includes the joint and no more, to saw through the bone, instead of operating at the next articulation.—(See Guthrie on Gun-shot Wounds, p. 384.) The division can also be readily made with cutting plyers.

It may happen, that the bones of the toes and only part of the metatarsal bones are carious, in which case the leg need not be cut off, but only so much of the foot as is disordered. A small spring saw is here the most convenient. When this operation is performed, the heel and the remainder of the foot will be of great service, and the wound heal up safely, of which Mr. S. Sharp says, he had in his time seen one example.—(Op. of Surgery, chap. 37, ed. 3.) Mr. Hey confirms this statement of Sharp's concerning the impropriety of removing the whole foot, when the metatarsal bones are carious, and every other part of the leg is sound, as the remainder of the foot is of immense service in walking, the use of the ankle not being destroyed.

Mr. Hey describes a new mode of removing the metatarsal bones, which on repeated trial has fully answered his expectations. By the term new, I here mean a particular method, which had not been previously described, though it may have been performed by others sooner than by Mr. Hey himself; for the merit of having first done it is imputed to the late Mr. Turner, of North Yarmouth, who did it with success about the year 1787.—(See Hutchison's Pract. Obs. p. 70.) Mr. Hey makes a mark across the upper part of the foot, to denote where the metatarsal bones are joined to those of the tarsus. About half an inch from this mark, nearer the toes, he makes a transverse incision through the integuments and muscles covering the metatarsal bones. From each extremity of this cut, he makes an incision along the inner and outer side of the foot to the toes; he removes all the toes from the metatarsal bones, and then separates the integuments and muscles, forming the sole of the foot, from the inferior part of the metatarsal bones, keeping the edge of the knife as near the bones as possible, in order to expedite the operation, and preserve as much muscular flesh in the flap as can be saved. He then separates the four smaller metatarsal bones at their junction with the tarsus, and divides, with a saw, the projecting part of the first cuneiform bone, which supports the great toe. The arteries being tied, Mr. Hey applies the flap, which had formed the sole of the foot, to the integuments which remain at the upper part, and keeps them in contact with sutures. The cicatrix being situated at the top of the foot, is in no danger of being hurt, while the place where the toes were situated is covered with such strong skin, viz. what previously formed the sole of the foot, that it cannot be injured by any moderate violence.—(See Practical Observations in Surgery, p. 535, &c.)

When the metatarsal bone of the great toe is alone diseased, Mr. Hey recommends dissecting it out from the cuneiform bone, instead of sawing it. The latter plan cannot be easily accomplished, without removing part of the integuments and muscles, and making a transverse as well as a longitudinal incision. These disagreeable things may be avoided by following the method of Mr. Hey, or that of Mr. C. Bell. For removing the metatarsal bone, either of the little or great toe, the latter gentleman directs us to carry a scalpel round the root of the toe, and then along the side of the foot. The flaps are then to be dissected back, the metatarsal bone is to be separated from the next, and its square head is to be detached from the tarsus.—(Operative Surgery, vol. 1, p. 390.)

The removal of the central metatarsal and metacarpal bones is an operation of much difficulty, and the sawing of them is hardly practicable, without injuring the soft parts. Hence, I am decidedly of opinion with Mr. C. Bell, that instead of a formal amputation, it is better to extract the diseased bones from the foot or hand, as, indeed, Mr. Hey was in the habit of doing.

That skilful surgeon, Langenbeck, however, has devised a ready mode of taking away the middle finger with its metacarpal bone from the os magnum, or the ring-finger, with its metacarpal bone, from the articulation of the latter with the os magnum and os cuneiforme. In order to find out these articulations, he draws a line from the upper head of the metacarpal bone of the thumb straight across to the metacarpal bone of the finger to be extirpated, and at this place he begins his first incision, which runs towards each side of the finger like an inverted V. The bone is then separated all round from the soft parts, and dislocated from the carpus, when nothing remains to be done but to cut the parts towards the palm, where the wound is also made to resemble an inverted V, but does not extend any farther than is necessary, to complete the separation.—(See Langenbeck's Bibl. b. 1, p. 575, and plate 3, f. 1.) This is unquestionably a simple and excellent method of operating, which Langenbeck also recommends as the best way of removing such bones of the metatarsus, as are not situated at the sides of the foot; care being taken to save a flap from the sole. It is often difficult, however, to know with certainty whether the disease is confined to the metacarpal or metatarsal bones; and if it be not, and the carpus or tarsus be affected, the operation will not answer, and amputation be indispensable. This happened in one of Langenbeck's cases, in which he had removed one of the metacarpal bones.

Modern surgeons never amputate the whole of the foot or hand, when there is a reasonable chance of preserving any useful portion of it, though the rest may be most severely shattered. Thus, when a soldier had been struck by a grape-shot, which shattered the metacarpal bones of the little and ring-fingers, grazed the middle finger, and tore up the integuments on the palm and back of the hand, Mr. Guthrie succeeded in saving the two fingers and thumb, although, in the removal of the other parts, no regular flaps could be made for covering the wound.—(On Gun-shot Wounds, p. 382.) In winter campaigns, the toes, and more or less of the foot, are often attacked with mortification from cold. In this circumstance, when the disorder does not extend beyond the middle of the foot or the toes, it is only necessary to cut away the gangrenous part. On the first entrance of the French army into Holland, after the revolution, Paroisse met with many of these cases, in which it was necessary merely to take away the metatarsal bones, or sometimes those of the tarsus. All the patients operated upon in this manner for the effects of cold were cured; walking afterward with more or less difficulty, according as the portion of the foot taken away had been greater or smaller.—(Opuscules de Chir. p. 218.)

M. Roux, in his late publication, finds fault with our ignorance of Chopart's method of removing a part of the foot. He says, "I am certain, the principal surgeons in England have never practised, and are even totally unacquainted with, the amputation of the foot at the junction of the two halves of the tarsus, or Chopart's operation."—(Voyage fait à Londres en 1814, ou Parallèle de la Chirurgie Angloise avec la Chirurgie Françoise, p. 338.) As it is an operation of considerable merit, I think it will be useful to introduce a description of it in the present work. It is performed in the nearly parallel articulations of the os calcis with the os cuboides, and of the astragalus with the os naviculare. Thus the heel is preserved, on which the patient can afterward walk. The performance of it is simple. The tourniquet having been applied, the

surgeon is to make a transverse incision through the skin which covers the instep, two inches from the ankle-joint. He is to divide the skin, and the extensor tendons and muscles in that situation, so as to expose the convexity of the tarsus. He is next to make on each side a small longitudinal incision, which is to begin below and a little in front of the malleolus, and is to end at one of the extremities of the first incision. After having formed in this way a flap of integuments, he is to let it be drawn upwards by the assistant who holds the leg. There is no occasion to dissect and reflect the flap; for the cellular substance connecting the skin with the subjacent aponeurosis is so loose, that it can easily be drawn up above the place where the joint of the calcaneum with the cuboides, and that between the astragalus and scaphoides, ought to be opened. The surgeon will penetrate the last the most easily, particularly by taking for his guidance the eminence which indicates the attachment of the tibialis anticus muscle to the inside of the os naviculare. The joint of the os cuboides and os calcis lies pretty nearly in the same transverse line, but rather obliquely forwards. The ligaments having been cut, the foot falls back. The bistoury is then to be put down, and the straight knife used, with which a flap of the soft parts is to be formed under the tarsus and metatarsus, long enough to admit of being applied to the naked bones so as entirely to cover them. It is to be maintained in this position with three or four strips of adhesive plaster, which are to extend from the heel, over the flap, to the inferior and anterior part of the leg.

Chopart used to tie every artery as soon as it was divided. On the instep, the continuation of the anterior tibial artery will require a ligature; and in the sole, the internal and external plantar arteries, in the thickness of the flap of soft parts, must generally be taken up. One-half of each ligature is to be cut away, and the other one is to be left hanging out between the plasters, at the nearest and most convenient point.

Walther and Graefe have given some very precise directions for the performance of this operation. A cut is first made, beginning half an inch below the outer ankle, and extending forwards along the side of the foot two inches. Another similar incision is then made from one inch below the inner ankle. The foot is now to be bent upwards, and the first two cuts united by a transverse incision, two finger-breadths from the front of the tibia. A flap is then dissected up, as far back as the commencement of the lateral incisions, or a line corresponding to the articulation of the astragalus with the os naviculare, and of the os calcis with the os cuboides. An assistant now checks the bleeding by applying the points of his fingers on the mouths of such vessels as bleed profusely, and holds up the flap. The extremity of the foot is now to be firmly inclined downwards, so as to stretch the ligaments connecting the tarsal bones together. The ligaments between the astragalus and os naviculare are to be first cut, when the foot may be twisted somewhat outwards, and the ligaments between the os calcis and os cuboides divided. The division is lastly completed by cutting through the soft parts regularly from above downwards, with the precaution of directing the amputating knife so as to leave a flap composed of part of the sole of the foot.—(See Abhandl. aus dem Gebiete der Prakt. Med. &c. Landshut, 1810, b. 1, p. 152; aan Graefe, Normen für die Abl. grössr. Gliedm. p. 142.)

Sometimes, in consequence of the soft parts of the instep being all gangrenous or otherwise destroyed, it is necessary to make the flap entirely from the sole of the foot, as Klein was obliged to do in one of his cases.—(Practische Ansichten bedeutendsten Chir. Operationen, h. 1, p. 28.) Indeed, Richerand thinks this mode generally advantageous, as the line of the cicatrix is not placed at the lower end of the stump, where it would be most exposed to injury.—(Nosogr. Chir. t. 2, p. 502, &c. ed. 4.) Langenbeck and Klein also condemn the painful and unnecessary measure of dissecting up a flap from the instep, as advised by Walther and Graefe. Chopart himself, as we have seen, merely drew back the integuments of the instep, without making any detachment of them from the subjacent parts. When the ends of the flexor tendons of the toes project too much from the inner surface of the lower flap, they are to be cut shorter, as Klein particularly directs; and I consider his advice, not to use sutures for keeping the flap applied, but merely strips of sticking-plaster, perfectly judicious.—(Op. cit. p. 33—34.)

[For amputation of the lower jaw see note on "Jaw-Bone." For amputation or excision of the upper jaw as first performed in this country by Dr. David L. Rogers, of this city, see note on "Osteosarcoma;" or for the details of the case, reference may be had to the N. Y. Med. and Phys. Journal for 1824, vol. 3, p. 301. For amputation or exsection of the clavicle, an operation performed for the first time by Dr. Mott, in 1829, see also note on "Osteosarcoma."—*Reese.*]

AMYLUM. Starch. Powdered starch is sometimes used as an external application to erysipelas; but chiefly in clysters when the neck of the bladder is affected with spasm. The following is the formula used at St. Bartholomew's Hospital. ℞. Mucilaginis amyli, aquæ distillatæ: sing. ʒij. Tinct. opii guttas quadraginta: Misce.

ANASTOMOSIS. (From ανα, through, and στομα, a mouth.) Anatomists and surgeons imply by this term the communications of the blood-vessels with each other, or their running and opening into each other, by which the continuance of a free circulation of the blood is greatly ensured, and the danger of mortification lessened. The immense importance of this part of our structure in all cases in which the main artery or veins of a limb are obliterated, is particularly conspicuous in the disease called aneurism.—(See Aneurism.)

Nay, such has been the providence of nature in this respect, that even where the thoracic aorta has been completely obstructed, the channels for the conveyance of the blood to the lower extremities have yet been found adequate to that purpose. This was proved in an example where the obstruction had been gradually produced by disease, and the anastomosing vessels of course had had time for enlargement; for this is a very different case from that in which a ligature is suddenly applied to the aorta; though, as far as can be deduced from the particulars of some experiments made on dogs by Sir Astley Cooper, and of one operation in which he tied the human abdominal aorta (Surgical Essays, part 1, p. 101), blood will still pass to the lower extremities in sufficient quantity for their nutrition. At least this inference is safely deducible from the very memorable operation to which I have referred, subject to one important condition, viz. that there be no additional cause of impediment to the passage of blood to the lower extremities besides the ligature above the bifurcation of the aorta. When Sir A. Cooper tied the human aorta in the abdomen, the experiment was made as the only possible means of hindering a man from bleeding to death, who had a large aneurism of the external iliac artery actually beginning to bleed, and extending too high to admit of any thing else being done. Now, although the unfortunate patient was not saved, and it must be acknowledged that the chances of any other result were very small, the case furnished the important proof, that if the abdominal aorta be suddenly and completely obstructed, the blood may yet pass in adequate quantity to the lower extremities, provided there exist no other cause of impediment to the passage of the blood into those members; for on the side occupied by the aneurism the circulation in the limb was stopped, while in the opposite limb the circulation and natural warmth were preserved. To this subject I shall hereafter return.—(See Aorta.)

The changes which take place in the arterial system of the limb, when the main artery is rendered impervious by the application of a ligature, are well described by Mr. Hodgson: "The blood, meeting with an obstacle to its progress through the accustomed channel, is thrown in greater quantity and with greater force into those branches which arise above the seat of the obstruction. The ramifications of these branches, in consequence of the unusual influx of blood, undergo a remarkable dilatation; the more minute vessels also, by which they anastomose with corresponding ramifications, arising from branches given off below the obstruction, are from the same cause sufficiently enlarged to allow a free passage of the blood into the inferior trunks of the limb. At first, the circulation is in this manner carried on through a congeries of minute anastomosing arteries; in a short time a few of these channels become more enlarged than the rest: as these increase in size, the smaller vessels gradually collapse, and ultimately a few large communications constitute permanent channels through which the blood is transmitted to the parts that it is destined to supply. This is one mode by which a collateral circulation is established.

"But in some situations more direct and ostensible inosculations are provided; so that when one channel is obstructed, the blood passes at once through the other in a sufficient stream for the nourishment of the part which it is destined to supply. Under these circumstances no dilatation of the collateral branches is necessary: the circulation, in such instances, may be said to be constantly carried on through inosculating trunks. These great communications principally exist in the extremities of the body where the dilating impulse which the blood receives from the heart is of course diminished. Thus the radical artery inosculates freely with the ulnar; the anterior with the posterior tibial; and the internal carotid with the vertebral arteries. Two modes therefore exist by which arteries communicate with each other—the anastomoses of minute ramifications and the direct inosculations of trunks."—(See Hodgson on the Diseases of Arteries and Veins, p. 234.) Refer also to Inosculation. The best general account of the inosculations in relation to aneurism is contained in Scarpa's Treatise on Aneurism; more especially the Italian edition, which is embellished with beautiful engravings.

ANCHYLOPS. (From αγχι, near, and ωψ, the eye.) Same as Ægylops.

ANCHYLOSIS. (From αγκυλος, crooked.) This denotes an intimate union of two bones which were naturally connected by a moveable kind of joint. All joints originally designed for motion may become anchylosed, that is, the heads of the bones forming them may become so consolidated together that no degree of motion whatever can take place. Bernard Conner (De stupendo ossium coalitu) describes an instance of a general anchylosis of all the bones of the human body. A still more curious fact is mentioned in the Hist. of the Acad. of Sciences, 1716, of a child 23 months old affected with universal anchylosis. In the advanced periods of life anchylosis more readily occurs than in the earlier parts of it. The author of the article Anchylosis in the Encyclopédie Méthodique, mentions a preparation in which the femur is so anchylosed with the tibia and patella, that both the compact and spongy substances of these bones appear to be common to them all without the least perceptible line of separation between them. In old subjects the same kind of union is common between the vertebræ and between these and the heads of the ribs.

Anchylosis is divided into the true and false. In the true, the bones grow together so completely that not the smallest degree of motion can take place, and the case

is positively incurable. The position in which the joint becomes thus unalterably fixed makes a material difference in the inconvenience resulting from the occurrence. In false anchylosis the bones have not completely grown together, and their motion is only diminished, not destroyed. True anchylosis is sometimes termed complete; false, incomplete.

In young subjects in particular, anchylosis is seldom an original affection, but generally the consequence of some other disease. It very often occurs after fractures in the vicinity of joints; after sprains and dislocations attended with a great deal of contusion; and after white swellings and abscesses in joints. Aneurisms, and swellings, and abscesses on the outside of a joint may also induce anchylosis. In short, every thing that keeps a joint for a long timem otionless may give rise to the affection, which is generally the more complete the longer the cause has operated.

When a bone is fractured near a joint, the limb is kept motionless by the apparatus during the whole time requisite for uniting the bones. The subsequent inflammation also extends to the articulation, and attacks the ligaments and surrounding parts. Sometimes these only become more thickened and rigid: on other occasions, the inflammation produces a mutual adhesion of the articular surfaces. Hence fractures so situated are more serious than when they occur at the middle part of a bone. After the cure of fractures, a certain degree of stiffness generally remains in the adjacent joints, but this is different from true anchylosis; it merely arises from the inactivity in which the muscles have been kept, and their consequent loss of tone.

The position of an anchylosed limb is a thing of great importance. When abscesses form near the joints of the fingers, and the tendons mortify, the fingers should be bent, that they may anchylose in that position, which renders the hand much more useful than if the fingers were permanently extended. On the contrary, when there is danger of anchylosis, the knee should always be kept as straight as possible. The same plan is to be pursued, when the head of the thigh-bone is dislocated in consequence of a diseased hip. When the elbow cannot be prevented from becoming anchylosed, the joint should always be kept bent. No attempt should ever be made to cure, though every possible exertion should often be made to prevent a true anchylosis. The attempt to prevent, however, is not always proper, for many diseases of joints may be said to terminate when anchylosis occurs.

When the false or incomplete anchylosis is apprehended, measures should be taken to avert it. The limb is to be moved as much as the state of the soft parts will allow. Boyer remarks, that this precaution is much more necessary in affections of the ginglymoid than of the orbicular joints, on account of the tendency of the former to become anchylosed, by reason of the great extent of their surfaces, the number of their ligaments, and the naturally limited degree of their motion.

The exercise of the joint promotes the secretion of the synovia, and the grating first perceived in consequence of the deficiency of this fluid soon ceases. A certain caution is necessary in moving the limb: too violent motion might create pain, swelling, and inflammation, and even caries of the heads of the bones. It is by proportioning it to the state of the limb, and increasing its extent daily, as the soft parts yield and grow supple, that good effects may be derived from it.—(See Boyer, Mal. des Os, t. 2.) The use of embrocations and pumping cold water on the joint every morning have great power in removing the stiffness of a limb remaining after the cure of fractures, dislocations, &c.

Unreduced dislocations are not always followed by anchylosis. Nature often forms a new joint, especially in persons of the lower order, who are obliged to move their limbs a great deal, in order to obtain a livelihood. The surrounding cellular substance becomes condensed, so as to form around the head of the luxated bone a membrane serving the purpose of a capsular ligament. The muscles, at first impeded in their action, become so habituated to their new state, that they resume their functions. This is particularly the case with bones which move in every direction, and have round heads; but in ginglymoid joints, the heads of the bones are only imperfectly dislocated, and the motion is greatly restrained by the extent of surface; while some of the numerous ligaments are only sprained, not ruptured. These causes promote the occurrence of anchylosis.

Anchylosis may follow sprains and contusions of the joints, and such shocks as the articular surfaces experience in leaping or falling on the feet from great heights. This is more likely to happen when the inflammatory symptoms, resulting from such violence, have not been properly counteracted by bleeding and other general remedies, while the plan of beginning to move the joint gently every day, as soon as the case will allow, has been entirely neglected.

When certain diseases of joints end in complete anchylosis, it is sometimes a desirable event. In fact, it is as much a means of cure, as the formation of callus is for the union of broken bones. The disease of the vertebræ, described by Pott, is cured as soon as the bones anchylose, nor can the patient be considered well before this event has taken place.—*W. H. [A highly interesting operation has been performed by Professor Mott for the cure of permanent anchylosis, or rather "immobility of the lower jaw," which had existed for ten years. A report of this case is published in the American Journal for Nov. 1829; but as the disease and operation are of so novel and interesting a character, Dr. Mott, at my request, has politely furnished me with the following description of the case, which cannot be unacceptable to the profession, and I therefore insert it here.

"A young man, twenty-one years of age, from North Carolina, called, with the lower jaw almost immoveably fixed to the upper. No motion in a downward direction could be discovered, nor was the most powerful effort with the hand upon the chin able in the slightest degree to alter its situation. He had been in this deplorable state for ten years. Unable to chew a mouthful of food, or even open the jaws for its reception, his food had to be introduced through a small opening, occasioned by an irregularity of the bicuspides teeth on the right side. On the left side, just within the angle of the mouth, a very firm band, of more than ligamentous hardness was to be seen and felt, reaching from this point along the alveolar ridge to the coronoid process.

Along the whole course of this adhesion to the gum of the lower jaw, there was not a vestige of a tooth, and he stated that from this part the jaw had been formerly separated, with the teeth attached to it. This morbid adhesion had been several times freely divided; it was cut from within the mouth in different directions, but never permitted the least motion of the jaw.

From the circumstance that he could give a little lateral motion to the jaw, I thought that his mouth might yet be opened, and the deformity removed. I then made an incision from the angle of the mouth on the left side through the check, nearly to the coronoid process, dividing the firm cicatrix within completely. The jaws being relieved by dividing all the adhesions between them, a piece of very broad tape was placed between the teeth by a probe and spatula, and tied some distance below the chin. To the loop thus formed I applied all the strength I could command, but not the least yielding of the jaw could be discovered.

I then applied the principle of the screw and lever, by an instrument prepared for the purpose, composed of two steel plates about three inches in length. When applied to each other, they were of a wedge-shape. To the large end was attached a screw, which, when turned, caused the thin extremity of the plates to expand. This instrument enabled me to open the mouth completely.

With considerable difficulty this vice was insinuated between the range of teeth on the left side, resting along their whole course. It was then expanded, by turning the screw, and such was the report that attended the yielding of the lower jaw, that several present thought it was broken, but the noise was like that attending the laceration of ligaments rather than such as attends the fracture of a bone. The mouth was immediately opened to a sufficient extent.

The wound was closed with the interrupted suture and adhesive plaster; to prevent the adhesion of the cheek to the jaws internally, pieces of sponge were interposed. The patient was enabled to chew his food, and to converse and articulate distinctly as the result of the operation, and he entirely recovered."

Dr. Mott has since repeated the operation with the same success on a gentleman from Louisiana.

In the North Amer. Med. and Surg. Journal for April, 1828, Dr. J. Rhea Barton has published a most successful operation performed on a case of anchylosis at the hip-joint, attended with very great deformity, after it had existed for more than eighteen months. The object of the operation was to substitute an artificial joint for the loss of the natural articulation at the hip, and it is most honourable to Dr. Barton, and alike gratifying to the profession and to humanity, to record, that it has been most completely successful. An abridged account of this novel and most interesting exhibition of consummate surgical skill is given in the Appendix to the late Philadelphia edition of Cooper's "First Lines," of 1828. It was performed on a sailor at the Pennsylvania Hospital in Nov. 1826.

In Dr. Francis's edition of Denman's Midwifery is described a peculiar affection of the hip-joint, in some respects novel and important. It is in effect an anchylosis, and is denominated "a displacement of bone without fracture or dislocation," inducing a morbid change in the form and cavity of the pelvis, such as might wholly defeat the process of natural labour. The patient, an adult subject, fell on the right hip; the injury done to the external parts was comparatively slight; but an inflammatory action took place in the bottom of the acetabulum, which caused total absorption of the bone, and the protrusion of the head of the thigh-bone itself into the cavity of the pelvis. Nor was the diseased action limited to these changes; large deposites of osseous matter were made within the pelvis surrounding the absorbed acetabulum; and the head of the thigh-bone was by the same material augmented to more than double its original size. The neck of the bone and also both trochanters were considerably increased in bulk. The capacity of the pelvis was diminished about two inches in its superior and lateral portion.—*Reese.*]

ANEURISM, or ANEURYSM. (From *ανευρυνω*, to dilate.) The tumours which are formed by a preternatural dilatation of a part of an artery, as well as those swellings which are occasioned by a collection of arterial blood, effused in the cellular membrane, in consequence of a rupture or wound of the coats of the artery, receive the name of aneurisms. According to these opinions, aneurisms are of two kinds; the first being termed true; the second spurious or false. Some modern writers have ventured to reckon another form of aneurism, which is said to happen when the external coats of an artery being weakened by mechanical injury or disease, the internal coat protrudes through the breach in the outer coat, so as to form a tumour distended with blood. This case has been denominated the internal mixed aneurism, or aneurisma herniam arteriæ sistens. The reality of this form of disease was believed by Dr. W. Hunter; and some delicate experiments, instituted by Haller on the mesenteric arteries of frogs, appear to have been the first ground of the opinion. Such an aneurism, however, has not been universally admitted, not that any body doubted the correctness of what Haller advanced, but because there might not always be a perfect analogy between the results of an experiment on animals, and those afforded by the observation of the diseases of the human body.

When Haller asserted, that by separating the muscular from the inner coat of the arteries he could, when he pleased, produce an aneurism in these animals; and when Hunter declared that such an experiment made the artery firmer than ever, in consequence of the adhesive inflammation taking place; the character and veracity of these eminent men naturally lead to the question, whether the experiments were conducted exactly in the same manner. Now, says Mr. Wilson, when we know that Haller did not suffer the surrounding parts to unite, and that John Hunter did, we can no longer be at a loss to account for the different conclusions.—(See Wilson's Anatomy, Pathology, &c. of the Vascular System, p. 378.)

However this may be with respect to the experiments made on certain animals, I am disposed to consider it fully proved by Mr. J. Hunter, Sir E. Home, and Professor Scarpa, that in the human subject an aneurism will not arise from the kind of weakness which is caused by cutting or even stripping off the external coat of a sound artery, whether the wound be closed or not.

This fact would at least appear to be well established, with respect to the generality of the arteries; but how far it is so in relation to the aorta, is another question, the inner membrane of which vessel is alleged to be more elastic than that of common arteries. Dubois and Dupuytren in fact are stated to have presented to the Faculty of Medicine at Paris preparations which exhibit the lining of the aorta protruding through the middle coat, in the form of a sac filled with blood.—(See Dict. des Sciences Med. art. Aneurisme, and Breschet in Transl. of Mr. Hodgson's work, p. 130.)

By the term mixed aneurism, Dr. A. Monro senior implied the state of a true aneurism, when its cyst had burst, and the blood was diffused in the adjacent cellular substance; an event which is frequent. Besides these varieties of aneurism, the aneurismal varix or venous aneurism, and the aneurism by anastomosis, constitute diseases which are usually regarded as cases pertaining to the present subject, though incapable of being comprised under the ordinary definition of an aneurism.

Nothing can be more manifest than the fact, that previously to the discovery of the circulation of the blood, no correct nor valuable opinions could have prevailed, respecting the diseases which now go under the name of aneurisms. Indeed, it was not until after the days of Aristotle that any distinction was made between the swellings of veins and those of arteries, such vessels not having been at that early period distinguished from each other. Their differences were first pointed out by Rufus of Ephesus.

Down to Galen, however, nothing like consistency was established in the notions respecting aneurism. His opinion was, that all tumours of this nature were produced either by anastomosis or by rupture; and though he has described their symptoms, he has not informed us of the characters by which each of these cases was distinguishable one from the other. Paulus Ægineta divides aneurisms into two sorts, both of which, he says, are attended with extravasation, and of course with rupture.

Vesalius, who first applied anatomy to the investigation of disease, has described an aneurism arising from the rupture of a dilated aorta; the first specimen, I believe, on record of this form of disease.—(Bonetus Sepulch. Anat. lib. 4, sect. 2.)

The combination of rupture with dilatation of the artery was afterward more particularly noticed by Nuck.—(Oper. Chir., &c. Lugd. 1692.)

It was Fernelius who first promulgated the doctrine that aneurisms were always dilated arteries.—(Universa Medicina, De Extern. Corp. Affect. lib. 7, cap. 3, Venet. 1564.)

This opinion was espoused by Forrestus, Diemerbroek, and others; but at length the inaccuracy of attempting to refer every aneurism solely to dilatation of the coats of the vessel, was established by the observations of Lancisi, Freind, Guattani, and Morgagni. In short, as Mr. Hodgson has stated, these authors proved that aneurism may be produced either by the rupture or the dilatation of the coats of an artery, or by a combination of both circumstances, the dilatation having preceded the rupture.—(On the Diseases of Arteries, &c. 8vo. Lond. 1815.)

This admission of aneurism by dilatation, and of

aneurism by rupture of the coats of an artery, together with the frequent combination of both circumstances, was indeed the prevailing undisturbed doctrine of every surgical school, until Professor Scarpa, inclining to the tenets of Sylvaticus (De Aneurysmate. Tract. Venetiis, 1600, 4to.), ventured to question the correctness of the common opinion about the dilatation of all the arterial coats. However, after the very clear and satisfactory elucidation of this disputed point by my friend Mr. Hodgson, the accurate views of the subject, first taken by Morgagni, and the other eminent writers specified above, may be regarded as established beyond the possibility of dispute. At the same time, it is not to be supposed that Scarpa means to say, that the arteries are not subject to a morbid dilatation; on the contrary, he gives a particular description of this affection, which he carefully discriminates from aneurism.

Previously to offering a more particular account of the doctrine taught by Scarpa respecting the formation of aneurism, as well as of the chief facts which may be adduced against a part of such doctrine, it seems proper to make the reader acquainted with the various species of the disease, their ordinary symptoms, and a few other circumstances.

When any part of an artery is dilated (attended with particular circumstances marking its difference from another form of dilatation which, as I shall explain, perhaps ought not to be set down as aneurismal), the swelling is commonly named a true or genuine aneurism. In such cases the artery is either enlarged at only a small part of its track, and the tumour has a determinate border, or the vessel is dilated for a considerable length, in which circumstance the swelling is oblong, and loses itself so gradually in the surrounding parts, that its margin cannot be exactly ascertained. The first case, which is the most common, is termed the circumscribed true aneurism; the last the diffused true aneurism; a case, however, which would be looked upon by Scarpa only as a specimen of dilatation different in several particulars from aneurism, as will be hereafter noticed. When blood escapes from a wound or rupture of an artery into the adjoining cellular substance, the swelling is denominated a spurious or false aneurism. In this instance the blood either collects in one mass, distends the cellular substance, and condenses it into a cyst, so as to form a distinctly circumscribed tumour; or it is injected into all the cavities of the surrounding cellular substance, and extends along the course of the great vessels, from one end of the limb to the other, thus producing an irregular oblong swelling. The first case is named a circumscribed false aneurism; the second a diffused false aneurism. —(Richter's Anfangsgr. b. 4.)

These appellations are, in my opinion, preferable to to the term cylindrical, applied by Sauvages to true aneurisms, or sacciform, proposed by Morgagni for false aneurisms.—(Advers. Anat. 2, Aortæ Animadv. 38, et Epist. Anat. 17, No. 27.) Because, as we shall see in the course of this article, though true aneurisms (including dilatations of all the arterial coats of every kind) do mostly affect the whole circumference of the vessel, and must therefore partake of a cylindrical shape, there are exceptions, in which a distinct circumscribed sac, composed of all the coats of the vessel, projects from one side of an artery, the diameter of which may not be at all increased. Here the disease might rather be named sacciform, the very appellation suggested by Morgagni for false aneurisms, in which the disease generally originates in this shape, from whatever particular side of the vessel the inner coats have given way. We see also that the subject actually demands more numerous distinctions, since aneurisms undergo in their progress various changes, which sometimes make an immense, and even a very sudden difference in their shape, cases which were at first circumscribed afterward becoming diffused.

The symptoms of a circumscribed true aneurism take place as follows: the first thing which the patient perceives is an extraordinary throbbing in some particular situation, and on paying a little more attention he discovers there a small pulsating tumour which entirely disappears when compressed, but returns again as soon as the pressure is removed. It is commonly unattended with pain or change in the colour of the skin. When once the tumour has originated, it continually grows larger, and at length attains a very considerable size. In proportion as it becomes larger, its pulsations become weaker, and indeed they are almost quite lost when the disease has acquired much magnitude. The diminution of the pulsation has been ascribed to the coats of the artery losing their dilatable and elastic quality in proportion as they are distended and indurated, and, consequently, the aneurismal sac being no longer capable of an alternate diastole and systole from the action of the heart. The fact is also imputed to the lamellated coagulated blood deposited on the inner surface of the sac, particularly in large aneurisms, in which the motion of some of the blood is always interrupted. Immediately such coagulated blood lodges in the sac, pressure can only produce a partial disappearance of the swelling. This deposition of lamellated coagulum in the aneurismal sac is a circumstance of considerable importance; for it has been well explained by Mr. Hodgson, that it is the mode by which the spontaneous cure of the disease is in most instances effected. "One of the circumstances which, in the most early stage, generally attend the formation of aneurism (says this author), is the establishment of that process which is the basis of its future cure. The blood, which enters the sac soon after its formation, generally leaves upon its internal surface a stratum of coagulum, and successive depositions of the fibrous part of the blood gradually diminish the cavity of the tumour. At length the sac becomes entirely filled with this substance, and the deposition of it generally continues in the artery which supplies the disease, forming a firm plug of coagulum, which extends on both sides of the sac to the next important ramifications that are given off from the artery. The circulation through the vessel is thus prevented, the blood is conveyed by collateral channels, and another process is instituted, whereby the bulk of the tumour is removed," &c.—(On the Diseases of Arteries &c. p. 114.) Whether there is any truth in Kreysig's conjecture, that some of the lymph may exude from the inside of the sac itself, I cannot pretend to say: he owns, however, that the inner concentric layers presenting the appearance of being deposited last, is a circumstance rather against his surmise, though he adverts to some other circumstances which incline him to look upon the opinion as possibly correct.—(German Transl. of Mr. Hodgson's Work, p. 124.)

In a preceding paragraph I have spoken of the diastole and systole of the aneurismal sac; for it is the general belief that the pulsation of the tumour is produced by the jet of blood into it at each stroke of the heart. This opinion, however, is disputed by an eminent writer, who asks, is it true that the pulsation of aneurisms proceeds from the entrance of a more considerable stream of blood into the sac, and the distention of the swelling thereby produced? In aneurisms, which have only a narrow communication with the arterial tube, or which are filled with laminated coagula, the idea, says he, is quite inadmissible: the aneurism is rather shaken, as it were, like other different swellings in the vicinity of an artery, by the stroke of the heart occasioning a stretching of the whole arterial system, and at the same time communicating an impulse to the column of blood.—(Kreysig, Germ. Tr. of Mr. Hodgson's Work, p. 143.) Here, however, I am by no means disposed to coincide with this distinguished physician, whose sentiments appear to me to be refuted by the fact, that whenever any change happens, calculated to lessen or entirely stop the influx of blood into the sac, the pulsation either diminishes or ceases in proportion. Thus, when Kreysig adverted to the pulsation of aneurisms, in which much coagulated blood was deposited, he might at the same time have mentioned the effect which such deposition has in weakening the pulsation, the layers of coagulated blood within the tumour being in the natural mode of cure, as Mr. Hodgson has correctly explained, "the means by which the force of the circulation is removed from the sac, and the fatal termination of the disease by rupture is prevented."—(On Diseases of Art. and Veins, p. 126.) In proportion as the aneurismal sac grows larger, the communication of blood into the artery beyond the tumour is lessened. Hence, in this state, the pulse below the swelling becomes weak and small, and the limb frequently cold and œdematous. On dissection, the lower continuation of the artery is found preternaturally small and contracted. The pressure of the tumour on the adjacent parts may also produce a variety of symptoms, ulceration, absorption of bone,

&c. Sometimes (says Richter) an accidental contusion or concussion may detach a piece of coagulum from the inner surface of the cyst, and the circulation through the sac be obstructed by it: nay, he asserts that the coagulum may possibly be impelled quite into the artery below, so as to induce important changes. The danger of an aneurism arrives when it is on the point of bursting, by which occurrence the patient usually bleeds to death, and this sometimes in a few seconds. The fatal event may generally be foreseen, as the part about to give way becomes particularly tense, elevated, thin, soft, and of a dark purple colour.—(Richter's Anfangsgr. band 1.)

A large axillary aneurism, which burst in St. Bartholomew's Hospital some years ago, did not burst by ulceration, but by the detachment of a small slough from a conical, discoloured part of the tumour; and soon after this case fell under my observation, I had an opportunity of seeing the process by which an inguinal aneurism burst: at a certain point the tumour became more conical, thin, and inflamed, and here a slough about an inch in width was formed. On the dead part becoming loose, a profuse bleeding began, which was stopped for a short time by pressure, but soon returned with increasing violence, and put an end to the patient's misery. We are then to conclude that external aneurisms do not burst by ulceration, but by the formation and detachment of a slough. I believe this is a fact which was first particularly pointed out in the early editions of my work, and it gives me pleasure to find that it is a statement which entirely coincides with that subsequently made by several writers of eminence, especially Mr. A. Burns (On Diseases of the Heart, p. 225), and Boyer (Traité des Maladies Chirurgicales, t. 2, p. 98.)

As far as my information extends, Mr. A. Burns first explained the very different mode of rupture which happens in internal aneurisms: these, he observed, generally burst by actual laceration, and not by sphacelation of the cyst.—(On Diseases of the Heart, p. 225.) But a still more particular account of the process by which external and internal aneurisms burst, is delivered by Mr. Hodgson. When the sac points externally (says this gentleman), it rarely or never bursts by laceration, but the extreme distention causes the integuments and investing parts to slough, and upon the separation of the eschar, the blood issues from the tumour. A similar process takes place when the disease extends into a cavity which is lined by a mucous membrane, as the œsophagus, intestines, bladder, &c. In such cases, the cavity of the aneurism is generally exposed by the separation of a slough which has formed upon its most distended part, and not by laceration. But when the sac projects into a cavity lined by a serous membrane, as the pleura, the peritoneum, the pericardium, &c., sloughing of these membranes does not take place, but the parietes of the tumour having become extremely thin in consequence of distention, at length burst by a crack or fissure, through which the blood is discharged.—(On the Diseases of Arteries, &c. p. 85.)

When the aneurism is of considerable size, the collateral arteries, which originate above the swelling, are manifestly enlarged. Boyer informs us, that in dissecting the lower extremity of a patient on whom Desault had operated eight months previously for a popliteal aneurism, he found in the substance of the great sciatic nerve an artery, whose diameter was equal to that of the radial at the wrist. This vessel had its origin from the ischiatic artery, and descended to the back part of the knee, where it anastomosed with the upper articular arteries. Boyer had also noticed in the same subject before the operation, that one of the branches of the upper internal articular artery was so much enlarged that its pulsation could be plainly felt on the internal condyle of the thigh-bone.—(Op. cit. p. 93.) It is such enlargement of the collateral arteries above the disease, which ensures to the limb below the tumour an adequate supply of blood when the obstruction to its passage through the diseased artery becomes considerable, or when this vessel has been rendered totally impervious by a surgical operation performed for the cure of the complaint.

In the advanced stage of an aneurism, the skin is found extremely thin, and confounded, as it were, with the aneurismal sac. The cavities of the cellular substance near the disease are either filled with serum or totally obliterated by adhesion. The adjacent muscles, whether they lie over the aneurism or to one side of it, are stretched, displaced, dwindled, and sometimes confounded with other parts. It is the same with the large nervous cords situated at the circumference of the tumour: they are pushed out of their natural situation, diminished in size, sometimes adherent to the outside of the sac, and so changed as scarcely to admit of being known again. Lastly, the cartilages and the bones themselves are not exempt from the mischief which the aneurismal swelling produces in all the surrounding parts: they are gradually destroyed, and at length not the least trace of their substance remains, just in the same way as the bones of the cranium are destroyed by fungous tumours of the dura mater.—(See Dura Mater.) Even the cartilages of the larynx and rings of the trachea are sometimes destroyed; this tube is pierced, and the blood escapes into it, or the aneurism bursts into the œsophagus.—(Boyer, Traité des Maladies, Chir. t. 2, p. 99.) As I shall hereafter explain, however, the pressure of an aneurismal tumour more quickly produces an absorption of bone than of cartilage.

While an aneurism is small and recent, it does not generally cause much pain, nor seriously impede the functions of the limb. But when it has increased, several complications are produced. Thus the dragging of the saphenal nerve, by femoral aneurisms, frequently occasions acute pain in the course of this nerve as far as the great toe. The distention of the sciatic nerve by the popliteal aneurism sometimes brings on intolerable pain, which extends to all the parts to which this nerve is distributed, and which can hardly ever be appeased by the topical use of opiate applications. The compression of the veins and lymphatics gives rise to œdema, numbness, and coldness of the limb. And, finally, the long-continued pressure of the aneurism on the neighbouring bones causes their destruction.—(Boyer, t. 2, p. 105.)

In true aneurism, the coats of the artery are not always in the same state, the kind of changes observed depending upon the progress of the tumour. In the early stage of the disease, either the whole cylinder of the vessel, or only a part of its circumference, is dilated; but this period is generally of short duration, especially in arteries of middling size, because their middle coat is capable of less resistance than that of the larger arteries, like the aorta, where this coat is yellowish, firm, and very elastic. As Breschet remarks, this difference of resistance in the middle coat of the aorta and the branches given off from it, accounts for the rarity of true aneurisms either in the small arteries or those of middling size, and their greater frequency in the principal trunk of the arterial system.

At length, in consequence of the increasing distention, some of the coats of the artery possessing the least elasticity give way, and these are found to be the internal and middle coats, while the external one still makes resistance and continues to be more and more dilated by the lateral impulse of the blood.

The second stage of true aneurism is that which is mostly met with; that in which the tumour increases more rapidly, and therefore begins to excite greater attention. The disease when it has attained this form is in point of fact no longer a true aneurism, but a case which Monro distinguished by the name of the consecutive or external mixed false aneurism. In this stage the patient's life is endangered, and death often brought on by the rupture of the tumour. Examinations of the dead subject under these circumstances have frequently led to mistaken notions, and doubtless if various swellings of this kind had not been found in different degrees or stages in the same individual, one might be disposed to join Scarpa in the belief, that no aneurism consists of a dilatation of all the arterial coats.—(Breschet, Fr. transl. of Mr. Hodgson's work, p. 128, 129.)

The false aneurism is always attended with at least a rupture, or giving way of the inner coat of the vessel, and usually with a breach in both this and the muscular coat, the outer elastic tunic forming the pouch in which the blood collects. But after the swelling has attained a certain size, this coat also bursts, and then the blood either becomes diffused, or a large circumscribed space is formed for it by the condensation of the surrounding cellular membrane. False aneurisms, when produced by a wound or puncture, are of course from the

first attended with a division of all the coats of the vessel. This form of the disease is often seen at the bend of the arm, where the artery is exposed to injury in venesection.—(See Hemorrhage.) In this circumstance, as soon as the puncture is made, the blood gushes out with unusual force, and in a bright scarlet, irregular, interrupted current; flowing out, however, in an even and less rapid stream when pressure is applied higher up than the wound. These last are the most decisive marks of the artery being opened; for blood may issue from a vein with great rapidity, and in a broken current, when the vessel is turgid and situated immediately over the artery, which imparts its motion to it. The surgeon endeavours precipitately to stop the hemorrhage by pressure, and in general a diffused false aneurism is the result. The external wound in the skin is closed so that the blood cannot escape, but this does not hinder it from passing into the cellular substance. The swelling thus produced is uneven, often knotty, and extends upwards and downwards along the track of the vessel. The skin is also usually of a dark purple colour. Its size increases as long as the internal hemorrhage continues, and if this should proceed beyond certain bounds, mortification of the limb ensues. Such is the diffused false aneurism from a wound.

The circumscribed false aneurism, from a wound or puncture, arises in the following manner. When proper pressure has been made in the first instance, so as to suppress the hemorrhage, but the bandage has afterward been removed too soon, or before the artery has healed, the blood passes through the unclosed wound, or that which it has burst open again, into the cellular substance. As this has now become agglutinated by the preceding pressure, the blood cannot diffuse itself into its cells, and consequently a mass of it collects in the vicinity of the aperture of the artery, and distends the cellular substance into the form of a sac. Sometimes, though not often, the circumscribed false aneurism originates immediately after the opening is made in the artery. This chiefly happens when the aperture in the vessel is exceedingly small, and consequently when the hemorrhage takes place so slowly that the blood, which is first effused, coagulates, and prevents the entrance of that which follows into the cavities of the cellular substance, and of course its diffusion. False aneurisms, proceeding from the rupture of the inner coats of an artery, are always at first circumscribed by the resistance of the outer tunic.

The circumscribed false aneurism consists of a sac composed of the external coat of the artery, or, in case this has given way, it is composed of an artificial pouch formed among whatever parts happen to be in the vicinity of the burst artery. This cavity is filled with blood, and situated close to the artery, with which it has a communication. Hence in false aneurisms a throbbing is always perceptible, and is more manifest the smaller such tumours are. The larger the sac becomes the less elastic it is, and the greater is the quantity of laminated coagula in it; so that in very large aneurisms of this kind the pulsation is sometimes wholly lost.

The tumour is at first small, and on compression entirely disappears; but returns as soon as this is removed. It also diminishes when the artery above it is compressed; but resumes its wonted magnitude immediately such pressure is discontinued. When there is coagulated blood in the sac, pressure is no longer capable of producing a total disappearance of the tumour, which is now hard. The swelling is not painful, and the integuments are not changed in colour. It continually increases in size, and at length attains a prodigious magnitude.

The following are generally enumerated as the discriminating differences between circumscribed true and false aneurisms: the true aneurism readily yields to pressure, and as readily recurs on its removal; the false one yields very gradually, and returns in the same way; and as it contains laminated coagula, it cannot be reduced in the same degree by compression as an aneurism formed by a dilatation of the arterial coats, where such strata of coagulated blood are usually absent. Frequently a hissing sound is audible when the blood gushes into the sac. The pulsation of the false aneurism is always more feeble, and as the tumour enlarges is sooner lost than that of the true one, which throbs after it has acquired a considerable volume.—(See Richter's Anfangsgr. b. 1.

FORMATION OF ANEURISMS.

If the doctrines of Scarpa, published in 1804, had proved correct, the grand distinction of aneurism into true and false must have been rejected as erroneous: "for," says he, "after a very considerable number of investigations, instituted on the bodies of those who have died of internal or external aneurisms, I have ascertained, in the most certain and unequivocal manner, that there is only one kind or form of this disease, viz. that caused by a solution of continuity or rupture of the proper coats of the artery, with effusion of blood into the surrounding cellular substance; which solution of continuity is occasioned sometimes by a wound, a steatomatous, earthy degeneration, a corroding ulcer, or a rupture of the proper coats of the artery, I mean the internal and muscular, without the concurrence of a preternatural dilatation of these coats being essential to the formation of this disease; and therefore that every aneurism, whether it be internal or external, circumscribed or diffused, is always formed by effusion."—(On Aneurism; transl. by Wishart, Pref.)

According to Scarpa, it is an error to suppose that the aneurism at the curvature or in the trunk of the aorta, produced by a violent and sudden exertion of the whole body, or of the heart in particular, and preceded by a congenital relaxation of a certain portion of this artery, or a morbid weakness of its coats, ought always to be considered as a tumour formed by the distention or dilatation of the proper coats of the artery itself, that is, of its internal and fibrous coats. Scarpa considers it quite demonstrable, that such aneurisms are produced by a corrosion and rupture of these tunics, and consequently, by the effusion of arterial blood under the cellular sheath, or other membrane covering the vessel. If ever there be a certain degree of preceding dilatation, it is not essential to constitute the disease, for it is not a constant occurrence; most aneurisms are unpreceded by it, and in those rare cases in which an aneurism is preceded and accompanied by a certain degree of dilatation of the whole diameter of the curvature of the aorta, there is an evident difference between an artery simply enlarged in diameter, and a pouch which forms an aneurismal sac.

Careful dissections, says Scarpa, will prove that the aorta contributes nothing to the formation of the aneurismal sac, and that this is merely the cellular membrane which, in the sound state, covered the artery, or that soft cellular sheath which the artery received in common with the neighbouring parts. This is raised by the blood into the form of a tumour, and is covered in common with the artery by a smooth membrane.

This eminent professor does not deny that from congenital relaxation the proper coats of the aorta may occasionally yield and become disposed to rupture; but he will not admit that dilatation of this artery precedes and accompanies all its aneurisms, or that its proper coats ever yield so much to distention as to form the aneurismal sac. The root of an aneurism of the aorta never includes the whole circumference of the artery; but the aneurismal sac arises from one side in the form of an appendix or tuberosity. On the contrary, the dilatation of the artery always extends to its whole circumference, and therefore differs essentially from aneurism. Thus, he urges that there is a remarkable difference between a dilated and aneurismatic artery, although these two affections are sometimes found combined together, especially at the origin of the aorta. If we also consider that the dilatation of an artery may exist without any organic affection, the blood being always in the cavity of the vessel; that in an artery so affected there is never collected any grumous blood or polypous layers; that the dilatation never forms a tumour of considerable bulk; and that while the continuity of the proper coats remains uninterrupted, the circulation of the blood is not at all, or not so sensibly changed; we shall be obliged to allow, that aneurism differs essentially from one kind of dilatation of an artery.

Some additional remarks on this topic more recently published by Scarpa will be presently considered.

By dissections of arteries both in the sound and morbid state, Scarpa endeavours to demonstrate what share the proper and constituent coats of the artery have in the formation of the aneurismal sac, and what belongs

to the cellular covering, and other adventitious membranes surrounding the artery.

The covering of an artery is merely an adventitious sheath which the vessel receives in common with the parts in the vicinity of which it runs. On cutting an artery across in its natural situation, the segment of the cut vessel retires and conceals itself in this sheath.

This cellular covering is most evident round the curvature and trunk of the aorta, the carotid, mesenteric, and renal arteries: it is less dense round the trunks of the brachial, femoral and popliteal arteries. The pleura lies over the cellular sheath of the arch of the aorta, and over that of the thoracic aorta; while that of the abdominal aorta is covered by the peritoneum. Both these smooth membranes adhere to and surround two-thirds of the circumference of the vessel. The great arteries of the extremities are not covered in addition to the cellular substance by any smooth membrane of this sort, but by a cellular sheath, which is demonstrably distinct from the adipose membrane, and serves to enclose the vessels, and connect them with the contiguous parts.

When air or any other fluid is injected by a small hole, made artificially between the cellular covering and the subjacent muscular coat of the artery, the injected matter elevates into a tumour the cellular membrane, which closely embraces the artery, without properly destroying its cells, which it distends in a remarkable manner. When melted wax is injected and pushed with much force, the cellular sheath of the artery is not only raised over the vessel like a tumour, but the internal cells of that covering are also lacerated, and on examining afterward the capsule of the artificial tumour, it appears as if it were formed of several layers, rough and irregular internally, smooth and polished externally. The same thing happens when any injection is pushed with such force into an artery as to rupture the internal and muscular coats at some point of their circumference. Nicholls performed this experiment several times before the Royal Society.—(Philos. Trans. an 1728.) As soon as the internal coat is ruptured, the muscular one also gives way; but the external cellular sheath being of an interlaced texture, and the thin laminæ of which it is composed being not simply applied to one another, but reciprocally intermixed, is capable of supporting great distention by yielding gradually to the impulse of the blood, without being torn or ruptured.

Scarpa is farther of opinion that the same phenomena may be observed when the internal coat of the aorta becomes so diseased as to be ruptured by the repeated jets of blood from the heart. In this circumstance, the blood, impelled by the heart, begins immediately to ooze through the connexions of the fibres of the muscular coat, and gradually to be effused into the interstices of the cellular covering, forming for a certain extent a kind of ecchymosis or extravasation of blood, slightly elevated upon the artery. Afterward, the points of contact between the edges of the fibres of the muscular coat being insensibly separated, the arterial blood, penetrating between them, fills and elevates in a remarkable manner the cellular covering of the artery, and raises it after the manner of an incipient tumour. Thus the fibres and layers of the muscular coat being wasted or lacerated, or simply separated from each other, the arterial blood is carried with great force, and in greater quantity than before, into the cellular sheath of the artery, which it forces more outwards; and finally, the divisions between the interstices of the cellular coat being ruptured, it is converted into a sac, which is filled with polypous concretions and fluid blood, and at last forms, strictly speaking, the aneurismal sac. The internal texture, although apparently composed of membranes placed one over the other, is, in fact, very different from that of the proper coats of the artery, notwithstanding the injured vessel and aneurismal sac are both covered externally in the thorax and abdomen with a smooth membrane.

Scarpa has examined a considerable number of aneurisms of the arch and of the thoracic and abdominal trunk of the aorta, without finding a single one in which the rupture of the proper coats of the artery was not evident, and in which, consequently, the sac was produced by a substance completely different from the internal and muscular coats.

The aneurismal sac never comprehends the whole circumference of the vessel. At the place where the tumour joins the side of the tube, the aneurismal sac presents a kind of constriction, beyond which it becomes more or less expanded. This would never happen, or rather the contrary circumstance would occur, if the sac were formed by an equable distention of the tube and proper coats of the affected artery. In incipient aneurisms, at least, the greatest size of the tumour would then be in the artery itself, or root of the swelling, while its fundus would be the least. But whether aneurisms be recent and small, or of long standing and large, the passage from the artery is always narrow, and the fundus of the swelling greater in proportion to its distance from the vessel. The sac is always covered by the same soft dilatable cellular substance which united the artery in a sound state to the circumjacent parts. Such cellular substance in aneurisms of the thoracic aorta is covered by the pleura, and in those of the abdominal aorta by the peritoneum, which membranes include the sac and ruptured artery, presenting outwardly a continued smooth surface, just as if the artery itself were dilated. But if the aorta be opened lengthwise on the side opposite the constriction or neck of the tumour, the place of the ulceration or rupture of the proper coats of the artery immediately appears within the vessel, on the side opposite to that of the incision. The edge of the fissure which has taken place is sometimes fringed, often callous and hard, and through it the blood formed for itself a passage into the cellular sheath, which is converted into the aneurismal sac. If, as sometimes happens in the arch of the aorta near the heart, the artery, before being ruptured, has been somewhat dilated, it seems at first as if there were two aneurisms; but the constriction which the sac next to the artery presents externally, points out exactly the limits beyond which the internal and muscular coats of the aorta had not been able to resist the distention, and where of course they have been ruptured. The partition which may always be seen dividing the tube of the artery from the aneurismal sac, and which is lacerated in its middle, consists of nothing else than the remains of the internal and muscular coats of the ruptured artery.

By carefully dissecting the proper coats of the ruptured aorta in its situation, and comparing them with the cellular substance forming the sac, Scarpa affirms that the truth of the preceding statement may be indisputably demonstrated.

When an incision is made lengthwise in the side of the vessel opposite the rupture, its proper coats are found either perfectly sound, or a little weakened and studded with earthy points, but still capable of being separated into distinct layers. On the contrary, in the opposite side of the aorta, where the rupture is, the proper coats are unusually thin, and are only separable from each other with difficulty, or even not at all; they are frequently brittle like an egg-shell, and are disorganized and torn at the place where they form the partition between the ruptured artery and the mouth of the aneurismal sac. Continuing to separate these coats from within outwards, we arrive at the cellular sheath surrounding the aorta. This sheath being much thickened in large aneurisms, and very adherent to the subjacent muscular coat of the artery at the place of the constriction of the sac, is very apt to be mistaken for a dilated portion of the vessel itself. But even in such cases we may at last separate it, without laceration, from the tube of the artery above and below the injury, and successively from the muscular coat as far as the neck of the aneurism. Then it is clear the muscular coat does not pass beyond the partition separating the cavity of the artery from that of the aneurismal sac, over which it is not prolonged, but terminates at the edge of the rupture like a fringe, or in obtuse points. Errors are more apt to occur in consequence of the aorta and sac being both covered by the pleura or peritoneum.

The portion of the aorta within the pericardium being only covered by a thin reflected layer of this membrane, such layer may also be lacerated when the proper coats give way, and blood be effused into the cavity of the pericardium. Examples of this kind are related by Walter, Morgagni, and Scarpa himself. In the latter instance, on making an incision into the concave part of the aorta, opposite the tumour which had formed under the layer of the pericardium, which had also burst by a small aperture, its internal coat, corresponding to the base of the swelling, was quite rough, interspersed

with yellow hard spots, and actually ulcerated for the space of an inch in circumference. The preparation is preserved in the museum at Pavia.

But all other parts of the aorta having, between them and the pleura and peritoneum, a cellular sheath of a stronger and more yielding nature, which allows itself to be distended into a sac, and being strengthened internally by polypous layers, and externally by the pleura or peritoneum, oppose for a long while the fatal effusion of blood.

Scarpa believes that what he calls the slow, morbid, steatomatous, fungous, squamous degeneration of the internal coat of the artery is more frequently the cause of its bursting than violent exertions of the whole body, blows, or an increased impulse of the heart. This kind of diseased change is very common in the curvature, and in the thoracic and abdominal trunks of the aorta. In the incipient state of such disease the internal coat of the artery loses, for a certain space, its beautiful smoothness, and becomes irregular and wrinkled. It afterward appears interspersed with yellow spots, which are converted into grains or earthy scales, or into steatomatous and cheese-like concretions, which render the internal coat of the artery brittle, and so slightly united to the adjoining muscular coat, that upon being merely scratched with the knife or point of the nail, pieces are readily detached from it, and on being cut it gives a crackling sound, similar to the breaking of an egg-shell. This ossification cannot be said to be proper to old age, since it is sometimes met with in subjects not much advanced in life. The whole of the side of the artery, in that portion which is occupied by the morbid affection, is, for the most part, hard and rigid, sometimes soft and fungous, and in most cases the canal of the artery is preternaturally constricted. In the highest degree of this morbid disorganization true ulcerations are found on the inside of the artery, with hard and fringed edges, fissures, and lacerations of the internal and fibrous coats of the artery.

Having presented the reader with an abridged account of the most important remarks made by Scarpa in support of the doctrine he defends, I now annex his conclusions. 1. That this disease is invariably formed by the rupture of the proper coats of the artery. 2. That the aneurismal sac is never formed by a dilatation of the proper coats of the artery, but undoubtedly by the cellular sheath which the artery receives in common with the parts contiguous to it; over which cellular sheath the pleura is placed in the thorax, and the peritoneum in the abdomen. 3. That if the aorta, immediately above the heart, appears sometimes increased beyond its natural diameter, this is not common to all the rest of the artery, and when the aorta in the vicinity of the heart yields to a dilatation greater than natural, this dilatation does not constitute, properly speaking, the essence of aneurism. 4. That there are none of those marks regarded by medical men as characteristic of aneurism from dilatation, which may not be met with in aneurism from rupture, including even the circumscribed figure of the tumour. 5. That the distinction of aneurism into true and spurious, adopted in the schools, is only the production of a false theory; since observation shows that there is only one form of the disease, or that caused by a rupture of the proper coats of the artery, and an effusion of the arterial blood into the cellular sheath which surrounds the ruptured artery.—(See Treatise on Aneurism, by A. Scarpa, transl. by J. H. Wishart, Edin. 1808.)

Such were the inferences made by Scarpa, in 1804, one of the most distinguished anatomists and surgeons of the present day upon the continent. It has been already stated, that, great as this authority is, several eminent modern surgeons, as Richerand, Boyer, Dubois, Dupuytren, Sabatier, Breschet, &c., did not yield to it, but still contended that in some aneurisms the coats of the artery were dilated. These professors in France coincided with what has been usually taught upon this subject in the surgical schools of Great Britain. Every lecturer here has been accustomed to describe the distinctions of aneurism into true and false, or into some cases which are accompanied with dilatation, and into others which are attended with rupture of the arterial coats. A few years ago Mr. Hodgson, of Birmingham, published a valuable treatise on aneurism, in which work he differs from Scarpa, and joins those surgical writers who believe in the occasional dilatation of the coats of the arteries in this disease. He inquires, "Is every aneurism produced by a destruction of the internal and middle coats of the vessel, and does not a partial dilatation of these coats occasionally precede and give rise to their destruction? I believe that this is frequently the case. We have seen that the disorganization of the coats of an artery, by destroying their natural elasticity, will give rise to permanent dilatation of the whole circumference of the vessel; and there is every reason to expect that a loss of its elasticity in a portion only of the diameter of the vessel, will give rise to a partial dilatation of its coats. Indeed, the proofs of a partial dilatation of the coats of an artery, particularly of the aorta, are incontestably established by the possibility of tracing the coats of the vessel throughout the whole extent of the expansion, and by the existence of those morbid appearances in the sac which are peculiar to the coats of the arteries.

"In the year 1811 (says Mr. Hodgson), I dissected an aneurism of the aorta, which was removed from the body of a young woman by my friend Dr. Farre. The sac was as large as a small melon, and had proved fatal by bursting into the posterior mediastinum, and subsequently into the cavity of the thorax. This aorta exhibited the formation of aneurism by partial dilatation in three distinct stages. The internal coat was throughout inflamed, and presented a fleshy and irregular appearance. At the arch of the aorta there was a dilatation not larger than the half of a small pea. About two inches lower in the same vessel was a second dilatation, which would have contained a hazel nut, and immediately above the the diaphragm was the large aneurism which had proved fatal. I removed that portion of the vessel which contained the smallest dilatation, and macerated it until its coats could be separated without violence. I found that the dilatation existed equally in the three coats of the vessel, and, when separated, each presented the appearance of a minute aneurism. The second dilatation exhibited the same circumstances in a more advanced stage. The coats of the vessels were more intimately adherent to each other than in a natural state, but it was evident that the dilatation consisted in a dilatation of the internal, the middle, and the external coats of the aorta. In the large aneurism the disorganized internal and middle coats could be traced for some distance into the sac, when the parts contained in the posterior mediastinum and the vertebræ formed the remainder of the cyst. There can be little doubt that the sac commenced in a dilatation of the coats of the vessel, similar to those appearances which existed in the superior portion of the dissection, and the artery appeared to illustrate the formation of aneurism by partial dilatation in three distinct stages."—(Hodgson on the Diseases of Arteries and Veins, p. 66. 68.) As far as Kreysig's information extends, nobody before Mr. Hodgson had examined the structure of an aneurismal sac in this accurate manner, viz. by maceration; and the results, he thinks, are not liable to the slightest objections.—(See the German transl. of Mr. Hodgson's work, with notes by Kreysig and Koberwein, p. 109. Hanover, 1817.)

Mr. Hodgson has seen this partial dilatation in almost all the arteries, which are subject to aneurism: at the division of the carotids and iliacs; in the arteries of the brain, &c.; and he agrees with Dr. Baillie (Morbid Anatomy, &c.), Laennec (Cerattius, Beschreib. d. Krankh. Preparate d. Anat. Theatres zu Leip. p. 408, 8vo. 1819), and others, that aneurisms at the origin of the aorta are generally formed by dilatation of the coats of the vessel.

"Partial as well as general dilatation (says Mr. Hodgson) frequently precedes the formation of aneurism in the arteries of the extremities. A gentleman had a large aneurism in the thigh, which had undergone a spontaneous cure. Upon examining the limb after death, the popliteal artery was found to be thickened and covered with calcareous matter. A small pouch, which would have contained the seed of an orange, originated from the side of this artery. This little sac was evidently formed by a dilatation of the coats of the vessel. A man died from the sloughing of an aneurism in the ham; in the femoral artery there was a small aneurism about as large as a walnut. The external coat was dissected from the surface of the tumour to a considerable extent. The internal and middle coats were evidently dilated, and contributed to the formation of the sac. The dilatation of these coats was gradual, and they continued for a considerable dis-

tance to form the sac, when they were inseparably blended with the surrounding parts."—(Op. cit. p. 70.)

When Mr. A. Burns bears testimony to the fidelity and accuracy of Scarpa's general detail, he adds, that perhaps it may not be uniformly found that "the root of an aneurism never includes the whole circumference of the tube of an artery." We have, says he, a preparation in which the reverse has taken place. In this case the whole cylinder of the vessel, from the heart to beyond the curvature, is equally dilated; and dilated to such an extent, that the tumour measures no less than ten inches in circumference. Scarpa limits dilatation, says Mr. Burns, to that state of an artery in which the coats remain in their natural relation to each other, and in which they were not altered in their texture, nor lined on their inner surface with "polypous layers." "This, however, was not the case in the instance which I have brought forward. In it you have seen that the coats were much dilated, and also very much altered in their structure. Externally and internally they had assumed the look of the membranes of the fœtus, only they were thicker and denser, but they were equally gelatinous and nearly as transparent; and on their inner surface, they were crusted over with the laminæ of coagulated lymph. By peeling off this incrustation, after the sac had been inverted, we saw plainly, that although the internal coats were round the complete cylinder of the vessel much diseased, and considerably dilated, yet they were not dilated in the same degree as the external coverings of the artery. At irregular distances, longitudinal rents were formed in the fibrous coats, and these chasms were filled with coagulating lymph. The internal coats over the whole circumference of the vessel had assumed the diseased condition which in aneurism is generally confined to a part of the cylinder. In this tumour all the coats continued for a time to dilate equally, but at length the internal gave way, forming longitudinal rents, through which the external coats could be seen after the lymphatic coating had been scraped off. In this instance, had the sac been dissected in the early stage, it would have presented precisely the same appearances as those described by Dr. Monro, and the one (the aneurism) lately examined by the surgical editor of the London Med. Review." Mr. Burns afterward expresses doubts whether the sac ever acquires a large size without dilatation. The case reported in the latter periodical work was the largest that he knew of, in which all the coats were found uniformly dilated. The sac, which was as large as the fist, was lined throughout with flakes of bone, and though the internal coat of the vessel was thus patched, and extremely thin and brittle, it did not, on minute inspection, any where exhibit a solution of continuity. Mr. A. Burns farther states, that the above case, reported by himself, was the only one out of fourteen which did not corroborate Scarpa's description.—(On Diseases of the Heart, &c. p. 204.) Mr. Wilson, after mentioning the frequency of aneurism in the aorta, carotid, subclavian, and axillary arteries, and its rarity in the brachial, tells us, that he knows of no example of aneurism below the elbow, where the swelling could not be traced to a wound of the coats of the artery. He adds, that true aneurism has not unfrequently occurred in the internal and external iliac arteries, in the inguinal, femoral, and very frequently in the popliteal. It has taken place in the posterior tibial artery, but he knows of no instance of it in the anterior tibial or peroneal arteries. "I have (says he) met with only one instance of true aneurism affecting any of the branches of the aorta which are distributed to the abdominal viscera. In the year 1809, on inspecting the body of a clergyman, in the presence of the late Sir W. Farquahr, a tumour very much resembling the heart in colour, shape, and size, appeared to hang down from the under surface of the left lobe of the liver. When this tumour was opened and carefully inspected, it appeared to have been formed by the left branch of the hepatic artery having become very much enlarged and aneurismal. It had burst, and the blood which had escaped was found in an imperfect cyst, partly in a fluid, and partly in a coagulated state, forming a large proportion of the tumour." This preparation is in Windmill-street.—(See Lectures on the Blood, and on the Anatomy, Physiology, and Surgical Pathology of the Vascular System, p. 379, 380, 8vo. Lond. 1819.)

The facts adduced by Mr. Hodgson appear sufficiently conclusive, and from them the following doctrine is clearly deducible.

First, That numerous aneurisms are formed by destruction of the internal and middle coats of an artery, and the expansion of the external coat into a small cyst, which giving way from distention, the surrounding parts, whatever may be their structure, form the remainder of the sac.

Secondly, That sometimes the disease commences in the dilatation of a portion of the circumference of an artery. This dilatation increases until the coats of the vessel give way, when the surrounding parts form the sac, in the same manner as when the disease is in the first instance produced by destruction of the coats of an artery.—(P. 74.)

The conclusions of Mr. Hodgson, as he himself explains, are supported by the observations of numerous writers.

The learned Sabatier says there can be no doubt that many aneurisms depend upon the dilatation of the arterial coats; but in far more numerous examples the internal tunics are ruptured, and it is the cellular coat alone which separates from them, and enlarges so as to form the aneurismal sac; "de sorte que les artères, qui sont dans ce cas, sont diloriquées, suivant l'expression de Lancisi."

It is difficult to conceive, he observes, how all the coats of an artery can dilate and yield sufficiently to form the investment of such immense tumours as some aneurisms are. Indeed, that very tunic, which composes the greater part of the thickness of the vessel, and which is termed the muscular coat, is known to consist of fibres whose texture is firm, and little capable of bearing extension. However, Haller, in describing a very large aneurism, situated in the aorta, near the heart, relates, that the innermost coat of this vessel was ruptured and torn, the loose jagged edges of the laceration being visible in the aneurismal sac. These were squamous, bony, and of little thickness; while the muscular and cellular coats were quite sound. Donald Monro noticed the same thing in five different aneurisms in the course of the femoral and popliteal arteries of a man who had been confined a long while to his bed after being operated upon for bubonocele. Monro succeeded in tracing the fibres of the muscular coat over the swellings, so that he had no doubt of this tunic being dilated.—(See Médecine Opératoire, t. 3, p. 160—162.)

According to Richerand, when an aneurism is recent and of small size, the dissection of the tumour exhibits a simple dilatation of the arterial coats; while in the other cases, where the aneurism is large, and has existed a considerable time, the internal and middle coats of the vessel are invariably lacerated. In the early stage of the disease, the blood which fills the aneurismal sac is fluid, and, on the contrary, in cases where the internal tunics of the artery are ruptured, the sac contains more or less coagulated lymph. The external or cellular coat composes the greater part of the cyst; and the coagulated lymph, with which it is filled, is arranged in layers, the density of which is described as being greater in proportion to the length of time which they have been deposited. Such as are nearest the sac are, therefore, represented as being most compact, and containing the smallest quantity of the colouring matter of the blood; more deeply, the concretions of lymph resemble simple coagula; and lastly, the blood which is still nearer the arterial tube retains its fluidity.

After the aneurismal sac has been cleansed from the lymph and coagulated blood which it contains, its parietes will appear to be almost entirely formed of the cellular coat of the artery. Towards the bottom may be observed the aperture, arising from the laceration of the internal and middle coats, which, being much less elastic than the external, are ruptured in an early stage of the disease. It is when these two tunics give way, that the aneurismal tumour undergoes a sudden and considerable increase in its size; for then the cellular coat alone has to sustain all the pressure of the blood, which now, becoming effused into a more ample cyst, loses a great deal of its impetus, coagulates and forms fibrous masses; circumstances to which may be ascribed the hardness of the swelling, the weakness of its pulsation, &c.—(Nos. Chir. t. 4, p. 82, ed. 2.)

But this author seems to venture far beyond the

bounds of accuracy, when he represents every small aneurism as exhibiting a dilatation of the arterial coats, unless his meaning refer more particularly to the outer coat alone.

The reality of what are called true internal aneurisms was ably urged by C. F. Ludwig, in a programma written expressly on that subject.—(Diagnostices Chir. Fragm. de Aneurysmate Interno; Lips. 1805.) But an interesting case, exemplifying an aneurismal dilatation of all the coats of the abdominal aorta, has been published by Professor Nægele of Heidelberg. The swelling was as large as a man's head, and weighed about five pounds. The aorta began to be dilated at the point where it passes into the cavity of the abdomen between the crura of the diaphragm. This dilatation extended gradually down to a point about four finger-breadths from the bifurcation of the aorta into the iliac arteries, at which point, strictly speaking, the large aneurismal sac commenced. The length of the whole dilated part of the vessel was eleven inches; that of the sac, six; and its diameter five inches. The artery was not equally dilated in every direction, the expansion being most considerable laterally and forwards. Professor Nægele and Ackermann found that the three coats of the aorta, the internal, muscular, and cellular, were all equally dilated. These gentlemen traced the muscular coat with the scalpel from the top to the bottom of the tumour, and not the slightest doubt could be entertained, that the case was a true aneurism.—(F. C. Nægele, Epistola ad T. F. Baltz, quâ Historia et Descriptio Aneurysmatis, quod in aorta abdominali observavit, continetur. Heidelb. 1816.)

In the valuable cases collected by H. F. Janin, very convincing evidence will be found of there being two kinds of aneurism; one attended with the rupture of the coats of the artery, the cellular coat alone forming the aneurismal sac; and the other, consisting in an equal dilatation of all the coats of the artery. Of the latter species of aneurism, Janin relates three very unequivocal cases.—(See Annales du Cercle Médical, t. 1, Art. 2, 1820.)

After the clear demonstration of an aneurismal sac being occasionally composed of all the coats of an artery, as afforded in the dissections and pathological preparations to which a reference has been made, the reader will be better prepared to judge of the difference existing upon this subject between Scarpa and other modern writers; and, as far as I can judge, the question is now reduced to one, whether any of the dilatations on record, said to comprise all the arterial coats, merit the name of aneurism. We have seen, that he has always unequivocally admitted that the arteries may be dilated, though the kind of dilatation to which he alludes, is thought by him, as well as by A. Burns, and my friend Mr. Hodgson (On Diseases of Arteries, &c. p. 58), to require discrimination in a pathological point of view. "It is proved (says Scarpa) by dissection, that the morbid dilatation is circumscribed by the proper coats of the diseased artery; and that the inner surface of the sac, formed by the partial or total protrusion of the arterial tube, is never filled with polypous laminæ, or layers of fibrine disposed over each other (a fact particularly dwelt upon by Mr. Hodgson, p. 82); which layers never fail to be formed in greater or smaller quantity in the cavity of an aneurism." The opinion that these layers of coagula are not met with in small dilatations of arteries, but are found in large expansions of them, he says, is contradicted by numerous careful observations, and especially by a specimen, actually before him when he was writing, where a morbid dilatation of the arch of the aorta, in the vicinity of its origin from the heart, six inches in length, and five in breadth, was entirely free from any of the lamellated coagula always found in aneurisms. On the contrary, the sac of the aneurism is formed from the parts surrounding the wounded or ruptured artery, into which pouch, the blood, entering as into a natural receiver, and quite out of the current of the circulation, moves only slowly, and constantly deposites these layers of fibrine, and this sometimes in such quantity as to fill the whole cyst. Scarpa, at the same time, particularly explains, that if accidentally furrows or fissures exist on the inside of the morbid dilatation, the fibrine may be deposited in these rough places, but only in them. These fissures and inequalities of the internal surface of the morbidly dilated artery, he regards strictly as so many beginnings of another disease of the vessel, quite different from dilatation, that is, of aneurism subsequent to dilatation.—(See Memoria sulla Legatura delle principali Arterie degli Arti, con una Appendice all' Opera sulle Aneurisma, fol. Pavia, 1817; or the Treatise on Aneurism, transl. by Wishart, ed. 2, p. 119, Edinb. 1819.)

In this manner, no doubt, Scarpa would account for the presence of lamellated coagula in the case reported by Mr. A. Burns (On Diseases of the Heart, p. 306), though the latter gentleman himself, for reasons already detailed in the foregoing pages, did not regard the expansion of all the coats of the artery, as corresponding to the morbid dilatation implied by Scarpa. Thus Scarpa farther agrees with other modern writers, in admitting the possibility of aneurism becoming ingrafted, as it were, on one of these unnatural dilatations, more than one example of which combination were indeed recited in his first work. In that treatise he has asserted, that what he calls morbid dilatation, always extends to the whole circumference of the vessel. But this point seems, from the appendix, to be renounced, as he now observes, "Where the morbid dilatation is partial, or on one side of the artery like a thimble (for very frequently, even in the arch of the aorta, this partial dilatation does not exceed the size of half a bean), the entrance for the blood into this capsule is as large as the bottom of the sac."—(Transl. by Wishart, p. 120, ed. 5.) According to Scarpa, where the morbid dilatation occupies the whole circumference of the arterial tube, the tumour always retain sa cylindrical or oval form; and, if situated in such manner that it can be compressed, it yields very readily to pressure, and almost disappears; and after death is found much smaller than during life. On the contrary, aneurism, whether preceded by dilatation or not, constantly originates from one side of the ruptured artery. The entrance for the blood is small, compared with the size of the fundus of the sac; the tumour assumes an irregular shape; yields with difficulty to pressure; retains nearly the same size in the dead that it had in the living body; and its sac, instead of becoming thinner as the swelling enlarges, as the coats of an artery do when they are simply affected with dilatation, attains greater thickness, the larger the aneurism grows. These essential differences between the two diseases are illustrated by an interesting case, met with by Professor Vacca, where a patient died with an aneurism of one subclavian artery, and a simple morbid dilatation of the whole circumference of the other.—(See Sprengel, Storia delle Operaz. di Chir. trad. Ital. Parte 2, p. 294.)

When these two different affections are situated in the thorax or abdomen, it is impossible to discriminate them from each other before death. The symptoms occasioned by the pressure of the tumour on the viscera, must be nearly the same, whether caused by a morbid dilatation or an aneurism. The means for retarding their fatal termination is also the same in both forms of the disease. With regard to the possibility of cure, however, Scarpa says, that there is great difference; for when the case is an internal aneurism, there may be some slight hope of a radical cure by the efforts of nature and art, which hope can never be entertained in a case of morbid dilatation; a fact which is accounted for by no laminated coagula being deposited in the latter disease.—(On Aneurism, transl. by Wishart, p. 124, ed. 2.) A great deal of the latter statement coincides with the observations of Mr. Hodgson, who particularly notices, that he has never met with lamellated coagula in such sacs, as consist either in a general or partial dilatation of the coats of the vessel.—(On Diseases of Arteries, &c. p. 82.) Whether this ever takes place in such cases may still be a question, because, if Professor Nægele has given a correct description of the aneurism of the abdominal aorta already mentioned, which aneurism was of a large size, and consisted of a dilatation of all the coats of the vessel, there was in this rare example a large quantity of these layers of coagulated blood. Yet, whether the Professor actually means the fibrine, arranged in laminæ, or only common coagulated blood, which, as every one knows, may be found either in the cysts of dilated or of ruptured arteries, may admit of doubt. The statement, therefore, made by Hodgson and Scarpa, may not be contrary to what was really seen by Nægele and Ackermann. The following case,

however, observed by Laennec, and quoted by a modern writer, must (if correctly reported) afford not only an unequivocal specimen of aneurism by dilatation of all the coats of the aorta, but of laminated coagula within its cavity. "In homine enim, qui repente sub atrocissimis pectoris doloribus corruit, præter aortam adscendentem in aneurysma ita expansam, ut neonati infantis caput æquaret, cystidam aneurismaticam immediate supra arteriæ cœliacæ ortam magnitudine nusis juglandis invenit, quæ luculenter ostendit sinum communicantem cum arteriæ cylindro per foramen magnitudine amygdalæ, diametro totius arteriæ illo loco non mutato. Saccus hic cultro anatomico accurate ac subtilliter subjectus, eamdem structuram, easdem ostendit membranas, quibus gaudebat arteria, e cujus latere excreverat: cæterum massis grumosis, sive fibrosis erat impletus. Inde igitur patet, hoc aneurysma sacciforme et laterali et partiali quidem tunicarum aortæ dilatatione ortum esse."—(J. H. G. Ehrhardt, De Aneurysmate Aortæ, p. 13, 4to. Lips. 1820.)

From what has been stated, then, it appears, that there is only one principal point of difference between Scarpa and other writers, and this resolves itself into the question, whether a dilatation of an artery, arising at one particular side of the vessel, and lined by its internal coat, ought not to be regarded as an aneurism, because its communication with the tube of the artery is more capacious than what exists in other aneurisms, where the inner coat has given way, and because it rarely (perhaps never) contains laminated coagula, unless fissures should happen to exist at some points of the inner arterial tunic thus expanded?

The greater number of aneurisms increase gradually, and sooner or later incline to the side on which the least resistance is experienced. De Haen mentions an aneurism of the aorta, which first made its appearance between the second and third ribs of the left side, and which, instead of growing larger, as is usual, subsided, and could neither be seen nor felt for more than a month before the patient's decease, although, on opening the body, a tumour of the arch of the aorta was found, three times as large as the first. De Haen imputes the sudden disappearance of the swelling to its weight, the yielding of the parts with which it was connected, and to its gravitating into the chest, when the patient lay on his right side; for the difficulty of breathing, and other complaints, produced by the pressure on the lungs, underwent a material increase as soon as the tumour ceased to protrude.

The pulsations which accompany true aneurisms continue to be strong, until the inner coats of the vessel give way, or the layers of coagulated blood, lodged in the sac, are numerous. Hence, when soft swellings, situated near any large arteries, lose their pulsatory motion, their course, precise situation, and other circumstances, ought to be most carefully investigated, before any decision is made about the mode of treatment.

A few years ago, I saw a man in St. Bartholomew's Hospital, who had a large swelling of great solidity, occupying the ham, and apparently extending a good way forwards round the condyles of the femur. Its hardness, shape, large size, and entire freedom from pulsation not only then, but at an earlier period, as far as could be collected from the patient's own account, led to the belief, that the case was probably a tumour complicated with exostosis of the femur, and as this opinion seemed to be confirmed by no fluid escaping from a puncture made with a lancet, amputation was performed. To our surprise, however, dissection proved, that the disease was a large diffused popliteal aneurism, in which the spontaneous cure by an obliteration of the sac with coagula was taking place.—(See Med. Chir. Trans. vol. 8, p. 497.)

In many instances the most fatal accidents have happened, in consequence of incisions having been made in aneurisms, which were mistaken for abscesses because there was no pulsation. Vesalius was consulted about a tumour of the back, which he pronounced to be an aneurism. Soon afterward an imprudent practitioner made an opening in the swelling, and the patient bled to death in a very short time. Ruysch relates that a friend of his opened a tumour near the heel not supposed to be an aneurism, and the greatest difficulty was experienced in suppressing the hemorrhage. De Haen speaks of a patient, who died in consequence of an opening which had been made in a similar swelling at the knee, although Boerhaave had given his advice against the performance of such an operation. Palfin, Schlitting, Warner, and others, have recorded mistakes of the same kind.—(Sabatier, t. 3, p. 167.) Ferrand, head surgeon of the Hôtel Dieu, mistook an axillary aneurism for an abscess, plunged his bistoury into the swelling, and killed the patient. "J'ai été témoin d'erreurs semblables, commises par les practiciens non moins fameux; et si des anèurismes externes on passe à ceux des artères placées à l'intérieur, les erreurs ne sont ni moins ordinaires ni de moindre conséquence."—(Richerand, Nosogr. Chir. t. 4, p. 75, éd. 2.)

Notwithstanding a pulsation is one of the most prominent symptoms of an aneurism, it is not to be inferred, that every swelling which pulsates is unquestionably of this description; for, as Mr. Warner has explained, it does happen that mere imposthumations, or collections of matter, arising from external as well as internal causes, are sometimes so immediately situated upon the heart itself, and at other times upon some of the principal arteries, as to partake in the most regular manner of their contraction and dilatation. He details the particulars of a boy, about thirteen years of age, whose breast-bone had been badly fractured, and who was admitted into Guy's Hospital a fortnight after the accident had happened.

The broken parts of the bone were removed some distance from each other. The intermediate space was occupied by a tumour of a considerable size; the integuments were of their natural complexion. The swelling had as regular a contraction and dilatation as the heart itself, or the aorta, could be supposed to have. Upon pressure the tumour receded; upon a removal of the pressure the tumour immediately resumed its former size; all these are allowed to be distinguishing signs of a recent true aneurism. The situation and symptoms of this swelling were judged sufficient reasons for considering the nature of the disease as uncertain: on which account, it was left to take its own course.

"The event was the tumour burst in about three weeks after his admission, discharged a considerable quantity of matter, and the patient did well by very superficial applications."—(Cases in Surgery, edit. 4, p. 155.)

An extraordinary form of disease, having very much the appearance of an aneurism, sometimes presents itself. A swelling, attended with considerable pain and a strong pulsation, is gradually produced high up the arm, and at length attains a very large size. The strength of the throbbings at first leads to the suspicion that the case must be an aneurism; but on careful examination the humerus is found to have given way at a point involved in the disease, and here to be as flexible as if there were a fracture. This circumstance, and the extension of the swelling too far away from the track of the artery, in time raise doubts about the case being an aneurism. The patient ultimately falls a victim to the effects of the disease on the constitution, and when the arm is dissected after death, the tumour is found to consist of a sarcomatous or medullary mass, occupying the central portion of the limb, and accompanied with a solution of continuity extending completely through the whole thickness of the bone. Two cases of this description were admitted into St. Bartholomew's Hospital in the course of the year 1820. One of these patients, a woman, I had an opportunity of seeing; and after her death the real nature of the disease was proved by dissection. My friend Mr. Vincent has seen a similar disease in the leg, resembling aneurism in the circumstance of pulsation, but attended with destruction of a part of the tibia, and a moveableness of the separated ends of the bone.

A few years ago, I saw a large abscess in the situation of the quadratus lumborum muscle, which pulsated so strongly that the case was supposed by several experienced men to be an aneurism of the abdominal aorta. The patient was a boy belonging to Christ's Hospital, and under the care of the late Mr. Ramsden, surgeon to that establishment, by whose discernment the real nature of the case was detected. It is curious that in this instance the pulsations of the swelling suddenly ceased, after having continued in a very strong and manifest way and without interruption for several weeks, during which it was under the observation of the above eminent practitioner.

As Mr. Wilson has observed, any encysted or even solid tumour, situated in the neighbourhood of, or upon a large artery, may have a considerable degree of motion communicated to it from the pulsation of the artery. The thyroid gland, when a bronchocele is formed, occasionally receives a pulsatory motion from the carotid arteries. This may be mistaken for an aneurism, from which disease, however, it can be discriminated by placing our fingers behind the tumour and drawing it forwards, when the pulsation ceases. But there are other criteria for distinguishing a swelling on or near an artery from an aneurism. In such a case the whole tumour moves at once, without any alteration of size. In an aneurism the swelling does not simply move, it expands. A tumour of the thyroid gland, having apparently a pulsatory motion, may be known not to be an aneurism of the carotid, by observing that from its connexion with the larynx it follows the movements of the latter in deglutition. Aneurisms, not of very long standing, and not containing a large mass of laminated coagula, may also be diminished, or rendered more or less flaccid, by pressing the artery leading to the disease.—(See Wilson on the Blood, Anatomy, Pathology, &c. of the Vascular System, p. 385; and Burns on the Heart, p. 257.) In cases of much ambiguity, the stethoscope will sometimes convey the necessary information. In a doubtful instance of aneurism of the groin Mr. Brodie found all obscurity cease on the application of this instrument.—(Sir A. Cooper's Lectures, vol. 2, p. 46.)

The following case, recorded by Pelletan, shows, that an artery running more superficially than natural, may under particular circumstances give rise to the suspicion of an aneurism. A strong, robust man, about forty years of age, was in the habit of going on foot to dine three leagues from Paris every day, on the completion of his business. One day having been this distance and returned, he felt an acute pain along the leg and in the right ankle. The pain did not subside, and a tumour appeared at the lower third of the leg opposite the space between the two bones. The skin was of a yellowish colour from effused blood, and a pulsation existed by which the hand of an examiner was lifted up. There seemed great reason for concluding that the case was an aneurismal swelling. In comparing the affected limb with the sound one, however, Pelletan perceived in the latter a similar kind of throbbing. In short, in both legs the pulsation of an arterial tube could be felt for three inches, and Pelletan distinctly ascertained that in the diseased member the throbbing did not extend to the whole of the tumour, but only lengthwise. By a particular disposition in this individual, the anterior tibial artery, which usually runs along the interosseous ligament, covered by the tibialis anticus and extensor communis digitorum pedis, came out from between these muscles at the middle of the leg, and lay immediately under the skin and the fascia.

The swelling and ecchymosis gradually dispersed, and the symptoms were supposed to originate from the rupture of some muscular fibres.—(Clinique Chir. t. 1, p. 101, 102.)

Whenever an aneurismal sac of immoderate size beats violently and for a long while against the bones, as the sternum, ribs, clavicle, and vertebræ, they are in the end invariably destroyed, so that the aneurismal sac elevates the integuments of the thorax, or back, and pulsates immediately under the skin. Scarpa, with the best modern writers, attributes the effect to absorption in consequence of the pressure.

J. L. Petit saw the condyles of the femur and the upper head of the tibia almost destroyed by an aneurism of the popliteal artery; and another case in which the caries and absorption of bone were very extensive, is reported by Rosenmüller.—(Anhang zu Scarpa üb. d. Pulsadergeschwulste, p. 364.) According to Mr. Hodgson, the carious and corroded state of the bones in aneurism is never attended with the formation of pus; "at least the discovery of pus in its vicinity has not been remarked by those who have examined such cases. In this respect, therefore, it differs essentially from common caries or ulceration of the bones. Exfoliation also is very rarely attendant upon it; from which circumstance one important practical observation is deducible, namely, that if the aneurism be cured the bones will recover their healthy state, without undergoing those processes which take place in the cure of caries or necrosis."—(On the Diseases of Arteries and Veins, p. 80.)

The same author confirms the remark made by Dr. W. Hunter (Med. Obs. and Inquiries, vol. 1, p. 384), Scarpa (On Aneurism, p. 100, ed. 2), and others, that cartilage is less rapidly destroyed by the pressure of aneurism than bone. This fact is strikingly illustrated in a case of aneurism of the thoracic aorta recorded in another modern publication: the bodies of the vertebræ from the fourth down to the ninth were carious; the four lowest in particular: yet the intervertebral cartilages were not materially affected.—F. L. Kreysig, Die Krankheiten des Herzens, b. 3, p. 176, 8vo, Berlin, 1817.)

A case is related by Pelletan, to which I refer the reader, as exemplifying not only the degree in which internal aneurisms may injure the vertebræ, but also the occasional possibility of such diseases being mistaken for rheumatism or a lumbar abscess.—(See Clinique Chir. t. 1, p. 97—100.)

CAUSES OF ANEURISM.

In many instances it is difficult to assign any cause for the commencement of the disease. Among the circumstances which predispose to aneurisms, however, the large size of the vessels may undoubtedly be reckoned. Those trunks which are near the heart are said to have much thinner parietes, in relation to the magnitude of the column of blood with which they are filled, than the arteries of smaller diameter; and since the lateral pressure of this fluid against the sides of the arteries, is in a ratio to the magnitude of these vessels, it follows that aneurisms must be much more frequent in the trunks near the heart than in such as are remote from the source of the circulation.—(Richerand, Nosogr. Chir. t. 4, p. 72, edit. 2.) The whole arterial system is liable to aneurisms; but, says Pelletan, experience proves that the internal arteries are much more frequently affected than those which are external.—(Clinique Chir. t. 1, p. 54.)

The curvatures of the arteries are another predisposing cause of the disease; and, according to Richerand, such cause has manifest effect in determining the formation of the great sinus of the aorta, the dilatation which exists between the cross and the origin of this large artery, and is the more considerable the older the person is: Monro even thought that one-half of old persons have an aneurism at the beginning of the aorta. And with respect to aneurisms in general, which are preceded by calcareous depositions, thickening, and disease of the coats of the vessel, they are most frequently met with in persons of advanced age. Aneurisms from wounds are of course often seen in individuals of every age. In old people the coats of the arteries are subject to a disease which renders them incapable of making due resistance to the lateral impulse of the blood. The disease here alluded to is what is described in a foregoing part of this article, one common effect of which is the deposition of calcareous matter between the inner and muscular coats of the arteries. "People in the early part of life," says Mr. Wilson, "are not very subject to these calcareous depositions; but I have occasionally met with them in the arteries of very young people. I have seen a well-marked deposition of the phosphate of lime in the arteries of a child under three years of age." He adds, that few persons above the age of sixty are free from these ossifications.—(On the Blood, and on the Anatomy, Pathology, &c. of the Vascular System, p. 375, Lond. 1819.)

Though spontaneous aneurisms are most common in old persons, the disease is not absolutely confined to them; for I assisted Mr. Docker at Canterbury in an operation for the cure of a popliteal aneurism in a postillion, whose age must have been under thirty; and Mr. Wilson says that he has met with several instances of the disease in the aorta and other vessels, where the patients were not more than forty years of age.—(Op. cit. p. 376.)

According to Sir Astley Cooper, the time of life when aneurism generally occurs, is between the ages of thirty and fifty; an age when exercise is considerable and strength on the decline. In very old age the disease is not so common. However, he operated successfully on a case of popliteal aneurism where the patient was eighty four or eighty-five years old. He operated with success on another man sixty-nine years of

MASS. MED. COLLEGE.

age. He has also seen a boy only eleven years old with aneurism of the anterior tibial artery. The man of more than eighty is the oldest, and the boy of eleven the youngest, aneurismal patients he has ever seen.—(See Lectures, vol. 2, p. 40.)

Richerand affirms, that out of twelve popliteal aneurisms which he has seen in hospital or private practice, ten were caused by a violent extension of the leg. This statement, he says, will derive confirmation from the following experiment.

Place the knee of a dead subject on the edge of a firm table, and press on the heel so as forcibly to extend the leg far enough to make the ligaments of the ham snap. Now dissect the parts, cut out the artery, and examine its parietes in a good light, when the lacerations of the middle coat will be observable and rendered manifest by the circumstance of those places appearing semitransparent where the fibres are separated, the parietes at such points merely consisting of the internal and external tunics.—(Nosogr. Chir. t. 4, p. 73, 74, édit. 2.) But the insufficiency of this explanation is clear enough from the fact that such violence as is requisite to break the ligaments of the knee, cannot be imagined to happen in the accidents which ordinarily bring on aneurism in the ham.

The implicit belief also which Richerand seems to place in the idea that the laceration of the middle coat of an artery will bring on an aneurism, while the inner coat is perfect, will appear to be unfounded, when it is remembered that Hunter, Home, and Scarpa even dissected off the external and middle coats of arteries, without being able in this manner to cause an aneurism. Nay, where the experiment has been made of applying a tight ligature to an artery, and immediately removing it again in order to determine whether the division of both the inner coats of the vessel would terminate in an obliteration of the tube of the vessel, no aneurism has been the consequence.

Pelletan accounts for the frequency of popliteal aneurisms somewhat differently from Richerand: speaking of the two principal motions of the knee, viz: extension and flexion, he remarks, that the first of these is so limited that it is actually an incipient flexion necessarily produced by the curvature backward both of the condyles of the femur and those of the tibia. This curvature, which would seem to protect the popliteal artery against any dangerous elongation that might otherwise be caused by a forcible extension of the joint, becomes the very source of such an elongation in persons who are accustomed to keep their limbs bent, or who from this state proceed hastily and violently to extend the leg. The arterial tubes are really shortened when the limbs are in the state of flexion, and lengthened when the extension of the members renders it necessary. Hence, says Pelletan, it is manifest that an habitually shortened state of these vessels, and their sudden elongation, must be attended with hazard of rupturing their parietes.—(Clinique Chirurgicale, t. 1, p. 112.)

The opinion of Pelletan, however, is quite untenable; because Mr. Hodgson has several times repeated the experiment mentioned by Richerand, and found, as that gentleman did, that the coats of the artery were never lacerated unless the degree of violence had been such as to rupture the ligaments of the knee.—(On Diseases of Arteries, &c. p. 64.)

Aneurisms are exceedingly common in the aorta, and they are particularly often met with in the popliteal artery. The vessels which are next to these the most usually affected, are the crural, common carotid, subclavian, and brachial arteries. The temporal and occipital arteries, and those of the leg, foot, fore-arm, and hand, are far less frequently the situations of the present disease. But although it is true that the larger arteries are the most subject to the ordinary species of aneurisms, the smaller arteries seem to be more immediately concerned in the formation of one peculiar aneurismal disease, now well known by the name of the aneurism by anastomosis, of which I shall hereafter speak.

According to surgical writers, the causes of aneurisms operate either by weakening the arterial parietes or by increasing the lateral impulse of the blood against the sides of these vessels. It is said to be in both these ways that the disease is occasioned by violent contusions of the arteries, the abuse of spirituous drinks, frequent mercurial courses, fits of anger, rough exercise, exertions in lifting heavy burdens, &c. In certain persons aneurisms appear to depend upon a particular organic disposition. Of this description was the subject whose arteries, on examination after death, were found by Lancisi affected with several aneurisms of various sizes. I have known a person have an aneurism of one axillary artery, which disease got spontaneously well, but was soon afterward followed by a similar swelling of the opposite axillary artery, which last affliction proved fatal. I have seen another instance in which an aneurism of the popliteal artery was accompanied with one of the femoral in the other limb. Boyer mentions a patient who died of femoral aneurism in La Charité, at Paris, and who had also another aneurism of the popliteal artery equal in size to a walnut.—(Traité des Maladies Chir. &c. p. 102, t. 2.) The greatest number of aneurisms that Sir Astley Cooper has seen in one patient is seven; and it is a remark made by this eminent surgeon, that when an aneurism occurs in the ham, the disease is frequently of a local nature; but that when it is between the groin and ham, disease of other arteries is very commonly met with.—(See Lectures, vol. 2, p. 37.) The most remarkable case, however, proving the existence of a disposition to aneurisms in the whole arterial system, is mentioned by Pelletan: "J'ai pourtant vu plusieurs fois ces nombreux aneurismes occupant indistinctement les grosses ou les petites artères, mais surtout celles des capacités: j'en ai compté soixante-trois sur un seul homme, depuis le volume d'une aveline jusqu'à celui de la moitié d'un œuf de poule."—(Clinique Chir. t. 2, p. 1.)

Aneurisms, and those diseases of the coats of arteries which precede the formation of aneurism, are much less frequently met with in women than men.—(Lassus, Pathologie Chir. t. 1, p. 348.) A few years before John Hunter died, Mr. Wilson heard him remark, that he had only met with one woman affected with true aneurism.—(Anatomy, Pathology, &c. of the Vascular System, p. 376.) Mr. Hodgson drew up the following table, exhibiting the comparative frequency of aneurisms in the two sexes, in different cases of this disease, and also in the different arteries of the body, as deduced from examples either seen by himself, during the lives of the patients, or soon after their death.

	Total.	Males.	Females.
Of the ascending aorta, the arteria innominata, and arch of the aorta . .	21	16	5
Descending aorta	8	7	1
Carotid artery	2	2	
Subclavian and axillary	5	5	
Inguinal artery	12	12	
Femoral and popliteal	15	14	1
	63	56	7

This table does not include aneurisms arising from wounded arteries, nor aneurisms from anastomosis.—(On the Diseases of Arteries and Veins, p. 87.)

Sir Astley Cooper confirms the fact of the much greater frequency of aneurism in the male than the female sex. Women, he says, rarely have aneurism in the limbs. In forty years' experience, he has seen only eight cases of popliteal aneurism in women, but an immense number in men. Most of the aneurisms which he has seen in females have been in the ascending aorta, or the carotids.—(Lectures, vol. 2, p. 41.)

It was observed by Morgagni, and it has been noticed in this country, that popliteal aneurisms occur with particular frequency in postillions and coachmen, whose employments oblige them to sit a good deal with their knees bent. In France, the men who clean out the dissecting rooms and procure dead bodies for anatomists, are said almost all of them to die with aneurismal diseases. Richerand remarks, that he never knew any of these persons who were not addicted to drinking, and he comments on the debility which their intemperance and disgusting business together must tend to produce.—(Nosogr. Chir. t. 4, p. 74, édit. 2.)

Aneurisms are supposed by Roux to be much more frequent in England than France; a circumstance which, before he proves it to be a fact, he vaguely refers to the mode of life and kind of labour to which a

large portion of the population of England is subjected Indeed, he connects this surmise with a reason for the very cultivated state of this part of knowledge in England: thinks that we have been placed in favourable circumstances for perfecting the treatment of aneurisms, and acknowledges that we have contributed more than his countrymen both in the last and present century to the improvement of this branch of surgery. —(Roux, Parallèle de la Chirurgie Angloise avec la Chirurgie Françoise, &c. p. 249.) But ere M. Roux ventured into such conjectures, he ought at least to have specified what particular occupations and kind of labour are known by Englishmen themselves to be frequently conducive to aneurism; for, with the exception of postillions and coachmen, of whom there is also abundance in France, I am not aware that any determinate class of persons is found in this country to be affected with particular frequency.

In some instances aneurisms of the axillary artery appear to have arisen from violent extension of the limb.—(See the cases recorded by Pelletan in Clinique Chir. t. 2, p. 49 and 83.) In other examples related by the some practical writer, aneurism arose from reiterated contusions and rough pressure on parts.—(Op. cit. p. 10 and 14.)

The extremity of a fractured bone may injure an artery and give rise to an aneurism, instances of which are recorded by Pelletan (Op. cit. t. 1, p. 178) and Durverney (Traité des Mal. des Os, t. 1). In Pelletan's case, the disease followed a fracture of the lower third of the leg. An aneurism of the anterior tibial artery from such a cause, is also described by Mr. C. White.—(Cases in Surgery, p. 141.)

The following case of an aneurism of the humeral artery after amputation is recorded by Warner: C. D. was afflicted with a caries of the joint of the elbow, which was attended with such circumstances as rendered the amputation of the limb necessary. The operation was performed at a proper distance above the diseased part, and the vessels were taken up with needles and ligatures.

In a few days the humeral artery became so dilated above the ligature upon it as to be in danger of bursting. Hence it was judged necessary to perform the operation for the aneurism, which was done, and the vessel secured by ligature above the upper extremity of its distended coats. Every thing now went on for some time exceedingly well, when suddenly the artery again dilated, and was in danger of bursting above the second ligature. These circumstances made it necessary to repeat the operation for the aneurism. From this time every thing went on successfully till the stump was on the point of being healed; when, quite unexpectedly, the artery appeared a third time diseased in the same manner as it had been previously, for which reason a third operation for aneurism was determined on and performed.

The last operation was near the axilla, and was not followed by any relapse.

Could the several aneurisms of the humeral artery (says Mr. Warner) be attributed to the sudden check alone which the blood met with from the extremity of the vessel being secured by ligature; or is it not more reasonable to suppose that the coats of the artery nearly as high as the axilla were originally diseased and weakened? The latter, in the opinion of this judicious writer, seems the most probable way of accounting for the successive returns of the disease of the vessel; since it is found from experience that such accidents have been very rarely known to occur after amputation, either of the arm or thigh, where nearly the same resistance must be made to the circulation in every subject of an equal age and vigour, who has undergone such operation.

If it should be supposed that the several dilatations of the coats of the vessel, continues Mr. Warner, arose merely from the check in the circulation, it will not be easy to account for the final success of this operation; and especially when we reflect that the force of the blood is increased in proportion to its nearness to the heart.—(See Cases in Surgery, p. 139, 140, edit. 4.) Ruysch has related an observation somewhat similar. —(Obs. Anat. Chir. t. 1, p. 4.)

Aneurisms sometimes follow the injury of a large artery by a gun-shot wound. The passage of a bullet through the thigh, in one example, gave rise to a femoral aneurism.—(See Parisian Chirurgical Journal, vol. 2, p. 109.) The same cause produced an aneurism high up the thigh of a soldier who was under the care of my friend Mr. Collier, at Brussels, after the battle of Waterloo.

PROGNOSIS.

In cases of aneurism the prognosis varies according to a variety of important circumstances. The disease may generally be considered as exceedingly dangerous; for, if left to itself, it almost always terminates in rupture, and the patient dies of hemorrhage. There are some examples, however, in which a spontaneous cure took place, and aneurismal swellings have been known to lose their pulsation, become hard, smaller, and gradually reduced to an indolent tubercle, which has entirely disappeared. After death the artery in such instances has been found obliterated, and converted into a ligamentous cord, without any vestige of the aneurism being felt. Aneurisms are also sometimes attacked with mortification; the sac and adjacent parts slough away; the artery is closed with coagulum; and thus a cure is effected. Lastly, tumours having all the character of aneurisms have been known to disappear under the employment of such pressure as was certainly too feeble to intercept entirely the course of the blood. Such examples of success, however, are not common, and whenever they happen, it is because the entrance of blood into the sac is prevented by the coagulation of that already contained in it, and because the artery above the swelling is filled with coagulum. They must, in fact, have been cured on the very same principle which renders the surgical operation successful.

Nothing is subject to more variety, than the duration of an aneurism previously to its rupture; the tumour bursting sooner or later, according as the patient happens to lead a life of labour, or ease, temperance, or moderation. Even the bursting of an internal aneurism may not immediately kill the patient: a stone-cutter died in the hospital Saint Louis with an enormous aneurism, situated on the left side of the lumbar vertebræ. The body was opened by Richerand, who found that the external tumour consisted of blood, which, after making its way through the muscles, had been effused into a cyst formed in the midst of the cellular substance of the loins. The track through which it came led into another aneurismal sac contained in the abdomen, and situated behind the peritoneum, on the left side of the lumbar vertebræ. In endeavouring to discover whence the extravasated blood proceeded, Richerand found that the abdominal aorta was entire, though in contact with the swelling. The original affection consisted of an aneurismal dilatation of the interior portion of the thoracic aorta, which had burst at the point where it lies between the crura of the diaphram. The blood had probably escaped very slowly, and it had accumulated in the cellular substance round the kidney, so that three cysts had burst successively before the patient died.—(Nosogr. Chir. t. 4, p. 82, édit. 2.)

Every aneurism, so situated that it can neither be compressed nor tied above the swelling, has generally been considered absolutely incurable, except by a natural process, the establishment of which is not sufficiently often the case to raise much expectation of a recovery on this principle. But it should be recollected that sometimes the size of the swelling appears to leave no room for the application of a ligature above it, while things are in reality otherwise, in consequence of the communication between the sac and the artery bearing no proportion to the magnitude of the tumour itself. At the present day, also, enlightened by anatomical knowledge, and encouraged by successful experience, surgeons boldly follow the largest arteries, even within the boundaries of the chest and abdomen, as we shall presently relate, and numerous facts have now proved that few external aneurisms are beyond the reach of modern surgery. It being certain that aneurisms cannot commonly be cured, except by an obliteration of the affected artery, it follows that the circulation must be carried on by the superior and inferior collateral branches, or else the limb would mortify. Experience proves that the impediment to the passage of the blood through the diseased artery obliges this fluid to pass through the collateral branches, which gradually acquire an increase of size. It is therefore a common notion that it must be in favour of the success of the operation, if the disease be of a certain standing;

and in direct opposition to the sentiments of Kirkland, Boyer even asserts that the most successful operations have been those performed on persons who have had the disease a long while.—(Maladies Chirurg. t. 2, p. 116.)

There is this objection to delay, however, that the tumour becomes so large, and the effects of its pressure so extensive and injurious, that after the artery is tied, great inflammation, suppuration, and sloughing often attack the swelling itself, and the patient falls a victim to what would not have occurred had the operation been done sooner.

The large size of an aneurism, as Mr. Hodgson has rightly observed, is a circumstance which materially prevents the establishment of a collateral circulation. When the tumour has acquired an immense bulk, it has probably destroyed the parts in which some of the principal anastomosing branches are situated; or by its pressure it may prevent their dilatation.—(On the Diseases of Arteries and Veins, p. 259.) The practice of permitting an aneurism to increase, that the collateral branches may become enlarged (says this gentleman), is not only unnecessary but injurious, inasmuch as the increase of the tumour must be attended with a destruction of the surrounding parts, which will render the cure of the disease more tedious and uncertain.—(P. 266.)

The most successful operations which I have seen were performed before the aneurismal swellings were very large. However, notwithstanding the great disadvantages of letting the swelling become bulky before the operation, the fact appears scarcely yet to have made due impression, and surgeons are yet blinded with the plausible scheme of giving time for the collateral vessels to enlarge; at least, I infer that things are so, from having lately seen a patient who has been advised to let the operation be postponed on such a ground, though the swelling in the ham was already as large as an egg.

The surgeon should not be afraid of operating, although appearances of gangrene may have taken place on the tumour; for, as Mr. Hodgson remarks, should it burst afterward, it is probable that both extremities of the artery in the sac will be closed with coagulum.—(Hodgson, p. 305.) Sir Astley Cooper tied the external iliac artery in two cases of inguinal aneurism, when gangrene existed, and though the tumours burst no hemorrhage ensued. The coagulum was discharged; the sac granulated; and the sores gradually healed.—(Medico-Chir. Trans. vol. 4, p. 431.)

The effects of the pressure of aneurisms upon the bones are justly regarded as an unpleasant complication, when they take place in an extensive degree, and, according to writers, they may sometimes induce a necessity for amputation.—(Boyer, Traité des Mal. Chir. t. 2, p. 117.) However, I have never seen a case of this description; and Mr. Hodgson, as we have already explained, informs us that the affection of the bones is hardly ever attended with exfoliations, or the formation of pus, so that if the aneurism can be cured, the bones will generally recover their healthy state, without undergoing those processes which take place in the cure of caries or necrosis.—(On Diseases of Arteries and Veins, p. 80.) At the same time there can be no doubt, that where the tumour has been allowed to attain a large size before an attempt is made to cure it, and where from this cause both the neighbouring soft parts and the bones have suffered considerably, the completion of a cure, that is to say, the full restoration of the use of the limb, must be far more distant than in other cases where the cure is attempted in an earlier stage. Here then we see another reason against the pernicious doctrine of waiting for the enlargement of the anastomising vessels in addition to that which has been urged above.

The age, constitution, and state of the patient's health are also to be considered in the prognosis; for they undoubtedly make a great difference in the chance of success after the operation.

The operation, however, should not be rejected on account of the age of the patient, if the circumstances of the case in other respects appear to demand it: for it has often succeeded at very advanced periods of life. "I have seen several aneurisms cured by the modern operation in patients above sixty years of age."—(Hodgson, p. 304.) Similar cases have fallen under my own notice. Sir Astley Cooper, already noticed, has operated with success for a popliteal aneurism on one patient aged 85, and on another 69 years old, with the same favourable result.

When an aneurism exists in the course of the aorta, the violent action of the heart, excited by an operation in the extremities, may cause it to burst, and prove instantaneously fatal. Two cases occurred a few years ago in this metropolis, in which the patients died from such a cause during operations for popliteal aneurisms.—(See Hodgson on Diseases of Arteries, p. 306; London Med. Review, vol. 2, p. 240; and Burns on Diseases of the Heart, p. 226.) Were the co-existence of the internal aneurism known, the operation for the other tumour would be improper, and the surgeon should limit the treatment to palliative means.

Experience proves, however, that the circumstance of there being two aneurisms in the limb should not prevent the operation, which is to be practised at separate periods. Facts in support of this statement are quoted by Mr. Hodgson.—(P. 310.)

OF THE SPONTANEOUS CURE AND GENERAL TREATMENT OF ANEURISMS.

The obliteration of the sac in consequence of a deposition of lamellated coagulum in its cavity, as Mr. Hodgson has well described, is the mode by which the spontaneous cure of aneurism is in most instances effected. The blood soon deposites upon the inner surface of the sac a stratum of coagulum; and successive depositions of the fibrous part of the blood by degrees lessen the cavity of the tumour. At length, the sac becomes entirely filled with this substance, and the deposition of it generally continues in the artery on both sides of the sac as far as the giving off of the next large branches. The circulation through the vessel is thus prevented; the blood is conveyed by collateral channels; and another process is instituted whereby the bulk of the tumour is removed.—(On the Diseases of Arteries, &c. p. 114.) Such desirable increase of the coagulated blood in the sac is indicated by the tumour becoming more solid, and its pulsation weak or ceasing altogether.

Another mode, in which the disease is spontaneously cured, happens as follows: an aneurism is sometimes deeply attacked with inflammation and gangrene; a dense, compact, bloody coagulum is formed within the vessel, shutting up its canal, and completely interrupting the course of the blood into the sac. Hence, the ensuing sphacelation and the bursting of the integuments and aneurismal sac are never accompanied by a fatal hemorrhage; and the patient is cured of the gangrene and aneurism if he has strength sufficient to bear the derangement of the health necessarily attendant on so considerable an attack of inflammation and gangrene.

When a patient dies of hemorrhage, after the mortification of an aneurism, it is because only a portion of the integuments and sac has sloughed, without the root of the aneurism, and especially the arterial trunk, being similarly affected. For cases illustrative of this statement, refer to Hodgson on Diseases of Arteries, p. 103, &c.

A third way, in which an aneurism may be spontaneously cured, is by the tumour compressing the artery above, so as to produce adhesion of its sides, and obliteration of its cavity. This mode of cure must be uncommon: it has been adverted to by Sir E. Home, Scarpa, Dr. John Thomson, and others; but some facts, tending to prove it, have been collected by Mr. Hodgson, and are published in his useful work.—(See p. 107, &c.)

A fourth mode of cure is illustrated in a case related by Sir Astley Cooper: a man, in Guy's Hospital, had an aneurism just below the groin. He was sitting before the fire, when he felt something burst in the upper part of his thigh. On examination he found no blood had escaped, and, in fact, the aneurism had not yet reached the skin, so as to be adherent to it. His thigh, however, was enormously swelled; he was unable to use his limb, and was put to bed. For three days afterward a pulsation was perceptible in the aneurism; but it then ceased, and the size of the limb began to diminish. At the end of four months, the aneurismal swelling had considerably subsided, he could use the limb, and in less than six months he was discharged from the hospital. He afterward fell a victim to the rupture of another aneurism in the abdomen. On examination of the body, it was found that the aneurism

in the thigh, just below Poupart's ligament, had burst under the fascia lata, and the femoral artery had been obliterated by the pressure of the large quantity of effused blood.—(See Lancet, vol. 1, p. 430.)

"The surgical treatment of aneurism (says Mr. Hodgson) consists in the obliteration of the cavity of the artery communicating with the sac, so that the ingress of the blood into the latter is either entirely prevented, or the stream which passes through it is supplied only by anastomosing branches, and consequently the force of the circulation is so much diminished, that the increase of the tumour is prevented, and the deposition of coagulum is promoted. By the absorption of its contents, and the gradual contraction of the sac, the cure is ultimately accomplished. The blood is conveyed to the parts, which it is destined to supply, by collateral vessels, some of which, being gradually enlarged, constitute permanent channels for the circulation. The obliteration of the artery is effected by the excitement of such a degree of inflammation in its coats as shall produce adhesion of its sides. These objects have been attempted by the compression or the ligature of the artery. The latter method constitutes the operation for aneurism."—(P. 165.)

Such are the principles of the ordinary mode of cure; but it appears from certain facts, recorded by Mr. Wardrop, Dr. Bush, and other practitioners, that some aneurisms may be cured by a surgical operation, which was first suggested by Brasdor, and the design of which is to hinder the free transmission of blood through the aneurismal sac by tying the artery on that side of it which is most remote from the heart. This practice, however, is only allowable in certain examples, in which the application of a ligature in the common way is no longer practicable, because its success is much less certain, as might easily be anticipated, since the plan does not comprise the very desirable object of directly preventing the entrance of blood into the aneurismal sac. To this subject, however, we shall presently return.

According to Scarpa, a complete cure of an aneurism cannot be effected, in whatever part of the body the tumour is situated, unless the artery from which the aneurism is derived be, by nature or art, obliterated, and converted into a perfectly solid ligamentous substance, for a certain extent above and below the place of the ulceration, laceration, or wound. When aneurisms are cured by compression, the cure is never accomplished, as some have supposed, by the pressure strengthening the dilated proper coats of the artery, and restoring, especially to the muscular coat, the power of propelling the blood along the tube of the artery, as it did previously to its supposed dilatation. Petit and Foubert thought, that the natural curative process sometimes consisted in a species of clot, which closed the laceration, ulceration, or wound of the artery, and resisted the impulse of the blood, so as still to preserve the continuity of the coats of the artery, and the pervious state of the vessel. Haller imbibed a similar sentiment from experiments made on frogs.

If the foregoing statement of Scarpa, respecting the obliteration of the tube of the adjacent portion of the artery, when an aneurism is cured, had been delivered merely as what is the most common course of things, it would not have been incorrect; but when he denies the possibility of the caliber of the vessel being ever preserved, whether the disease be cured by art or nature, he is exceeding the bounds of accuracy.

Notwithstanding aneurisms cannot in general be cured, as Scarpa has explained, unless the artery be rendered impervious for some extent above and below the tumour, I believe we must make an exception to this observation with respect to the few aneurisms of the aorta (especially those of its arch) which, according to the records of surgery, have been diminished and cured by Valsalva's treatment. In such examples, we are not to suppose that the aorta becomes obliterated at its very beginning; but that the diminution of the quantity of circulating blood, the reduced impetus of this fluid, the lessened distention of the aneurismal sac, the general weakness induced in the constitution, and the increased activity of the lymphatic system, all necessary effects of Valsalva's method, have combined to bring about a partial subsidence of the tumour.

"It is a common opinion (says Mr. Hodgson), that the radical cure of an aneurism cannot take place without the obliteration of the artery from which the disease originates. It is probably owing to this idea, that aneurisms of the aorta have generally been considered as incurable diseases, and consequently that so little attention has been given to their treatment."—(P. 118.) The facts, however, which this gentleman has related satisfactorily prove, 1st, that a deposition of coagulum may take place in an aneurismal sac, to such an extent as entirely to block up the communication between its cavity and that of the artery from which its originates; secondly, that a sac thus filled with coagulum cannot prove fatal by rupture; and, thirdly, that the gradual absorption of its contents, and the consequent contraction of the sac, may proceed to such an extent as to effect the cure of the disease, without any obstruction taking place in the caliber of the vessel from which it originates. See cases 20, 21, 22, &c.—(Hodgson on Diseases of the Arteries, &c. p. 119, &c.) In support of this doctrine, some facts are also cited from Corvisart.—(Essai sur les Maladies du Cœur, p. 313, &c.)

A part of these cases, it is true, are not viewed exactly in this light by Kreysig, who argues (as I think, without much probability), that they might have been only adipose swellings, connected with or formed in, the parietes of the artery, a disease described by Stenzel.—(German transl. of Mr. Hodgson's book, p. 174.)

That a punctured artery may occasionally be healed in this manner, Scarpa himself proves, by a case which he examined, where an aneurism took place from the wound of a lancet in bleeding. In the article Hemorrhage we shall see that Jones's experiments show the same thing, and the particular circumstances in which it may happen. But the occurrence is rare, and Scarpa says that it can hardly be called a radical cure, as the cicatrix is always found in a state ready to burst and break, if the arm be, by any accident, violently stretched or struck where the wound was situated.

In the spontaneous cure of aneurisms, arising from arteries of inferior size to that of the aorta, repeated examinations have proved, that the deposition of coagulum does not in general merely fill up the sac, but obliterates the tube of the artery above and below the disease to the next important ramifications. Yet even here, exceptions probably take place; for Mr. Hodgson has brought forward one instance in which a small sac, which originated from the anterior artery of the cerebrum, was completely filled with firm coagulum, which did not extend into the cavity of the vessel.—(On Diseases of Arteries, p. 132.) And he reports the particulars of a true femoral aneurism, communicated to him by Sir A. Cooper, in which, after the patient's death, the femoral artery was found dilated into a sac, which was lined on all sides with very firm layers of coagulum, in the centre of which was an irregular canal, through which the circulation was continued. As the inside of this canal presented a membranous appearance, it was inferred that the aneurism had been cured.—(Op. cit. p. 134.) Here I may be permitted to remark, that if this case be correctly reported, viz. if it were a true aneurism by dilatation of all the arterial coats, and the inside of it was every where lined by firm layers of coagulum, it amounts to a proof that such a deposition is not entirely confined to aneurisms by rupture, as Scarpa supposes. And, in addition to this fact, I may mention, as referring to the same question, a case of aneurism from dilatation of the arterial coats, observed by Guattani, where the same process took place. "Arteriæ iliacæ ovalem hanc partem aneurysmaticam polyposa substantia variæ densitatis adeo infarctam esse denotebam, ut tunicarum ejusdam forma penitus destructa in uniformem massam, spongiæ cera imbutæ similem, transformata videretur."—(Hist. 17, Collect. Lauth. p. 158.)

Whenever the ulcerated, lacerated, or wounded artery is accurately compressed against a hard body like the bones, it ceases to pour blood into the surrounding cellular sheath, because its sides, being kept in firm contact, for a certain extent above and below the breach of continuity, become united by the adhesive inflammation, and converted into a solid ligamentous cylinder. Molinelli, Guattani, and White have given examples and plates illustrative of this fact. When aneurisms get well spontaneously, the same fact is observed after death, as Valsalva, Ford, &c. have demonstrated. I have myself seen, in St. Bartholomew's Hospital, an instance in which a man had had a spon-

taneous cure of an aneurism in the left axilla, but afterward died of hemorrhage from another aneurismal swelling under the right clavicle: the artery on the left side was found completely impervious. My friend Dr. Albert had under his care, in the York Hospital, Chelsea, a dragoon, who recovered spontaneously of a very large aneurism of the external iliac artery: the tumour sloughed, discharged about two quarts of coagulated blood, and then granulated and finally healed up. Paoli relates a similar termination of a popliteal aneurism. Moinichen and Guattani relate other examples. Hunter found the femoral artery quite impervious and obliterated at the place where a ligature had been applied fifteen months before. Boyer noticed the same fact in a subject eight years after the operation. Petit describes the spontaneous cure of an aneurism at the bifurcation of the right carotid: the subject having afterward died of apoplexy, the vessel, on dissection, was found closed up and obliterated from the bifurcation as far as the right subclavian artery. Desault had an opportunity of opening a patient, in whom a spontaneous cure of a popliteal aneurism was just beginning: he found a very hard bloody thrombus, which extended for three finger-breadths within the tube of the artery above the sac, and was so firm as to resist injection, and make it pass into the collateral branches.

Both the spontaneous and surgical cures of aneurisms have generally two stages: in the first, the entrance of the blood into the aneurismal sac is interrupted; in the second, the parietes of the artery approach each other, and becoming agglutinated, the vessel is converted into a solid cylinder. This doctrine is corroborated by the tumour first losing its pulsation, and then gradually diminishing and disappearing.

In order that compression may make the opposite sides of an artery unite, and thus produce a radical cure of an aneurism, Scarpa says, the degree of pressure must be such as to place these opposite sides in firm and complete contact, and such as to excite the adhesive inflammation in the coats of the artery. The point of compression must also fall above the laceration or wound of the artery; for when it operates below, it hastens the enlargement of the tumour: and Scarpa adds, that, in practice, bandages which are expulsive and compressive are more useful for making pressure than any tourniquets or instruments, many of which are contrived to operate without retarding the return of blood through the veins.

In order that pressure may succeed, the coats of the vessel at the place where it is made, must be sufficiently free from disease to be susceptible of the adhesive inflammation. When the arterial coats round the root of the aneurism are much diseased, Scarpa considers them as insusceptible of the adhesive inflammation, although compressed together in the most scientific manner, and even when tied with a ligature, which only acts by making circular pressure on the vessel.

This statement would appear to derive confirmation from the following fact: Mr. Langstaff amputated the thigh of a person seventy-five years of age; but the vessels were so ossified that they could not be effectually tied, and the patient died within twenty-four hours. It is generally supposed, says Mr. Lawrence, that this condition of the arterial coats is incompatible with their union under the application of the ligature. The opinion should be received, however, with some limitation. In a man fifty-nine years of age, bleeding took place nearly a month after amputation from the ossified femoral artery, and Mr. Lawrence was therefore obliged to expose and tie that vessel again for the suppression of the hemorrhage, when he found a hard tube, which cracked immediately the ligature was tightened: the bleeding, however, never returned.—(See Med. Chir. Trans. vol. 6, p. 193.) This case is mentioned, not with any view of encouraging surgeons to apply ligatures round diseased portions of arteries, a thing which should always be avoided when possible, but to let them be aware that an ossified artery is sometimes susceptible of being permanently closed, when a ligature is put round it. With respect to Scarpa's idea of making pressure operate so as to place the two opposite parietes of the artery at the mouth of the aneurismal sac completely in contact, in order that they may be united by the adhesive inflammation, and the cavity of the vessel be obliterated, I should think, with Mr. Hodgson, that if pressure will succeed only under these circumstances, it will answer very seldom, because, in almost all aneurismal sacs, a sufficient deposition of coagulum will have taken place to prevent the possibility of placing the opposite side of the artery at the mouth of the aneurism in a state of complete contact.—(On Diseases of Arteries, &c. p. 172.) Possibly, however, Scarpa's directions refer to a point of the vessel rather beyond the usual limits of the laminated coagula: and he is particular in recommending the practice only where the aneurism is soft and small.

Some advise trying compression in every case of aneurism, whether small, circumscribed, soft, flexible, indolent, or elevated, diffused, hard, and painful. But in the latter case Scarpa represents compression as decidedly hurtful. He says also that every bandage which compresses the aneurism, and also circularly constricts the affected part, is always injurious. The bandage, likewise, which compresses only the aneurism and directs the point of pressure below the rupture in the vessel; that which, on account of the great size, exquisite sensibility, depth of the root of the aneurism, and fleshy state of the surrounding parts, cannot effectually compress the artery against the bones, so as to bring the opposite sides of the vessel into contact; and lastly, the compression applied to a spontaneous aneurism, attended with a steatomatous, ulcerated, earthy disease of the arterial coats, ought to be considered as more likely to do harm than benefit. In cases of a completely opposite description, bandages have produced, and may produce, a radical cure, and should not be entirely disused.—(Scarpa on Aneurism, ed. 2, p. 221.)

Guattani first employed compression systematically for the cure of aneurisms, and out of fourteen cases in which he adopted the plan, four were cured by it. Mr. Freer details other examples; but, in general, pressure has hitherto been applied to the tumour itself, a method less likely to answer than that of making pressure on a sound part of the artery. Mr. Freer recommends the employment of Sennfio's instrument, or the following method: first, place a bandage, moderately tight, from one extremity of the limb to the other; then put a pad upon the artery, a few inches above the tumour; next, surrounding the limb with a tourniquet, let the screw be fixed upon the pad, having previously secured the whole limb from the action of the instrument by a piece of board wider than the limb itself, by which means the artery only will be compressed when the screw is tightened. The tourniquet should now be twisted till the pulsation in the tumour ceases. In a few hours the limb will become œdematous and swelled, when the tourniquet may be removed, and the pressure of a pad and roller will afterward be enough. By experiments which this gentleman made on the radial arteries of horses, these vessels were found to become inflamed, and to be rendered impervious by such a process.—(Freer, p. 112.) In a modern work Dubois is stated to have cured an aneurism of the thigh by steady pressure on the vessel for twenty-four hours.—(Med. Chir. Trans. vol. 4, p. 437.)

Sir A. Cooper describes another machine for compressing the femoral artery in cases of popliteal aneurism: it was used by Sir W. Blizard.

"The points of support for this instrument were the outer part of the knee and the great trochanter, a piece of steel passing from one to the other; and to the middle of this a semicircular piece of iron was fixed, which projected over the femoral artery, having a pad at its end moved by a screw, by turning which the artery was readily compressed, and the pulsation in the aneurism stopped without any interruption to the circulation in the smaller vessels." But although the patient on whom it was tried possessed unusual fortitude, he was incapable of supporting the pressure of the instrument longer than nine hours.—(Med. and Phys. Journal, vol. 8.) Few patients, indeed, can endure the pressure of such instruments a quarter of this time, when they are put on sufficiently tight to afford any chance of obliterating the artery; and on account of the suffering which they produce, they are rarely used by modern surgeons.

Whenever the treatment by pressure is attempted, the plan should be assisted with repeated bleedings, spare diet, and perfect quietude in bed. Digitalis has also been sometimes prescribed, with the view of lessening the impetus of the circulation. It is likewise a favourite plan with some practitioners to apply snow or powdered ice to the tumour, as I shall notice in de-

scribing Valsalva's treatment of aortic aneurisms. These last applications have been employed for the purpose of promoting the coagulation of the blood within the aneurismal sac, and the consequent obliteration of the cavity of the aneurism and the artery. Various examples in which it has been thought to have produced a cure are recorded by Guerin.—(Recueil Period. de la Soc. de Santé de Paris, No. 3. Pelletan, Clinique Chir.; and Ribes, Bulletins de la Faculté de Méd. de Paris, 1817, No. 1 and 2, p. 284.) The employment of ice, however, is not considered proper in every case. Breschet says, that when the swelling is large, the parts very tense, their texture changed, and the skin thin, the practice is likely to accelerate the formation of a slough; and he confirms a remark made by Mr. Hodgson, that some patients cannot continue this treatment longer than a few minutes, while others find it absolutely insupportable —(Fr. Transl. of Mr. Hodgson's Work, t. 1, p. 212—229.)

The grand means most to be depended upon for curing aneurisms, is tying the artery above the tumour. This more certainly prevents the great ingress of blood into the sac, and, what is quite as important, more certainly excites the adhesive inflammation within the tied part of the vessel, and, by holding the opposite sides of it steadily in contact, brings about their union, and an obliteration of the tube of the vessel, with tolerable regularity. The chief current of blood into the sac is thus stopped, the contents of the aneurism are afterward gradually absorbed, and the tumour dwindles away in proportion. The natural course of the blood being now permanently interrupted in the arterial trunk, it passes more copiously into the collateral branches, and these enlarging and anastomosing with others which originate from the large arteries beyond the obstruction, the necessary circulation is carried on.—(See Anastomosis and Inosculation.)

The ligature of the superficial femoral artery may be performed with the same confidence of success as the ligature of the brachial artery; that is, without any fear of destroying the circulation or depriving the subjacent limb of its vitality. Indeed, the numerous and conspicuous anastomoses which are met with all round the knee, correspond exactly with those which are observed round the elbow, and at the bend of the arm. This is not a peculiarity of the arteries of the extremities, but it is a general rule which nature has followed in the distribution of all the arteries, that the superior trunks communicate with the inferior by means of the lateral vessels. After the principal trunk of an artery is tied, its lateral branches not only carry on the circulation in the parts below the ligature, but do so with greater quickness and activity than they did previously, while the course of the blood was unimpeded through the principal trunk. This evidently arises from the increased determination of blood into the lateral vessels, as well as from the enlargement of the diameter of these vessels. After the amputation of the thigh, while the blood flows in a full stream from the superficial femoral artery, very little or no blood is poured out of the lateral vessels; but as soon as that artery is tied, the blood issues with impetuosity from the small arteries which run along within the vasti and cruræus muscles; and on these smaller arteries being also tied, the blood immediately oozes out from the minute arterial vessels of the muscles and cellular membrane. When the principal trunk of an artery is tied, its lateral branches gradually acquire a much larger diameter. After amputation of the thigh on account of a popliteal aneurism, the size and situation of which could not fail materially to impede the course of the blood through the trunk of the femoral artery, it has often been remarked, that, although both the trunk and the greater and smaller branches had been tied with the nicest accuracy, the patients have been in danger of losing their lives on account of the repeated copious hemorrhages from the innumerable small lateral vessels that had become unusually enlarged. In several cases, during the treatment, and especially after the radical cure, of popliteal aneurism by tying the superficial femoral artery in the upper third of the thigh, all the ramifications of the recurrent popliteal arteries have been felt beating strongly round the knee. We have already noticed that Boyer found in a man who some years previously had been operated on for a popliteal aneurism, but had afterward died from a caries of the tibia, that an arterial branch which runs in the substance of the sciatic nerve was dilated so much as to be equal in diameter to the radial artery. White, in dissecting the arm of a lady who, fifteen years before, had been operated on for an aneurism in the bend of the arm, found the brachial artery obliterated and converted into a solid cylinder for three inches below the place of the ligature, and as far as the division into the radial and ulnar arteries; but the recurrent radial and ulnar branches had become so much enlarged that taken together, they exceeded the size of the brachial artery above the situation of the ligature. In the dead body, it is found that an anatomical injection will pass more freely from one extremity to the other of an aneurismatic than of a sound limb, and this even when no vessels are visibly enlarged. Although it be self-evident that the circulation through the collateral vessels ought to be much more easy and quick the lower down the ligature is applied to the principal trunk; yet experience shows that this difference is not to be estimated very high; for in cases of popliteal aneurism, cæteris paribus, the success is the same, whether the femoral artery be tied very low down or very high up in the thigh.—(Scarpa.)

This facility of the passage of the blood through the lateral vessels is not the same in subjects of all ages; and in the same subject it is not the same in the inferior as in the superior extremity. An age under forty-five, and the operation being done on the arm, which is nearer the source of the circulation than the lower extremity, increase the chance of success. However, notwithstanding these are the opinions of Scarpa, and as general ones may not be incorrect, surgeons in England now operate for aneurisms of the lower extremity, and on patients much older than forty-five, with a degree of confidence which nothing but great success could inspire.

According to Scarpa, the circumstances chiefly preventive of success, especially in the popliteal and femoral aneurisms, are the following: rigidity, atony, or disorganization of the principal anastomoses, between the superior and inferior arteries of the ham and leg; sometimes depending on an advanced age, or on it together with the large size of the aneurism, which by long continued pressure has caused a great change in the neighbouring parts; or sometimes on steatomatous, ulcerated, earthy, cartilaginous disorganization of the proper coats of the artery, not confined to the seat of the rupture, but extending a great way above and below the aneurism, and also to the principal popliteal recurrent arteries, tibial arteries, and, occasionally, to portions of the whole track of the superficial femoral artery. Sometimes the pressure of a large aneurism renders the thigh-bone carious. In such circumstances, the ligature is apt to fail in closing the trunk of the artery; and, if it should succeed, the state of the anastomosing vessels will not admit of a sufficient quantity of blood being conveyed into the lower part of the limb. Hence, when the patient is much advanced in life, languid and sickly; when the internal coat of the artery is rigid, and incapable of being united by a ligature; when the aneurism is of long standing and considerable size, with caries of the os femoris or tibia; when the leg is weak and cold, much swelled, heavy, and œdematous; Scarpa considers the operation contra-indicated. I must, however, declare in this place that I have seen very large aneurisms, as well as aneurisms in persons of advanced age, cured by the Hunterian plan in St. Bartholomew's Hospital; and with respect to the affection of the bones, though it may be an unfavourable circumstance, its consequences are not so serious as those of ordinary caries, as I have already explained.

It appears, then, that the obliteration of the artery for a certain extent above and below the place of rupture, forms the primary indication in the radical cure of aneurism, whether compression or the ligature be employed; all other means are only auxiliary. Internal remedies may be useful, inasmuch as they tend to moderate the determination of the blood towards the place where the artery has been tied or compressed.

In the articles Hemorrhage and Ligature, I have related in detail the effects of the ligature upon a tied artery, and particularly the various processes which arise from its application and terminate in the permanent obliteration of the vessel. In the same places I have explained what are the best ligatures for use, as well as the safest manner of using them. Confining myself,

in the sequel of this article, to what expressly relates to aneurism, I shall here merely annex the following general directions, as stated by Mr. Hodgson.

First, The cord should be thin and round, such a ligature being most likely to effect a clean division of the internal and middle coats of the vessel, and not liable to produce extensive ulceration or sloughing.

Secondly, The ligature should be tight, in order to ensure the complete division of the internal and middle coats, and to prevent its detachment, it being almost impossible, even with the thinnest ligature, entirely to cut through a healthy artery.

Thirdly, The vessel should be detached from its connexions only to such an extent as is necessary for the passage of the ligature underneath it.

Fourthly, The immediate adhesion of the wound should be promoted by all such means as are known to promote that process in general.—(On the Diseases of Arteries, p. 225, 226.)

In the course of his experiments upon brutes, to ascertain the operation of the ligature, Dr. Jones arrived at a fact which offered the probability of leading to an improvement in the operation for aneurism.—(Treatise on Hemorrhage, chap. 3.) When a small, firm ligature is applied to an artery, it causes a division of the internal and middle coats; and if it be afterward removed, an effusion of lymph takes place between the cut surfaces into the cavity of the vessel. If several divisions of the internal and middle coats be thus effected in the vicinity of each other, the effusion of lymph was found by Dr. Jones to be sufficiently extensive to obliterate the cavity of the vessel. In the year 1800, Mr. C. Hutchison tied the brachial arteries of two dogs, and removed the ligatures immediately after their application: in both instances, as he assures us, the complete obliteration of the canal of the artery was the consequence of the operation.—(See Practical Obs. in Surgery, p. 103.) If, immediately after the operation for aneurism, the ligature should be removed, and yet the vessel become obliterated, it would be highly advantageous, as there would then be left in the wound no extraneous substance to prevent its union, or promote secondary hemorrhage by extending the sloughing or ulcerative process too far. It is to be regretted that success has not attended the repetition of the experiment by others. Mr. Hodgson tried it, but the artery did not become impervious.—(See Experiments A and B, p. 228, 229, of this gentleman's work.) Mr. Dalrymple of Norwich made the experiment not less than seven times on horses, and three times on sheep, and failed in every instance to obtain the same result as Dr. Jones. Not only was no coagulum formed, but even when the animal had been suffered to live until the thirteenth, fifteenth, and eighteenth days after the operation, the canal of the artery was not found obliterated. In each case, indeed, its caliber was contracted; but it was still capable of transmitting a lessened column of blood.—(Travers, in Med. Chir. Trans. vol. 4, p. 442.) Thus it appears, that an effusion of lymph is an invariable consequence of the operation, and as Mr. Travers has observed, the want of union is therefore owing to the opposite sides of the vessel not being retained in a state of contact, so as to allow of their adhesion. The presence of the ligature in the common mode of its application effects this object; and for the success of Dr. Jones's experiment it appeared only necessary that the opposite sides of the wounded vessel should be retained in contact, until their adhesion was sufficiently accomplished to resist the passage of the blood through the tube. This object might probably be effected by compression; but the inconveniences attending such a degree of pressure as would retain the opposite sides of an artery in contact at the bottom of a recent wound are too great to admit its employment. It occurred to Mr. Travers, that if a ligature were applied to an artery, and suffered to remain only a few hours, the adhesion of the wounded surfaces would be sufficiently accomplished to ensure the obliteration of the canal; and by the removal of the ligature at this period, the inconveniences attending its stay would be obviated. The danger produced by the residence of a ligature upon an artery arises from the irritation which as a foreign body it produces in its coats. Ulceration has never been observed to commence in less than twenty-four hours after the application of a ligature; while it is an ascertained fact, that lymph is in a favourable state for organization in less than six hours, in a wound the sides of which are preserved in contact.—(Jones, ch. 4, exp. 1.) If it be sufficient, therefore, to ensure their adhesion that the wounded coats of an artery be kept in contact by a ligature only three or four hours, ulceration and sloughing may in a great degree be obviated by promoting the immediate adhesion of the wound. Justified by this reasoning, Mr. Travers performed several experiments, by which he ascertained that if a ligature were kept six, two, or even one hour upon the carotid artery of a horse, and then removed, the adhesion was sufficiently advanced to effect the permanent obliteration of the canal. It appeared probable, that the same result would be obtained upon the healthy artery of a human subject.—(See Travers's Obs. in Med. Chir. Trans. vol. 4, and Hodgson on the Diseases of Arteries and Veins, p. 228, et seq.)

Sir A. Cooper performed one operation for a popliteal aneurism, with the view of ascertaining the efficacy of such a method on the human subject. He completely stopped the flow of blood for thirty-two hours, and then removed the ligature; but the pulsations of the tumour commenced again. He next applied the ligature forty hours longer, at the end of which time no pulsation recurred on the ligature being taken away. On the twelfth day, however, a considerable bleeding took place, and it was necessary to take up the vessel anew.

Mr. C. Hutchison tried this method, as modified by Mr. Travers, in an operation which he performed for a popliteal aneurism in a sailor, in Nov. 1813. A double ligature was passed under the femoral artery. The ligatures were tied with loops or slip knots, about a quarter of an inch of the vessel being left undivided between them. All that now remained of the pulsation in the tumour was a slight undulatory motion. Nearly six hours having elapsed from the application of the ligatures, the wound was carefully opened, and the ligatures untied and removed without the slightest disturbance of the vessel. In less than half a minute afterward the artery became distended with blood, and the pulsations in the tumour were as strong as they had been before the operation. Mr. Hutchison then applied two fresh ligatures; hemorrhage afterward came on; amputation was performed, and the patient died.—(See Practical Obs. in Surgery, p. 102, &c.) Now, as Mr. Hutchison chose to apply other ligatures on finding that the pulsation returned, the above case only proves that the artery is not obliterated in about six hours, and we are left in the dark respecting the grand question, namely, whether the vessel would have become obliterated by the effusion of coagulating lymph and the adhesive inflammation, notwithstanding the return of circulation through it. As for the hemorrhage which occurred, I think it might have been expected, considering the disturbance and irritation which the artery must have sustained in the proceedings absolutely necessary for the application of not less than four ligatures, and the removal of two of them. According to my ideas only one ligature ought to have been used, and none of the artery detached. We also have no description of the sort of ligatures which were employed; an essential piece of information in forming a judgment of the merits of the preceding method. The application, removal, and reapplication of ligatures are not consistent with the wise principles inculcated by the late Dr. Jones, and have in more instances than that recorded by Mr. Hutchison, brought on ulceration of the artery, and hemorrhage.

The limits of this work prevent me from entering into the particulars of the very interesting experiments undertaken by Mr. Travers, upon the arteries of animals, for the purpose of ascertaining the earliest period when a ligature might be removed from an artery, without any risk of the vessel not being duly obliterated. A full detail of them may be seen in another work (See Med. Chir. Trans. vol. 4 and 6), and others, in relation to the same question, may likewise be perused in Scarpa's appendix to his great work on aneurism.—(Memoria sulla Legatura delle principali Arterie degli Arti, &c. fol. Pavia, 1817.) The cases above related, and other considerations, long ago satisfied me that flattering as the suggestion of Dr. Jones was, the plan of removing the ligature previously to its natural separation would never answer in the operation for the cure of aneurism, unless either an obliteration of

the arterial tube would follow with reasonable certainty the taking away of the ligature directly after it had been applied and it had divided the inner coats of the vessel; or, at all events, unless the ligature could be withdrawn at a determinate period, when either the same obliteration would surely ensue, or be already complete; and all this with such regularity and infallibility in every case, that the surgeon would have no chance of being called upon to apply another ligature, do a second operation, or disturb the artery in any kind of way whatsoever.

Mr. Travers, in the prosecution of this inquiry, in which he evinced a full determination to be guided by no motive but the love of truth, at length tried the temporary application of the ligature in a case of brachial aneurism, which he operated upon Feb. 14, 1817. The artery was tied an inch and a half above the bend of the elbow with a noose ligature. The pulsation in the radial artery immediately ceased. On the 16th, at four o'clock in the afternoon, the ligature was removed with little difficulty, after having remained on the artery fifty hours. No pulsation ensued in the vessel below the point where the ligature had been applied, and the case was completely successful.

On the 28th November, 1817, in a case of popliteal aneurism, Mr. Travers tied the femoral artery at one o'clock. On the 29th, at four in the afternoon, the ligature was removed without difficulty after having been on the vessel twenty-seven hours. At this period no pulsation could be felt in the sac; but at seven in the evening a faint pulsation was perceptible. On the 30th, the pulsation, though very distinct, was less strong than before the operation. On the 2d, 3d, and 6th of December the pulsation is described as still continuing. On the latter day pressure was applied by means of a roller from below the knee to the groin, and was continued for a month, during which time the pulsation in the sac evidently became more feeble. On the 10th of January the tumour became tense and severely painful, and no pulsation in it could be distinguished. The next day the swelling was more diffused and less prominent; and on the 12th, as the disease underwent no amendment, Mr. Travers tied the artery again about two inches above the place where the former ligature had been applied. The next day the pain had diminished. The ligature was afterward allowed to separate of itself; and the case went on favourably to the cure. According to Mr. Travers, the first of these cases tends to prove that the continuance of the ligature upon the artery for a period of fifty hours, as certainlyand completely answers the purpose of its application, as if allowed to remain until thrown off by the natural process.

In the second case, Mr. Travers infers from the suspension of pain, and the diminished strength of the pulsation, for a month after the application of the temporary ligature, that a degree of impediment to the current of blood in the artery had been produced; circumstances which once led him to entertain hopes that the cure of the aneurism was gradually accomplishing. At length, however, the increase of the tumour, and the aggravation of pain and inflammatory symptoms, dispelled such expectation, and it was thought necessary to tie the femoral artery a second time, and adopt the common mode.

There are one or two points about this case on which the author does not particularly dwell, though they require consideration, ere one can form a correct judgment of the accuracy of one of his positions, "that nonpulsation of the sac is a sign auspicious or otherwise, simply as it stands connected with increase or diminution of bulk and pain."—(Med. Chir. Trans. vol. 9, p. 415.) The first question is, how are we to account for the sudden accession of pain, the absence of pulsation, the increase of the swelling, and the other changes which happened on the 10th of January? Judging from the particulars given, I should say that at this period the aneurismal sac gave way, and the disease changed from the circumscribed into the diffused form; an alteration which would account for the pulsation being entirely lost, the increase of pain, and the extension of the swelling, &c. Now although the circumstance of the sac giving way, or the increase of pain, swelling, &c. on the 10th of January, may be taken as an argument, that the application of the ligature for twenty-seven hours had failed in producing obstruction enough in the vessel to retard the progress of the disease, we ought to remember that at the time when these changes happened, a trial of pressure was making to which one might impute the change of the aneurism from the circumscribed to the diffused form with quite as much probability, as to the enlargement of the sac by blood sent into it through the imperfectly obliterated artery. However this may be, certain it is, that the second operation was done when no pulsation existed in the swelling; and perhaps, therefore, the case would have been doubly interesting, had the artery not been tied a second time until circumstances had unequivocally proved that this cessation of pulsation, attended as it was with an inflammatory state of the tumour, would not ultimately have ended in the cure of the disease.

Here, however, I may be speaking rather in the spirit of an experimenter whose curiosity has not been fully satisfied than as a surgeon, who should always be governed by the paramount consideration of extricating his patient from danger; and this will appear the more likely when I add that my mind has long been made up about the inexpediency of the temporary ligature as an innovation in surgery. The last case induced Mr. Travers to relinquish the temporary ligature; and among other reflections which incline him to give up the practice, he candidly states, "that the adhesive union is prevented by the enclosure of a foreign body in the wound long before suppuration has commenced. Suppuration is as certain to take place, though the ligature be removed after a few hours, as if it were left to be cast off; and the granulating process is more languidly performed after an interruption in its early stage, for the purpose of removing the obstacle to union, than where no such interruption has been given, and the obstacle has been removed by nature's own means. Hence it follows that the theory which, in removing the ligature within a given time, proposed the double advantage of a quicker as well as a surer process, fails in both points when brought to the test of practice upon the human subject."—(See Med. Chir. Trans. vol. 9, p. 416, 417.)

We have seen that when a temporary ligature which had been applied to the brachial artery fifty hours, was withdrawn by Mr. Travers, pulsation in the aneurismal tumour at the bend of the elbow did not return, and the disease was cured; but that in another instance where the ligature had been allowed to remain on the femoral artery only twenty-seven hours, a feeble pulsation was renewed a few hours afterward in a popliteal aneurism, and as the swelling became painful and more diffused some weeks after this experiment, though no pulsation could then be perceived, the femoral artery was tied a second time, and the ligature left to separate in the usual manner.

But from a case more recently published it would seem that the employment of a temporary ligature for only twenty-four hours on the femoral artery, may obliterate the vessel, and accomplish the cure of a popliteal aneurism. The patient was a seafaring man, aged 32; and the operator, Mr. Roberts, of Caernarvon; Mr. Evans and Mr. Carrey, other surgeons of that town, being present at the application, and also at the removal of the ligature. No pulsation recurred in the tumour; the edges of the wound were brought together with adhesive plaster; and in eleven days the part was quite healed.—(Med. Chir. Trans. vol. 11, p. 100.) This is the strongest case, I believe, which has been adduced in support of the use of the temporary ligature, whether we consider the little time which it was applied, the permanent cessation of all pulsation, the quickness with which the wound healed, or the complete recovery of the use of the limb; for when the patient was met six months after the operation, "he could go to the mast head with as great facility as at any period of his life." This fact proves also that there is a degree of irregularity in the period when the temporary ligature may be removed without the pulsation in the tumour below the constricted part ever returning. Whether the variety is to be referred to temperament, the kind of ligature used, its greater tightness in one case than another, or other circumstances, is not at present determined.

The greatest advocate which this practice has gained is Scarpa, whose sentiments, however, about the most advantageous form of ligatures, and mode of applying them in cases of aneurism, are very much at variance with what is inculcated by the best and most expe-

rienced surgeons in this country. Instead of using a fine ligature, composed of a single piece of thread, twine, or silk, he employs a cord consisting of from four to six threads, according to the size of the artery which is to be tied; and instead of aiming expressly at the division of the internal coats of the vessel with his ligature, as the generality of English surgeons do, for reasons explained in another part of this work (See Hemorrhage), he prefers a largish ligature, and interposes between the artery and the knot a small cylinder of linen spread with ointment, with the view of preventing the inner coats of the vessel from being divided. His reasons for this practice may be explained in a few words: he admits that whenever there is a concurrence of all the circumstances capable of inducing in the tied artery the proper degree of adhesive inflammation, above and below the place where a single circular ligature has been applied, this method is adequate to produce a speedy and steady closure of the arterial tube. But, says he, it sometimes happens, at least in man, that the pressure made by the circular ligature produces the ulcerative process more quickly in the artery than the adhesive inflammation. In fact, the circular ligature ulcerates the artery in general about the third day after the operation; and the adhesive inflammation does not always complete its course in this period of time. During this delay of the adhesive inflammation, the ulcerative process, occasioned by the pressure of the ligature, attacks more quickly even than surgeons generally suppose, the external cellular sheath of the artery, and penetrates into the cavity of the yet pervious vessel—and this of course with increased quickness, when the inner coats of the artery are already divided by the ligature. The dangers of non-adhesion and too rapid ulceration of the artery, Scarpa thinks, are placed at the greatest distance by preserving undivided all the three coats of the vessel under the pressure of the ligature; and hence his partiality to larger ligatures than are now used by the best surgeons in England, and to the interposition of a cylinder of linen between the knot and the vessel, as recommended by Paré, Heister, and Platner. If, however, he has had reason to suspect that a simple circular ligature has frequently failed in England, because other innovations have been occasionally substituted for it, and because we should not have sought for a better, if we had already had the best, how much more vulnerable is his own practice on a similar principle; since, generally speaking, it has not retained half so many approvers as they who still express their preference to other methods, and more especially to the use of a single ligature, uncomplicated with other extraneous substances! Is it probable, he asks, that the single circular ligature, which was formerly used with doubtful success by the greatest surgeons, should not have become, as is pretended, the most certain means of preventing secondary hemorrhage? "It is now wished (says he) to ascribe the failures of Mr. Hunter and of many other operators, not to the circular ligature, but to the improper treatment of the wound in general, and in particular to the introduction into it of lint, and more especially to the irritation occasioned by the ligature of reserve." On the contrary, it is argued by Scarpa, that though Mr. Hunter, after his first trials, simplified the local treatment, though all skilful surgeons merely covered the wound with a pledget of soft ointment, and most of them omitted the reserve-ligature, yet, notwithstanding these reforms, secondary hemorrhage after the use of a simple circular ligature was not rendered less frequent.—(On Aneurism, p. 23, ed. 2.) With respect to the latter general assertion, its incorrectness may be learned by reference to the details of Mr. Hunter's own operations, and by going into the principal hospitals of this metropolis, where the use of a simple circular ligature for the cure of aneurisms very rarely fails, as far as secondary hemorrhage is concerned. Why then did the operation more frequently fail here in former times? The answer is plain: the kind of ligature now employed in England cannot be compared to what was used in Mr. Hunter's time, or even to what was here in fashion five-and-twenty years ago. And besides the universal rejection of ligatures of reserve, practitioners now have a more thorough comprehension of what ought to be avoided in the operation, have a just fear of separating and disturbing the artery too much, know how to appreciate the advantage of closing the wound, and attach due importance to the choice of smaller or more eligible ligatures.—(See Hemorrhage and Ligature.) When, therefore, Scarpa supposes, that in England the practice with the circular ligature in the treatment of aneurism is materially the same now as heretofore, and that secondary hemorrhage is as frequent, he has not availed himself of all the information on this subject, which he might have acquired from Mr. Wishart, the able translator of his writings on aneurism, or from an attentive perusal of Mr. Hodgson's valuable treatise.

In an equality of circumstances, conducive to the success of the Hunterian operation, Scarpa thinks, that the fact is not proved, as it is presumed to be, that the rupture of the internal and middle coats of the artery does excite the adhesive inflammation and union of the artery more effectually than is done by the simple compression and close contact of its two opposite internal parietes in a sound and uninjured state. This remark is partly true, and partly incorrect, at the same time that it involves a question which must be deferred till we come to the article Hemorrhage. The truth in the observation is, that an artery may generally be rendered impervious with tolerable certainty, by compressing its opposite parietes steadily and firmly together for a certain time, without dividing its inner coats: the inaccuracy of it depends upon the fact, that surgeons have no instrument nor contrivance (not excepting even the ligature of four or six threads, with the interposition of the cylinder of linen spread with ointment), which can retain the opposed undivided surfaces of the inner coats of the vessels closely together in the manner commended by Scarpa, and for the due time, without the objection of denuding more of the artery than need be done in the application of a small ligature; or without the serious inconvenience and risk necessarily attending the introduction of a larger quantity of extraneous matter into the wound than is desirable, with the view of averting all chance of the ulceration of the artery reaching beyond prudent limits. And when metallic instruments are used for the same purpose, objections not less real are incurred, as will be hereafter more particularly explained.

Scarpa considers that his mode of ligature ought to be preferred, as combining the triple advantage of preserving entire all the three coats of the artery; of exciting quickly, and in a proper degree, the adhesive inflammation in them; and of retarding, as much as possible, the ulcerative process of the arterial tube.

Partly impressed, however, with the truth of the tenets laid down by Dr. Jones (see Hemorrhage), Scarpa enjoins attention to the following rules: 1. Not to insulate and detach the artery any farther than is necessary for allowing a ligature to be passed around it. 2. Not to let the cylinder of linen exceed a line in length, or a little more, above and below the breadth of the tape which is about a line for the large arteries of the extremities. 3. That the ligature be not too tight. 4. And that it be never applied immediately below the origin of a large lateral branch.—(See Scarpa on Aneurism, p. 44, ed. 2.)

Some farther consideration of Scarpa's mode of applying the ligature will be introduced in the article Hemorrhage; and I now proceed to notice his sentiments concerning the advantage which may be derived from removing the ligature in cases of aneurism, as soon as the tube of the vessel has been obliterated by the adhesive inflammation. From the facts recorded by Scarpa, it is inferred, that with the kind of ligature and the cylinder of linen used in his practice, the closure of the artery by the adhesive inflammation and the two internal coagula is sufficiently far advanced on the third or fourth day after the operation to resist the impulse of the blood; and hence (says he) there is no rational motive for waiting beyond this time for the spontaneous separation of the ligature, or for allowing it, by its farther presence, to ulcerate, and even open the artery at the principal point of adhesion. He then comments on the advantages to the wound, derived from the removal of all extraneous matter from it on the third or fourth day. With respect to the general period of such removal, however, he makes one exception, viz. the case of great and evident debility from sickly constitution, or very advanced age, as it is observed, that in such patients, the reunion of a simple wound is frequently protracted to the sixth day. In cases of this description, Scarpa recommends delaying

the removal of the ligature to the completion of the fifth or sixth day, but under the express condition that the ligature has been applied with the interposition of a cylinder of linen; as it is proved, that a common circular ligature causes ulceration of the artery before the third day, and it is not till the sixth day, that the external coat of the vessel begins to ulcerate, when the other modification of the ligature is adopted.—(P. 50.)

Scarpa supports the preceding advice by four cases, in which his kind of ligature was applied, and withdrawn at the end of the third or fourth day, and the arterial tube obliterated. However, I do not think, that in England, these cases, when minutely and attentively considered, will be regarded as inducements to persevere in the use of temporary ligatures. In every instance the wound is described as suppurating, and sometimes plentifully. In one, the foot mortified, and amputation became necessary. In another, the very day after the disturbance of removing the ligature, the thigh was attacked with erysipelas, and on the eighth day the wound is represented as being foul, and the erysipelas not yet cured.

Independently of the uncertainty of the period when the arterial tube is closed by the adhesive inflammation in various patients, it appears to me, that the disturbance of the vessel and wound, by the steps necessary for the loosening and removal of the ligature, will ever form an insuperable objection to the practice. Scarpa appears to have some apprehension of this kind himself; for he remarks, "In the act of removing the ligature, there can be no doubt it is of great consequence, that the artery be not rudely handled or stretched. And, indeed, if, on untying the running knot, the subjacent knot could be with the same facility untied, we could not wish for a better mode of performing this part of the operation. But the knot, although a simple one, is not so readily untied as the running knot, on account of the moisture with which the threads forming the ligature are soaked, or because the ligature has been previously waxed."—(P. 64, ed. 2.) In fact, his apprehensions then lead him to suggest the scheme of placing, previously to making the knot, a thread longitudinally on each side of the cylinder, and at the time of removing the ligature, the threads are to be drawn in opposite directions, in order to undo the knot, without displacing or stretching the artery. Thus, instead of one small ligature, which is all that an English surgeon leaves in the wound, Scarpa recommends his ligature of four or six threads, a roll of linen, and two other threads; a quantity of extraneous substances, which cannot fail to be a source of serious irritation and mischief. I shall therefore take leave of the proposal of removing the ligature on the third or fourth day, or any other particular day, with expressing my belief, that if there were only the following objection to the plan, it would never be adopted in this country; namely, the advocates for this practice are necessarily obliged to renounce the infinite advantage of bringing the edges of the wound together directly after the operation. Had the suggestion of Dr. Jones proved invariably correct, and the ligature admitted of being withdrawn immediately after the inner coats of the vessel had been divided by it, the case would have been very different, as there would then have been no foreign body at all left in the wound; the parts might have been immediately brought together with the greatest chance of union by the first intention, and no subsequent disturbance, either of the artery or of the wound, would have been incurred.

The next practice which I shall notice, is that of applying two ligatures to the artery, and cutting it through in the interspace. This suggestion may be said to be as ancient as the time of Celsus, who has advised the method to be followed in the treatment of a wounded artery; "Quæ (arteriæ) sanguinem fundunt apprehendendæ, circaque id quod ictum est duobus locis deligandæ intercidendæque sunt, ut in se ipsæ cocant, et nihilominus ora reclusa habeant."—(De Medicinâ, lib. 5, c. 26, § 21.) The fact is curious, though I mention it without the least intention of detracting from the great merits of several modern surgeons, that the Greeks were acquainted with the practice, lately recommended, of tying and dividing the trunk of the artery high above the tumour, as will appear from the following extract:—(Ætius, 4, Serm. Tetr. 4, cap. 10.) At vero quod in cubiti cavitate fit aneurisma, hoc modo per chirurgiam aggredimur: primum arteria superne ab ala ad cubitum per internam brachii parte simplicem sectionem, tribus, aut quatuor digitis infra alam, per longitudinem facimus, ubi maxime adtactum arteria occurrit: atque ea paulatim denudata, deinceps incumbentia corpuscula sensim excoriamus ac separamus, et ipsam arteriam cæco uncino attractam duobus fili vinculis probe adstringimus, mediamque inter duo vincula dissecamus; et sectionem polline thuris explemus, ac linamentis inditis congruas deligationes adhibemus. Afterward we are directed to open the aneurismal tumour at the bend of the elbow, and when the blood has been evacuated, to tie the artery twice and divide it again. If the ancients had only omitted the latter part of their operation, they would absolutely have left nothing to be discovered by the moderns.

This method of applying two ligatures to the artery, and dividing the vessel between them, was revived in France about sixty years ago by Tenon, who, as well as some later surgeons, was totally unacquainted with its antiquity.—(See Pelletan, Clinique Chir. t. 1, p. 192.) At one time it had also modern advocates in Mr. Abernethy and Professor Maunoir of Geneva, each of whom supposed the plan an invention of his own.—(See Surgical and Physiol. Essays, part 3, 8vo. Lond. 1797; and Mémoires Phisiologiques et Pratiques sur l'Aneurisme, &c. 8vo. Genève, 1802.)

When an artery is laid bare and detached from its natural connexions, and the middle of such detached portion tied with a single ligature, as was Mr. Hunter's practice, Mr. Abernethy conceived that the vessel so circumstanced would necessarily inflame and be very likely to ulcerate. The occurrence of bleeding from this cause at first led to a practice, which this gentleman justly censures, viz. applying a second ligature above the first, and leaving it loose, but ready to be tightened in case of hemorrhage. As the second ligature, however, must keep a certain portion of the artery separated from the surrounding parts, and must, as an extraneous substance, irritate the inflamed vessel, it must make its ulceration still more apt to follow. The great object, therefore, which Mr. Abernethy insisted upon, was that of applying the ligature close to that part of the artery which lies among its natural connexions; a just principle, the truth and utility of which still remain incontrovertible, though there may be a better way of accomplishing what Mr. Abernethy intended than the measures which this gentleman was led to recommend.

The peculiarity in Mr. Abernethy's first operation, consisted in applying two ligatures round the artery, close to where it was surrounded with its natural connexions. For this purpose, he passed two common-sized ligatures beneath the femoral artery, and having shifted one upwards, the other downwards, as far as the vessel was detached, he tied both the ligatures firmly.

The event of this case was successful. An uneasy sensation of tightness, however, extending from the wound down to the knee, and continuing for many days after the operation, made Mr. Abernethy determine, in any future case, to divide the artery between the two ligatures, so as to leave it quite lax.

Mr. Abernethy next relates a case of popliteal aneurism, for which Sir Charles Blicke operated, and divided the artery between the ligatures. The man did not experience the above kind of uneasiness; and no hemorrhage ensued when the ligatures came away, although there was reason to think, that the whole arterial system had a tendency to aneurism, as there was also another tumour of this kind in the opposite thigh.

The reasoning which induced this gentleman to revive this ancient practice was ingenious; for when the artery was tied with two ligatures, and divided in the foregoing manner, it was argued that it would be quite lax, possess its natural attachments, and be as nearly as possible in the same circumstances as a tied artery upon the face of a stump. Strictly speaking, however, as Mr. Hodgson first pointed out, an artery tied in two places, and divided in the interspace, cannot be regarded as placed exactly in the same condition, as an artery tied in amputation. In the latter case, the retraction of the vessel corresponds with that of the surrounding parts, which are divided at the same instant, and therefore its relative connexions stand as before the operation. But in the operation for

aneurism, the retraction of the artery takes place, without being attended with a corresponding retraction of its connexions. How far the retraction of the artery is beneficial or injurious is by no means evident; and the advantages arising from it may in most situations be obtained without dividing the vessel, by placing the limb in a bent position. One important object, however, is gained by the division of the artery; namely, that it is generally in that case tied close to its connexions, and it is very evident how liable the application of the ligature in the middle of a denuded extent of the vessel must be to produce ulceration or sloughing of its coats. The same object, however, will be gained by tying the undivided artery close to its connexions at the end nearest to the heart; and the existence of a single ligature at the bottom of the wound will be less liable to give rise to suppuration and the formation of sinuses than the employment of two. When an artery is divided, the portions situated beyond the ligatures must slough, and prove an additional cause of suppuration in the wound. Experience has amply proved the safety of employing a single ligature, and it is at present used by many of the most experienced operators in this country.—(See Hodgson on the Diseases of Arteries, &c. p. 221, &c.)

According to Scarpa, numerous examples of the failure of the plan of applying two ligatures, and cutting through the artery in the interspace, are already generally known to the profession, and there are many expert and ingenious surgeons, who do not dissemble the disadvantage and uncertainty of this practice. He speaks of one failure which occurred to Mr. Abernethy himself. But I entertain doubts how far any inference against the method can be drawn from Monteggia's instance, in which a ligature of reserve had been used. Nor can I understand how a circumstance which Scarpa strongly insists upon, can be well founded; I mean the danger of the ligature being forced off the mouth of the artery by the impulse of the blood. Any risk of this kind cannot exist if the ligature be duly applied, as Dr. Jones has particularly explained; and at all events, how can it be greater here than after amputation, where it is not usually made a subject of complaint? Indeed the several examples of secondary hemorrhage after this method, quoted by Scarpa from the practice of Monteggia, Morigi, and Assalini, may be more rationally imputed either to reserve-ligatures having been also used, or the common fear in Italy of applying the ligatures tightly; in which event one can readily suppose that the ligature might really slip, or by remaining a long time on the vessel might give rise to dangerous ulceration. Thus Morigi speaks of one case in which the bleeding occurred on the nineteenth day.—(Scarpa on Aneurism, p. 14, ed. 2.) On the whole, I am disposed to believe, that when this method has been executed precisely according to Mr. Abernethy's directions, it has not often failed; and I am acquainted with only one case in London in which it was followed by secondary hemorrhage. However, in the year 1807, Mr. Norman of Bath tied the femoral artery with two ligatures, and divided the vessel between them; the upper ligature came away on the sixteenth day after the operation; the lower one on the fifteenth; and the following day a profuse hemorrhage came on, the patient losing a pound of blood. Pressure with a compress and wet bandage was continued for some time, and the wound healed.—(See Med. Chir. Trans. vol. 10, p. 123.) This is the only case of secondary hemorrhage, which he has met with after operating for aneurisms.

Scarpa very properly urges, that the application of two ligatures and dividing the artery in the interspace can never be an eligible mode, where the smallness of the space, the depth of the artery, and the importance of the surrounding parts, do not permit the vessel to be separated and insulated to such an extent as is required for dividing it, with a probability of the division of it being sufficiently distant from the two ligatures. Such, for example, are the cases of ligature of the carotid in the vicinity of the sternum; of the iliac above Poupart's ligament; of the internal iliac, a little below its origin from the common iliac; of the axillary artery between the point of the coracoid process and the acromial portion of the clavicle; or of the subclavian in its passage between the scaleni muscles. Scarpa then comments on the difficulty and even impossibility of taking up the end of the truncated artery again in many situations were hemorrhage to ensue; and he joins Mr. Hodgson in thinking the advantages of the method, even where it is practicable, by no means demonstrated. Nay, he goes farther; for he agrees with Heister, Callisen, and Richter, in setting it down as worse than useless, on account of the portion of the artery between the ligatures being converted into a dead and putrid substance, which rests upon the bottom of the wound, from which it cannot be removed until the two ligatures are separated. Here, deeply impressed with the truth of principles which perhaps he has rather lost sight of in speaking of his own particular method, he comments on the little probability of the wound uniting, under the disadvantage of two ligatures hanging out of it, and of sloughs at its bottom. He argues correctly, that the laying bare and insulating a large portion of artery would often be objectionable on the ground that it could not be done without the surgeon being obliged to apply the principal ligature too near the origin of a large lateral branch; as, for example, would happen in a case of inguinal aneurism, situated an inch and a quarter below the origin of the profunda. Thus a coagulum could not be formed, and the artery would be in danger of not being closed. On the contrary, by employing only a single ligature at an inch and a quarter below the origin of the profunda, the operation would be equally simple and successful.—(Scarpa on Aneurism, p. 19—21, ed. 2.)

The above considerations would certainly lead me to avoid the practice of detaching an artery from its surrounding connexions any more than is absolutely necessary for the conveyance of a single ligature under it; but I fully concur with Sir Astley Cooper in the prudence of using two ligatures, and applying them in the way recommended by Mr. Abernethy, whenever the artery has been extensively separated from its sheath in the operation.—(See Lancet, vol. 1, p. 433.)

The frequent occurrence of accidents after the introduction of Mr. Hunter's operation might have been ascribed to more probable causes than the condition of an undivided artery, upon which the ligature was applied. The employment of numerous ligatures gradually tightened, or the introduction of extraneous bodies into the wound, were alone sufficient to produce ulceration of the artery: and such practices were adopted in most of the cases in which secondary hemorrhage took place.

After the reasons which have been urged against the plan of tying the artery with two ligatures, and dividing it in the interspace, it may appear superfluous to notice a modification of this practice, intended as a security against the slipping of the ligature. But as the proposal has had the approbation of some men of eminence, and I heard of an instance in which it was practised not long ago, the subject may still be worthy of notice.

Sir Astley Cooper has published a case of popliteal aneurism, in which the femoral artery had been tied with two ligatures, as firmly as could be done without risk of cutting it through. "But (says he) as I was proceeding to dress the wound, I saw a stream of blood issuing from the artery, and when the blood was sponged away one of the ligatures was found detached from the vessel. Soon after, the other was also forced off, and thus the divided femoral artery was left without a ligature, and unless immediate assistance had been afforded him, the patient must have perished from hemorrhage." The same kind of accident has occurred in Mr. Cline's practice. For the prevention of it Sir Astley at first tried the method of conveying the ligatures by means of two blunt needles under the artery, an inch asunder and close to the coats of the vessel, excluding the vein and nerve, but passing the threads through the cellular membrane surrounding the artery. When these were tied, and the artery had been divided between them, the ligatures were prevented from slipping by the cellular membrane through which they passed.

Afterward, however, he preferred a different mode of securing the ligature suggested to him by Mr. H. Cline, and it was put to the test of experiment in operating for a popliteal aneurism on Henry Figg, aged 29. "An incision being made on the middle of the inner part of the thigh, and the femoral artery exposed, the artery was separated from the vein and nerve and all the surrounding parts, to the extent of an inch; an

eye-probe, armed with a double ligature, having a curved needle at each end, was conveyed under the artery, and the probe cut away. The ligature nearest the groin was first tied; the other was separated an inch from the first and also tied. Then the needles were passed through the coats of the artery, close to the ligatures between them, and the ends of each thread were again tied over the knots made in fastening the first circular application of the ligatures. Thus a barrier was formed beyond which the ligature could not pass." The event of this operation was successful.—(Med. and Phys. Journ. vol. 8.)

A similar proposal appears to have been mentioned by Dionis, and to have been noticed by some subsequent writers. In the 13th chapter, in Richter's Anfangsgründe der Wundarzneykunst, we read the following passage:

"The artery when drawn out, is to be twice surrounded with the common ligature. This is to be tied in a knot, and, when the artery is large, one end of the ligature is to be passed by means of a needle through the vessel before the knot, then both ends are to be tied together and left hanging out of the wound as in the ordinary way."—(Ed. 3, 1799.)

What power can possibly force the ligature, when tied with due tightness, off the extremity of the vessel? No action of the heart or artery itself, no turgid state of this vessel, could do so. If a piece of string were tied round any tube for the purpose of preventing a fluid from escaping from its mouth, provided the string were applied with due tightness, and the knot in such a manner as not to yield, no fluid could possibly escape, however great the propelling power might be, as long as the string and structure of the tube did not break. And if a ligature were applied so slackly as to slip, who can doubt that hemorrhage would still follow, even though the ligature were carried through the end of the vessel and tied in the foregoing way?

Where ligatures have slipped off very soon after being applied, I conclude that the arteries either could not have been tied with sufficient tightness, perhaps through an unfounded fear of the ligature cutting its way completely through all the coats of an artery, or else that the knot or noose became slack from causes which will be understood by considering what is said on this matter in the article Hemorrhage. The inner coats of the artery, we know from the experiments of Dr. Jones, ought to be cut through when the artery is properly tied, because the circumstance is always useful in promoting the effusion of lymph within the vessel, and the process of obliteration by the adhesive inflammation.

The preceding method is so contrary to the grand principle of always avoiding the detachment of the artery from its surrounding connexions, and is so inconsistent with the wise maxim of doing the operation with as little disturbance of the vessel as possible, that it is not surprising that it should have met with only a small number of followers. In fact, it is not only liable to every objection which can be urged against the double ligature and division of the artery, as formerly proposed by Celsus and a few of the moderns, but on account of its greater tediousness, more extensive separation and destruction of the vessel, and other reasons, is still less worthy of imitation.

With respect to ligatures of reserve, the interposition of agaric, cork, and other hard substances between the knot and the artery, these contrivances are now so fully rejected by all good surgeons, for reasons which will be quite intelligible after the perusal of another part of this work (see Hemorrhage), that I shall not at present detain the reader with animadversions on their danger. As for several kinds of metallic compressors intended to be applied to the exposed artery for the purpose of rendering it impervious, they are inventions which have been made and extolled by some surgeons of high repute, whose names would give importance even to a less meritorious proposition.

Dubois conceived that hemorrhage might sometimes proceed from the circumstance of a ligature making its way too fast through the artery. He thought, also, that the sudden stoppage of the current of blood by a tight ligature might bring on gangrene of the limb, particularly when the aneurism was not of long standing, so that the collateral branches had not had time to enlarge. Dubois, therefore, proposed a method of gradually stopping the flow of blood through the artery; and by this ingenious imitation of the process of nature, to promote the gradual dilatation of the collateral arteries, and obviate all risk of gangrene in the lower part of the limb. This gentleman put his plan in execution, and two instances of success are recorded. The cases were popliteal aneurisms. A ligature was passed under the artery in the manner of Hunter; its two ends were then put through an instrument called a serre-nœud, with which the compression was gradually increased. It is stated, that in one of these cases the plan made the artery inflame and become impervious in the course of the first night, so that on the following day the throbbing of the tumour had ceased. —(Richerand, Nosogr. Chir. t. 4, p. 109, edit. 4.) Here, however, it is to be suspected that the pressure of the apparatus was greater than was calculated; and that the stoppage of the pulsation was more owing either to this cause, or to the coagulation of the blood in the sac and adjoining portion of the artery, than to the process of obliteration, which could hardly have been so rapidly accomplished.

Assalini's compressor is an instrument calculated, as its inventor states, to produce an obliteration of the trunks of arteries, without dividing or injuring their coats. It is nothing more than a small pair of silver forceps, the blades of which are broad and flat at their extremities, between which the artery is compressed. A spring, composed of a piece of elastic steel, is attached to the inside of one of the handles, and by pressing against the opposite handle retains the flat ends of the blades in contact. This spring is intended to be very weak in its operation; but by means of a screw, which passes through the handles, the pressure admits of being regulated and increased at the option of the surgeon.

A representation of Assalini's compressor may be seen in his Manuale di Chirurgia, parte prima, p. 113. In the same book, or in my friend Mr. Hodgson's valuable Treatise on the Diseases of Arteries and Veins, which every practical surgeon ought to possess, a case may be perused in which this instrument was successfully employed by Professor Monteggia, and withdrawn entirely as early as sixty hours after its application. This last distinguished surgeon also used the compressor in an example in which the femoral artery was wounded and bled in an alarming degree. After forty hours the pressure was lessened, and in four hours more, as not a drop of blood issued from the vessel, and there seemed to be no good in leaving an extraneous body in the wound any longer, the instrument was taken out altogether.—(See Assalini's Manuale di Chirurgia, p. 110.)

When Assalini was in England, he acquainted Mr. Hodgson that in two cases of popliteal aneurism, in which he had himself employed this means of obliterating the femoral artery, the instrument was removed at the expiration of twenty-four hours; no pulsation returned in the tumours; and the patients were speedily cured.

With respect to the particular merit of this invention, it certainly possesses the recommendation of ingenuity; but it operates much in the same manner as several other mechanical contrivances, the serre-nœud of Desault, the presse-artère of Deschamps, that of Mr. Crampton (see Med. Chir. Trans. vol. 7), the pincers of Baron Percy, &c. If there be a real advantage in the division of the internal coats of an artery by the ligature, as the experiments of Jones seem to prove, and as many of the best surgeons in this country inculcate (see Hemorrhage and Ligature), then the compressor cannot be an eligible means of obliterating an artery. It may be said, however, that experience has proved its efficacy; but let it be recollected, that almost every method of operating for aneurisms has sometimes answered. Farther experience is requisite to determine whether Assalini's compressor would succeed as often as, or more frequently than, the scientific application of the right kind of ligatures (see Ligature), which may perhaps seem slower in their effect, only because they are not in general removed as early as Assalini's instrument. In fact, the experiments of Mr. Travers have now proved that the ligature is the quickest in its operation.—(See Med. Chir. Trans. vol. 6, p. 643, &c.)

In 1816, some ingenious observations were published by Mr. Crampton, on the effects of the ligature and of compression in obliterating arteries. The purport of

his remarks is to prove, like the later observations of Scarpa: 1st, That the obliteration of an artery can very certainly be effected, independently of the rupture or division of any of its coats; 2dly, That this operation the ligature, so far from being essential to the process not unfrequently defeats it.—(See Med. Chir. Trans. vol. 7, p. 344, 345.)

With respect to the first of these assertions, I presume that all practical surgeons have known and admitted it, especially if the words very certainly be left out. Every system of surgery for half a century past, has recorded the occasional cure of aneurism by different modes of compression, by which the adhesive inflammation is excited in the artery, or the coagulation of the blood in the aneurismal sac brought about. As, however, the most experienced surgeons have found the method less certain than the use of the ligature, it is not represented by any modern writers as deserving equal confidence; though there are circumstances, in which simple pressure may be sometimes tried with the hope of doing away all occasion for an operation. The cases, however, in which compression is applied directly to the artery itself by means of ligatures, with the intervention of other substances as advised by Scarpa, &c. or by various contrivances, like those of the serre-nœud, the presse-artère, and Assalini's forceps, all require the exposure of the artery; and if commendable, therefore, cannot be so on the principle of saving the patient the pain of an operation, but because they are more effectual than the employment of the ligature. This last point remains to be proved. From the comparatively small number of instances in which the preceding modes of compression have been practised, several examples of failure might be quoted.

With regard to Mr. Crampton's second assertion, that the division of the inner coats of the vessel, so far from being essential to the process of obliteration not unfrequently defeats it, I think the last part of the observation is altogether unproved. We must admit that the division of the inner coats is not essential, because arteries sometimes become obliterated under a variety of circumstances in which such division is not made; but still the great question remains whether it renders the process more certain. Mr. Crampton founds his conclusion, that it not unfrequently prevents the obliteration and gives rise to secondary hemorrhage, upon a few very uncommon cases in which aneurismal swellings have taken place above the ligature.—(See Warner's Case, p. 101 of this Dictionary.) Here Mr. Crampton presumes, without proof, that the occurrence happened from the division of the inner coats of the artery, though Mr. Warner himself suspected, with more probability, that it proceeded from a diseased state of the vessel. Besides, this event be it produced in whatever manner it may is so rare, that I only know of three examples of it on record, and have never known it occur during the last 30 years, that I have been in the constant habit of seeing numerous operations performed. In Mr. Warner's time such large ligatures were also in use that it appears to me they were more likely merely to press the sides of the artery together, like Mr. Crampton's presse-artère, than effect a complete division of the inner coats of the vessel, as is accomplished by the small ligatures in modern use.

Those metallic instruments, intended to be applied directly to an exposed artery for the purpose of obliterating it by compression, are liable as Scarpa remarks, to all the inconveniences which are inseparable from the presence of hard bodies, introduced and kept for several days in the bottom of a wound; especially when this is recent, in which case they cannot be retained in a proper direction without difficulty, or exactly at such a depth as will not be attended with hurtful pressure upon the wound itself and important parts in its vicinity. And with regard to the forceps of Assalini, Monteggia has observed, "if the obliteration of the artery is retarded, the forceps equally divides the artery by causing the death of the included portion. I also saw in one case, the extremity of the instrument resting at the bottom of the wound on the subjacent femoral vein, rupture its anterior half also, although we were sure it had not been included by it." —(Instituz. di Chir. ed. 2, t. 2.) And although Cumano in a case of popliteal aneurism, obtained on the fourth day the closure of the femoral artery by means of Assalini's forceps, he does not conceal that the cure of the wound was rather difficult; and in comparing the ligature with the forceps he adds his belief, that if an equal result is derived from both the preference will be given to the ligature, unless the other instrument be brought to such perfection that the inconveniences will be removed from which he found it not exempt, though the operation succeeded.—(Annali di Med. del Dottore Omodei, Settembre, 1807, p. 209, and Scarpa on Aneurism, p. 45, ed. 2.) Some experiments were a few years ago instituted by Mr. Travers, in order to determine the merit of Assalini's forceps compared with the ligature: and his conclusion from the facts elucidated in the investigation is, that the ligature is a more powerful means of effecting the obliteration of the tube of an artery.—(See Med. Chir. Trans. vol. 6, p. 643, &c.)

My friend Mr. Lawrence, a few years ago, extended to operations for aneurism the method of tying the artery with a very small firm silk ligature, the whole of which is immediately afterward cut off with the exception of the noose and knot, and an endeavour then made to heal the wound by the first intention. In a case of popliteal aneurism, Mr. Carwardine, late of Thaxted, tied the femoral artery in this manner, and the wound united entirely by the first intention, not a particle of pus having been formed at any time; and the part continued perfectly sound at the distance of some months from the operation. On the 29th of March, 1817, I saw Mr. Lawrence try the practice in a similar case: with the exception of the integuments, the wound united by adhesion. However, it continued to discharge a small quantity of matter till the end of May, when the ligature came away, and it healed firmly. In an aneurism of the humeral artery, Mr. R. Watson, of Stourport, Worcestershire, tied that vessel and cut off the ends of the ligature, as proposed by Mr. Lawrence. The operation was done on the 2d of March, and the wound was quite healed by the 10th of April. On the 3d of May, a small tubercle which had been felt under the skin in the centre of the cicatrix, appeared above the skin, and proved to be the knot of the ligature. There was no inflammation nor discharge; but the ring of the ligature was firmly impacted in the centre of the cicatrix. In about a week from this time the whole of it was expelled. In another case, where Mr. Hodgson tied the ulnar artery and cut off the ends of the small ligature, the skin healed over the vessel, but a firm almost cartilaginous knot gradually formed, from the centre of which the bit of ligature was extracted five or six months afterward, by a small puncture. For additional observations on this part of the subject, see Med. Chir. Trans. vol. 8, p. 490, &c.

Mr. Carwardine's case is a strong one in favour of this method: but I am not aware that sufficiently numerous trials of it have been made to enable one to form a correct estimate of its merits. With the exception of the example communicated by Mr. Carwardine to Mr. Lawrence, I apprehend that on the whole the cures on record cannot be said to have been completed sooner than others generally have been, in which one end of the small circular ligature was left for the removal of the noose. Thus, in two cases where the practice was tried by Mr. Norman, of Bath, the results were by no means encouraging. In one of these instances, a part of the wound appeared to have united by the first intention, but matter afterward formed, and it was a considerable time before the ulcer healed. The ligature was never seen to come away; but from the circumstance of the suppuration, Mr. Norman apprehends that it must have been voided. In a second example, the attempt to procure a permanent adhesion of the parts over the ligature did not succeed; a long and troublesome suppuration ensued, and the wound was not healed till the latter end of April, though the operation was done on the 7th of March.—(Norman, in Med. Chir. Trans. vol. 10, p. 120—121.) As catgut, however, was employed for the ligatures in these two operations, I do not know that it is fair to consider the method exactly as that recommended by my friend Mr. Lawrence, who particularly directs very small ligatures of dentist's silk to be used. But besides the different material employed, we are left uninformed of the thickness of the catgut; and in this respect also there would probably be no greater similarity between the ligatures of these gentlemen, than there is in regard to the substances of which such ligatures were made.

In favour of catgut as a ligature, when the ends of it are to be cut off, a case published by Sir A. Cooper deserves particular notice. The wound was found completely united on the fourth day after the operation, notwithstanding the patient was eighty years of age. The catgut, previously to its application, was softened in warm water. The recovery was complete; a fact strongly proving the propriety of not rejecting an operation on account of age, if no other objections exist.—(See Surgical Essays, part 1, p. 126.)

From what has been stated in the Lancet, however, it seems that Sir Astley has renounced both the use of catgut ligatures, and the plan of cutting off both ends of each ligature. With respect also to silk ligatures in particular, if we take into the account the little ulcerations, suppurations, and hard knots, which occurred even after their use in this manner, I fear, that though these complaints might be attended with no severe inconvenience, they will deter many surgeons from adopting the innovation; unless it can be proved that these inconveniences, slight as they were, are counterbalanced by the quicker healing of the incision, or some other decided benefit. As a mode attended with the least possible risk of being followed by secondary hemorrhage, however, I consider it inferior to no practice which has yet been suggested; nor do I know of any serious objections to it in any point of view, provided exactly such ligatures are used as Mr. Lawrence recommends.

In cases of aneurism, a single small ligature, composed of dentist's silk, inkle, or twine, is now usually preferred by the majority of the best surgeons in England; but as the right qualities of ligatures are elsewhere considered (see Hemorrhage and Ligature), I need not here dwell upon the subject. It is not meant to assert, that the use of a single ligature is never followed by secondary hemorrhage; for this would be untrue. The accident I believe will sometimes happen after this or any other mode, under certain circumstances, and in unfavourable subjects. A fact of this kind we find recorded, which happened in the practice of a truly eminent and experienced surgeon (see A. Burns on Diseases of the Heart, p. 230); but from the inquiries which I have made, it appears to me proved, that cæteris paribus, a single small ligature, applied with as little disturbance and detachment of the artery as possible, will be more rarely followed by secondary hemorrhage, abscesses, sinuses, &c. than any other known method. Thus, in the several cases reported by Mr. Norman, the single ligature was never followed by any of those inconveniences, which, he justly thinks, will be rarer after this practice than any other, "if the artery be not removed from its situation, or more detached than the ligature separates it."—(See Med. Chir. Trans. vol. 10, p. 123.)

Before entering into the consideration of particular aneurisms, I wish to mention a few other circumstances, worthy the attention of every practical surgeon. The first is the partial entrance of blood into the aneurismal sac, after the artery has been tied at some distance from the tumour. This fact was first particularly pointed out, and its reasons explained by Sir E. Home, who published three examples of its occurrence.—(See Trans. for the Improvement of Med. and Chir. Knowledge, vol. 1, p. 173, and vol. 2, p. 239.) But the circumstance had never, I believe, been considered with due attention, until Mr. Hodgson made it one of the subjects of his reflections in his valuable treatise.

"When an artery is tied close to an aneurismal sac, the ingress of blood into the latter is in most instances prevented; the coagulum which it contains is absorbed, and the membranes of which the sac is composed, gradually contract, until its cavity is permanently obliterated. But when the artery is tied at a distance from the disease, the ingress of blood into the latter is not altogether prevented; for the anastomosing branches which open into the trunk, below the seat of the ligature, convey a stream which passes through the aneurism. The impulse of this current, however, is so trifling that the enlargement of the sac not only ceases, but the deposition of coagulum in it increases, in consequence of the languid state of the circulation. The coagulum accumulates until the cavity of the sac, and the mouth of the artery leading into it, are obliterated," &c.—(See Hodgson on the Diseases of Arteries, p. 266.)

This fact, which is of great importance, both in a practical and pathological point of view, is proved (says this gentleman), 1st, by the occasional recurrence of pulsation in the tumour after the operation; 2dly, by cases in which the cavity of the sac has been exposed, and hemorrhage has been the consequence; and, 3dly, by dissection, in which it has been found, that the cavity of the aneurism, as well as that of the artery from which it originated, was pervious, from the part which was obliterated by the direct operation of the ligature.

For a detail of the facts relative to this interesting point the reader is referred to Mr. Hodgson's valuable publication.—(P. 267, et seq.)

Some very uncommon instances are recorded, in which the return or continuance of pulsation in the tumour is said to have prevented the cure; the aneurismal sac having begun to enlarge again. The two cases of this kind, however, which happened in the practice of Pott and Guerin (Trans. of a Soc. for the Impr. of Med. and Chir. Know. vol. 1, p. 172; and Journ. de la Soc. de Santé, No. 3, p. 197), cannot be well depended upon, as it may be doubted, whether the artery was really tied. Some better established facts, relating to this part of the subject, have been very recently published. One is a case by Dr. Monteath, jun., of Glasgow, which is very remarkable; as the disease, viz. a popliteal aneurism, recurred nine months after the femoral artery had been unequivocally tied in the upper third of the thigh. On the 27th of February, 1819, this gentleman performed the operation, using a single ligature; the pulsation of the tumour in the ham instantly ceased; and the wound healed by the first intention, except where the ligature was situated, which came away on the thirtieth day. By this time, the tumour was diminished to one-half of its original size, and in two months more, only a hard knot was perceptible, in which no pulsation whatever could be felt. After the considerable lapse of time above specified, the patient informed Dr. Monteath, that the tumour had reappeared, being rather larger than a plum. The pulsation in it was distinct, though not so strong as in ordinary aneurism. As the size of the swelling and strength of the pulsation increased gradually, a compress and bandage were applied without confinement; but as this treatment was ineffectual, the patient was afterward kept in bed, bled, and put on a spare diet. A thick compress was placed over the tumour, and the limb was firmly bandaged from the toes to the groin. A trial of this plan for three days not having produced any benefit, a tight tourniquet was applied over the tumour; but the pain was such in half an hour, that the instrument was taken off, from which moment no pulsation was felt. Next day the tumour not only did not throb, but had a firm feel; and the bandage being continued, the cure was gradually completed. Had the disease not yielded to these means, Dr. Monteath meant to have tied the inguinal or external iliac artery, with the view of cutting off the supply of blood to the sac, through the anastomosing branches.—(Scarpa on Aneurism, by Wishart, p. 510—512, ed. 2.)

The following cases were mentioned by Sir Astley Cooper: a man underwent the operation for aneurism; the femoral artery was tied; the pulsation ceased; and the patient in a little while was supposed to be cured of the aneurism, and discharged. Upon his return to labour, however, a swelling arose in the ham, without pulsation. The swelling subsided in consequence of rest; but afterward, while the man was at work, the swelling returned with great pain. At length, as Sir Astley conceived that there was no prospect of the limb becoming useful again, it was amputated. Upon an examination of the parts, he found that the femoral artery, below the place of the ligature, had been conveying blood. It does now and then happen (says he) that a blood-vessel will arise from the artery close above the ligature, and pass into the artery immediately below it, by which means the circulation is produced. Sir Astley then referred to a specimen in the hospital museum, where this fact is illustrated in the brachial artery.—(See Lancet, vol. 1, p. 298.)

The external iliac artery was taken up by Mr. Norman, of Bath, for the cure of an inguinal aneurism, and when the collateral circulation was fully established a few days after the operation, the tumour was again supplied with blood in sufficient quantity to pro-

duce a distinct pulsation; "a fact (says Mr. Norman) of practical importance, as it shows, that though the ligature on the iliac artery stops the direct influx of blood into the tumour, and is the means by which the disease is cured, yet that there exists a necessity for employing strict rest, the antiphlogistic regimen, and, in some cases, the abstraction of blood, to assist nature in her operation of obliterating the aneurism." And in another instance, after the same gentleman had tied the femoral artery for the cure of popliteal aneurism, the pulsation, though stopped for a time in the tumour, afterward recurred in such a degree, that much doubt was entertained whether the disease would have been cured by the ligature on the femoral artery, had not continued and rather powerful pressure been adopted.—(Med. Chir. Trans. vol. 10, p. 99. 118, &c.)

M. Roux, in a late work, has offered some criticisms on the English method of operating for aneurisms. It would hardly be fair play to endeavour to offer a serious refutation of them, because, when he wrote, it was his misfortune not to be duly informed of all the facts and experiments recorded in the inestimable treatise on hemorrhage by the late Dr. Jones. "Still less confident than we are (says Roux) in the treatment by compression, and in the use of topical remedies for the cure of external aneurisms, the English surgeons have immediate recourse to the operation with the ligature. Hunter's method is that which they universally practise. They will not even allow, that there are any cases in which the operation by opening the sac should be preferred, &c. And it is singular, the very same motive which would incline us in some cases of aneurisms, properly so called, to adopt the operation of opening the sac, is alleged by the English surgeons as a circumstance in favour of the Hunterian method. Let us suppose an aneurism so formed, that near the centre of the tumour or rather near the opening, by which the artery communicates with the swelling, are situated the orifices of the collateral arteries, which would be useful for the re-establishment of the circulation. Here it is clear, that in practising the operation by the Hunterian method, that is to say, in tying the artery above the tumour, the last ramifications are not indeed sacrificed; but the orifices and first branches of these collateral arteries. Let there be, for example, at the upper part of the femoral artery an aneurism, which, though formed originally below the origin of the profunda, now extends above it. Here it is manifest that in tying the femoral artery above the swelling, we should lose the important resource of the profunda for re-establishing the circulation in the lower part of the limb. The desire and hope of saving the profunda would in such a case make us adopt the operation of opening the sac, in preference to the Hunterian method; and Scarpa himself, so great an advocate for this last mode, Scarpa, who seems only to have composed his work to cry up this method, makes an exception of the case, which I have just been supposing. The English surgeons, on the contrary, would urge the following objection to the operation by opening the sac in this and other analogous examples. They contend that the ligatures would be applied too near to the origin of the collateral arteries, which are to receive the blood after the operation. They are prepossessed with the idea, that when an arterial trunk is tied at a given point, the too great proximity of the principal collateral arteries disposes to subsequent hemorrhage," &c. (p. 256, 257): a circumstance which Mr. Roux seems to doubt.

Now, before attempting to reply to these observations, we ought to know what exact distance Roux means, when he speaks of the profunda, or a large collateral artery, originating near the opening by which the aneurism communicates with the main artery. Here he is not at all precise; and were he to tie the femoral artery immediately below the point where the profunda arises, he would expose his patient to great danger of bleeding. I say this, well aware of the case which he has adduced to prove the contrary. In the example brought forward, he applied several ligatures (p. 260), some of which were the ligatures d'attente, or loose ligatures left ready to be tightened in case of need. These were of course higher up than the ligature which was tightened. It is therefore impossible, that this last could have been close to the origin of the profunda. There must have been room left for the application of the ligatures d'attente; and be it also recollected, that the French still persist in the use of large flat cords, and not small firm round ligatures, which are now found to be most advantageous.—(See Hemorrhage.) In this part of the Dictionary we shall find that the nearness of a collateral vessel impedes the formation of the internal coagulum, which has a material share in the process by which the artery is closed.

With respect to the circumstance of hemorrhage being more likely to follow when the ligature is placed close below, than at some distance from a great collateral artery, there cannot be a doubt of the fact. Roux when in London saw an occurrence of this kind himself, and has published it in his book. It was a case in which Sir A. Cooper tied the external iliac artery; but the patient died of hemorrhage a fortnight afterward, and, on opening the body, it was ascertained that the obturator artery, which usually arises either from the trunk of the internal iliac, or from the epigastric, proceeded from the external iliac, and arose immediately above the point to which the ligature was applied.—(See Parallèle de la Chir. Angloise avec la Chir. Françoise, &c. p. 278, 279.)

From a preparation, spoken of by Mr. Travers, and some experiments made by the same gentleman, it would appear, that the presence of a collateral branch hinders the formation of the internal coagulum, but will not always prevent the closure of the vessel by the adhesive inflammation. In the preparation referred to, a ligature was applied to the external iliac, between the epigastric and circumflex iliac arteries, "and having been in contact with the former at the angle which it makes at its origin from the iliac, ulceration had taken place, and the bleeding had proved fatal. There was no coagulum formed in the iliac trunk, though the operation had been performed several days, the circulation through the epigastric having continued. But the lymph-plug at the seat of the ligature on the iliac artery was complete."—(Med. Chir. Trans. vol. 6, p. 656.) Indeed, it must be allowed, with this gentleman, that the fluidity of the blood does not prevent the adhesive process, a fact which, he observes, is also proved in the indirect obstruction of a vessel, by means of a temporary ligature or compressor. When, therefore, the vicinity of a large branch to the ligature is spoken of as a circumstance conducive to secondary hemorrhage, I mean, that it is so inasmuch as the internal coagulum is useful in promoting the closure of the vessel, and its formation is prevented.

Brasdor first, and afterward Desault, conceived, that when an aneurism was so situated that a ligature could not be applied to the artery leading to the swelling, a cure might possibly arise from tying the vessel on that side of the tumour which was most remote from the heart. Desault conjectured that by this means, the circulation through the sac would be stopped, the blood in it would coagulate, that the circulation would go on by the collateral arteries, and that the tumour would be finally absorbed. Deschamps tied the femoral artery below an inguinal aneurism; but the progress of the disease, instead of being checked, seemed to be accelerated by the experiment. The operator was obliged, as a last resource, to open the tumour, and try to take up the vessel. In this attempt the patient lost a large quantity of blood, and died eight hours afterward.—(See Œuvres Chir. de Desault, par Bichat, t. 2, p. 563; and Recueil Périodique de la Société de Médecine de Paris, t. 5, No. 17.)

The operation of tying the artery below the tumour was repeated by Sir A. Cooper, not for an aneurism of the femoral artery in the groin, but for an aneurism of the external iliac, where tying the artery above the swelling was impracticable. The femoral artery was therefore tied immediately below Poupart's ligament, between the origins of the epigastric and the profunda. The pulsations of the tumour continued; but the progress of the disease was checked. After a time, indeed, the swelling decreased, and this in so considerable a manner, that hopes began to be entertained that perhaps the external iliac artery might soon admit of being tied above the disease. The ligatures came away without any unfavourable occurrence, and when the wound was healed, the patient was sent into the country for the benefit of the change of air. Afterward, however, the tumour gave way; an extravasation of blood took place in the abdomen and cellular membrane of the pelvis, and the patient died. Sir

A. Cooper had no opportunity of seeing the case, and as the body could not be opened, farther particulars were not obtained.

I believe no additional trials of this practice were made in any part of the world, and that, in fact, the general feeling of the profession was decidedly against it, until my friend Mr. Wardrop lately directed his particular attention to the subject, and both by reasoning and facts exemplified beyond all dispute, that Brasdor's method of operating ought to be adopted in certain aneurisms, the circumstances of which forbid the application of a ligature on the cardiac side of the tumour. Experience has amply proved what I have already repeatedly mentioned, that after the Hunterian operation, some flow of blood frequently continues through the aneurismal sac, owing to the anastomoses, but that the impetus of the stream having been sufficiently reduced by the effect of the ligature, the curative process is not prevented from taking place. The pulsation, which is sometimes felt for the first few days, at length subsides, in consequence of the circulation being stopped by the increased quantity of coagula, and the tumour begins to diminish. It is from facts of this kind that Mr. Wardrop deduces what he calls "a new principle for operating in aneurisms so situated, as hitherto to have been considered beyond the reach of art, and to which the Hunterian principle of operating is totally inapplicable."—(On Aneurism, p. 15, 8vo. Lond. 1828.) Mr. Wardrop observes, that the changes produced by Brasdor's method, both in the artery and the sac, are precisely those which nature employs when she cures the disease by a spontaneous process. No sooner is the ligature applied on the distal side of the aneurismal tumour, than, as after the Hunterian plan, the anastomosing vessels dilate, and perform the function of the obliterated or obstructed trunk. The cases in which the operation has been done prove also what would not have been expected, that the tumour, directly after the application of the ligature, diminishes instead of undergoing enlargement. "If the circulation be turned into a new channel, and if that channel completely fulfil the purpose, the sac, with its contents, as well as the portion of artery extending between the aneurism and the ligature, and also the blood contained in it, will now be in a passive state; and though the blood will continue for a certain time to be influenced by the impulse of the circulation carried on in that part of the vessel which passes into the tumour, still its motion must become not only languid, but its current irregular, a state which, we know, admits of its speedy coagulation. Whenever the coagulation of the blood does take place, then the cure of the aneurism may be said to be accomplished; the sac will contract; the coagulum will be absorbed; some portions in contiguity with the sac will become organized, and consolidate; others, if the quantity be very large, will escape by a process of ulceration through the skin; and ultimately, a gradual coalescence of the tumour will thus take place."—(Wardrop, p. 20.)

{In the Medical Repository for 1823, vol. 7, No. 4, p. 404, Dr. David L. Rogers, then Resident Surgeon of the N. Y. Hospital, has published a paper entitled Observations on Aneurisms, in which this operation is contended for as being applicable to the carotid artery, and to this alone. He is wrong, however, in giving the projection of this operation to Desault, for although it is described in his works by Bichat, yet it was proposed by Brasdor. And as this seems to be a controverted point, I have taken some pains to trace the progress of this improvement, and find that the operation was first proposed by Brasdor nearly half a century ago, so that the projection of the plan unquestionably belongs to him. Bichat next gave directions for its performance in his edition of Desault, and here the error of Allan Burns probably originated, which has been since repeated by so many. Deschamps was the first who performed the operation in a case of femoral aneurism; then Sir A. Cooper repeated it on the external iliac, then Mr. Home's case occurred, all of which were unsuccessful. Mr. Wardrop's first case of carotid aneurism was performed in 1825, by tying the vessel on the anti-cardial side of the sac with complete success. Mr. Wardrop's second trial was not so fortunate, and, as will be perceived, it is questioned whether the artery was tied at all. See Mr. Cooper's remarks on this case, infra. Mr. Lambert next operated as will be seen in this article, without success, and Dr. Bushe's and Dr. Evans's cases were the only successful instances I can find, so that the former of these is the second and the latter the third in which Brasdor's method has succeeded. Dr. Mott's case is therefore the fourth successful instance on record, and certainly the only one in which it has been attempted in America. So much light has been elicited on this dark subject by the cases alluded to, that there can be little doubt but the operation on the distal side of the aneurism will now rescue from the grave many valuable lives, which had otherwise been lost to the world, and abandoned as beyond the resources of our art.—*Reese.*}

In the summer of 1825, Mr. Wardrop first tried Brasdor's method. The case was a carotid aneurism in a female 75 years of age. The disease was so close to the clavicle, that it was quite impracticable to tie the vessel on the cardiac side of the tumour. Immediately the artery was tied, the swelling underwent a diminution. On the fourth day it had lessened by one-third. Afterward the throbbing continued strong for a few days, at the expiration of which it became obscure, and, at the same time, the tumour began to diminish again. Previously to the complete cure, ulceration occurred, and several large masses of coagulated blood were discharged, along with some healthy pus. Three years after the operation, the patient continued to enjoy good health.

December 10, 1826, Mr. Wardrop attempted a similar operation for the cure of a carotid aneurism in another woman aged 57. Some reduction of the throbbing, and other relief, are stated to have ensued; but the patient died of a complication of complaints on the 23d of the following March, 1827. "Up to the day of her death, a tumour remained in her neck of about the bulk of an almond, which pulsated strongly, felt very thin in its coats, and its contents could be readily squeezed out of it, but returned rapidly, when the pressure was removed."—(P. 33.) In the dissection it deserves notice, that the carotid was found completely pervious, and that no cicatrix nor other appearance, enabled Mr. Bennet to ascertain the precise point to which the ligature had been applied.—(P. 35.) These circumstances might raise a doubt about the artery having been tied at all; but, supposing the ligature to have been duly applied, they prove to my mind the failure of the operation, inasmuch as the tumour and carotid artery were probably in almost the same state as if nothing had been attempted. The blood passed freely through them, and was not compelled to circulate through new channels. Without wishing, however, to enter into the question whether the artery were tied or not, I shall dismiss this example with two plain inferences: 1st, that if the artery were tied, the operation failed to bring about the desired obliteration of the vessel and coagulation of the blood in the swelling; 2dly, that if it were not tied, what was done is neither favourable nor unfavourable to the practice of which we are now considering the merits. A third example of the operation is reported in vol. 12 of the Lancet. The carotid was tied above the aneurism by Mr. Lambert, March 1st, 1827, in the presence of Mr. Wardrop, Mr. B. Cooper, and Mr. Callaway. On the third day the tumour seemed much consolidated, and reduced in size. On the tenth day there was some bleeding from the wound; but it was suppressed by the application of a compress wet with cold water; and in a few days, the swelling had entirely disappeared, and all that could be felt of it on pressing the finger deeply down, was a small hard tumour, having a very faint undulatory thrill. Unfortunately, this patient, also a female, fell a victim to hemorrhage on the 1st of May, in consequence of ulceration extending from the cicatrix through the platisma myoides to the artery. Without detailing other appearances noticed in dissection, suffice it to mention, that "at the root of the right common carotid artery was a consolidated tumour of a pyramidal shape. A probe could not be passed upwards from the arteria innominata, and water forcibly injected at this part would not pass, so completely and effectually closed was the lower part of the carotid artery. On making a longitudinal section of the tumour, we observed at its lower part a firm coagulum of blood, of about the size of a French olive. It accurately closed the opening at the base of the carotid, and it was this which afforded the resistance to the probe and injection of water passing upwards from the

arteria innominata. The coats of the artery, surrounding the coagulum, were thickened to about four times their natural size, and lined by a thin layer of fibrine. Above the coagulum, the coats of the artery were thickened to the extent of at least six times their natural size, and, in addition to a layer of fibrine closely adherent to the inner surface of the artery, and continuous with that surrounding the coagulum at the lower part of the tumour, there were three other layers of coagulated lymph.—At the upper part of the thickened portion of the artery, and just above the omo-hyoideus, where the ligature had been applied, was an ulcerated opening on the anterior and tracheal surface of the carotid artery a quarter of an inch in length, and rather less in breadth, covered by a coagulum of dark-coloured lymph, communicating with the opening in the integuments." This case, according to my judgment, must be received as another proof that Brasdor's method is capable of producing those changes in the tumour, artery, and circulation, which, if not succeeded by some accidental untoward occurrence, like the ulceration, leading in this case to fatal hemorrhage, may bring about the perfect cure of the disease.

If any doubt remained of this fact after the cases already cited, it would be dispelled by the results of some other trials of the practice, and more particularly by the history of the case of Mary Covis, aged 36, on whom Dr. Bushe [now Professor of Anatomy and Surgery in Rutgers Medical Faculty of Geneva College, New-York] operated, under very trying and difficult circumstances, with great skill and complete success.—(Lancet, vol. 1, 1828.) The tumour extended from the clavicle on the right side upwards nearly to the os hyoides, pressing the trachea towards the opposite side, and passing under the sterno-mastoid muscle to nearly an inch beyond its outer border. For nine days previously to the operation the patient had not been able to swallow any thing; her respiration was alarmingly obstructed, and her voice nearly lost. In the operation the artery immediately above the aneurism was found dilated, not more than half an inch of its extremity being sound, and on this a single silk ligature was placed. As soon as the artery was tied, the tumour became softer and less prominent, and though she had not swallowed any thing for nine days, she took, before the wound was dressed, about ten ounces of wine and water. The operation was performed September 11th, 1827. April 19th, 1828, the woman was in perfect health. There was then scarcely a remnant of the tumour; the inordinate action of the heart had ceased; and respiration and deglutition were natural. As Mr. Wardrop remarks, the facts recorded prove beyond all dispute, that the future growth of an aneurismal tumour may be arrested, and the disease cured, by placing a ligature on the distal side of the sac, especially if no branch of the artery intervene between the sac and the ligature; for if a considerable branch, and one that afterward enlarged sufficiently, were to be in this situation, the operation would have little or no effect in producing any diminution of the impetus of the blood in the aneurism, from the cavity of which the blood would pass as freely into the enlarged branch as it previously did along the trunk itself. Hence we see why Brasdor's operation will probably be attended with greater success on carotid than other aneurisms, the common carotid artery giving off in its course no branches which might interfere with the principles of the practice.

[Professor Bushe being now engaged in teaching anatomy and surgery in this city, has politely acceded to my request in furnishing me from his note-book, the following case, the practical importance of which in relation to this subject entitle it to a place here. It is referred to in the Lancet, No. 244, vol. 2, May 3d, 1828.

"As every fact that can tend to prove or disprove an unsettled point must be considered more or less valuable, it may not be useless to subjoin a concise account of a patient who, in the summer of 1823, was admitted into the Whitworth Medical Hospital, Dublin, under the care of Dr. Cuming. His complaint on admission was registered as paralysis of the right arm; but a large tumour being discovered in the axilla, the late Professor Todd was called to see the patient; and after careful examination he gave it as his opinion that it was an aneurism, which from its magnitude had lost its pulsation; but to settle the point, he punctured it, and florid blood followed the insertion of a probe. When passed inwards for about three inches, the nature of the case being decided, the man was removed to the Richmond Surgical Hospital; where, from an attack of erysipelas consequent on the puncture, he died in a few days. Mr. Todd requested that I might examine the body, and from notes made after the dissection I abstract the following: 'The aneurism, which was of large size, occupied the right axilla; the sac in many places was almost absorbed, and adhered firmly to the upper and outer part of this cavity; when opened, it contained large quantities of laminated fibrine, and in its centre was a cavity holding about eight ounces of coagulated blood; communicating with the cavity, there was an opening of one-eighth of an inch in the axillary artery, below which the vessel was obliterated for the space of half an inch, corresponding to the situation where the sac so firmly adhered.'—Here then was a case where the aneurism was undergoing a spontaneous cure in consequence of the pressure of the tumour having obliterated the artery on its distal side; and I look upon it as a valuable fact towards confirming the utility of reviving the operation of Brasdor and Deschamps; and so much was I impressed with this opinion, that before Mr. Wardrop published his first essay, I recommended the operation in a case of large carotid aneurism in a public hospital; but my chance was to be laughed at. However, when I again meet the two surgeons who so wantonly ridiculed me, it will be my turn to laugh at them."—*Reese.*]

Mr. Wardrop himself regards Brasdor's operation as not merely applicable to examples in which it is impracticable to place a ligature on the cardiac side of the sac, but as likely to merit the preference when the tumour is large, and likely to inflame after the circulation through the sac is interrupted. This inference he makes from the fact of the immediate diminution of the swelling, which has usually followed the application of the ligature on the distal side of the aneurism. He also deems it probable that in this method there is less risk of hemorrhage from the part of the vessel on which the ligature is applied than in the Hunterian operation. On the principle that it is sufficient for the cure of an aneurism, that the impetus of the blood through it be diminished, as the deposite of lamellated coagula within the sac will then increase, Mr. Wardrop urges the propriety of extending Brasdor's method to aneurisms of the arteria innominata; but the very interesting and valuable cases which he has adduced in confirmation of his views of these particular aneurisms will be more conveniently noticed in the sequel. As an admirer of the improvement of surgery, I must not quit this part of the subject, without expressing the conviction that I entertain of the service which Mr. Wardrop has rendered the profession and the public by his able and enlightened view of a valuable operation, which without his exertions and example might long have remained quite neglected, or briefly mentioned in the history of surgery as a dangerous proceeding, unworthy of farther trials.

[This suggestion of Mr. Wardrop has been acted upon by D. Evans, Esq., surgeon at Belper, Derbyshire, who successfully tied the carotid for aneurism of the innominata and root of the carotid. The details of this splendid operation are so interesting, that I cannot withhold from the profession the record of this highly important and successful triumph of modern surgery over this most horrible disease. It is extracted from the Lancet, No. 271, vol. 1, Nov. 8th, 1828.

"William Hall, ætat. 30, a butcher and horse-dealer, an athletic and spirited young man, about five feet six inches high, has been accustomed to laborious exercise, frequently riding from 70 to 100 miles a day, and has always enjoyed excellent health until the appearance of the following symptoms:—About 14 months ago he was seized with shortness of breath, troublesome cough and tightness over the chest after much exertion, especially in walking fast up a hill.

These symptoms continued until the 6th of March, when he had an attack of bronchitis, which he attributed to cold. His expectoration was copious, consisting of mucus slightly streaked with blood, and his cough came on in violent paroxysms, which were followed by a sense of suffocation.

On the 10th of March, after a fit of coughing, a soft, pulsating tumour about the size of a walnut suddenly made its appearance behind, and extending a little above, the right sterno-clavicular articulation, and

covered externally by the sternal portion of the sterno-mastoid muscle. The tumour was greatly diminished by firm pressure, but could not be made to disappear entirely.

The pulsation of the tumour, which was synchronous with that of the heart, was increased in force by pressure upon the right subclavian artery, and was diminished and sometimes completely arrested by pressure upon the right carotid above the tumour.

The pulsations of the right carotid and subclavian arteries were stronger than those of the left; but there was no apparent difference in the pulsations of the radial arteries.

As soon as the tumour made its appearance, the cough and dyspnœa ceased to be troublesome, and his health was soon re-established. His chest sounded well upon percussion, and the respiratory murmur was distinctly heard all over it. No unnatural pulsation could be detected by the use of the stethoscope between the tumour and the heart. A loud and powerful pulsation was heard over the tumour, unattended with any unusual sound.

In taking into consideration the situation of the tumour, its sudden appearance after a violent paroxysm of coughing, and its soft, pulsating character, together with the symptoms above enumerated, little doubt could be entertained of its nature, and I concluded that the root of the carotid artery was the seat of the disease.

Considering this a favourable case for the operation lately revived, and so ably advocated by Mr. Wardrop, I was induced to obtain the opinion of two eminent surgeons in London respecting its propriety. Both, however, disapproving of the operation, it was therefore determined, with the approbation of my friends, Mr. Bennet and Mr. Brown, of Derby, that a fair trial should be made of Valsalva's plan of treating aneurisms.

The nature of the disease was fully explained to the patient, who fortunately was a man of strong sense and most determined resolution, and from his employment leading him to study the diseases of horses, there was no difficulty in making him comprehend the dangerous tendency of the disease. He therefore submitted with perfect confidence to the proposed plan of treatment; and I cannot sufficiently admire the fortitude and cheerfulness with which he bore the long privation which it was necessary to enforce, and the implicit faith which he placed in all the remedies adopted for his relief.

April 3. He was accordingly ordered to bed, to be bled to the extent of eight ounces every third day; his diet to consist of small quantities of gruel, broth, and tea. Small doses of digitalis were likewise administered. This plan of treatment was continued until the 13th of July. During the first month there appeared some little improvement; his pulse was frequently as low as 47 in the minute, the tumour became harder, its pulsations less forcible and more remote; from which it was supposed that coagula might be forming. The blood hitherto had seemed perfectly healthy, and it was noticed that if the bleeding were delayed beyond the usual time, the symptoms were aggravated.

In the beginning of May a great alteration for the worse took place, which was supposed to be owing to his taking a small quantity of animal food. The blood after each bleeding became buffed; pulse 80 in the minute; the tumour rapidly increasing in the course of a few days, and becoming very painful upon pressure. Twenty leeches were applied without any relief. A few days afterward a diarrhœa supervened, the inflammatory state of the tumour abated, the pain ceased, and the swelling in some degree subsided. After this attack his pulse was never less than 80 in a minute, although the same plan of treatment was rigidly adhered to.

From this time until the 1st of July the tumour remained stationary; but from the latter date until the 20th he gradually got worse; the tumour increased, and now reached as high as the cricoid cartilage, and by its pressure upon the trachea and œsophagus partially impeded respiration and deglutition. His shirt-collar, which, prior to his illness, would button comfortably, could not now be made to meet by more than three inches; his countenance became bleached; pulse more feeble; and it was evident that the lowering system had been carried as far as it could with safety.

Under these circumstances the operation was recommended as the only remaining chance. Its advantages and disadvantages were fairly stated, and the chance of success, although small, made him anxious that it should be performed. Dr. Bennet, of Derby, saw the patient on the 17th, and concurred in the propriety of the operation as a last hope.

On the morning of the 22d of July, the day proposed for the operation, the patient became so agitated that the pulsation of the tumour, of the heart, and the large arteries, especially the abdominal aorta, was perceptible to the eye. The operation was performed in the presence of Messrs. Bennett and Brown, of Derby; Mr. Ingle, of Ashby-de-la-Zouch; and Mr. Walne, of Chancery Lane, surgeons.

In consequence of the tumour extending so high up the neck, there was some difficulty in getting down to the sheath of the artery, which was opened to the extent of half an inch. The artery appeared healthy, and was easily secured by a single ligature of strong silk.

Immediately after tightening the ligature the pulsation in the different branches of the external carotid artery ceased, except a slight fluttering in the extreme branches of the temporal. The pulsation of the tumour continued without diminution.

23d and 24th. He went on well. The pulsation in the tumour was stronger than it was before the operation, and the pulsation of the right radial artery was observed to be more forcible than that of the left.

25th. He became feverish; pulse 120, and full; the right lip of the wound swollen and painful. Six ounces of blood were taken away from the arm, and some saline medicine administered. The blood was much buffed.

26th. Morning. Much better; pulse 92, stronger in the right radial artery than in the left; pulsation in the tumour still very forcible.

Evening. The fever and pain in the tumour returned. He was again bled. Blood still buffed.

27th. Better again this morning. He was taken worse at nine o'clock in the evening. Pulse 100; delirious; anxious countenance and sickness. No diminution in the size of the tumour.

28th. Much better, and continued so all day.

29th. At seven, A. M., he was taken suddenly worse, and appeared to be dying; his countenance ghastly, and covered with perspiration; tracheal rattle, and inability to swallow. He appeared conscious, but could only speak in a whisper; pulsation in the tumour still forcible; the pulse in the right radial artery scarcely perceptible, while the left pulsated as strongly as it did the previous day. These symptoms were accompanied with a profuse ptyalism. He remained in this state for several hours, at the expiration of which time he rallied; and by the evening (with the exception of the salivation, which continued) he appeared quite as well as on the preceding day.

As he continued to improve from this period, it will not be necessary to enter into a daily report of the case. I shall therefore content myself with noticing the most prominent symptoms which occurred. One of the most remarkable was the obliteration of the arteries of the right arm and forearm, which was first observed in the arteries of the forearm on the 29th of July, the eighth day after the operation; for until that day the arteries of the right arm pulsated with greater force than those of the left. The process of obliteration was attended with severe paroxysms of pain, chiefly felt in the course of the brachial and axillary arteries.

The brachial artery after its obliteration was hard and painful to the touch, and felt very like an inflamed absorbent vessel. The right arm wasted, and became partially paralyzed, and continued to diminish for three weeks; at the expiration of which time several anastomosing branches were observed pulsating on the back part of the arm. As these vessels enlarged, the limb improved very slowly, not having yet (Oct. 19) perfectly acquired sensation, nor its muscles the power of obeying volition.

On the 11th day after the operation, he was attacked with intermitting paroxysms of pain in the right side of the head and face, of the same character as the pain in the right arm, though not so violent; this pain ceased within a fortnight. The right side of the head and face became emaciated, and any one looking at him would immediately discover that the right half of the face was much smaller than the left. The blood having since found its way into the temporal and facial

arteries, the right side of the face is now nearly as plump as the left.

The ptyalism, which began on the 29th of July, continued until the middle of September, during which time he spit daily about a pint of saliva; a more generous diet and a small quantity of ale were then allowed, and the salivation subsided.

Three weeks after the operation he was able to sit up to his meals. The first time that he got out of bed, he perceived that the whole of the right side was numbed, and weaker than the left. The pulsation in the tumour, which had hitherto been more powerful than it was before the artery was tied, now (Aug. 15) began to diminish rapidly, and by the 23d of August, the thirty-third day after the operation, had so much subsided, that it was doubtful whether it arose from the passage of blood into the tumour, or from the impulse given to it by the subclavian artery beneath.

In five weeks after the operation, he was sufficiently recovered to be able to take daily exercise in a gig or on horseback, and from this time he has continued to improve in health without interruption.

The obliteration of the right brachial artery is now complete, and above the insertion of the latissimus dorsi the pulsation of the axillary artery can be easily felt.

The pulse in the radial artery is scarcely perceptible in the right arm, increases daily, but is yet far from being of the size of the left. Sensation and susceptibility of the influence of volition are more perfect on the whole of the right side of the body, but still that side is more feeble than the left. The tumour is hard and firm, and has diminished about one-third since the operation. By pressing it from above downwards, a feeble, deep-seated pulsation is felt, but in grasping the tumour and using lateral pressure no pulsation can be perceived.

On the 13th of October the wound was nearly healed; the ligature had not come away, and as it acted as a source of irritation to the small wound, it was cut off level with the skin.

The most peculiar features which this interesting case presented were:—1st, The obliteration of the arteries of the right arm; 2d, The profuse salivation; 3d, The disposition to paralysis of the whole of the right side of the body.

The first two symptoms commenced on the 8th day after the operation; and I think there can be little doubt that the obliteration of the arteries of the arm was accomplished by inflammation extending from the aneurismal sac to the internal membrane of the subclavian artery, and thence to the brachial artery. Might not the active obliteration of such large arteries as those of the arm and forearm, be the cause of the unpleasant train of symptoms which occurred on the 8th day after the operation? The salivation appeared to be connected with the state of the digestive apparatus; for, as soon as ale and a generous diet were allowed, it gradually subsided.

I am at a loss to assign the cause of the numbness and debility of the whole of the right side of the body (which were only observed when he first left his bed), unless they originated in a greater quantity of blood circulating in the left hemisphere of the brain than in the right, which undoubtedly would be the case after the application of a ligature to the common carotid.

What tends to confirm this opinion is, that now (13 weeks after the operation) the balance of circulation in the brain being re-established, the numbness and debility of the right side of the body have nearly disappeared.

In conclusion, it is worthy of notice, that, since the operation, he has become more irritable in temper, and his memory is evidently weaker.

So far as this case has yet proceeded, it amply justifies the operation; and the man probably owes his life to Mr. Wardrop's fortunate suggestion and example. Should any untoward circumstance occur, leading to any other conclusion, it shall be communicated.

It is now five weeks since he resumed his usual avocations, and he regularly attends the markets and fairs of Derby, a distance of seven miles.—*Reese.*]

That Brasdor's operation must sometimes fail, and particularly that it should have failed in the trials made of it by Deschamps and Sir A. Cooper, is not at all surprising. These cases were both inguinal aneurisms; and it does not follow, because the method will answer in carotid aneurisms, that it will answer in aneurisms in every other situation. I should say, indeed, that unless it retard, in a certain degree, the circulation through the sac, it will never answer in any case; and how much this must depend upon the existence or not of one or more branches between the sac and the ligature, is completely obvious.

The memorable instance in which Sir A. Cooper tied the aorta, in a case of inguinal aneurism, extending very high up, and already burst, I shall notice under the head *Aorta.*

I shall finish these general observations on the treatment of external aneurisms, or such as admit more particularly of surgical treatment, with observing, that in England, surgeons now lose few patients either from gangrene in the limb or secondary hemorrhage; and this, notwithstanding they may sometimes prefer applying a ligature above the profunda to cutting open the aneurismal tumour. I firmly believe, that such matchless success is to be totally ascribed to their perfections in the mode of operating; the choice of a proper kind of ligature; the right plan of applying it; the rejection of the employment of several ligatures at a time; and the great care which is taken to promote the healing of a wound as quickly as possible; the avoidance of all unnecessary and hurtful extraneous substances in the wound; and above all, the relinquishment of the formidable proceeding of cutting open the tumour.

In the consideration of particular aneurisms, I shall begin with those which may be cured by a surgical operation; and here we shall be fully satisfied that "l'art de guérir ne triomphe jamais plus heureusement que lorsqu'il peut employer la médecine efficace, c'est à dire, les moyens chirurgicaux ou opératoires."—(*Velletan, Clinique Chir. t.* 1, *p.* 110.)

OF THE POPLITEAL ANEURISM, AND OPERATION FOR ITS CURE.

Notwithstanding the solitary example in which M. A. Severinus, early in the 17th century, tied the femoral artery near Poupart's ligament in a case of aneurism (*De Efficac. Med. lib.* 1, *p.* 2, *c.* 51), the practice of tying arteries wounded either by accident or in the performance of surgical operations, and even the plan of tying the humeral artery for the cure of the aneurism at the bend of the arm, were known long before the operation for the relief of the popliteal aneurism was attempted. The considerable size of the femoral artery, its deep situation, the urgent symptoms of the disease, and ignorance of the resources of nature for transmitting blood into the limb after the ligature of the vessel, are the circumstances which appear to have deterred former surgeons from this operation.

Valsalva treated popliteal aneurisms on the debilitating method, and published one or two equivocal proofs of its success. In Pelletan's first memoir on aneurism, and in the third vol. of Sabatier's Médecine Opératoire, as I shall hereafter notice again, are two cases of axillary aneurisms, which were cured by Valsalva's treatment. But encouraging as such examples may be, experience is not yet sufficiently favourable to this practice to allow it to bear a comparison in point of efficacy with the surgical operation, or to justify the general rejection of this last more certain means of cure. As Pelletan admits, Valsalva's treatment is extremely severe; the event of it doubtful; and should the plan fail, the patient might not be left in a condition to bear an operation, for the success of which it seems necessary that a certain strength of vascular action should exist, in order that the blood may be freely transmitted through such arterial branches as are to supply the places of the main trunk after it has been tied.

The time, therefore, has not yet arrived when surgical operations for the relief of aneurisms should be relinquished.—(*Clinique Chir. t.* 1, *p.* 114.)

The cure of popliteal aneurisms by means of compression is occasionally effected; but it happens too seldom to claim a great deal of confidence, or to lessen in any material degree the utility and importance of operative surgery in this part of practice. Pelletan records the cure of one popliteal aneurism by compression and absolute repose during eleven months (*t.* 1, *p.* 115); Boyer relates two instances (*Traité des Mal. Chir. p.* 204, *t.* 2); one is mentioned by Richerand *Dict. des Sciences Méd. t.* 2, *p.* 96); the practice of Dubois is said to have furnished several examples of

the same success (*vol. cit. p.* 97); and a case, in which Dupuytren effected a cure by compressing the femoral artery by means of an instrument applied just above the place where the vessel perforates the tendon of the triceps muscle, is detailed by Breschet.—(*Fr. transl. of Mr. Hodgson's work, t.* 1, *p.* 249, *&c.*)

The circumstances under which the employment of compression affords the best chance of success have been already mentioned, as well as the prudence of assisting this plan with perfect quietude, venesection, spare diet, and cold astringent applications, especially ice, which was first recommended by Donald Monro, and subsequently highly praised by Guerin.

Aneurisms in general, and among them the popliteal case, are all attended with some little chance of a spontaneous cure; yet this desirable event is too uncommon to be a judicious reason for postponing the operation, especially as it is the usual course of the disease to continue to increase; while in the early stage the cure may be more speedily accomplished. In fact, the experience of modern operators leaves no room for apprehending that the anastomoses will not suffice for the due nourishment of the leg, and consequently proves that waiting beyond a certain time for the enlargement of the collateral vessels to take place is altogether an unnecessary and disadvantageous method. Popliteal aneurisms, as well as other external tumours of the same nature, stand the best chance of a spontaneous cure, when any cause induces a general, violent, and deep inflammation all over the swelling; for then the communication between the sac and the artery is likely to become closed with coagulating lymph, and the pulsation of the tumour to be suddenly and permanently stopped. If in this state the disease sloughs, and the patient's constitution holds out, the coagulated blood in the sac and the sloughs are gradually detached, leaving a deep ulcer, which ultimately heals. An example, in which a popliteal aneurism was cured by such a process, is related in the *Trans. for the Improvement of Med. and Chirurgical Knowledge, vol.* 2, *p.* 268.

In former times, when all hopes of curing a popliteal aneurism by Valsalva's method, by compression, or a natural process, were at an end, amputation of the limb was considered as the sole and necessary means of saving the patient's life. But about fifty years ago, the confidence of surgeons in the sufficiency of the anastomosing vessels or the continuance of the circulation began to increase, and, in opposition to the tenets of J. L. Petit and Pott, experience soon proved, that in general, not only might the patient's life be saved, but his limb also, and this without any operation that could be compared with amputation in regard to severity. On looking back to the history of amputation, we shall find that A. N. Guenault was one of the earliest writers who disapproved of amputation as not truly indispensable for the cure of popliteal aneurism.

It is alleged that Teislere, Molinelli, Guattani, Mazotti, and some other celebrated Italian surgeons, were the first who ventured to tie the popliteal artery for the cure of aneurism. The path, as Pelletan remarks, had been pointed out to them by Winslow and Haller, whose valuable descriptions and plates of the arterial anastomoses about the knee-joint, showed by what means the lower part of the limb would be nourished, after the ligature had been placed on the principal arterial trunk. For almost thirty years, however, the practice of tying the popliteal artery was confined to the Italian surgeons. Pelletan believes that he was the first who attempted such an operation at Paris nearly thirty years ago (alluding to about the year 1780, the Clinique Chirurgicale being dated 1810).

However, this operation of opening the tumour and tying the popliteal artery itself, was a severe and often fatal proceeding, and does not admit of being compared with the Hunterian operation, in point either of simplicity, safety, or success, as I shall explain, after the detail of a few particulars relating to the popliteal aneurism.

On whatever side of the artery the tumour is produced, it can be plainly felt in the hollow between the hamstrings, and in general its nature is as easily ascertained by the pulsation in every part of the tumour. Though the disease may not occur in the popliteal artery so often as in the aorta itself, it certainly is seen more frequently in the former vessel than any other branch which the aorta sends off. As Sir E. Home has observed, this circumstance has never been satisfactorily explained; and, what is rather curious, in many recent instances of this disease the patients have been coachmen and postillions. Morgagni found aneurisms of the aorta most frequent in guides, postboys, and other persons who sit almost continually on horseback; a fact, which he imputes to the concussion and agitation to which such persons are exposed. Some allusion to this subject has already been made in the foregoing pages. Whether an explanation of the frequency of popliteal aneurisms can be correctly referred to the obstruction which the circulation in the artery must experience when the knee is in a state of flexion, may be questioned, though it is on a similar principle that the great frequency of aneurisms of the curvature of the aorta is attempted to be solved.—(*Home in Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 1, *&c. and Monro in Ed. Med. Essays, vol.* 5.)

Were this the only, or even the principal cause, surely one would have reason to expect aneurisms to be at least as frequent in the axilla, and in the bend of the elbow, as in the ham.

The popliteal aneurism was generally supposed to arise from a weakness in the coats of the artery, independently of disease. If this were true, we might reasonably conclude, that except at the dilated part the vessel would be sound. Then the old practice of opening the sac, tying the artery above and below it, and leaving the bag to suppurate and heal up, would naturally present itself. As the arterial coats were found to be altered in structure higher up than the tumour, and the artery immediately above the sac seldom united when tied, but, when the ligature came away, the patient was destroyed by hemorrhage, Mr. Hunter concluded, that some disease affected the coats of the vessel before the actual occurrence of aneurism. Dissatisfied with Haller's experiments on frogs, showing that weakness alone could give rise to aneurism, he tried what would happen in a quadruped, whose vessels were very similar in structure to the human. Having denuded above an inch of the carotid artery of a dog, and removed its external coat, he dissected off the other coats, layer after layer, till what remained was so thin, that the blood could be seen through it. In about three weeks the dog was killed, when the wound was found closed over the artery, which was neither increased nor diminished in size.

It being conjectured that the prevention of aneurism, perhaps arose from the parts being immediately laid down on the weakened portion of the artery, Sir E. Home stripped off the outer layers of the femoral artery of a dog, placed lint over the exposed part of the vessel to keep it from uniting to the sides of the wound, and in six weeks killed the animal and injected the artery, which was neither enlarged nor diminished, its coats having regained their natural thickness and appearance.

These experiments strengthened Mr. Hunter's belief that aneurismal arteries are diseased; that the morbid affection frequently extends a good way from the sac along the vessel; and that the cause of failure in the old operation arose from tying a diseased artery, which was incapable of uniting before the ligature separated. These reflections led him to propose taking up the artery in the anterior part of the thigh, at some distance from the diseased portion, so as to diminish the risk of hemorrhage, and be enabled to get at the vessel again in case it should bleed. The stream of blood into the sac being stopped, he concluded that the sac and its contents would be absorbed, and the tumour gradually disappear, so as to render any opening of it unnecessary.

[Dr. David Hosack was the first surgeon who performed this operation in America, which he did successfully as early as 1808. Three cases of aneurism were cured by him, by the ligature of the femoral artery, and will be found reported in his valuable volume of "Essays on Medical Science," by which it will be seen, that this distinguished gentleman in the former part of his life was an operative surgeon of more than ordinary skill. He has since devoted his energies to teaching the theory and practice, and in the less ostentatious character of a general practitioner has acquired a reputation second only to Rush, with whom his name will be transmitted to posterity as among the most eminent in their profession in this or any other

country. He began his distinguished career as a surgeon, and, like many others, thus laid the foundation of professional distinction.—*Reese.*]

The first operation of this kind ever done was performed on a coachman by Mr. Hunter, in St. George's Hospital, December, 1785. An incision was made on the anterior and inner part of the thigh, rather below its middle, which wound was continued obliquely across the inner edge of the sartorius muscle, and made large in order to facilitate the performance of whatever might be necessary. The fascia covering the artery was then laid bare for about three inches, after which the vessel itself could be felt. A cut about an inch long was then made through the fascia, along the side of the artery, and the fascia dissected off. Thus the vessel was exposed. Having disengaged it from its connexions by means of the knife and a thin spatula, Mr. Hunter put a double ligature under it with an eye-probe. The doubled ligature was then cut, so as to make two separate ones. The artery was now tied with both these ligatures, but *so slightly as only to compress the sides together.* Two additional ligatures were similarly applied a little lower, with a view of compressing some length of artery, so as to make amends for the want of tightness, as it was wished to avoid great pressure on any one part of the vessel. The ligatures were left hanging out of the wound, which was closed with sticking plaster. On the second day, the aneurism had lost one-third of its size, and on the fourth, the wound was every where healed, except where the ligatures were separated. On the ninth, there was a considerable discharge of blood from the apertures of the ligatures, but it ceased on applying a tourniquet, and did not recur. On the fifteenth day after the operation, some of the ligatures came away, followed by a small quantity of matter; and about the latter end of January, 1786, the man went out of the hospital, the tumour having become still less. In the course of the spring, abscesses in the vicinity of the cicatrix followed, and some pieces of ligature were occasionally discharged. In the beginning of July, a piece of ligature about an inch long came away, after which the swelling went off entirely, and the man left the hospital again on the 8th, perfectly well, there being no appearance of swelling in the ham. This subject died of a fever in March, 1787; and on dissection, the femoral artery was found impervious from the giving off of the arteria profunda down to the place of the ligature, and an ossification had taken place for an inch and a half along the course of this part of the vessel. Below this portion the vessel was pervious, till just before it came to the aneurismal sac, where it was again closed. What remained of the sac was somewhat larger than a hen's egg, and it had no remains of the lower opening into the popliteal artery. The rest of the particulars of this dissection are very interesting.—(See *Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 1, *p.* 153.)

This celebrated case completely established the important fact, that simply taking off the force of the circulation is sufficient to cure an aneurism, as the tumour is afterward diminished and removed by the action of the absorbent vessels.

In order to confirm the same fact, Sir E. Home related a case of femoral aneurism which got well without an operation, but on a similar principle to what occurs when the artery is tied. A trial of pressure had been made without avail. The tumour became very large, and such inflammation took place in the sac and integuments that mortification was impending: no pulsation could now be felt in the tumour, or the artery above it. The correct inference of Sir E. Home was, that a coagulum, which we know always occurs in an artery previously to mortification, seemingly to prevent bleeding, had formed in this instance, and in conjunction with the effusion of coagulable lymph about the root of the aneurism, had kept the blood from entering the sac.

Mr. Hunter's second operation was on a trooper. Instead of using several ligatures, which were found hurtful, he tied the artery and vein with a single strong one; but unluckily the experiment was made of dressing the wound from the bottom, instead of attempting to unite it at once; and the event was, that the man died of hemorrhage.

After this case Mr. Hunter's practice was to tie the artery alone with one strong ligature, and unite the wound as speedily as possible.

Having recorded Mr. Hunter's cases, which first established the present method of operating for the cure of popliteal aneurisms, I shall not repeat the strong reasons which exist against the employment of reserve-ligatures; metallic compressors; two ligatures, with the division of the vessel between them; the interposition of pieces of linen, wood, cork, agaric, &c. between the knot and the vessel; the use of large ligatures; and other contrivances, the merits or rather demerits of which have been already fully considered in the preceding section. My next duty is, to explain the method of performing the Hunterian operation, as brought to its modern state of improvement, and adapted to the wise principles which first emanated from the valuable experiments and investigations of Dr. Jones.—(See *Hemorrhage.*)

In the arrangement of the assistants, one of them should be so placed, that if required, in consequence of any accidental wound of that vessel in the operation, he can compress the femoral artery as it passes over the brim of the pelvis: but, as Scarpa justly observes, no pressure of this kind is to be made, unless the accident referred to should happen, because the pulsations of the artery, inasmuch as they indicate the track of the vessel, must tend materially to facilitate the operation. The surgeon is to explore with his fore-finger the course of the artery from the crural arch downwards, and when he comes to the place, where the vibration of this vessel begins to be less distinctly felt, this point is to be fixed upon for the lower end of the external incision. This angle of the wound will fall nearly on the inner edge of the sartorius, just where this muscle crosses the track of the femoral artery, and at the very apex of the triangle formed by the convergence of the triceps and vastus internus. A little more than three inches above the place here fixed upon, the surgeon is to begin with a convex-edged bistoury the incision through the integuments and cellular substance, and carry the wound down the thigh in a slightly oblique line from without inwards, so as to make it follow the course of the artery, as far as the apex of the above-mentioned triangular space, or the point where the vessel passes under the inner edge of the sartorius muscle. In order to make this first external incision with correctness, I consider it a good rule always to take particular notice of the line described by the sartorius on the thigh, the inner margin of which muscle at the place where it meets the artery, as we have seen, forms at once the lower boundary of the incision, and an important guide to the vessel itself. By observing the track of the sartorius attentively, we shall likewise avoid all chance of making the wound too low down, so as to have this muscle intervening between the incision and the artery; a greater source of embarrassment in the operation, and of troublesome consequences afterward, than perhaps any other error; for when this has happened, and the surgeon has not room enough afforded by the higher part of the wound to get at the artery above the sartorius, he is compelled to dissect and raise up this muscle from its natural connexions, ere he can plainly discover the vessel. This inconvenience made a deep impression on me in the first case where I tied the femoral artery; for the intervention of the sartorius in a stout soldier upon whom the operation was done, threw me into the dilemma of either dissecting at the outer edge of this muscle, and drawing it inwards, or of enlarging the wound upwards. The latter proceeding was that to which I gave the preference, because it seemed to me an excellent maxim in this operation to avoid making any farther detachment of parts from their natural connexions than is absolutely necessary; and I knew that when the wound was extended a little higher up, the artery would present itself more superficially, quite unconcealed by any muscle whatever. Strongly, therefore, as my principles have led me to condemn Scarpa's modification of the ligature, his use of from four to six threads, and his interposition of a roll of linen between the knot and the vessel, I feel pleasure in expressing my conviction of one excellence in his mode of operating; an improvement which is now obtaining, if it has not already obtained, the universal approbation of the surgical profession. This amendment consists in making the incision in the upper third of the thigh, or a little higher than the place where Mr. Hunter used to make

the wound. Scarpa's reason for this practice is to avoid the necessity of removing the sartorius muscle too much from its position, or of turning it back, to bring the artery into view, so as to be tied. I have seen the best operators, even professors of anatomy, embarrassed by having the sartorius muscle immediately in their way after the first incision; and as the vessel is more superficial a little higher up, the place is farther from the diseased part of the artery, and there is no hazard of the anastomoses failing to keep up the circulation: this part of Scarpa's practice is highly deserving of imitation.

"The part of the limb (observes Mr. Hodgson) in which the femoral artery can be tied with the greatest facility, is between four and five inches below Poupart's ligament. The profunda generally arises from the femoral artery an inch and a half or an inch and three-quarters below Poupart's ligament; it very rarely arises so low as two inches. If, therefore, the ligature be applied to the femoral artery at the distance of four or five inches below Poupart's ligament, the surgeon will not be embarrassed by meeting with the profunda during the operation, and the chance of causing secondary hemorrhage, by tying the artery close to the origin of this vessel, will be obviated."—(*On the Diseases of Arteries, &c. p.* 434.)

The trouble arising from cutting too low down, so as to have the sartorius intervening between the outer wound and the artery, may be more accurately estimated, when it is known that Desault, for the removal of this inconvenience, considered it right actually to make a complete transverse division of that muscle, a thing which, it is said, may be done without any ill consequences.—(*Boyer, Traité des Mal. Chir. t.* 2, *p.* 145.) I shall not presume, however, to second this last piece of advice, because, though it may have been done by Desault, it appears to me that the artery can always be taken up very well without the proceeding here recommended.

A few years ago Mr. C. Hutchison published a tract, in which he is an advocate for the practice of making the incision at the outer edge of the sartorius, and then raising that muscle and drawing it inwards, in order to arrive at the artery. This advice proceeded from the apprehension that the plan of taking up the femoral artery at the inner edge of the sartorius was attended with risk of injuring the saphena vein and large lymphatics.—(*Letter on the Operation for popliteal Aneurism*, 1811.) The same method is commended by Boyer and Roux (*Nouveaux Elémens de Méd. Opératoire, t.* 1, *p.* 729), when the operation is done low down in the thigh. But as operating in this situation is liable to the several objections of approaching too near the disease, of aiming at taking up the artery where it lies more deeply than it does higher up, and of every inconvenience which may arise from the interposition, dissection, and reflection of the sartorius muscle, the method must be rejected, unless it can be proved that so many disadvantages are fully counterbalanced by other considerations. If the plan which I shall presently recommend be adopted, there will never be the slightest risk of wounding the saphena vein: and, therefore, I do not consider it advisable or necessary, for the avoidance of this accident, to make the wound *precisely upon the sartorius*, as my intelligent friend Mr. Hodgson suggests; a method attended with the inconvenience of having the fibres of that muscle between the external wound and the artery, and perhaps inconsistent with the excellent directions which he afterward delivers concerning the right mode of performing the external incision, when he says, with Scarpa, that this cut should be "continued down to the fibres, which form the inner margin of the sartorius."—(*On the Diseases of Arteries, &c. p.* 436.)

Now, if the point where this margin first lies over the artery be the proper place for the lower termination of the external incision, we shall clearly be deviating from the precise course of the vessel by letting the higher portion of the wound be over the fibres of that muscle. And when it is farther reflected, that the serious evils of wounding the trunks of the lymphatics in this operation are not demonstrated in modern practice, while the saphena vein may always be avoided with certainty and facility, I cannot admit, that there is any solid reason for letting the situation and direction of the external wound be determined by such apprehensions. At all events, for the motives above explained, it should be a fixed maxim in this operation never to extend the wound lower than the point where the inner margin of the sartorius crosses the artery: and then all detachment and displacement of this muscle will be unnecessary, and every embarrassment which might proceed from its interposition between the outer wound and the artery, will be completely avoided.

With the view of preventing injury of the femoral vein, Mr. Carmichael recommends the needle to be introduced on the pubal side of the artery, where the vein presents itself to view, and can be most easily avoided. He remarks, that the only part of the thigh from Poupart's ligament to the tendon of the triceps, in which the femoral vein is not completely covered by the artery, lies within the space which extends from Poupart's ligament to the point where the artery meets the sartorius muscle. At the part of this space most distant from Poupart's ligament, the vein begins to disclose itself at the pubal side of the artery, from beneath which it emerges more and more as it ascends. —(See *Trans. &c. of the Fellows, &c. of the King's and Queen's College of Physicians, Ireland, vol.* 2, *p.* 357.)

The skin and cellular substance are to be divided in the situation and to the extent above specified, down to the femoral fascia, under which the artery lies, and may be felt beating. The next object, therefore, is, to divide the fascia, which is here much thinner than at the outer side of the limb, and may be cut with another stroke of the bistoury; or (what is safer, with the view of abstaining from all chance of wounding the artery), a slight cut may first be made in the fascia, the division of which may then be made to the requisite extent by introducing under it a grooved director, on which the farther incision may be made with perfect security. The fascia is to be divided in the direction of the external wound; but to what extent, is a point on which surgical writers differ, and, indeed, they must here differ, as long as they are not unanimous about the method of applying the ligature round the artery; because if it be intended to use a broad ligature, with a cylindrical piece of linen interposed between it and the artery, or especially if it be designed to apply two ligatures and divide the vessel in the interspace, more of the artery must be exposed, and of course more of the fascia must be cut, than when it is simply meant to surround the vessel with a single small ligature. Such operators also as have contracted the pernicious habit of insulating the artery all round sufficiently far to let them thrust their fingers under it, will likewise require an extensive opening in the fascia. This detachment of the vessel for an inch or more, for the purpose of placing the finger under it, is a measure which deserves to be condemned in the strongest terms, as it is the very thing which produces some risk of injuring the saphena vein, and has a tendency to bring on secondary hemorrhage, inasmuch as it occasions unnecessary handling, stretching, and disturbance of the artery and surrounding parts, and an inevitable division of the vessels by which the arterial coats are supplied with blood.

According to Mr. Hodgson, the extent of the cut in the fascia should be about an inch; for he wisely avoids all unnecessary separation of the artery from its surrounding parts. On the contrary, Scarpa, who insulates and raises the vessel, previously to tying it, insists upon the prudence of cutting the fascia the whole length of the external wound; for, says he, if this practice be neglected, it most frequently happens, that in the succeeding inflammatory stage, the bottom of the wound swells and becomes very tense, and the matter which is formed under the fascia, not finding a ready exit, occasions abscesses which seriously retard the cure. But Scarpa, instead of planning a method of relieving the consequences, might have employed himself more to the purpose in considering how they were to be prevented, and why in his method they most frequently happen. Now, without laying any stress upon two waxed ligatures, each composed of six threads, with an additional extraneous substance, viz. a roll of linen, in the noose, we should be more surprised to hear that the wound after his method did not become affected with swelling, tension, and suppuration, than that these were the usual effects. After describing the division of the fascia, he observes: "*With the point of the fore-finger of the left hand, already touch-*

ing the femoral artery, the surgeon will separate it from the cellular substance, which ties it laterally and posteriorly to the contiguous muscles; and making the point of the same finger pass gradually under and behind the femoral artery (supposing the surgeon has not enormously large fingers), he will raise it alone from the bottom of the wound, or (when it cannot be avoided) along with the femoral vein. If it is along with the femoral vein, the surgeon, holding the artery and vein thus raised, and almost out of the wound, will cautiously separate the vein from the artery with a bistoury or spatula, or simply with his fingers," &c.—(See *Scarpa on Aneurism, p.* 280, *ed.* 2.)

When we combine the irritation and mischief of all this work with the ill effects of filling the bottom of the wound with soft lint, I would ask, what more certain plan could Scarpa or any other person have suggested for bringing on the unpleasant state of the wound which he describes as most frequently taking place!

I shall suppose the fascia has now been divided, under which the surgeon distinctly feels the pulsations of the femoral artery, which is still invested by the cellular sheath. The femoral vein lies directly under this vessel, while the branches of the anterior crural nerve, separated from it by dense cellular substance, are more externally, yet somewhat more deeply situated. The next object, therefore, is to pass a single ligature round the artery, without including, or in any manner meddling with, the subjacent femoral vein, or detaching and disturbing the artery. For this purpose the best direction is that given by my friend Mr. Lawrence, especially when combined with Mr. Carmichael's plan of letting the needle be introduced on the pubal side of the artery: "after dissecting down to the artery, a slight scratch or incision may be made through the sheath, close to the side of the vessel. Then, with a narrow aneurism-needle, nearly pointed at the end, and made as thin at its edge as it can be without cutting, a single silk ligature is to be conveyed round it, the point of the needle being kept in contact with the artery. A needle of this form makes its way easily through the cellular substance, and the vessel is detached only in the track of the instrument."—(See *Med. Chir. Trans. vol.* 6.)

Of the kind of ligature to be employed, I need only say here, that it should be a single one composed of firm materials, in order to avoid the necessity for increasing its diameter more than would be desirable for reasons elsewhere considered.—(See *Hemorrhage* and *Ligature.*) The ligature having been put under the artery, one end of it is to be drawn completely through the track made for it by the needle, which instrument is then to be taken away, leaving the ligature under the vessel. The ligature is now to be tied in a steady, firm manner, but without any immoderate force, which can never be necessary even for the division of the inner coats of the vessel. In this part of the operation, a few practitioners give the preference to what is termed the *surgeon's knot*; and commend this plan of fastening the ligature; a plan which consists in putting the end of the cord twice through the noose, before the constriction is made. The only good of the surgeon's knot is, that it does not so readily slip and loosen as a common one; but Scarpa thinks a simple knot best, as it does not, like the other, prevent the surgeon from calculating the force with which the artery is constricted.—(*On Aneurism, p.* 281, *ed.* 2.) And besides this reason against the surgeon's knot, another objection to it is the irregularity with which a ligature in this form will lie round the vessel. A simple noose should therefore be first made and tightened, and then a second one, so as to form a common knot; and now, as a matter of precaution against the possibility of the ligature slipping and becoming loose, the surgeon, if he pleases, can tie the knot once again. One end of the ligature is next to be cut off near the knot; and the sides of the wound are to be brought together with strips of adhesive plaster, the irritation of sutures being carefully avoided. The remaining end of the ligature should always be brought out at the nearest point of the external wound to the knot on the artery.

The effects which in general immediately follow the operation are, a total cessation of the pulsation of the aneurismal tumour; a manifest sinking and flaccidity of the swelling; a diminution of pain in the seat of the disease; and a strong vibration of the articular arteries round the knee. As Mr. Hodgson has remarked, the unusual influx of blood into the minute ramifications, when a main artery is suddenly rendered impervious, is generally attended with a remarkable increase in the temperature of the limb. After tying the femoral artery for the cure of popliteal aneurism, the same phenomenon occurs, at least after a short time, during which the temperature of the leg and foot frequently continues lower than that of the sound limb. But in a few hours it generally rises, and is sometimes several degrees higher than that of the opposite member. This state lasts several days, at the end of which time, the heat of the limb which has been operated upon will be found to be about the same as that of other parts of the body.—(*Hodgson on Diseases of Arteries, &c. p.* 256.) It is only while the limb is colder than natural, that it ought ever to be fomented or covered with flannel. In particular examples, there is no increase of temperature in the limb, at any period after the operation; a fact which Mr. Hodgson refers to the probability of a collateral circulation having already been established, in consequence of the obstruction to the passage of the blood through the main artery by the accumulation of the coagulum in the aneurismal sac. Of course, unless a collateral circulation be established, the operation cannot succeed, as the limb will mortify; it behooves us, therefore, to be aware of the circumstances which may prevent the due transmission of the blood to the inferior part of the limb. These are ably explained and commented upon in Mr. Hodgson's work: 1st, An extensive transverse wound, by which the principal anastomosing branches are divided. 2dly, Tight bandages and pressure operating so as to obstruct the same vessels. 3dly, The immense bulk of the tumour, and the pressure upon the principal collateral arteries. 4thly, Calculous depositions in the coats of the arteries of the limb. 5thly, Advanced age. 6thly, A languid state of the circulation; a fact indicating the wrongness of venesection, as a general practice after the operation, though it may yet be right to adopt this treatment, where the pulsations return in the tumour with unusual strength, and appear to stop the diminution of the swelling, as already mentioned. 7thly, The abstraction of heat from the limb by cold evaporating lotions; a plan which can only be right when there is a great increase of heat in the limb, a tendency to inflammation, or a return of strong pulsations in the tumour.

Sir Astley Cooper saw a case, in which the application of whitewash occasioned mortification and the patient's death. In cold weather, he always covers the limb with flannel or a stocking, and sometimes puts jars filled with hot water to the feet.—(*See Lancet, vol.* 2, *p.* 42.)

When the operation is done according to the principles laid down in this article, the patient is not too old, nor enfeebled, and the after-treatment is properly conducted, mortification cannot now be said to be a frequent event. In one case, operated upon by Sir Astley Cooper in 1823, the whole of the foot and part of the leg mortified; but it should be noticed, that in this instance the whole limb was extremely swollen previously to the artery being taken up.—(See *Lancet, vol.* 1, *p.* 436.) In all his extensive practice, he has seen but three or four instances of a failure of the operation from gangrene.—(*Lectures, &c. vol.* 2, *p.* 60.) Mr. Liston has related one example which he ascribed to the improper use of fomentations with hot salt water.—(See *Edinb. Med. Journ. No.* 90, *p.* 3.) As, however, the patient seems to have been of a very phlogistic diathesis, and to have been attacked with inflammation of other parts, the reality of the alleged cause appears questionable. I have seen but one example of gangrene, and in that, only one toe, and a portion of the skin of the instep, sloughed in a very debilitated subject. This partial gangrene of the foot has been particularly noticed by Deschamps and Scarpa, the latter of whom regards it as an unusual thing, only likely to happen in old, weak, or unhealthy subjects; and "at any rate (says he) if this should happen in any of these enervated individuals, the patients may console themselves for the loss of one or two of their toes, with the cure of a popliteal aneurism, and the avoidance of a painful and dangerous incision in the ham, and of the tedious suppuration which would have followed it."

Sir Ast. Cooper has known retention of urine brought on by the operation in one or two examples, and the use

of the catheter indispensable.—(*Lectures, &c. vol.* 2, *p.* 58.) Mr. C. Bell met with a case in which the femoral artery divided below the profunda into two equal branches, the most superficial of which was alone noticed and tied in the operation. The patient died of constitutional disturbance, arising from inflammation in the whole course of the sartorius. After two or three days, the pulsation of the tumour, which had been very strong, ceased, in consequence of the coagulation of the blood within the sac; another fact, exemplifying that this desirable change will not be prevented by a current of blood being still propelled through the aneurismal cavity.—(See *Quarterly Journ. vol.* 3, *p.* 607.)

Mr. Liston has recorded a case, in which the pulsasation and tumour returned several months after the operation. "On consulting with Dr. Thomson, it was agreed to try the effect of methodical bandaging, from the points of the toes upwards, and a compress over the tumour, with rest, cold applications, and moderate diet." These means had the desired effect; and the patient did not complain much of those pains which so frequently remain after the operation for aneurism.

According to Mr. Liston, these pains are in general distinctly referable to the sacro-ischiatic nerve and its branches, and are explained by the state of the vessels in the substance of the nerve. In the natural state the neurilemal vessels, when injected, are not larger than sewing threads: but when the enlargement of the collateral branches is requisite, owing to the obstruction of the trunk, they also are called on to contribute their share in the new circulation; and they become enormously distended. In one remarkable specimen, in which the limb was injected and examined fifteen years after the superficial femoral atery had been secured for aneurism in the ham, the vessels in the sacro-ischiatic nerve had attained the size of crow-quills, and were convoluted in an extraordinary manner. The pains in the limb, noticed by Mr. Liston as occurring after the operation, he acknowledges, however, are by no means so severe as those experienced previously, and which are produced by the compression and stretching of the nerves by the sac.—(*Edin. Med. Journ. No.* 90, *p.* 2.)

When the operation succeeds, a considerable portion of the artery above the aneurismal tumour is rendered impervious, the vessel indeed being sometimes converted into a solid cord from the origin of the profunda to that of the tibial arteries.—(*A. Cooper, Med. Chir. Trans. vol.* 2, *p.* 254.) In general, however, the obliteration of the artery is less extensive; a fact particularly noticed in one of Mr. Hunter's cases (*Trans. of a Soc. for the Improvement of Med. and Chir. Knowledge, vol.* 1, *p.* 153), and vainly urged by Deschamps, as a proof of the insufficiency of the new method.—(See *Observations et Réflexions sur la Ligature des principales Artères blessés, et particulièrement sur l'Aneurisme de l'Artère poplitée, p.* 76, *Paris*, 1797.) It appears from the observations of Mr. Hodgson, that the artery generally becomes impervious, for the space of three or four fingers' breadth, at the place where the ligature is applied; below which part its tube is unclosed, and continues so for some distance, when the obliteration again commences, and descends along a considerable extent of the popliteal artery to the origin of the inferior articular, or tibial arteries. Thus, says this author, an insulated portion of the femoral artery preserves its cavity, from each extremity of which considerable anastomosing branches arise; the upper branches convey blood into the vessel, and the lower transmit it into anastomosing channels, that originate below the knee. —(*On Diseases of Arteries, &c. p.* 278.) Now, as Mr. Hodgson is unacquainted with any case, except that recorded by Sir Astley Cooper, where, after the modern operation, the artery was obliterated from the seat of disease in the ham to the part at which the ligature was applied, he thinks it probable that, in most instances, a double collateral circulation exists in the limb, after this method of cure.

In consequence of the motion of the blood being more or less impeded in the aneurismal sac by the application of the ligature to the femoral artery, the aneurismal cavity soon becomes completely filled with coagula, which even block up the adjoining portion of the arterial tube. The coagulated blood in the sac is afterward absorbed; and a gradual diminution and final disappearance of the aneurism in the ham ensue; with the exception of a slight induration, which sometimes remains, composed of a remnant of the sac itself, or of the fibrous part of the blood. This slight hardness in the cavity of the ham occasions no inconvenience, and does not hinder the patient from performing the motions of the knee and leg with quickness and safety.—(*Scarpa, p.* 257, *edit.* 2.)

After the operation, the circulation is carried on principally by the arteria profunda, whose branches communicate with the articular arteries of the popliteal, and with arteries sent to the knee by the anterior and posterior tibial. Large branches in the sciatic nerve, sent off by the arteria profunda, communicate very freely with the popliteal artery, the articular, and branches of the posterior tibial. As Sir Astley Cooper has farther explained, the freedom of anastomosis sometimes leads to a reproduction of an aneurism. The femoral artery was tied by Mr. Key, and the patient, after being discharged cured, returned with a painful tumour in the ham, attended with an obscure pulsation. The limb was amputated, and a large artery, passing to the tumour, and situated nearly in the usual place of the femoral, required a ligature.—(*Lectures, &c. vol.* 2, *p.* 60.)

When the advantages of the foregoing method of operating are contrasted with the dangers and severity of the practice of laying open the aneurismal tumour, and applying ligatures round the diseased part of the vessel, it is surprising to find any living surgeons still expressing a preference to the latter mode of treatment under any circumstances whatsoever. Yet Boyer, Roux, and a few of the modern French surgeons, are in this way of thinking, which reminds me of their slowness to adopt, at every opportunity, union by the first intention, one of the greatest and most decided advances to perfection ever made in the practice of surgery. The severity and difficulties of the old method of operating, in cases of politeal aneurism, are most faithfully depicted by Scarpa. In the ham, says he, the artery lies very deep. The space is limited and narrow, within which it can be brought into view and tied, without risk of tying along with it, or of destroying, some of the principal anastomoses formed by the articular arteries of the knee. On account of the depth of the artery, it is difficult to pass any instrument round it, without including other parts; and it is no less difficult to draw the ligature on the vessel with a proper degree of tightness. Scarpa then comments on the disadvantages of tying the lacerated, diseased part of the vessel, which is sometimes so high up, that, in order to apply the ligature above it, it is necessary to cut through the long head of the triceps, and make a passage through into the thigh. Or, the diseased or lacerated part of the artery is situated so low down in the calf of the leg, that it is impossible to avoid including, either in the incision or the ligature, the lower anastomosing articular arteries, on the preservation of which the circulation and life of the subjacent part of the limb in a great measure depend. We must add to all this the violence unavoidably done to the great sciatic nerve, which an assistant must hold drawn to one side of the wound nearly the whole time of the operation. The proceeding is also liable to other great difficulties, as may be seen from a case reported by Masotti (*Dis. sul Aneurysma, p.* 54), where the popliteal artery was so firmly united, and, as it where, confused with the vein, the nerve, the tendons of the neighbouring muscles, and the periosteum, that the cavity of the ham presented the appearance of an intricate mass of parts, not easily separable from one another. Lastly, the operation leaves a large deep wound, laying open the whole cavity of the ham, and followed by copious suppuration, sinuses and necrosis of the heads of the femur and tibia. If the patient be not hurried into the grave by these affections, and even if the parts in the ham heal, he is almost always left with an incurable contraction of his knee, and perpetual lameness. Thus, Masotti (*Op. cit. p.* 17) relates one case, where the subsequent effect caused such destruction of the soft parts in the ham, that not a vestige of artery, vein, or sciatic nerve was left, and the patient remained all the rest of his life with a paralytic leg, and ulcers and fistulæ all round the knee.—(*Scarpa on Aneurism, p.* 251.)

I shall now advert to a few facts in the history of surgery, which eventually led to the bold and successful operations adopted in modern times for the cure of aneurisms of the femoral and popliteal arteries. The earliest case of which the particulars are recorded, amounting to a satisfactory proof that the lower extremity might be duly supplied with blood, notwith-

standing the femoral artery had been tied high up in the thigh, is the example related by M. A. Severinus of a false aneurism of the thigh, about eight fingers' breadth below the groin, caused by a musket-ball wound. In this instance, Severinus tied the femoral artery above and below the aperture in it, and not only was the patient's life saved, but the use of the limb also preserved.—(*Chirurgiæ Efficacis, p.* 2, *Enarratoria.*) The next authentic case of the ligature of the femoral artery, is that reported by Saviard, where Bottentuit, in 1688, tied this artery on account of a false aneurism, the result of a sword-wound, at the inner and upper part of the thigh. The surgeons called into consultation were immediately convinced, that the only thing to be done was to take up the femoral artery; but they were fearful lest the patient should perish of bleeding ere the opening in the vessel could be found; and in case the artery were secured, they apprehended the obstruction of the circulation would be followed by mortification of the limb. The patient was therefore first prepared for his fate by the administration of the sacrament. A band was then applied round the upper part of the limb, and tightened by means of a stick with which it was twisted, a piece of pasteboard being put under the knot, in order to render the constriction less painful. The tumour was then opened, the clotted blood extracted, and the opening in the artery detected by slackening the tourniquet. A curved needle, armed with a double ligature, was then introduced under the femoral artery, and one of the cords was tied above, and the other below the wound in the vessel. Then follows a curious passage, showing the operator's judgment at that time, respecting the impropriety of interposing any cylinder of linen between the knot of the ligature and the artery, as some of the old surgeons at that time used to do, as well as a few of the moderns. "*On ne mit point de petites compresses sur le corps de l'artère au-dessus du nœud, comme font quelques uns, parceque l'on jugea qu'il étoit d'une grande conséquence de lier très-étroitement une artère si considérable, ce que l'on n'auroit pas été sûr de faire en interposant la petite compresse,*" &c. For greater security, assistants who relieved each other in turn kept up constant pressure on the tied part of the vessel for twenty-four hours. In six weeks, the patient recovered, and afterward enjoyed such good health that he went through several campaigns.—(*Saviard, Nouveau Recueil d'Observations Chir. Obs.* 63, 12*mo. Paris*, 1702.)

Now, with respect to these two cases, it merits attention, that though Heister, Morgagni, and others, endeavoured to explain the success, by supposing that each of the patients in question must have had two femoral arteries, both Severinus and Saviard were wise enough to avoid making any such erroneous inference themselves. At a later period, Guattani laid bare the femoral artery, as it passed under Poupart's ligament, compressed it against the ramus of the pubes, by means of graduated compresses retained with a firm roller, and thus obtained the speedy obliteration of the vessel, and cured the aneurism, which had been first injudiciously opened.—(*De Externus Aneurismatibus, Hist.* 15, 4*to. Romæ*, 1772.) In the same book is given the case of an inguinal aneurism, which, when it had continued three months, and become equal in size to a large fist, was attacked with gangrene, whereby the aneurismal sac was quickly destroyed, and the femoral artery was obliterated for a considerable extent from the crural arch downwards. The sloughs were thrown off, however, and the ulcer had in a great measure healed, when the patient fell a victim to debility.—(*Hist.* 17.) Here it is to be remarked, that during the five weeks this man lived after the obliteration of the femoral artery above the origin of the profunda, not only the circulation and life of the whole limb were preserved, but the auxiliary arteries, coming from within the pelvis, proved capable of limiting the progress of the mortification of the parts round the aneurism, and of commencing the healing process in a manner which raised great hopes of a cure. A similar fact is also recorded by Dr. Clarke.—(*Duncan's Med. Comment. vol.* 3.)

[In cases of aneurism in the thigh, it is not always practicable to decide with absolute certainty whether the disease is situated in the femoral artery, or in the *profunda*; and even when it obviously originates with the former, the latter is often deeply involved, particularly when the disease has been of long standing. Many unsuccessful cases have been reported; and I know of one which has failed in the hands of a distinguished surgeon, the aneurismal tumour still remaining, although the femoral artery was tied above the tumour. In this case the disease is no doubt seated in the profunda.

Many surgical writers and teachers have inculcated the doctrine, that when the aneurism is situated in the thigh, the ligature must always be applied *below* the bifurcation, lest the circulation of the limb should suffer. A distinguished surgeon of Philadelphia, preferred opening the sac of a femoral aneurism, and applying his ligature below the profunda, rather than venture to tie the artery higher up. The operation failed, however, and the tumour still remains. That such fears are wholly groundless, may be confidently asserted from analogy, furnished as we are with the knowledge that the innominata, the common iliac, and even the aorta itself, may be obliterated, and yet the anastomosing vessels continue the circulation. But Dr. Whitridge, an accomplished surgeon of Charleston, S. C., has afforded a demonstration in a case of aneurism in the thigh from a gun-shot wound, in which he tied the femoral artery just below Poupart's ligament, and of course above the point at which the profunda goes off. This case has been completely successful, and the patient recovered without any sensible interruption in the circulation, and without any untoward symptom.

The cases in which the femoral artery divides high up, which Professor Godman has shown are by no means unfrequent, may account for the occasional failures of this operation, and should not be lost sight of by the judicious surgeon. As a general rule, however, applicable to all other cases, when the aneurism is situated immediately below the bifurcation, and in the vicinity of the profunda, it is safer, and also better surgery, to apply the ligature above. The action of the profunda may endanger the success of the operation, and the most profound surgeon may sometimes mistake the seat of the disease.—*Reese.*]

These and other cases which might be quoted, furnished ample proof of the efficiency of the anastomosing vessels in the support of the limb, though the femoral artery had been tied, or obliterated in a very high situation.

Besides these facts, surgeons derived every encouragement to attempt the cure of popliteal aneurism, by the ligature of the artery above the tumour, from the elucidations given by Winslow and Haller concerning the numberless inosculations which exist between the upper and lower articular arteries. Haller even drew the conclusion, that if the course of the blood were intercepted in the popliteal artery, between the origins of the two orders of articular branches, such anastomoses would suffice for carrying on the circulation in the leg. And at length, Heister, weighing the anatomical observations of Winslow and Haller, and the facts recorded by Severinus and Saviard, first proposed applying to popliteal aneurisms an operation, which, with the exception of those two cases, had until his time been restricted chiefly to aneurisms of the brachial artery.—(*Dis. de Genuum Structurâ eorumque Morbis. Disp. Chir. Halleri, t.* 4.)

It was in Italy that the earliest operations were undertaken for the cure of popliteal aneurisms, by Guattani, or rather by a German surgeon named Keysler, as would appear from a letter written by Testa to Cotunni.—(See *Pelletan, Clinique Chir. t.* 1.) The success obtained by those surgeons soon led others to imitate them, and by degrees, the practice of tying the femoral artery became common both in cases of aneurism and wounds; and from the observations of Heister (*Haller Disp. Chir. t.* 5), Acrell (*Murray de Aneurysm. Femoris*), Leslie (*Edin. Med. Comment.*), Hamilton (*B. Bell's Surgery, vol.* 1), Burschall (*Med. Obs. and Inq. vol.* 3), Leber (*Dehaen, Ratio Medendi, t.* 7), and Jussy (*Ancien Journ. de Méd. t.* 42), it was proved beyond the shadow of a doubt, that the circulation might continue in the limb after the obliteration of the femoral artery, whether such obliteration were effected by direct pressure or the ligature.

The exact period when the first operation of laying open the tumour and tying the popliteal artery was performed in England, is not, as far as I know, particularly specified. However, judging from the observations made on this practice in the writings of Pott

(*Remarks on Palsy, &c.* 8vo. *Lond.* 1779), of Wilmer (*Cases and Remarks in Surgery*, 8vo. *Lond.* 1779), of Kirkland (*Thoughts on Amputation*, 8vo. *Lond.* 1780), and of others, it is clear that this method of treatment had been often done in this country earlier than the dates of those works, and as would appear with little or no success. The earliest attempt of this kind in France was made by Chopart in 1781 (*Roux, Nouveaux Elémens de Méd. Opératoire, t.* 1, *p.* 556), about five-and-twenty years after the examples set by Guattani in Italy; but Chopart failed in his endeavours to repress the bleeding from the exposed cavity of the tumour, and was therefore obliged to amputate the limb. Subsequently to this attempt, the operation was undertaken by Pelletan in two instances, the terminations of which were successful: consequently, this surgeon may be regarded as entitled to the honour of having proved to his countrymen the possibility of curing the popliteal aneurism, by laying open the tumour, and securing the artery in the ham.

The severity and frequent ill success of this method of operating I have already noticed, nor shall I repeat the objections to it. With respect to the Hunterian practice, the great peculiarities of which were tying the artery at some distance above the disease, and not opening the swelling at all, Richerand seems offended that Hunter's name should be affixed to an operation, which he conceives was in reality the invention of Guillemeau. Here we observe, Ætius again puts in a prior claim, and with much more effect, because the method of which he speaks truly resembled Mr. Hunter's, inasmuch as the vessel is directed to be tied at some distance above the swelling, while Guillemeau only tied the artery close above the disease, and *opened the swelling, a serious deviation from the Hunterian practice.*

Guillemeau, a disciple of Ambrose Paré, having to treat an aneurism at the bend of the arm, the consequence of bleeding, exposed the artery above the tumour, tied this vessel, then opened the sac, took out the coagulated blood, and dressed the wound, which healed by suppuration. After more than a century, Anel, on being consulted about a similar case, tied the artery above the swelling, which was left to itself. The pulsation ceased, the tumour became smaller, and hard, and after some months no traces of the disease were perceptible.

In 1785, Desault operated in the same manner for a popliteal aneurism: the swelling diminished by one-half, and the throbbings ceased; on the 20th day it burst, coagulated blood and pus were discharged in large quantities, and the wound, after continuing a long time fistulous, at length healed. Towards the end of the same year, says Richerand, Hunter applied the ligature somewhat differently; instead of placing it close to the swelling, or directly above it, he put it on the inferior part of the femoral artery.—(See *Nosogr. Chir. t.* 4, *p.* 98, 99, *edit.* 2.)

Unquestionably, Anel did, in one solitary instance, tie the humeral artery immediately above an aneurism at the bend of the arm, and effected a cure without opening the swelling (*Suité de la Nouvelle Méthode de guérir les fistules lachrymales, p.* 251, *Turin*, 1714); but he did not think of applying the plan to the femoral artery, or draw the attention of French surgeons sufficiently to the matter, to make them imitate this operation: on the contrary, the method fell into oblivion, and was never repeated. With regard to Desault's operation, said to have been done in an earlier part of 1785 than Mr. Hunter's first operation, it is only necessary to say, that Desault tied the popliteal artery itself, while the grand object in Mr. Hunter's method was to take up the femoral artery, at a distance from the disease, and that it is this last mode alone which has gained such approbation, and been attended with unparalleled success.

The French surgeons have not practised the Hunterian operation with the same degree of success with which it is now performed in England, and consequently they very commonly pursue the old method of opening the sac, &c. Even Boyer avers his relinquishment of what he calls Anel's plan.—(*Traité des Mal. Chir. t.* 2, *p.* 148.) But we shall not be surprised at their ill success, when we hear that they neglect the right principles on which ligatures ought to be applied to arteries, as explained by Dr. Jones in his work on hemorrhage. Even Baron Dupuytren adheres to the use of ligatures of reserve; and Boyer applies four loose ligatures round the artery, besides two tight ones; and consequently, a large portion of the vessel lies separated from its natural connexions, and irritated by these extraneous substances. Hunter's first operation nearly failed also on account of so many ligatures, none of which were tightened so as to cut through the inner coats of the artery, and thus promote its closure. —(See *Hemorrhage.*) With reference to the operation of popliteal aneurism, *Rosenmuller's Chir. Anat. Plates* deserve to be consulted, *Part* 3, *Tab.* 8 & 9. Scarpa's and Tiedemann's matchless engravings, and Haller's Icones should likewise be examined.

ANEURISMS OF THE LEG, FOOT, FOREARM, AND HAND.

Doubts were not long ago entertained respecting the possibility of curing an aneurism at the upper part of the calf of the leg by tying the femoral artery in the middle of the thigh.—(*Instituto di Ital. Scienze ed Arti, vol.* 1, *parte* 2, *p.* 266.) The author here referred to was led by this uncertainty to have recourse in one instance to the severe method of laying open the tumour, in order to get at the vessel lower down. On this case, Scarpa makes some correct reflections: the operator (says he) assured himself, that, *on compressing the femoral artery at the upper part of the thigh, the tumour at the top of the calf ceased to pulsate; and that, when the compression was continued for some time, the swelling partly disappeared, and became softer.* It ought to have been evident, therefore, that the aneurism might have been cured by tying the trunk of the femoral artery, as described in the foregoing section. In Scarpa's work is a case in which an aneurism at the bifurcation of the popliteal artery was cured by the ligature of the femoral artery. —(See *p.* 451, *ed.* 2.) Mr. Hodgson has seen three aneurisms situated at the commencement of the tibial arteries, cured by the same operation.—(*On Diseases of Arteries, &c. p.* 437.) But, as Scarpa remarks, though the Hunterian operation answers in the cure of aneurism in the bend of the arm, and at the upper part of the calf of the leg, it is not so effectual for aneurisms situated on the back or palm of the hand, or the dorsum or sole of the foot. The free communication which the ulnar and radial arteries keep up with each other in the hand, and the tibial arteries have have in the foot, prevent the operation from succeeding whether the brachial or femoral artery, or one of the two large arteries of the forearm or leg, be tied. In proof of this statement, Scarpa cites two cases of aneurism seen by himself; one on the instep, the other in the sole of the foot; and a third case of the same disease in the latter situation; all of which were found to be incurable by the ligature of the anterior tibial artery. —(*P.* 311.) He thinks, however, that the operation of tying this vessel where it passes over the dorsum of the foot might succeed, if aided by compression, applied so as to stop the current through the other main channel; and he seems to approve of this practice, because the plan of tying the artery above and below the disease (which is the most certain means of cure) could not be done, without extensive incisions in the sole of the foot. In an aneurism at the lower part of the leg, Mr. Hodgson judiciously insists upon the prudence of tying the artery, as near as possible to the tumour, because the recurrent circulation through the large inosculations in the foot might still cause the swelling to enlarge, in consequence of the blood sent into the sac from the lower extremity of the vessel, passing through the aneurismal cavity into branches arising from the artery between the aneurism and the ligature.—(*P.* 438.) However, in one case of aneurism of the anterior tibial artery, Mr. H. Cline applied a ligature just above the tumour without success, and Sir Astley Cooper expressly recommends making an incision in the sac, and applying a ligature both above and below the swelling.—(*Lectures, &c. vol.* 2, p. 63.) When an aneurism arises from the radial, ulnar, or interrosseous arteries near the elbow, tying the brachial will suffice; but if the disease be lower down, the vessel from which it proceeds must be taken up near the swelling.—(*Hodgson, p.* 393.) A case, strikingly illustrative of this truth is recorded by Mr. Liston. J. M. P., aged 19, applied to him on the 28th of July, on account of an aneurism of the left radial artery, about the middle of the forearm, occasioned by a wound. The tumour was as large as a walnut, and so compressible, that it could

easily be made to disappear. Pressure was tried at first, with apparent benefit; but as it did not succeed, the humeral artery was tied on the 8th of August, and with the effect of completely removing the tumour. On the eighteenth day afterward, however, a small slough was detached from the cicatrix, and about three o'clock next morning, a violent hemorrhage took place. Mr. Liston then deemed it necessary to lay open the sac, and tie the artery above and below the wound in it.—(See *Edinb. Med. Journ. No.* 90, *p.* 4.)

Scarpa mentions a case, where the dorsal artery of the thumb was wounded; but as the hemorrhage returned several times, and pressure failed in suppressing it, the surgeon took up the radial artery at the wrist. After cutting off this direct current of blood towards the injured vessel, pressure on the wound proved effectual. Three months afterward, the patient having died, the radial artery was found impervious for three fingers' breadth below where the ligature had been applied, and the dorsal artery was likewise obliterated from the root of the thumb to the beginning of the palmar arch.

Mr. Todd has published a case in which he cured a large aneurismal swelling of the posterior side of the forearm, by tying the brachial artery. From the description, I conclude that the disease was an aneurism by anastomosis, as it is termed; but the particulars given by the author leave us in doubt on this point.—(See *Dublin Hospital Reports, vol.* 3, *p.* 135.)

The manner of exposing and tying the principal arteries of the leg and forearm, will be described under the term *Arteries*.

OF ANEURISMS HIGH UP THE FEMORAL ARTERY.

Several facts already specified in the preceding columns as having occurred many years before the operation of tying the external iliac artery was attempted, amounted to a full proof, that the circulation might go on in the lower extremity notwithstanding the artery in the groin were tied or obliterated. On this point, some of Guattani's cases were most decisive.

The ligature of the external iliac artery, for aneurisms of the femoral artery in the bend of the groin, has now been practised so frequently, and the instances of success are so numerous, that all doubt concerning the propriety and utility of the attempt has entirely ceased. The French, who have evinced great backwardness in espousing the Hunterian method of operating for aneurisms, though it is decidedly one of the greatest improvements in modern surgery, have also shown great reluctance even to believe, much less to practice, the operation of tying the external iliac artery. A Parisian surgeon, however, who was in London a few years ago, saw the thing done, and the eyes of his brethren in the capital of France have since been a little more open. Still, as Roux remarks, "We cannot but blame the indifference with which the operation is mentioned in some of the latest French surgical publications. At this moment (1815) we can reckon twenty-three facts relative to tying the external iliac artery, and on fifteen of the patients it has perfectly succeeded. In these twenty-three operations, I comprehend the two which were done in France; one at Brest, by Delaporte, and the other at Lyons, by Bouchet; cases, the authenticity of which cannot be doubted. In the number of successful cases, is to be comprised Bouchet's operation, since the patient lived more than a year afterward, and then died of the consequences of an inguinal aneurism of the opposite side. Of the other twenty-one operations, fifteen were performed in London only, in the several hospitals of this metropolis, by Abernethy, Ramsden, A. Cooper, Brodie, and Lawrence; gentlemen who would never publish forged cases.

"Sir A. Cooper alone had tied the external iliac artery six times before my journey to London, and during my stay there, I saw him perform the operation once. Four of his patients were entirely well; one of the three others died, the thirteenth week after the operation, of the bursting of an aneurism of the aorta. At this period, the circulation in the limb had been re-established. I saw the limb after it had been injected among Sir A. Cooper's anatomical preparations. Large and beautiful anastomoses existed round the pelvis, between the dilated branches of the internal iliac and femoral arteries. With respect to the sixth patient, the leg mortified, and the thigh was amputated without success. The seventh died of hemorrhage, which took place the fourteenth or fifteenth day after the operation."—(*Parallèle de la Chir. Angloise avec la Chir. Francoise, p.* 275, 276.) Sir Astley Cooper has now tied the external iliac artery in nine cases.—(See *Lancet, vol.* 2, *p.* 44.)

The many facts already published, exemplifying the propriety of this operation, must be highly gratifying to Mr. Abernethy, by whose judgment it was first suggested, and by whose enterprising hand it was first practised.

Mr. Abernethy has been called upon in several cases to take up the external iliac artery, and they all prove that the anastomosing vessels were fully capable of conveying blood enough into the limb below, and that a vessel even of this size could become permanently closed after being tied. Three of the operations done by this gentleman, I was an eye-witness of, and it is therefore with confidence that I can speak of the ease and simplicity of the requisite measures for securing the external iliac artery.—(See *Abernethy's Surg. and Physiol. Essays; and Surgical Observations*, 1804; *Edin. Med. and Surg. Journal for January*, 1807.)

In Mr. Abernethy's first operation, performed in 1796, an incision, about three inches in length, was made through the integuments of the abdomen, in the direction of the artery, and thus the aponeurosis of the external oblique muscle was laid bare. This was next divided from its connexion with Poupart's ligament, in the direction of the external wound, for the extent of about two inches. The margins of the internal oblique and transverse muscles being thus exposed, Mr. Abernethy introduced his fingers beneath them to protect the peritoneum, and then divided them. Next he pushed this membrane, with its contents, upwards and inwards, and took hold of the external iliac artery with his finger and thumb. It now only remained to pass a ligature round the artery, and tie it; but this required caution, on account of the contiguity of the vein to the artery. These Mr. A. separated with his fingers, and introducing a ligature under the artery with a common surgical needle, tied it about an inch and a half above Poupart's ligament.—(*Surg. Essays.*)

The following was the method which Mr. Abernethy adopted, the second time of tying the external iliac artery.

An incision three inches in length was made through the integuments of the abdomen, beginning a little above Poupart's ligament, and extending upwards; it was more than half an inch on the outside of the upper part of the abdominal ring, to avoid the epigastric artery. The aponeurosis of the external oblique muscle being exposed, was next divided in the direction of the external wound. The lower part of the internal oblique muscle was thus uncovered, and the finger being introduced below the inferior margin of it and of the transversalis muscle, they were divided with the crooked bistoury for about one inch and a half. Mr. Abernethy now introduced his finger beneath the bag of the peritoneum, and carried it upwards by the side of the psoas muscle, so as to touch the artery about two inches above Poupart's ligament. He took care to disturb the peritoneum as little as possible, detaching it to no greater extent than was requisite to admit his two fingers to touch the vessel. The pulsations of the artery made it clearly distinguishable, but Mr. Abernethy could not put his finger round it with facility. In order to be able to do so, he was obliged to make a slight incision on each side of it. Mr. A. now drew the artery gently down, so as to see it behind the peritoneum. By means of an eye-probe, two ligatures were conveyed under the vessel; one of these was carried upwards as far as the artery had been detached, and the other downwards; they were firmly tied, and the vessel was divided in the interspace between them.—(*Surg. Observ.* 1804.)

In a third instance of tying this vessel, Mr. Abernethy operated exactly as in the foregoing case, and with complete success.—(See *Edin. Surg. Journ. Jan.* 1807.)

Mr. Freer, of Birmingham, who may be said to claim the honour of having seconded Mr. Abernethy in this new practice, made an incision about one inch and a half from the spine of the ileum, beginning about an inch above it, and extending it downwards about three inches and a half, so as to form altogether an incision four inches and a half long, extending to the base of the tumour. The tendon of the external ob-

lique being exposed, was carefully opened, and also the internal oblique, when the finger being introduced between the peritoneum and transversalis, served as a director for the crooked bistoury, which divided the muscle. Avoiding all unnecessary disturbance, Mr. Freer separated the peritoneum with his finger, till he could feel the artery beating, which was so firmly bound down, that he could not get his finger under it without dividing its fascia. The vessel having been separated from the surrounding parts, a curved blunt needle, armed with a strong ligature, was put under it, and tied very tight, with the intention of dividing the internal coats of the vessel. The operation led to a perfect cure.—(*Freer on Aneurism*, *p.* 83, 4*to.* 1807.)

Mr. Tomlinson, of the same town, was also an early performer of the operation: he applied only one ligature, and, of course, left the artery undivided: the event was attended with perfect success.

The following is Sir Astley Cooper's mode of operating as described by Mr. Hodgson:—A semilunar incision is made "through the integuments in the direction of the fibres of the aponeurosis of the external oblique muscle. One extremity of this incision will be situated near the spine of the ileum: the other will terminate a little above the inner margin of the abdominal ring. The aponeurosis of the external oblique muscle will be exposed, and is to be divided throughout the extent and in the direction of the external wound. The flap which is thus formed being raised, the spermatic cord will be seen passing under the margin of the internal oblique and transverse muscles. The opening in the fascia which lines the transverse muscle through which the spermatic cord passes, is situated in the midspace between the anterior superior spine of the ileum and the symphysis pubis. The epigastric artery runs precisely along the inner margin of this opening, beneath which the external iliac artery is situated. If the finger, therefore, be passed under the spermatic cord, through this opening in the fascia, it will come into immediate contact with the artery which lies on the outside of the external iliac vein. The artery and vein are connected together by dense cellular membrane, which must be separated to enable the operator to pass a ligature by means of an aneurism-needle round the former."—(*On Diseases of Arteries*, *p.* 421, 422.)

The foregoing incision, the convexity of which is turned outwards and downwards, extends from within and a little above the anterior superior spinous process of the ileum, to above and a little within the middle part of Poupart's ligament. As soon as the tendon of the external oblique muscle has been divided, the knife may be put down, and the internal oblique and transverse muscles raised from Poupart's ligament by introducing the finger behind them. Care must be taken to avoid the epigastric artery which runs from the pubis side of the external iliac to the inner side of the incision. Baron Dupuytren, when performing the operation at the Hôtel-Dieu in Paris, in the autumn of 1821, wounded the epigastric artery.—(*See Averill's Operative Surgery*, *p.* 37.) The hemorrhage was so copious that two ligatures were required. The patient afterward died of peritonitis, which, in all probability, was brought on by the disturbance of the parts in the proceedings requisite for securing the ends of the wounded vessel. The external iliac vein must also not be included in the ligature, as such a proceeding would cause a dangerous interruption to the return of the blood. When little of the artery is exposed, one ligature will suffice; in the contrary circumstance it is best to apply two.—(See *Lancet*, *vol.* 2, *p.* 44, 45.)

Mr. Norman, of Bath, who has tried both modes of operating, found that proposed by Sir A. Cooper a more easy way of finding the external iliac artery than the longitudinal incision practised by Mr. Abernethy. "The objection (says Mr. Norman) to Sir A. Cooper's mode of operating in cases where the tumour extends high up, is by no means well founded; for the lower part of the bag of the peritoneum lying on the edge of Poupart's ligament, must in every case be exposed and detached, in order to get at the artery which lies behind the posterior part of that membrane, and this is most easily effected by an incision in the direction of Poupart's ligament; while two-thirds of the longitudinal incision are made on a part of the peritoneum, which lines the abdominal muscles, and the lower portion only of the incision reaches that part of the membrane which is to be separated. The consequences of this are, that the peritoneum is in much greater danger of being wounded, and that the probability of a hernia forming after the cure is much increased by the extensive division of the oblique muscles."—(See *Med. Chir. Trans. vol.* 10, *p.* 101.) As far as I am able to judge, these remarks are well founded, and they coincide with some observations which were made some years ago by Roux, who, while he inclined to Mr. Abernethy's method, saw the disadvantage of letting the direction of the wound in this instance correspond to the course of the artery. Hence, after many trials on the dead subject, he laid down the rule that the beginning of the wound should never be farther than half an inch from, and a very little higher than, the anterior superior spine of the ileum, and that it should be carried very obliquely downwards to the middle of Poupart's ligament.—(See *Nouveaux Elémens de Méd. Op. t.* 1, *p.* 747, *&c.*)

Mr. Todd, also, after repeated trials of Mr. Abernethy's and Sir Astley Cooper's methods on the dead subject, concluded that the plan recommended by the latter afforded the greatest facility of applying the ligature to the artery, because more room was obtained by it, and with less disturbance of the peritoneum, than in the other way. Where, however, it becomes necessary to apply a ligature to a higher part of the artery, in consequence of secondary hemorrhage, Mr. Todd conceives that Mr. Abernethy's method should be adopted —(See *Dublin Hospital Reports*, *vol.* 3, *p.* 92.)

In a case operated upon by Mr Kirby, a hernia followed in the situation where the abdominal muscles had been divided.—(See *Cases with Observations*, *p.* 109, 8*vo. Lond.* 1819.)

In one case, Dr. Post found the peritoneum so thickened and diseased that he could not raise it from the subjacent parts, and he was obliged to make an opening in it. The protruding viscera were then pushed back, and with a needle a ligature was introduced under the artery, the peritoneum being also included in the ligature. Notwithstanding the disadvantageous method of operating, and the return of pulsation in the swelling, the patient had so far recovered in three months that he had regained the use of the limb.—(See *American Med. and Phil. Reg. vol.* 4, *p.* 443.)

In one remarkable case, Mr. Newbiggin, by tying the external iliac artery, cured both an inguinal and a popliteal aneurism together.—(See *Edin. Med. and Surg. Journal, for Jan.* 1816, *p.* 71, *&c.*)

The many operations which have now been done on the external iliac artery have impressed me with a conviction that in subjects under a certain age there is no reason to fear that the anastomoses will not generally suffice for the supply of the lower extremity. Out of twenty-five cases I only know of three in which the limb was attacked with gangrene. These three were patients of Sir A. Cooper, Bouchet of Lyons, and Mr. Collier. The proportion is not so much as one in eight. The three instances of gangrene were not all in the circumstances which permitted the event to be imputed to the anastomoses not having had sufficient time to enlarge, though perhaps Mr. Collier's case was such. On the other hand, we are to notice that Dr. Cole's patient was operated upon a few days after the wound, and yet the limb was duly supplied with blood, and did not become gangrenous. It appears, therefore, to me, that the occasional occurrence of gangrene cannot be admitted as a just reason for delay, until the collateral vessels have had time to enlarge. I believe that in all aneurismal diseases, early operating is the best and most judicious practice. This was one principal cause, as Kirkland observes, which occasioned the bad success of the old surgeons in the treatment of popliteal aneurisms, and he foretold, many years ago, that operations for the cure of aneurisms would answer better if not deferred so long as formerly.—(See *Thoughts on Amputation*, *&c.* 8*vo. Lond.* 1780.) I join Kirkland in this sentiment, not without recollecting that all aneurisms are attended with a chance of getting well spontaneously in the course of time. In saw the inguinal aneurism which did so under Dr. Albert in the York Hospital; but as this also is a rare incident, I do not believe that it ought to influence us against having speedy recourse to an operation. Besides, the cure by inflammation and sloughing appears to me to be attended in reality with more peril than a well-executed operation, and consequently has less recommendations than many may imagine. Had not Dr. Albert's patient been a very strong man, he would certainly have fallen

a victim to the extensive disease which the bursting and sloughing of the tumour created. Thus Delaporte's patient died of the mass of disease which the tumour itself made; for it had been suffered to attain too large a size, so that when it inflamed the effects were fatal.—(See *Richerand, Nosogr. Chir. t.* 4, *p.* 113, *edit.* 4.)

I believe Dr. Wilmot's observation is perfectly correct, that if a comparison were made between the operation of tying the external iliac artery and that of tying the artery in the thigh, we should find the recoveries after the first more frequent in proportion to the number of times it has been done, than after common operations lower down.*—(See *Dublin Hospital Rep. &c. vol.* 2, *p.* 214.)

The greatest artery that conveys blood into the lower extremity, after the external iliac has been tied, is the gluteal; but, besides it, the ischiatic, the obturator, and the external pudic, which anastomoses freely with the internal pudic, are important vessels in keeping up the circulation.

I subjoin a list of some of the successful examples of this operation. Mr. Abernethy, 2 cases (*Surgical Works, vol.* 1); Freer and Tomlinson, 2 (*Freer on Aneurism*, 1807); Sir A. Cooper, 4 (*Hodgson on Diseases of Arteries, p.* 417); Goodlad, 1 (*Edin. Med. and Surg. Journ. vol.* 8, *p.* 32); Brodie, 1 (*Hodgson, op. cit. p.* 419); Lawrence, 1 (*Med. Chir. Trans. vol.* 6, *p.* 205); J. S. Soden, 1 (*Same work, vol.* 7, *p.* 536); G. Norman, 1 (*Same work, vol.* 10, *p.* 95, *&c.*); E. Salmon, 1 (*Same work, vol.* 12); Bouchet, 1 (*Roux, Med. Opératoire, t.* 1, *p.* 744); J. S. Dorsey, 1 (*Elements of Surgery, vol.* 2, *p.* 180, *Philadelphia*, 1813); Mouland, 1 (*Bulletin de la Faculté de Médecine de Paris, t.* 5, *p.* 535); Dupuytren, 1 (*French Transl. of Mr. Hodgson's work, t.* 2, *p.* 215); Dr. Cole, 1 (*Rapport des Travaux de la Société d'Emulation de la Ville de Cambrai*, 1817, or *Lond. Med. Repository*); Dr. Wilmot, 1 (*Dublin Hospital Reports, vol.* 2, *p.* 208, *&c.*); Kirby, 1 (*Cases with Observations, &c.* 8*vo. Lond.* 1819); Dr. Post, 1 (*American Med. and Philos. Register, vol.* 4); Newbiggin, 1 (*Edin. Med. and Surg. Journ. Jan.* 1, 1816); J. C. Warren, 1 (*New-England Journal, or Anderson's Quarterly Journal, vol.* 1, *p.* 136). In this case the epigastric artery arose from the anterior and inner part of the sac, and gave origin to the obturator, while the circumflex ilii originated from the outer part of the sac. All these vessels were greatly enlarged, and the epigastric rendered the necessary detachment of the external iliac troublesome.

Some particulars of the case of ruptured inguinal aneurism, in which Sir A. Cooper tied the aorta, will be hereafter noticed.—(See *Aorta.*)

Rosenmuller's Chir. Anat., Tiedemann's and Scarpa's Plates, in illustration of the operation of tying the external iliac artery, merit notice.

CASES OF GLUTEAL ANEURISM CURED BY TYING THE INTERNAL ILIAC ARTERY.

The gluteal artery is large; from its situation liable to wounds; from its size subject to aneurism. Dr. Jeffray, of Glasgow, was consulted in a case where the gluteal artery had been wounded. He urged the propriety of tying the vessel where it had been injured. This sensible advice was at first rejected, and when the friends at last consented, the operation was too late, as, while preparation was making for it, the tumour burst, and the patient expired in a few moments.

Thenden also mentions an instance in which the gluteal artery was wounded in the dilatation of a gunshot wound, and the patient lost his life.—(See *Scarpa on Aneurism, p.* 407, *ed.* 2.)

Mr. John Bell, however, tied the gluteal artery in a case where it was wounded, and the patient was saved.

[The late Dr. Cocke and Davidge, professors in the University of Maryland, tied the gluteal artery for an aneurism of immense size, with entire success. The patient was one whose gluteal muscles were exceedingly large, and the extent and boldness of the incision rivalled the herculean case reported by Mr. Bell. It will presently be seen that even when the extent of the disease forbids this attempt, the ligature of the internal iliac will afford a means of relief.—*Reese.*]

Mr. Stevens, surgeon in Santa Cruz, the gentleman who has proved the practicableness of putting a ligature round the internal iliac artery, informs us that "one of the first surgeons in London had a patient with gluteal aneurism. The tumour was large; allowed to burst; and the person bled to death.

"I sincerely trust," says he, "that the following case may be the means of preventing such an occurrence in future.

"Maila, a negro woman from the Bambara country in Africa, was imported as a slave into the West Indies in the year 1790. She was purchased for the estate of Enfield Green; now the property of the heirs of P. Ferrall, Esq. I saw her first in the beginning of December, 1812. She had a tumour on the left hip, over the sciatic notch. It was nearly as large as a child's head, and pulsated very strongly. She could assign no cause for the disease. It had commenced, about nine months before, with slight pain in the part; and had gradually increased to its present size. She was now much reduced, in great misery, and ready to submit to any operation.—(See *Medico-Chir. Trans. vol.* 5, *p.* 425.) Mr. Stevens had tied the internal iliac on the dead body, and believed that it might be done with safety on the living. The following is some account of the operation: "On the 27th of December, 1812 (says Mr. Stevens), I tied the artery in the presence of Dr. Lang, Dr. Van Brackle, Mr. Nelthropp, and Mr. Ford, the manager of the estate. An incision, about five inches in length, was made on the left side, in the lower and lateral part of the abdomen, parallel with the epigastric artery, and nearly half an inch on the outer side of it. The skin, the superficial fascia, and the three thin abdominal muscles, were successively divided; the peritoneum was separated from its loose connexion with the iliacus internus and psoas magnus; it was then turned almost directly inwards, in a direction from the anterior superior spinous process of the ileum, to the division of the common iliac artery. In the cavity which I had now made, I felt for the internal iliac, insinuated the point of my fore-finger behind it, and then pressed the artery between my finger and thumb. Dr. Lang now felt the aneurism behind; the pulsation had entirely ceased, and the tumour was disappearing. I examined the vessel in the pelvis; it was healthy and free from its neighbouring connexions. I then passed a ligature behind the artery and tied it about half an inch from its origin. The tumour disappeared almost immediately after the operation, and the wound healed kindly. About the end of the third week the ligature came away, and in six weeks the woman was perfectly well.

This is the first example in which the internal iliac was tied. The operation was not attended with much difficulty or pain, and not an ounce of blood was lost.

Mr. Stevens had no difficulty in avoiding the ureter, which, when the peritoneum was turned inwards, followed it. Had it remained over the artery, Mr. Stevens says that he could easily have turned it aside with his finger.—(See a particular history of this case in *Medico-Chirurg. Trans. vol.* 5, *p.* 422, *&c.*)

A second instance, in which the internal iliac artery was tied, was some time ago communicated to the public. The operation was performed by Mr. Atkinson, of York, on account of a gluteal aneurism. The following are a few of the particulars, as related by this gentleman:—Thomas Cost, aged 29, presented himself at the York County Hospital, April 29th, 1817. He was a tall, strong, active bargeman, not corpulent, but very muscular. He was enduring great pain from a large, renitent, pulsating tumour, situated under the gluteus of the right side; an obvious aneurism. It had existed about nine months, and was the consequence of a blow from a stone. In a consultation with Dr. Lanson and Dr. Wake, the necessity of the operation was determined upon, and it was performed on the 12th of May without any material difficulty or interruption, except such as was the consequence of the division of, and bleeding from, the small muscular arteries. Having got command of the internal iliac artery within the pelvis, which, says Mr. Atkinson, required the complete length of the fingers to accomplish, it was tied. Sufficient proof of its being the identical artery was repeatedly obtained by the pressure upon it stopping the pulsation and causing a subsidence of the tumour. Dr. Wake, Mr. Ward, and all the pupils were quite assured of the circumstance. The artery being then tied, the pulsation of the swelling entirely ceased. Some

[* Dr. Mott has tied the external iliac four times with complete success.—*Reese.*]

delay in placing the ligature arose from the needle not being sufficiently pliable; but for future operations of this kind Mr. Atkinson very properly recommends the ligature to be put round the artery by means of an instrument resembling a catheter, the wire of which has a little ring at its extremity, and can be pushed out some way beyond the end of the tube.

The patient went on tolerably well for some time after the operation; the pulse never exceeded 130, and after a time sunk to 85 or 90. He became exhausted, however, partly by the discharge, and partly by hemorrhage, and died on the 31st of May, about nineteen days after the operation. In the dissection, the cavity on the external part of the peritoneum, in the situation of the incision, was completely filled with coagulated blood. "The ligature, on moving a part of this (blood) with a sponge, readily followed it, and without doubt had been disengaged for some days." The internal iliac, which appeared to have been tied, had separated about an inch and a half from the bifurcation with the external iliac. By "separated" I conclude Mr. Atkinson means, that the upper part of the internal iliac was separated from the continuation of the same vessel.—(See *Medical and Phys. Journ. vol.* 38, *p.* 267, *&c.*) Although this gentleman has not given a very clear account of some part of the dissection, and he has also omitted to describe the place of his external incision, or the exact parts which he divided in the operation, yet I think that all the circumstances of the case taken together leave not the smallest doubt of the internal iliac artery having been actually tied. The complete stoppage of the pulsation as soon as the ligature was applied, and the testimony of several respectable practitioners who were present, seem indeed to remove all ambiguity. The profession is much indebted to Mr. Atkinson for this important communication, which was in some measure required, in order to confirm Mr. Stevens's similar case, as it is well known that some distinguished anatomists and surgeons in this metropolis formerly expressed very strong doubts of the practicable nature of the operation.

The internal iliac artery is also said to have been tied with success by an army surgeon in Russia, upon whom the late Emperor Alexander settled a pension as a reward for the skill displayed in the treatment of the case.—(See *Averill's Operative Surgery, p.* 39.)

[The internal iliac has also been tied in this country *successfully* for the cure of gluteal aneurism by Professor White, the younger, of Berkshire Med. Institution. This case is published in the second number of the American Journal of Medical Sciences, and is also referred to in Johnson's Medico-Chirurgical Review for April, 1828. It is the fourth instance in which it has been ever attempted; and three out of the four have been successful. The only time it was ever performed in Great Britain is the only instance of its failure.—*Reese.*]

In a modern publication are given a few particulars of a case, which was supposed to be an aneurism of the gluteal artery, and cured by means of pressure, a light vegetable diet, gentle laxatives, and digitalis.—(See *Trans. of the Fellows, &c. of the King's and Queen's College of Physicians in Ireland, vol.* 1, *p.* 41, *8vo. Dub.* 1817.) From the very imperfect account here given of the tumour, it is impossible to form any conclusion respecting its nature.

Sandifort has recorded an instance of an aneurism of the internal iliac artery itself.—(See *Tabulæ Anatomicæ, &c. Præcedit Obs. de Aneurismate Arteriæ Iliacæ internæ, rariore ischiadis Nervosæ causa, fol. Lugd.* 1804.)

The common iliac has never been tied in any case of aneurism of the external or internal iliac; but Professor Gibson had occasion to put a ligature round it in an example of gun-shot wound. "The patient lived fifteen days after the operation, and then died from peritoneal inflammation, and from ulceration of the artery. The circulation in the limb of the injured side was reestablished about the seventh day after the artery was tied."—(See *American Med. Recorder, vol.* 3, *p.* 185; *and Gibson's Institutes of Surgery, vol.* 2, *p.* 145. *Philadelphia*, 1825.)

[As an act of justice to my distinguished friend Professor Mott, I here insert a detailed account of this Herculean operation, which Dr. Cooper admits has never before been performed. It is alike honourable to him, to the profession, and to our country. It is introduced entire, as communicated to me by the doctor at my solicitation.

A detailed account of the first operation ever performed upon the *arteria iliaca communis* for the cure of *aneurism*, and especially of the first attempt to apply the ligature to so great a vessel, without dividing the peritoneum, may prove interesting to the profession generally, and must be immediately serviceable to practitioners of surgery.

"On the 15th of March, 1827, I was requested to visit a patient with Dr. Osborn (of Westfield, New-Jersey, about twenty-five miles distant from New-York), whom we found labouring under a large aneurism of the right external iliac artery.

Israel Crane, aged thirty-three years, by occupation a farmer, of temperate and regular habits, having generally enjoyed excellent health, says, about the middle of January he felt some pain about the lower part of the belly, which he attributed to a fall received during the winter. He is in the habit of using great efforts in lifting heavy logs of wood, as his employment at this season consists in carrying wood to market. It, however, was not until a fortnight since that he perceived any tumour about the lower part of the abdomen. Upon examination, the abdomen on the right side was considerably enlarged from about the crural arch, as high as the umbilicus. When the hand was applied to the parietes of the abdomen, a pulsation was felt and rendered visible to some distance. To the touch the tumour beat violently, and appeared to contain only fluid blood. It commenced a little above Poupart's ligament, and reached, judging by the touch, from without near the navel, inwards almost to the linea alba, outwards and backwards filling up all the concavity of the ileum, and reaching beyond the posterior spinous process of that bone.

The rapid increase of this aneurismal tumour occasioned, as the countenance of our patient indicated, the most extreme agony. His sufferings at times were so great that his screams could be heard at a distance from the house. He had been bled several times, taken light food, and was kept constantly under the effect of opium. He was now informed of the serious nature of his case, and that without an operation very little chance of his life remained; with great composure he immediately consented to whatever would give him the best prospect of saving his life.

From the extent and situation of the tumour he was apprized of the uncertain nature of the operation, as well as the difficulty of performing it, and indeed that it would require an artery to be tied, which never had been before operated upon for aneurism. With these views of his situation, he cheerfully submitted to be placed upon a table of suitable height, in a room which was well lighted.

Then, in the presence of Dr. Osborn, Dr. Liddle, and Dr. Cross, the following operation was performed:—

The pubes and groin of the right side being shaved, an incision was commenced just above the external abdominal ring, and carried in a semicircular direction half an inch above Poupart's ligament, until it terminated a little beyond the anterior spinous process of the ileum, making it in extent about five inches. The integuments and superficial fascia were now divided, which exposed the tendinous part of the external oblique muscle; upon cutting which in the whole course of the incision, the muscular fibres of the internal oblique were exposed; the fibres of which were cautiously raised with the forceps and cut from the upper edge of Poupart's ligament. This exposed the spermatic cord, the cellular covering of which was now raised with the forceps, and divided to an extent sufficient to admit the fore-finger of the left hand to pass upon the cord into the internal abdominal ring. The finger serving now as a director, enabled me to divide the internal oblique and transversalis muscles to the extent of the external incision, while it protected the peritoneum. In the division of the last-mentioned muscles outwardly, the circumflex ilii artery was cut through, and it yielded for a few minutes a smart bleeding. This, with a smaller artery upon the surface of the internal oblique muscle between the rings, and one in the integuments were all that required ligatures.

With the tumour beating furiously underneath, I now attempted to raise the peritoneum from it, which we found difficult and dangerous, as it was adherent to it in every direction. By degrees we separated it with

great caution from the aneurismal tumour, which had now bulged up very much into the incision. But we soon found that the external incision did not enable us to arrive to more than half the extent of the tumour upwards. It was therefore extended upwards and backwards about half an inch within the ileum, to the distance of three inches, making a wound in all about eight inches in length.

The separation of the peritoneum was now continued, until the fingers arrived at the upper part of the tumour, which was found to terminate at the going off of the internal iliac artery. The common iliac was next examined by passing the fingers upon the promontory of the sacrum, and to the touch appearing to be sound, we determined to place our ligature upon it, about half way between the aneurism and the aorta, with a view to allow length of vessel enough on each side of it to be united by the adhesive process.

The great current of blood through the aorta made it necessary to allow as much of the primitive iliac to remain between it and the ligature as possible, and the probable disease of the artery higher than the aneurism required that it should not be too low down. The depth of this wound, the size of the aneurism, and the pressure of the intestines downwards by the efforts to bear pain, made it almost impossible to see the vessel we wished to tie. By the aid of curved spatulas, such as I used in my operation upon the *innominata*, together with a thin, smooth piece of board, about three inches wide, prepared at the time, we succeeded in keeping up the peritoneal mass, and getting a distinct view of the arteria iliaca communis, on the side of the sacro-vertebral promontory. This required great effort on our part, and could only be continued for a few seconds. The difficulty was greatly augmented by the elevation of the aneurismal tumour, and the interception it gave to the admission of light.

When we elevated the pelvis, the tumour obstructed our sight; when we depressed it, the crowding down of the intestines presented another difficulty. In this part of the operation I was greatly assisted by Dr. Osborn and my enterprising pupil, Adrian A. Kissam.

Introducing my right hand now behind the peritoneum, the artery was denuded with the nail of the fore-finger, and the needle conveying the ligature was introduced from within outwards, guided by the fore-finger of the left hand in order to avoid injuring the vein. The ligature was very readily passed underneath the artery, but considerable difficulty was experienced in hooking the eye of the needle, from the great depth of the wound and the impossibility of seeing it. The distance of the artery from the wound was the whole length of my aneurismal needle.

After drawing the ligature under the artery, we succeeded by the aid of our spatulas and board in getting a fair view of it, and were satisfied that it was fairly under the primitive iliac, a little below the bifurcation of the aorta. It was now tied; the knots were readily conveyed up to the artery by the fore-fingers; all pulsation in the tumour instantly ceased. The ligature upon the artery was very little below a point opposite the umbilicus.

The wound was now dressed with five interrupted sutures, passing them not only through the integuments, but the fibres of the cut muscles, so as to bring their divided edges together at all parts of the incision which was muscular. Adhesive plaster to assist the stitches, lint and straps to retain it, completed the dressing. The operation lasted rather less than one hour.

He was removed from the table, and put into bed upon his back, with the knee a little elevated upon pillows to relax the limb as much as possible, and to avoid pressure upon it. It was considerably cooler than the opposite leg, and flannels were applied all over it, and a bottle of warm water to the foot. From the habit he had been in of taking largely of anodynes, a tea-spoonful of the tinct. opii was administered, with directions to repeat it in an hour if the pain should be severe.

In less than one hour from the operation, considerable reaction of the heart and arteries took place; he felt, as he stated, altogether relieved from the excruciating agony he had suffered since the aneurism commenced. The whole limb had now recovered its natural temperature.

March 16*th*. The day after the operation, pulse eighty; skin moist; limb warm as the other; complains of some pain at the ligature; ordered a purgative of neutral salts.

17*th*. Pulse eighty, and fuller than yesterday; took ℥ x. of blood from his arm; skin moist; tongue brown; considerable uneasiness in the limb; no pain at the ligature; leg of natural heat; salts had a good effect.

18*th*. Pulse seventy-five; skin moist; tongue white; pain in the limb considerable; no pain at the ligature or in the wound; limb warm.

19*th*. Bled him to-day ten ounces, the pulse being tense, and beating eighty strokes in a minute; repeated the cathartic: suppuration appearing to have taken place, the dressings were removed.

20*th*. Pulse seventy and soft; skin moist; wound looks well; pain in the limb continues; leg warm as the other; cathartic operated well.

21*st*. Pulse seventy and soft; wound looks well; repeated the laxative; pain in the leg rather less; continues warm. There has been at no time tension of the abdomen or any particular uneasiness in that part. The patient thus far has been altogether more comfortable than could have been imagined. He takes more or less opium daily, from the long habit he has been in of taking anodynes.

26*th*. No unpleasant symptom; wound looks well; bled again to ℥ xij., as there was a little tumefaction and inflammation about the wound.

30*th*. Our patient continues to do well; wound dressed daily.

April 3*d*. Not being able to leave the city, I requested Dr. Proudfoot, my late pupil, and a most promising young surgeon, to visit the patient. He reports that he was free of fever; wound all healed but where the large ligature was passing. The ligature appearing to be detached, the Dr. took hold of it and removed it: this was on the eighteenth day from the time of its application. Limb of the natural temperature; enjoined upon him to keep very quiet and in bed.

8*th*. There are no disagreeable appearances whatever; he appears to be doing remarkably well; has been bled once since the last report; takes a purgative every other day, and an opiate every night; pulse as in health; no pain; says he is entirely comfortable; wound is dressed with dry lint.

16*th*. Has improved rapidly since the last report. Two days after the ligature came away he very imprudently got out of bed, without experiencing any difficulty except weakness. Rode out to-day; wound perfectly healed.

April 26*th*. He has been using crutches for a few days to favour the lame leg, which as yet feels rather weak. General health greatly improved.

30*th*. Is perfectly restored in health; has a little stoop in his walk, which he says is occasioned by the external cicatrix. Leg is not yet of its full size, nor quite so strong as the other. From the period of the operation to the recovery of our patient, he did not appear to suffer more pain, or have more unpleasant symptoms, than would ordinarily take place in a flesh wound of equal extent. Much of this, in my opinion, is to be attributed to the prompt and judicious antiphlogistic treatment pursued by Dr. Osborn, to whom I am indebted for the daily reports of the case.

May 29*th*. My patient visited me to-day, having come twenty-five miles; he was so much improved in health that I did not recognise him. Examined the cicatrix, and found it perfectly sound; could not discover any remains of an aneurismal tumour; felt the epigastric artery much enlarged and beating strongly, and a feeble, though distinct pulsation in the femoral artery immediately below the crural arch. The leg has its natural temperature and feeling, and he says it is as strong as the other.

Much credit is due the patient for his firmness on the occasion; although apprized of the great danger attending so formidable an experiment, and the uncertainty of its result; yet with a fortitude unshaken, and a full conviction that it was the only chance of prolonging his life, he cheerfully and resolutely submitted to the operation.

The gratification his visit afforded me is not to be imagined, save by those who have been placed under similar circumstances. The perfect success of so important and novel an operation, with the entire restoration of the patient's health, was a rich reward for the anxiety I experienced in the case, and in a measure compensated for the unexpected failure of my operation on the *arteria innominata*."

Professor Bushe has lately tied the common iliac in a child less than two months old for a congenital aneurism of one of the labiæ. She recovered from the operation, but perished a few weeks afterward from abscess of the knee-joint.—*Reese.*]

ANEURISMS OF THE BRACHIAL ARTERY.

Surgical writings contain many histories of aneurisms in the bend of the arm, produced by the puncture of the brachial artery in venesection, or caused by a deep wound inflicted at the bend of the arm along the inner side of the humerus or in the axilla. Such cases must indisputably be formed by effusion. Although Morand and others have found, that, along with aneurisms caused by a wound of the brachial artery, the diameter of the vessel is sometimes unusually enlarged through its whole length above the seat of the tumour, this enlargement, which is very rare, might have existed naturally before the puncture occurred. Even were it frequent, such an equable longitudinal expansion of the tube of the artery could not explain the formation of the aneurismal sac in the bend of the arm, along the inner side of the humerus, or in the axilla, after wounds.—(*Scarpa, p.* 160.)

The proximate cause of these cases may invariably be traced to the solution of continuity in the two proper coats of the artery, and the consequent effusion of blood into the cellular substance. The effect is the same, whether from an internal morbid affection, capable of ulcerating the internal and fibrous coats of the artery, the blood be effused into the neighbouring cellular sheath surrounding the artery, which it raises after the manner of an aneurismal sac; or the wound of the integuments having closed, the blood issue from the artery, and be diffused in the surrounding parts. The cellular substance on the outside of the wounded vessel is first injected, as in ecchymosis; the blood then distends it, and elevates it in the form of a tumour, and, the cellular divisions being destroyed, converts it at last into a firm capsule or aneurismal sac.—(*Scarpa, p.* 167.)

The circumscribed or the diffused nature of the aneurism, and the rapidity or slowness of its formation, depend on the greater or less resistance to the impetus of the blood, during the time of its effusion, by the interstices of the cellular substance surrounding the artery, and by the ligamentous fasciæ and aponeuroses, lying over the sac. The aponeurosis of the biceps muscle being only half an inch broad, and situated lower than the common place for bleeding, cannot, at least in most cases, materially strengthen the cellular substance surrounding the artery, as is commonly supposed.—(*Scarpa, p.* 168—170.) This author refers the greatest resistance to the intermuscular ligament, which, after having covered the body of the biceps muscle, extends over the whole course of the humeral artery, and is implanted into the internal condyle. This ligamentous expansion has a triangular shape, the base of which extends from the tendon of the biceps to the internal condyle, while the apex reaches upwards along the inner side of the humerus towards the axilla, in the course of the artery. The humeral artery and median nerve, kept in their situation by the cellular sheath and this ligamentous expansion, run in the furrow formed between it and the internal margin of the biceps.—(*Scarpa, p.* 171.) This author anatomically explains many circumstances relative to the diffusion, circumscription, shape, &c. of brachial aneurisms by this intermuscular ligament. While aneurisms, from an internal cause, are not unfrequent in the aorta, thigh, and ham, they are very rare in the brachial artery; though a few such instances are recorded.—(*Scarpa, p.* 174. *Pelletan, Clinique Chir. t.* 2, *p.* 4.)

The mode of distinguishing a wound of the brachial artery in attempting to bleed, and the method of trying to effect a cure by pressure are described in the article *Hemorrhage.*

Anel was the first who tied the brachial artery for the cure of the aneurism at the bend of the arm, in the same way that Hunter did the femoral for the cure of aneurisms in the ham, viz. with one ligature above the tumour, without making any incision upon or into the sac itself.

The operation is performed as follows:—The surgeon having traced the course of the brachial artery, and felt its pulsations above the aneurism, he may either cut down to the vessel immediately above the tumour, or much higher in the long space between the origins of the superior and inferior collateral arteries. The integuments are to be divided in the course of the artery, and also the cellular sheath for the space of about two inches and a half. The surgeon, now introducing his left fore-finger to the bottom of the wound, will feel the denuded vessel, and if it is not sufficiently bare, he must divide the parts which still cover it, observing to introduce the edge of the knife on the side next to the internal margin of the biceps, to avoid dividing any of the numerous muscular branches which go off from the opposite side of the artery. He is then to insulate with the point of his finger the trunk of the vessel, alone if he can, or together with the median nerve and vein, and raise it a little from the bottom of the wound. He is to separate the median nerve and vein for a small space from the artery, and with an eyed needle is to pass a ligature under the latter, and then tie it with a simple knot.

In the operation it should always be recollected that the median nerve lies on the inside of the artery, and, therefore, that the instrument used for putting the ligature under the vessel should be passed from within outwards, by which means the inclusion of the nerve may be most easily avoided.—(*Boyer, Traité des Maladies Chirurgicales, &c. t.* 2, *p.* 193.)

The operation is well described by Mr. Hodgson: "The surgeon divides the integuments along the ulnar margin of the biceps muscle by an incision two inches and a half in length. The thin fascia which surrounds the arm will thus be exposed, and must be cautiously divided in the direction of the external wound. The artery lies immediately under the fascia, close to the margin of the biceps. The median nerve is situated on the ulnar side of the artery which lies between its two venæ comites. The internal cutaneous nerve is also situated under the fascia in the middle of the arm, and lies on the ulnar edge of the median nerve. The cellular membrane which connects these parts is to be divided, until the coats of the artery are fairly exposed. This part of the operation will be effected with facility, if an assistant compress the artery above the wound, so as to stop the circulation through it, and render it in some degree flaccid. The point of an aneurismal needle is then to be introduced close to the ulnar, and brought out on the radial side of the artery, so as to avoid including the median nerve, or the veins which accompany the artery."—(*On Diseases of the Arteries, &c. p.* 391.)

Whoever, after the above directions, says Scarpa, shall have the treatment of a *circumscribed* aneurism in the bend of the arm, will no longer, it is to be hoped, follow the method of those who, supposing the tumour to be formed by the dilatation of the artery, used first to divide the integuments over the tumour, insulated the sac, and sought for the vessel above and below the aneurism, in order to tie it in two places; and then endeavour to make the sac slough away. The operation is now reduced to the greatest simplicity, viz tying the artery merely above the tumour.—(See *Scarpa, p.* 358, 359.)

When the aneurism is *diffused* and accompanied with violent inflammation and swelling of the whole arm, from the excessive distention of the clots of effused blood, Scarpa recommends the old operation of opening the tumour, and tying the artery at the bottom of the sac, above and below the wound made by the lancet. In this method, a tourniquet must be applied to the upper part of the arm, near the axilla; or, if the limb be very painful and swelled, it is better to let an assistant compress the artery from above the clavicle, against the first rib. The incision having been made into the tumour, and the blood discharged, a probe is to be introduced into the puncture in the vessel, from below upwards, so as to raise the artery. This, being separated from the parts beneath and the median nerve, for a small extent, is to have two ligatures put under it, one of which is to be tied above, the other below, the wound in the vessel. Then the tourniquet, or pressure, is to be taken off, and if there be no bleeding, the wound is to be brought together.—(See *Scarpa, p.* 359.) With reference to this operation, Rosenmüller's Chir. Anat. Plates, part 2, tab. 11, Scarpa's plates, Tiedemann's beautiful engravings of the arteries, and Camper's Demonstr. Anat. Pathol. lib. i. are worth consulting.

It was on the brachial artery, that Mr. Lambert

(*Med. Obs. and Inquiries, vol.* 2) made the experiment of closing the puncture in the vessel by means of the twisted suture, under an idea, that the plan would not, like compression, obliterate the arterial tube, and therefore that the risk of gangrene would be lessened. Now, although in the trial which was made the bleeding was permanently stopped, Lambert was mistaken in supposing that the previous state of the wounded part of the artery was preserved by the adoption of the twisted suture, instead of pressure or the ligature. If ever a small puncture in an artery heal, so as to leave the tube of the vessel pervious, it is under the circumstances pointed out by Dr. Jones.—(See *Hemorrhage.*) Had Lambert had an opportunity of examining the state of the vessel some time after the above operation, he would have found its canal obliterated; and had he known the freedom with which the collateral arteries anastomose with the recurrent arteries of the forearm, he would have known how to explain more correctly the re-establishment of the pulse. I need merely add, that as the false idea of preserving the perviousness of the artery was the only foundation for the method, the practice ought never to be revived, as not affording equal security from hemorrhage to what is obtained by the ligature, or even compression.

AXILLARY ANEURISMS.

Aneurisms occasionally take place in the axilla, and make it necessary to tie the subclavian artery. A question here naturally presenting itself is, whether the surgeon should attempt the operation in an early period of the disease, or wait till circumstances are urgent; the aneurism large and far advanced; the arm œdematous and insupportably painful, from the stretching of the axillary plexus of vessels; the patient worn out by suffering and loss of rest; and the tumour in danger of bursting? In all cases of aneurisms, unquestionably, there is a certain chance of the disease getting well spontaneously: and one axillary aneurism, in a man in St. Bartholomew's Hospital a few years ago, had certainly disappeared of itself, as was proved by the account which the patient while living gave of his case, and by the obliteration of the artery, found on inspection after death.

I believe, however, we ought not to suffer our conduct to be too much influenced by the hope of so unfrequent an event, and, from the observations which I have made on this subject, it is my decided opinion, that the operation should never be delayed, so as to allow the tumour to acquire an immoderate size. The operation is always difficult; but the difficulty is seriously increased, when the swelling has extended far towards the breast, and has become so large as to push the clavicle considerably upwards. The several examples in which the subclavian artery has now been successfully tied furnish abundant proof, that the anastomoses are fully competent to the supply of the limb with blood. The plan, therefore, of delaying the operation long, with the view of allowing the inosculating arteries to enlarge, must be as questionable here as in some other cases of aneurism, and at all events, the maxim may be safely advanced, that, previously to the operation, the tumour should never be suffered to acquire an enormous size.

That the limb would receive an adequate supply of blood was well proved, even without the performance of the operation, by cases in which the axillary and subclavian arteries had been rendered impervious by disease; as, for instance, by the pressure of an aneurism of the aorta.—(For an account of such facts, the reader is particularly referred to *Hodgson's Treatise on the Diseases of Arteries, p.* 111; *Journal de Médecine by Corvisart, Leroux, and Boyer, t.* 2, *p.* 29; *Corvisart, Essai sur les Maladies du Cœur, p.* 215.)

"In these cases (says Mr. Hodgson), the only unusual circumstance which was observed during the life of the patients, was the deficiency of the pulse at the wrist. The limbs were well nourished, although a considerable extent of the main artery (the subclavian) was obliterated even before it had given off any branches."—(*P.* 47.)

This vessel was tied by Mr. Hall, in Cheshire, when it had been wounded with a scythe, and its ends exposed; the arm was preserved, though it remained somewhat weakened, which might be owing to the division of some large nerve.—(See *J. Bell on Wounds, p.* 60, *edit.* 3, and *Scarpa, p.* 372.) Mr. White, of Manchester, relates another instance of this vessel being tied, in the case of a wound; but mortification of the limb and death followed. Three of the nerves were found included in the ligature.—(*Lond. Med. Journ. v.* 4.) In cases of wounds of the axillary, or any other large arteries of the extremities, the surgeon, before proceeding to apply a ligature, should first ascertain the precise place of the wound in the artery; and for this purpose, it may sometimes be proper, in certain wounds of the shoulder, to make an incision in the axilla so as to expose the injured part of the vessel; or, if circumstances do not forbid it, the external wound may be dilated, until the exact part where the artery has been wounded is discovered. In proof of the propriety of acting in this manner, and applying a ligature above and below the wound in the vessel, Scarpa quotes a case, in which such practice was successful on a patient under M. Maunoir, of Geneva: the artery had been injured with a sabre near the head of the humerus; but after the wounded part of the vessel had been traced, and secured in the way above suggested, the patient, a boy fourteen years of age, was saved from the dangers of hemorrhage, and recovered the use of his arm, as fast as this was possible, with the loss of the first phalanges of the last three fingers from gangrene.—(See *Scarpa on Aneurism, p.* 412, *ed.* 2, *and Journ. de Méd. t* 40, *Mars*, 1811.)

There are two modes of operating for axillary aneurisms: one, by cutting below the clavicle, in order to take up the axillary artery itself; the other, by making the wound above the bone, for the purpose of securing the subclavian artery at the point where it emerges from behind the anterior scalenus muscle.

The first of these methods has been attempted by Desault, Pelletan, the late Mr. Keate, Mr. Chamberlaine, &c. It was in a case of wound of the axillary artery that Desault operated. An incision, six inches long, was made below the external third of the clavicle; two thoracic arteries cut were immediately tied; the two lower thirds of the great pectoral muscle were next divided with a bistoury guided on a director: a large quantity of coagulated blood was now discharged; and the artery was directly taken hold of, and tied, together with the brachial plexus of the nerves. The arm mortified, and the patient died. This case, we must agree with Scarpa, was not a fair trial of the operation, inasmuch as the inclusion of the plexus of nerves in the ligature was an improper measure, and must have promoted the occurrence of sphacelus. It seems also probable, from the account, that the vein was likewise tied; another serious and objectionable proceeding. Besides, it is worthy of notice, that the case was a wound of the axillary artery, attended with a copious effusion of blood in the cellular membrane. In all examples of this kind, gangrene is more readily induced, than when the case is a mere circumscribed aneurismal tumour.—(See *Œuvres Chir. de Desault, par Bichat, t.* 2, *p.* 553.) As for Pelletan's example, it hardly deserves recital, because the operation in fact was not achieved. His colleagues objected to dividing the pectoral muscle; a random thrust was made with a needle and ligature; but the artery was not included, and the experiment was not repeated.—(See *Clinique Chir. t.* 2, *Obs.* 7, *p.* 49.)

In a case of axillary aneurism, which had actually burst, and the hemorrhage from which could only be stopped by pressing the artery against the first rib, Mr. Keate, the surgeon-general, practised the following operation, which was attended with complete success. His plan was to take up the artery, above the diseased and ruptured part, in its passage over the first rib. Accordingly he made an incision obliquely downwards, divided the fibres of the pectoral muscle that were in his way, and, when he came to the artery, passed a curved, blunt-pointed silver needle, armed double, as he conceived, under the artery, and tied two of the ends. After a careful examination, finding that the artery pulsated below the ligature, he determined on passing another ligature higher up, and nearer to the clavicle: he, therefore, passed the needle more deeply, so as evidently to include the artery. In a few days the swelling of the arm began to subside, the wound suppurated, and the ligatures came away with the dressings. The arm afterward recovered its feeling, and the patient regained, in a great measure, the entire motion of the shoulder, &c.—(See *Med. Review and Magazine for* 1801.)

Mr. Keate's operation is objectionable, inasmuch as it was a dive made with a needle, and attended with great danger of wounding and tying parts which should be left undisturbed.

Mr. R. Chamberlaine, of Kingston, Jamaica, took up the axillary artery below the clavicle, in a patient who had an aneurism in the left axilla, occasioned by a wound with a cutlass on the 5th of October, 1814. On the 10th of January, the tumour had considerably increased, and was less compressible than it had been when first seen by Mr. Chamberlaine. The operation was done on the 17th of January, 1815: "a transverse incision, of three inches in length, was made through the skin and platysma myoides, along and upon the lower edge of the clavicle, three finger's breadth from the sternal end of that bone, and terminating about an inch from the acromion scapulæ. This incision divided a small artery, which was immediately secured. A second incision, of three inches in length, was also made obliquely through the integuments over the deltoid and pectoral muscles, meeting the first nearly in the centre. The cellular membrane and fat lying between them at the upper part were now removed. The next step consisted in detaching the clavicular portion of the pectoralis major, and taking away the fat and cellular membrane lying over the subclavian vessels. The artery was now brought into view, and its pulsations made it clearly distinguishable from the contiguous parts." After several ineffectual efforts, Mr. Chamberlaine succeeded in conveying a ligature under it, by means of an eye-probe, curved for the purpose, and the point of which was brought up with the aid of a pair of forceps. On the 22d of February, the wound was completely healed; the aneurismal tumour reduced to the size of a turkey's egg, and very solid; the arm smaller than its fellow, but its muscular power improving.—(See *Medico-Chir. Trans. vol.* 6, *p.* 128, *&c.*) Mr. Chamberlaine expresses his conviction, that the operation would have been much facilitated, had he been furnished with the instruments described in Mr. Ramsden's work for passing the ligature under the artery: a still better invention, however, for passing a ligature under a deep artery, is the needle lately constructed by Mr. Weiss, surgeons' instrument maker, in the Strand. An engraving and description of this valuable instrument may be found in the *Edin. Med. and Surgical Journal*, *No.* 76.

The subclavian artery might be got at below the clavicle as follows: the surgeon is to begin an incision in the integuments about an inch from the sternal end of this bone. The cut is to run towards the acromion, deviating a little downwards from a line parallel to that of the clavicle. This wound will bring into view some fibres of the great pectoral muscle originating from the last-mentioned bone. These are next to be divided. Some cellular substance will be found underneath, which is to be carefully raised with a pair of dissecting forceps, and cut. The operator will thus arrive at the great subclavian vein, and cephalic vein uniting with it. Under the subclavian vein, and a little farther backwards, more under the clavicle, the subclavian artery may be felt and tied.—(See *C. Bell's Operative Surgery*, *vol.* 2, *p.* 370.)

On the whole, however, I think, Mr. Hodgson's directions for the performance of this operation are the best which have been given. A semilunar incision through the integuments, which is to have its convexity downwards, and to begin about an inch from the sternal end of the clavicle, being continued towards the acromion for the extent of three or four inches, so as to end near the anterior margin of the deltoid muscle, without reaching into the space between the deltoid and pectoral muscle, in order to avoid wounding the cephalic vein. This incision will expose the fibres of the pectoral muscle, which are now to be divided in the direction and extent of the external wound. The flap is then to be raised, by dividing the loose cellular membrane which connects the pectoral muscle to the parts underneath it. The pectoralis minor will now be seen crossing the inferior part of the wound; and, by introducing his finger between the upper edge of this muscle and the clavicle, the surgeon may feel the pulsations of the axillary artery. Here one of the cervical nerves lies above, but in contact with the artery; the other nerves are behind it. In the dead subject, the axillary vein is situated below it; but, in the living, the vein is distended, and conceals the artery. The cellular membrane connecting these parts is to be separated by careful dissection, or by lacerating it with a blunt instrument. A ligature having been drawn under the artery with an aneurism-needle, the ends of the cord are to be raised, and a finger passed down, so as to compress the part surrounded by the ligature. If the artery be included, the pulsation in the aneurism will immediately cease. This precaution is highly necessary, lest one of the cervical nerves should be tied, instead of the artery.—(See *Hodgson on Diseases of Arteries*, *&c. p.* 362.)

When an aneurism extends a certain way inwards, or towards the trachea, the operation below the clavicle becomes impracticable, and it is now requisite to make the incision above that bone, and take up the subclavian artery at the point where it comes out from between the scaleni muscles and lies on the flat surface of the first rib.

In the dead subject without any tumour under the clavicle, this operation is easy enough; but in a living patient the difficulty is much increased by a large axillary aneurism, for then the clavicle is sometimes so much elevated, and the artery lies so deeply, that a ligature can hardly be carried under it without a particular needle for the purpose. This was the case in an attempt which I once saw made by Mr. Ramsden to tie the artery, and in which one of the cervical nerves affected by the pulsation of the artery was mistaken for it and tied, so that the aneurism soon afterward burst, and a fatal hemorrhage arose. Hence the advice given by my friend Mr. Hodgson, always to operate in this case while the tumour is small, cannot be too well remembered. A direction given by Mr. Liston is also important; namely, "before tightening the ligature, try the effect of compression with the fingers on the pulsation, as by taking this precaution (says Mr. Liston) I saved myself and my patient the pain of tying the nerve, which I got hold of in my first operation, in place of the artery."—(*Lancet*, *No.* 195, *p.* 234.) The chief difficulty in the operation is that of passing the ligature round the artery; but it may be done either with an ingenious needle which Mr. Ramsden has described, and which is exactly similar in principle to Desault's *aiguille à ressort*, or with the still preferable instrument constructed by Weiss. Another very ingenious contrivance for tying deep arteries has also been recently proposed by Dr. Prevost of Geneva.—(See *Edin. Med. and Surgical Journ. No.* 79.) The instruments used by Dr. Mott when he took up the arteria innominata will be presently noticed.

In order to avoid the inconveniences of the needles ordinarily used for conveying ligatures under deep arteries, Desault (says Bichat) invented "une aiguille à ressort," composed of a silver tube or sheath, which was straight at one end and bent at the other in a semicircular form. This sheath enclosed an elastic wire, the projecting extremity of which was accurately fitted to the end of the sheath, and perforated with a transverse eye. The instrument was passed under the artery, and as soon as it had reached the other side of the vessel, the sheath was kept fixed, while an assistant pushed the elastic wire, which, rising from the bottom of the wound, presented the aperture or eye to the surgeon, who now passed the ligature through this opening. The wire was next drawn back into its sheath again, and the whole instrument brought from beneath the artery, by which means the ligature was conveyed under the vessel.—(See *Œuvres Chir. de Desault, par Bichat*, *t.* 2, *p.* 560.) Another very ingenious method of passing the ligature under the artery, is that practised by Mr. Key; but as the comprehension of it is difficult without the plate, I shall here merely refer to that gentleman's description of it.—(See *Med. Chir. Trans. vol.* 13, *p.* 10.)

The invention of the foregoing instruments makes a material diminution in the difficulty of taking up the subclavian artery from above the clavicle; nor can it be wondered, that without such assistance, the operation should have baffled even so skilful a surgeon as Sir A. Cooper.—(See *Lond. Med. Review*, *vol.* 2, *p.* 200.)

The following example is the first in which the attempt to tie the subclavian artery by cutting above the clavicle was ever accomplished.

John Townly, a tailor, aged thirty-two, addicted to excessive intoxication, of an unhealthy and peculiarly anxious countenance, was admitted into St. Bartholomew's Hospital on Tuesday, the 2d of November, 1809, on account of an aneurism in the right axilla. The

prominent part of the tumour in the axilla was about half as big as a large orange, and there was also much enlargement and distension underneath the pectoral muscle, so that the elbow could not be brought near the side of the body.

"The temperature of both arms," says Mr. Ramsden, "was alike, and the pulse in the radial artery of each of them was correspondent. After the patient had been put to bed, some blood taken from the left arm, and his bowels emptied, his pulse, which on his admission had been at 130, became less frequent; his countenance appeared more tranquil; and he experienced some remission of the distressing sensations in the affected arm: his relief, however, was of short duration."

The pulsation of the radial artery of the affected arm gradually became more obscure, and soon after either ceased or was lost in the œdema of the forearm and hand. On the evening of the twelfth day, a dark spot appeared on the centre of the tumour, surrounded by inflammation, which threatened a more extensive destruction of the skin. A farther postponement of the operation being deemed inadmissible, Mr. Ramsden performed it the next day in the following manner.

"A transverse incision was made through the skin and platysma myoides, along and upon the upper edge of the clavicle, about two inches and a half in length, beginning it nearest to the shoulder, and terminating its inner extremity at about half an inch within the outward edge of the sterno-cleido-mastoideus muscle. This incision divided a small superficial artery, which was directly secured. The skin above the clavicle being then pinched up between my own thumb and finger and those of an assistant, I divided it from within outwards and upwards, in the line of the outward edge of the sterno-cleido-mastoideus muscle to the extent of two inches.

My object in pinching up the skin for the second incision, was to expose at once the superficial veins, and by dissecting them carefully from the cellular membrane, to place them out of my way without wounding them. This provision proved to be useful, for it rendered the flow of blood during the operation very trifling, comparatively with what might otherwise have been expected; and thereby enabled me with the greatest facility to bring into view those parts which were to direct me to the artery.

My assistant having now lowered the shoulder, for the purpose of placing the first incision above the clavicle (which I had designedly made along and upon that bone), I continued the dissection with my scalpel, until I had distinctly brought into sight the edge of the anterior scalenus muscle, immediately below the angle which is formed by the traversing belly of the omo-hyoideus and the edge of the sterno-cleido-mastoideus; and having placed my finger on the artery at the point where it presents itself between the scaleni, I found no difficulty in tracing it, without touching any of the nerves, to the lower edge of the upper rib, at which part I detached it with my finger nail, for the purpose of applying the ligature.

Here, however, arose an embarrassment which (although I was not unprepared for it) greatly exceeded my expectation. I had learned, from repeatedly performing this operation many years since, on the dead subject, that to pass the ligature under the subclavian artery with the needle commonly used in aneurisms would be impracticable; I had, therefore, provided myself with instruments of various forms and curvatures to meet the difficulty, each of which most readily conveyed the ligature underneath the artery, but would serve me no farther; for being made of solid materials and fixed into handles, they would not allow of their points being brought up again at the very short curvature, which the narrowness of the space between the rib and the clavicle afforded, and which, in this particular case, was rendered of unusual depth by the previous elevation of the shoulder by the tumour.

After trying various means to overcome this difficulty, a probe of ductile metal was at length handed me, which I passed under the artery, and bringing up its point with a pair of small forceps, I succeeded in passing on the ligature, and then tied the subclavian artery at the part where I had previously detached it for that purpose. The drawing of the knot was unattended with pain; the wound was closed by the dry suture, and the patient was then returned to his bed." —(See *Practical Observations on the Sclerocele, &c., to which are added four cases of operations for Aneurisms*, p. 276, *&c.*)

It only seems necessary for me to add, that immediately the artery was tied the pulsation of the swelling ceased; that the arm of the same side continued to be freely supplied with blood, and was even rather warmer than the opposite arm; that the operation, which was severe from the length of time it took up, was after a time followed by considerable indisposition; that the patient died about five days after its performance; that after the artery had been tied, the œdema of the arm and the aneurismal tumour partly subsided; and that, on examination after death, nothing but the vessel was found included in the ligature.

In this publication are descriptions of instruments which will be of great service to any future performer of this operation. The chief one is a needle, resembling that which was invented and used by Desault, and of which I have already endeavoured to give an idea. By means of this instrument, I conceive that the main difficulty of the operation will in future be avoided. Had Mr. Ramsden had its assistance, his patient would have been detained a very little time in the operating theatre, and the event of the case might have been completely successful. Having witnessed all the circumstances of the case, the inference that I drew from them was, that if the operation could have been done in a moderate time, which now seems practicable with the aid of the aiguille à ressort, or the instrument sold by Mr. Weiss, the case in all probability would have ended well. The preceding case is particularly memorable, as being the first instance in which the subclavian artery was scientifically tied, without any random thrust of a needle, and without the inclusion of any part besides the artery in the ligature. It furnished encouragement to repeat the experiment; held out the hope, that axillary aneurisms might be cured as well as inguinal ones; and confirmed the competency of the anastomosing arteries to nourish the whole upper extremity, when the subclavian is tied where it emerges from behind the anterior scalenus muscle.

In the year 1811, the subclavian artery was tied in the London Hospital, in a case of axillary aneurism, by Sir W. Blizard, who found no difficulty in getting the ligature under the artery, with a common aneurism-needle. A single ligature was applied. At first hopes of recovery were entertained; but the patient, who was old and debilitated, afterward sunk and died on the fourth day.—(See *Hodgson's Treatise*, p. 375.)

In the year 1815, Mr. Thomas Blizard tied the subclavian artery in the same hospital. The case was an aneurism in the left axilla, and, like all the other examples of this kind upon record, was attended with great pain in the tumour and limb. There was no pulse in the left radial artery, though there was scarcely any difference in the temperature of both arms. "An incision about three inches in length was made through the integuments at the root of the neck, on the acromial side, and parallel with the external jugular vein. The platysma myoides being divided, the cellular membrane was separated with the finger, until the pulsation of the subclavian artery was felt where the vessel passes over the first rib. The finger being pressed upon this part of the artery, the cellular sheath investing it was carefully opened with the point of a knife. A ligature was then conveyed underneath the artery, by means of a common aneurism-needle, with the greatest facility." As soon as the ligature was tied, the pulsation in the tumour ceased. On the second day after the operation the left arm began to have more feeling, and was as warm as the right. However, difficulty of breathing, twitchings, delirium, &c. afterward ensued, and the patient died on the evening of the eighth day, previously to which event the ring and middle fingers turned black. On opening the body, the pericardium exhibited the effects of a high degree of inflammation, and the heart was covered with flakes of lymph, its posterior surface being of a deep red colour. The inner membrane of the ascending aorta was of a bright scarlet hue, much diseased, and studded with white patches. A reddish appearance was also noticed in the lining of the right carotid, left subclavian, and even the abdominal aorta. The boundaries of the aneurismal tumour were in a state of sphacelation. These are all the circumstances which I wish here to notice; but more particulars may be perused in Mr. Hodgson's work, p. 602.

It is remarkable, that in the cases operated upon in the London Hospital, and some others on record, no difficulty was experienced in passing the ligature under the artery with a common aneurism-needle; a circumstance which must have depended upon the space between the clavicle and the first rib having been less deep in these instances than the two which fell under my own observation, or in others which occurred in the practice of Dr. Colles, Sir Astley Cooper, and Mr. Liston.—(See *Lond. Med. Review, vol.* 2, *p.* 200; *and Edin. Med. and Surg. Journal, January*, 1815, *No.* 64.) In Mr. Key's case, "the depth of the angle in which the artery was enclosed rendering it impossible to pass a ligature under it, about three-quarters of an inch of the clavicular portion of the sterno-mastoid was divided, which afforded sufficient room, and rendered the concluding part of the operation easy; the artery became readily exposed to view, and an armed aneurismal needle was passed with facility under it."—(*Med. Chir. Trans. vol.* 13, *p.* 5.)

In Dr. Colles's first case, the artery was tied before it reached the scaleni muscles, as the tumour, which was in the right subclavian artery, extended from the sternal origin of the sterno-mastoid muscle along the clavicle, a little beyond the arch of that bone, and rose nearly two inches above it, in a conical form, the apex of the cone being situated at the outer edge of the foregoing muscle. After a tedious dissection, it was found that only a quarter of an inch of the artery was sound, and on this portion the ligature was placed. Great difficulty was encountered in passing it round the artery, and the pleura was supposed to have been slightly wounded. Before tightening the ligature the breathing became laborious, and the patient complained of oppression about the heart. These symptoms, indeed, were so violent, that it was judged prudent not immediately to tighten the ligature. On the fourth day, however, the artery was constricted, when the pulse at the wrist ceased, the patient not seeming to suffer much from what had been done. The patient then went on pretty well till the ninth day, when he was seized with a sense of strangling, and pain about his heart, and, becoming delirious, died nine hours after the beginning of this attack. On dissection the aorta was found diseased, and the disease extended into the subclavian artery.

In another instance, Dr. Colles tied this vessel at the point where it emerges from between the scaleni muscles, without any particular difficulty. The operation, however, was soon followed by a train of severe symptoms, delirium, and mortification, and the patient died on the fifth day.—(See *Edin. Med. and Surg. Journ. January*, 1815.)

The first case in which complete success attended the operation of tying the subclavian artery, where it first comes from behind the anterior scalenus muscle, was that under the care of Dr. Post, of New-York. The patient was a gentleman, with an aneurism in the left axilla. Dr. Post performed the operation on the 8th of September, 1817, in the following manner. "An incision, commencing at the outer edge of the tendon of the mastoid muscle, was carried through the integuments about three inches in length, in a direction deviating a little from a parallel line with the clavicle. This divided the external jugular vein, the bleeding from which required a ligature for its suppression; and in proceeding with the operation, three or four arterial branches were cut, which it was also necessary to secure. The subclavian artery was then sought immediately on the outside of the scaleni muscles, and was easily laid bare. Passing over the artery at this place, in contact with it, were three considerable branches of nerves, running downwards towards the chest from the plexus above. These were separated, and a ligature passed under the artery with great facility, by the instrument well adapted to this purpose invented by Drs. Parish, Hartshorn, and Hewson, of Philadelphia. On tying the ligature, all pulsation ceased in the limb." In the afternoon, the temperature of the limb was observed to be rather higher than that of the other arm. On the 17th of September, the aneurismal tumour burst, and about three ounces of dark coagulated blood were discharged. On the 26th, the ligature came away from the subclavian artery. Oct. 11th, the wound was entirely healed; and on the 16th of the same month, the patient required no farther attendance, his only complaints being now a little occasional pain in the fingers, and a superficial sinus at the part where the tumour burst.—(See *Med. Chir. Trans. vol.* 9, *p.* 185, &c.)

Mr. Liston, of Edinburgh, has the honour of being the surgeon that first succeeded, in Europe, in curing an axillary aneurism, by taking up the subclavian artery from above the clavicle, on the 3d of April, 1820. The particulars of the case are very instructing. They prove the risk there always is of tying one of the axillary nerves instead of the artery, unless great caution be employed; and, in fact, Mr. Liston himself first passed his ligature under a nerve, and would have tied it, had he not wisely tried what effect constricting the included part would have upon the pulsation of the tumour. As the subclavian artery seemed diseased at the point where it emerged from behind the anterior scalenus, Mr. Liston cautiously divided this muscle to about its middle, so as not to injure the phrenic nerve. At length, with the aid of an aneurism-needle, he passed a strong round silk ligature under the artery, and laying hold of the loop with a small hook withdrew the needle. In consequence of the great depth of the artery, the knot could not be made with the fingers; but with the assistance of a kind of forceps, each extremity of which had a little notch in it, the business was accomplished.—(See *Edin. Med. and Surgical Journ. No.* 64.)

Several other successful operations of this kind have subsequently been done by English surgeons. One by Dr. Gibbs, in the General Naval Hospital of St. Petersburgh (see *Med. Chir. Trans. vol.* 12, *p.* 531); another by Mr. Bullen, in the Lynn Dispensary (see *London Med. Repository for Sept.* 1823); a third by Mr. Wishart at Edinburgh (see *Edin. Med. and Surg. Journ. No.* 78); a fourth by Mr. Key, in Guy's Hospital (see *Med. Chir. Trans. vol.* 13, *p.* 1); and a fifth by Mr. B. Cooper, in the same establishment.

[Professor Gibson, of the University of Pennsylvania, has cured a case of axillary aneurism occasioned by the reduction of an old luxation of the humerus, by tying the subclavian artery.—(See *American Journal, vol.* 2, *p.* 136.)—*Reese.*]

The instructions delivered by Mr. Hodgson for the performance of this operation, are the best with which I am acquainted. When the subclavian artery (says this gentleman) has emerged from behind the anterior scalenus muscle, it passes obliquely over the flat surface of the first rib, with which it is in immediate contact. The cervical nerves are situated above and a little behind the artery; the subclavian vein passes before it, and underneath the clavicle. If the finger be passed down the acromial margin of the anterior scalenus muscle, the artery will be found in the angle formed by the origin of that muscle from the first rib. The shoulder being drawn down as much as possible, the skin is to be divided immediately above the clavicle, from the external margin of the clavicular portion of the mastoid muscle, to the margin of the clavicular insertion of the trapezius. No advantage whatever, says Mr. Hodgson, is gained by cutting the clavicular attachment of the sterno-cleido-mastoideus. On this point, however, there is some difference of opinion; Mr. Key having found, in his operation, that the division of the clavicular portion of that muscle greatly facilitated the introduction of the ligature under the artery.—(See *Med. Chir. Trans. vol.* 13, *p.* 5 *and* 10.) The exposed fibres of the platysma myoides are now to be carefully divided, without wounding the external jugular vein, which lies immediately under them, near the middle of the incision, and should be detached, and drawn towards the shoulder with a blunt hook. The cellular membrane, in the middle of the incision, is then to be cut, or separated with the finger, until the surgeon arrives at the acromial edge of the anterior scalenus. He passes his finger down the margin of this muscle, until he reaches the part where it arises from the first rib, and in the angle formed by the origin of the muscle from the rib he will feel the artery. The ligature is now to be conveyed under the vessel with an aneurism-needle, or that recommended by Desault.—(*Hodgson on Diseases of Arteries, &c. p.* 376, *&c.*)

Breschet thinks that the safest and easiest method is that adopted by Dupuytren. An incision, three or four inches long, is to be made at the lower and outer part of the neck, and extended to the clavicle. This first incision, situated behind the external edge of the sterno-mastoid muscle, should go through the skin,

the cellular membrane, and platysma myoides. Some venous branches, running into the jugulars, will then be met with, which should be surrounded by a double ligature, and divided in the interspace. A director is then to be introduced under the omo-hyoideus muscle, in order to facilitate its division, and the surgeon will at length reach the external edge of the anterior scalenus. A curved probe-pointed bistoury is then to be gradually and cautiously passed behind that muscle, with the flat surface of the blade against it, and deeply enough to divide the external third, or half of the fibres of the same muscle, or even all of them if requisite. The insulated artery will then be felt at the bottom of the wound, situated in the area of a triangle, the upper side of which is formed by the brachial plexus, the lower by the subclavian vein, and the inner by the scalenus. A ligature is then to be conveyed under the artery by means of the needle invented by Deschamps. —(See *French transl. of Mr. Hodgson's work*, *t.* 2, *p.* 126.) Whether cutting the anterior scalenus and omo-hyoideus will facilitate the operation is questionable; but the assertion that these measures increase its safety, is what I cannot understand.

With respect to tying the subclavian artery on the tracheal side of the scalenus, we have seen, that it was performed by Dr. Colles, and the event was fatal. Descriptions of the operation may be found in Mr. Hodgson's work, p. 382. When I consider the manner in which the subclavian artery, before it passes behind the anterior scalenus, is surrounded by parts of great importance, I can scarcely bring my mind to think, that the measures requisite for taking up the vessel in this situation, will ever leave the patient much chance of recovery. "Between the aorta and scaleni muscles (says Mr. A. Burns) the subclavian arteries are connected with several important vessels and nerves. They are in the vicinity of the nervus vagus, of the recurrent laryngeal nerve, of the sympathetic nerve, of the phrenic nerve, and the subclavian vein; and, on the left side, the subclavian artery is intimately connected with the termination of the thoracic duct. These parts are all grouped together in a very narrow space, and the perplexity of their dissection is farther increased by the interlacement of the different nerves with one another. The natural connexions of these parts are best shown by merely raising the external extremity of the sterno-mastoid muscle. If this be done, the nervus vagus will be brought into view, lying on the forepart of the subclavian artery, almost directly behind the sternal end of the clavicle; and exactly opposite to the nervus vagus, but behind the artery, the lower cervical ganglion of the sympathetic nerve will be brought into view. The recurrent nerve, on the right side, hooks round the subclavian artery, and, in its course towards the larynx, ascends along the tracheal side of the sympathetic nerve. On the left side, it twines round the arch of the aorta, and in mounting upwards, is interposed between the subclavian artery and œsophagus. The subclavian vein lies anterior to the artery, and in the collapsed state, sinks nearer to the thorax;" but, when distended in the living body, it overlaps the artery. The thoracic duct enters the subclavian vein, about the eight of an inch nearer to the acromion than the point where the internal jugular vein empties itself into the subclavian vein. The termination of the thoracic duct is situated between the sternal and clavicular portions of the sterno-mastoid muscle.—(*A. Burns, on the Surgical Anatomy of the Head and Neck*, *p.* 28.)

A case in which an axillary aneurism, unattended with pulsation, was punctured, and the child bled to death, is noticed in a modern periodical work.—(See *Med. Chir. Journ. vol.* 4, *p.* 78.)

For anatomical views of the parts concerned in the operation of taking up the subclavian artery, consult *Rosenmüller's Chir. Anat. Plates*, *part* 2, *tab.* 8 *and* 9; *Tiedemann's and Scarpa's beautiful engravings.*

Some valuable anatomical remarks, in relation to the operation, are given by Mr. A. Burns.—(*Surgical Anatomy of the Head and Neck*, *p.* 28, *&c.*)

In certain cases of subclavian aneurism, it has been proposed to tie the arteria innominata. In the dead subject, Mr. Allan Burns applied two ligatures to it, and after cutting through the vessel in the interspace, he injected the aorta, when the injection was found to pervade the anastomosing vessels of the right arm, and all those of the head. But notwithstanding this fact, and others noticed by Mr. Hodgson, tending to show the probability that a ligature upon the arteria innominata would not prevent the arm and head from receiving an adequate supply of blood, other objections were made to the practice. The principal of these were founded upon the difficulty of the operation in the living body; the inflammation, likely to be excited by it in neighbouring important organs; the danger of hemorrhage from the adhesion of the vessel being likely to be broken by the force of the circulation; and the equal practicableness, in most cases, of tying the subclavian artery on the tracheal side of the scalenus.

Dr. Mott, an eminent surgeon at New-York, impressed with the value of Mr. Allan Burns's remarks upon this subject, has, ever since he became acquainted with them, maintained in his lectures the propriety of attempting to tie the arteria innominata, under particular circumstances of subclavian aneurism. At length, Dr. Mott put this new operation to the test of experience in the New-York Hospital, on the 11th of June, 1818. The case was a subclavian aneurism on the right side, and the patient, a sailor, aged fifty-seven, to whom seventy drops of tinct. opii were first given. Dr. Mott began the first incision directly over the swelling above the clavicle, extended it along this bone and ended it at the trachea, just above the upper portion of the sternum. Here he commenced the second incision, of about the same length as the first, and reaching along the inner margin of the sterno-cleido-mastoideus. Dr. Mott next detached the skin from the subjacent platysma myoides, cut through the latter, and cautiously divided the sternal portion of the mastoid muscle, in the direction of the first incision. The internal jugular vein now presented itself close to the swelling, and adherent to it; a circumstance that rendered the subsequent part of the operation very difficult. After detaching a portion of the latter vein from its connexion, Dr. Mott cut through the sterno-hyoideus and sterno-thyroideus, and turned them back over the trachea. The carotid was now exposed a few lines above the sternum, and after he had separated the par vagum and internal jugular vein from it, they were drawn towards the outer side of the neck. Dr. Mott then laid bare the subclavian artery, which part of the operation he chiefly accomplished with the handle of the scalpel, as there was nothing to be separated but cellular membrane. The subclavian artery was found to be very much enlarged and diseased, and as Dr. Mott recollected that this state of the vessel had seemingly hindered its successful closure in the example operated upon by Dr. Colles, of Dublin, he decided to take up the arteria innominata itself. In detaching the cellular membrane from the lower surface of the subclavian artery, a small branch, situated about half an inch from the innominata, was injured, and the wound was six or eight times filled with blood from it. The hemorrhage was soon suppressed, however, by means of a little pressure. Had not the bleeding been so easily stopped, Dr. Mott would have concluded, from the situation of the vessel, that it was the internal mammary; but if it were not this branch, he conceives it must have been an artery not regularly originating in this situation; perhaps the superior intercostal.

Dr. Mott continued the operation with a small, round-ended, sharp scalpel, until he came to the division of the arteria innominata, which great vessel he traced below the sternum, and after freeing it from all the cellular membrane with the handle of the scalpel, and drawing aside the recurrent and phrenic nerves, he tied it with a round silk ligature, about half an inch from its bifurcation.

Most surgeons, says Dr. Mott, complain of the difficulty of tying large arteries in a deep small wound. Hence, he recommends a set of instruments, invented for the purpose, in Philadelphia, by Drs. Parish, Hartshorn, and Hewson; consisting, 1st. Of several blunt-pointed needles, of various sizes and curvatures, furnished with an eye at each end, and calculated at one end to screw into a strong handle. 2dly. Two strong instruments, with handles, having at one end an eye or hole; they resemble those sometimes used for applying a ligature to the tonsils. 3dly. A small round pointed scalpel. 4thly. A small hook, fixed in a very strong handle.—(*Parish, in Eclectic Rep. vol.* 3, *p.* 229.)

After Dr. Mott had introduced the ligature into the

eye of one of the above-described needles, and screwed the needle into a handle, he pressed with its convexity the cellular membrane and pleura carefully downwards, while he carried it from below upwards round the artery. As the point now appeared on the other side of the vessel, the above-mentioned hook was passed into its eye, and the handle unscrewed from the other end of it, when it was easily drawn out from under the artery, and the ligature left under the vessel.

In this part of the operation, Dr. Mott urges the necessity of being particularly attentive to two important circumstances; one is, to convey the ligature round the artery from below upwards, as the only way to prevent injury of the pleura; and the other is, to fix the hook in the eye of the needle, before the handle is unscrewed from its other end, because, after this has been done, the needle loses all steadiness, and it is then difficult to get the hook into the eye.

With respect to the foregoing instruments, I may observe, that they are superseded by the needle lately constructed by Mr. Weiss.

Dr. Mott now made a noose, pressed it with the fore-finger down to the artery, and tightened it very gradually, in order not to stop the flow of blood through the vessel all at once. A moderate constriction was kept up some seconds, so that the effect of the ligature upon the heart and lungs might be observed; and as no disturbance was produced in the functions of these organs, Dr. Mott tightened the ligature, and stopped the current of blood through the vessel. At this instant, the pulsation of the right temporal and radial arteries ceased. The noose was tightened still more with the above-mentioned ligature irons, and then a second knot was made. Dr. Mott was greatly pleased at finding his patient's countenance remain perfectly unchanged, and no complaint made of pain in any other part. Immediately after the ligature had been applied, the aneurismal swelling lost one-third of its size, and the clavicle could be felt through its whole extent. The divided muscles and detached skin were now brought into their natural situation, the wound closed with three sutures and adhesive plaster, and a compress applied. In the operation three small arteries were tied: the first lay under the sternum, and seemed to be a branch of the internal mammary; the second was a descending branch of the superior thyroideal; and the third a branch of the inferior thyroideal. From two to four ounces of blood were lost, most of which came from an injured small branch of the subclavian. The operation took up about an hour. The curved spatulæ recommended by Dr. Colles, were found very useful for holding the carotid and par vagum aside, while, by their uniform pressure, they materially assisted in restraining the effusion of blood from small vessels, and as taking up little room, were infinitely more convenient in a deep narrow wound, than the fingers of an assistant.

The day after the operation, the veins of the right forearm and hand had a turgid appearance. When the circulation in them was promoted by pressure, they became empty for some distance above the pressed part, but filled again immediately the pressure was removed; a circumstance that seemed to show, that the circulation in this arm, notwithstanding the ligature of the arteria innominata, still went on with great celerity, though no pulse could be felt in the brachial and radial arteries. On the contrary, the pulse was very plain in the front branch of the temporal artery, just above the outer angle of the orbit. The left external carotid beat with unusual force. In a few days, however, the pulse became perceptible again at the right wrist.

My limits will not allow me to enter into all the details of this interesting case: suffice it to mention, that the patient suffered considerable febrile disturbance at some periods after the operation, and it was necessary twice to have recourse to venesection. He was also afflicted with a severe cough. The discharge from the wound was copious and fetid. The main ligature separated on the fourteenth day. On the twentieth day, the patient was sufficiently recovered to walk in the garden. On the twenty-first day, the wound was almost closed; the patient could move his right arm with the same facility as his left, and he was gaining such strength, that no doubts were entertained about the successful result of the operation. On the twenty-third day, hemorrhage came on from the wound: it was stopped by the introduction of lint and the employment of pressure. About twenty-four ounces of blood were lost, whereby the patient was so depressed that the pulse was no longer distinguishable. On the twenty-fourth day, in the evening, he lost four ounces more blood; on account of his restlessness and the painful state of his arm, two grains of opium were administered to him. After one or more returns of bleeding, he died on the twenty-sixth day.

When the body was opened, no traces of inflammation or its consequences were found either in the arch of the aorta, the origin of the innominata or the lungs. The aorta was now slit open longitudinally, and a probe then cautiously passed through it into the innominata, when the instrument went through the latter vessel into the cavity of the wound. The inner coat of the innominata was smooth and soft; but about half an inch from the place where the ligature had cut through the vessel, marks of inflammation were noticed, and a coagulum adhered to the sides of the artery with considerable firmness, so that nature had probably endeavoured, by means of adhesive inflammation, to close the vessel, but had been prevented from completing the salutary process by the destructive ulceration. One portion of the parietes of the innominata was thickened by inflammation, and an anomalous branch, as large as a crow's quill, arose from this artery.

The ulcer was twice as extensive inwardly as it was superficially, reaching laterally to the trachea, and under the clavicle to the swelling. The tripod of great vessels, viz. the innominata, the subclavian, and the carotid, was destroyed by ulceration to the extent of about an inch, and the ends of both the last vessels opened into the wound. At this place the pleura was considerably thickened by a layer of organized lymph.

The inner surface of the carotid was covered with a coagulum, and its coats so much thickened, that a probe could hardly be passed into it. The consolidation reached up to the division into the external and internal carotid. The subclavian was pervious as far as the situation of the disease. The diameter of the brachial and other arteries of the right arm was natural. The external mammary artery was enlarged, but not the internal. The clavicle was carious, and several lymphatic glands under it in the state of suppuration.

Though the result of the operation was unsuccessful, it proves, as Dr. Mott correctly remarks, some interesting points; namely, that tying an artery of such magnitude, and so near the heart, may be done without occasioning any disturbance either in the functions of the brain, the heart, the lungs, or the right arm.

The suppuration, which continually extended itself more and more deeply, is set down by Dr. Mott as the cause of the patient's death; for, as no bleeding took place for several days after the detachment of the principal ligature, it is plain that this must have fulfilled its duty, and that the artery had been closed.—(See *New-York Med. and Surgical Register*, 1818, *vol.* 1.)

[This new and formidable operation, the practicability of which Dr. Mott has thus demonstrated, and the safety of which is now decided in any future aneurism in which it may become necessary, is justly considered one of the most splendid achievements ever accomplished, and is destined to give the author's name immortality; and this, with the successful case of ligature of the iliacus communis, confers upon American surgery imperishable laurels. As an evidence of the estimation in which this operation is held in Europe, I feel a national pride in inserting the following extract of a letter from that distinguished surgeon, Professor Colles, of Dublin, written to Dr. Mott soon after his case of ligature on the innominata had reached him. I think this tribute to the able operator is the more important, since efforts have been made by the envious to detract from the merit of the operation; and it has been publicly stated that the same operation has been performed in Europe, and even by Dr. Colles himself. That this is not the fact will be obvious from the extract which follows, and which I introduce without any farther comment.

"I shall not attempt to say how much the profession is indebted to you for this bold and splendid operation. That it did not succeed I lament on your account; that it will hereafter succeed, there cannot be a doubt in

the mind of any reasoning man. Your feelings during the first twenty-two days after the operation are to be envied. The hopes of success continued so strong and so well founded, while the slight degree of uncertainty as to the issue must have exalted those feelings to the highest intensity. I have never read the account of an operation in which I would rather have been the operator."—*Reese.*]

The arteria innominata was also tied by Graefe on the 5th of March, 1822, in the Clinical Hospital of the University of Berlin, on account of a subclavian aneurism. The carotid was exposed and traced down to the innominata, to which a ligature was applied by means of a blunt tenaculum constructed for the purpose, the vessel being tied at most about an inch from the curvature of the aorta, and two inches from the heart. As soon as the ligature was tightened, the pulsation of the arteries of the right arm, right carotid, and right temporal artery ceased; at the same instant the throbbing of the aneurism stopped, and the tumour became flaccid. The constriction of the cord produced no disturbance of any function. The patient went on so well for several weeks afterward, that no doubt was entertained of his recovery. However, when the wound was nearly healed, hemorrhage came on, and though it was suppressed, and hope began to be again indulged, the bleeding recurred, and the patient died on the sixty-seventh day. Below the ligature the innominata was found closed with lymph. Graefe has written a distinct essay on the method in which the operation was done; the daily particulars of the case, and preparation from it, are placed in the Royal Anatomical Museum at Berlin.—(See *Journ. der Chirurgie von C. F. Gräefe, and Ph. v. Walther*, *b.* 3, *p.* 596, *&c.*, *b.* 4, *p.* 587.) Of Mr. Wardrop's practice of tying the subclavian artery in aneurism of the arteria innominata itself, we shall presently speak.

CAROTID ANEURISMS.

There is no part of the body where the diagnosis of aneurisms is more liable to mistake than in the neck. Here the disease is particularly apt to be confounded with tumours of another nature. We have already cited in this article examples in which aneurisms of the arch of the aorta so resembled those of the carotid as to have deceived the surgeon who was consulted. The swelling of the lymphatic glands, or of the cellular substance which surrounds the carotid artery, the enlargement of the thyroid gland, and especially abscesses, may resemble an aneurism by the pulsations communicated to them by the neighbouring artery. On the other hand, aneurisms of long standing, which no longer throb, and the integuments over which are changed in colour and likely to burst, may the more easily be mistaken by an inattentive practitioner for chronic abscesses, as the neck is remarkably often the seat of such diseases.—(*Boyer, Traité des Maladies Chirurgicales*, *t.* 2, *p.* 185.)

Scarpa mentions one unfortunate patient who was killed by a knife being plunged in a carotid aneurism, on the supposition that the case was an abscess.

I need scarcely observe, that by opening a carotid aneurism a surgeon would expose himself to the disgrace and mortification of seeing the patient die under his hands, as happened in the example cited by Harderus.—(*Apiar. Observationum*, *Obs.* 86.)

The possibility of tying the carotid artery in cases of wounds and aneurisms, without any injurious effect on the functions of the brain, is now completely proved. Petit mentions that the advocate Vieillard had an aneurism at the bifurcation of the right carotid, for the cure of which he was ordered a very spare diet, and directed to avoid all violent exercise. Three months afterward the tumour had evidently diminished; and at last it was converted into a small, hard, oblong knot, without any pulsation. The patient having died of apoplexy seven years afterward, the right carotid was found closed up and obliterated from its bifurcation, as low down as the right subclavian artery.—(*Acad. des Sciences de Paris*, *an* 1765.) Haller dissected a woman whose left carotid was impervious.—(*Opuscula Pathol. Obs.* 19, *tab.* 1.) An example of the total closure of both carotids in consequence of ossification, is stated by Koberwein to be recorded by Jadelot.—(*German transl. of Mr. Hodgson's work*, *p.* 293.) Hebenstreit, vol. 4, p. 266, ed. 3, of his translation of B. Bell's Surgery, mentions a case in which the carotid artery was wounded in the extirpation of a scirrhous tumour. The hemorrhage would have been fatal had not the surgeon immediately tied the trunk of the vessel. The patient lived many years afterward. This is probably the earliest authentic instance in which a ligature was applied to the carotid artery. Mr. Abernethy's case is perhaps the second: and that in which Mr. Fleming, a naval surgeon, tied the common carotid in a sailor who attempted suicide, and who was saved by the operation, is still later, not having occurred till the year 1803.—(See *Med. Chir. Journ. vol.* 3, *p.* 2.)

Dr. Baillie knew an instance in which one carotid was entirely obstructed, and the diameter of the other considerably lessened, without any apparent ill effects on the brain.—(See *Trans. for the Improvement of Med. and Chir. Knowledge*, *vol.* 1, *p.* 121.) Sir Astley Cooper has also recorded an example in which the left carotid was obstructed by the pressure of an aneurism of the aorta; and yet during life no paralysis nor impairment of the intellects had occurred.—(See *Med. Chir. Trans. vol.* 1, *p.* 223.) A similar case is related by Pelletan.—(*Clinique Chir. t.* 1, *p.* 68.)

Mr. Abernethy was under the necessity of tying the trunk of the carotid in a case of extensive lacerated wound of the neck, where the internal carotid and the chief branches of the external carotid were wounded. The patient at first went on well: but in the night he became delirious and convulsed, and died about thirty hours after the ligature was applied. This case fell under my own notice, and the inference which I drew was, that the man died more from the great quantity of blood which he lost, and the severe mischief done to the parts in the neck, than from any effect of the ligature of the artery on the brain.

In another instance in which the common carotid was tied, on account of a wound of the external carotid by a musket-ball, complicated with fracture of the condyle and coracoid process of the lower jaw, every thing went on favourably until the seventh day after the operation. Neither the intellectual faculties nor the functions of the organs of sense had been at all disturbed. But at that period stupor, confusion of ideas, restlessness, a small unsteady pulse, discoloration of the face, and loss of strength came on, followed in the evening by a violent paroxysm of fever. On the eighth day three copious hemorrhages took place from the whole surface of the wound, and on the ninth the man died. In this case, however, the affection of the brain, and the other unfavourable symptoms, would be ascribed by nobody to the effects of the ligature on the carotid, but every one would see the cause in the severe and extensive local mischief produced partly by the musket-ball, and partly by the mode in which the operation was performed, the surgeon having extended his incisions from the parotid gland to within an inch of the clavicle!—(See *Journ. Général de Méd. &c. par Sedillot.*)

That the carotid may be tied without injuring the functions of the brain, and that aneurisms of this artery admit of being cured by the operation, is now fully proved. The following is the second instance in which I have been present at the operation of tying the carotid trunk on account of a wound.

A soldier of the 44th regiment was wounded in the neck with a pike at the battle of Waterloo, and was brought to Brussels. After he had been some little time in the hospital, the bleeding, which had stopped, recurred with great violence, both from the mouth and the external wound itself; and it was therefore judged necessary to tie the common carotid, which was done by my friend Mr. Collier. The operation was performed by making an incision along the inner edge of the sterno-cleido-mastoideus, raising this muscle from the sheath including the artery, &c., and holding aside the jugular and lower thyroid veins, which swelled up every instant to a very large size, so as to overlap the artery. This vessel being disengaged from the nerve was then tied. Though the operation was done by candle-light it was skilfully performed, and reflects great credit on Mr. Collier. A detail of the case may be found in a modern work.—(*Med. Chir. Trans. vol.* 7, *p.* 107.)

Another example in which the carotid artery was tied and the patient saved, in a case where it was wounded with a penknife, was published by Dr. John Brown, surgeon to the county of Meath Infirmary.—

(See *Dublin Hospital Reports, vol.* 1, *p.* 301, *&c.*) In this instance, the internal jugular vein "did not appear, nor was it a source of the slightest inconvenience during the operation."—(*P.* 305.) A case, very analogous to the foregoing, is recorded by Mr. Hodgson, and the event equally successful. "The jugular vein afforded no trouble in the operation: it was not even seen." A gradual improvement of the power of deglutition marked the gradual subsidence of the tumour, which pressed against the pharynx. Nor was any changed perceived in the state of the patient's mind after this operation, who remained as she had been previously, melancholy and dejected.—(*P.* 332.)

Acrel mentions an example in which the carotid artery was wounded by a gun-shot, and the hemorrhage permanently stopped by compression. A similar case is related by Van Horne, in his annotations to the work of Botallus.—(*De Vuln. Sclopetus.*) Baron Larrey has likewise related a case in which the carotid was wounded by a musket-ball, and life saved by the instant application of pressure.—(*Mém. de Chir. Mil. t.* 1, *p.* 309.) However, considering the size of the vessel, and its unfavourable situation for being effectually and steadily compressed, some doubts may be entertained, whether the vessel wounded might not rather have been one of its branches.

November 1, 1805, Sir Astley Cooper operated on Mary Edwards, aged forty-four, who had an aneurism of the right carotid artery: the tumour reached from the vicinity of the chin to beyond the angle of the jaw, and downwards to within two inches and a half from the clavicle.

The swelling had a strong pulsatory motion. The woman also complained of a particular tenderness of the scalp on the same side of the head, and of such a throbbing in the brain as prevented her from sleeping.

An incision, two inches long, was made at the inner edge of the sterno-cleido-mastoideus muscle, from the lower part of the tumour to the clavicle. This wound exposed the omo-hyoideus and sterno-hyoideus muscles, which being drawn aside towards the trachea, the jugular vein presented itself to view. The motion of this vein produced the only difficulty in the operation, as, under the different states of breathing, the vessel sometimes became tense and distended under the knife, and then suddenly collapsed. Sir Astley Cooper introduced his finger into the wound to keep the vein out of the way of the knife, and having exposed the carotid artery by another cut, he passed two ligatures under this vessel by means of a curved aneurism-needle. Care was taken to exclude the recurrent nerve on the one hand, and the par vagum on the other. The ligatures were then tied about half an inch asunder; but the intervening portion of the artery was left undivided.

The pulsation of the swelling ceased immediately the vessel was tied; and on the day after the operation, the throbbing in the brain had subsided, while no diminution of nervous energy in any part of the body could be observed.

The patient was occasionally afflicted with bad fits of coughing, but upon the whole went on at first pretty well. On the eighth day, however, a paralysis of the left leg and arm was noticed, attended with a great deal of constitutional irritation. November 8th, the patient could move her arm rather better; but became unable to swallow solids. Nov. 12th, the palsy of her arm had now almost disappeared. The ligatures came away. Nov. 14th, she was in every respect better; she swallowed with less difficulty; and the tumour was smaller, and quite free from pain. On the 17th, she became very ill; the tumour increased in size, and was sore when pressed. The wound was as large as immediately after the operation, and discharged a sanious serum. Great difficulty of swallowing, and a most distressing cough were also experienced. The pulse was ninety-six, and the left arm again very weak. On the 21st, the patient died, the difficulty of swallowing having previously become still greater, attended with a farther increase of the tumour, the skin over which had acquired a brownish-red colour.

On opening the swelling after death, the aneurismal sac was found inflamed, and the clot of blood in it was surrounded with a considerable quantity of pus. The inflammation extended on the outside of the sac, along the par vagum, nearly to the basis of the skull. The glottis was almost closed, and the lining of the trachea was inflamed and covered with coagulating lymph. The pharynx was so compressed by the tumour, which had been suddenly enlarged by the inflammation, that a bougie of the size of a goose-quill could hardly be introduced into the œsophagus. Sir Astley Cooper concludes with expressing his opinion that *these causes of failure may, in future, be avoided by operating before the tumour is of such size as to make pressure on important parts; or, if the swelling should be large, by opening it, and letting out its contents, as soon as inflammation comes on.*—(See *Med. Chir. Trans. vol.* 1.)

In one case under the care of Mr. Coates, of Salisbury, the making of an opening, about a month after the operation, gave relief by discharging seven ounces of fetid blood and pus; but three weeks afterward, hemorrhage came on from the sac, and the patient was carried off by repeated loss of blood. On dissection, an artery capable of admitting a probe was found to pass into the cavity of the sac.—(See *Med. Chir. Trans. vol.* 11, *part* 2.)

In June, 1808, Sir Astley Cooper operated, in Guy's Hospital, on a man aged 50, who had a carotid aneurism, attended with pain on one side of the head, throbbing in the brain, hoarseness, cough, slight difficulty of breathing, nausea, giddiness, &c. The patient got quite well, and resumed his occupation as a porter. There was afterward no perceptible pulsation in the facial and temporal arteries of the aneurismal side of the face.

On the opposite side, the temporal artery became unusually large. The tumour was at last quite absorbed, though a pulsation existed in it till the beginning of September. The man's intellects remained perfect; his nervous system was unaffected; and the severe pain, which before the operation used to affect the aneurismal side of the head, never returned.

The swelling, at the time of the operation, was about as large as a pullet's egg, and situated on the left side about the acute angle made by the bifurcation of the common carotid, just under the angle of the jaw.

Sir Astley Cooper began the incision opposite the middle of the thyroid cartilage, at the base of the tumour, and extended the wound to within an inch of the clavicle, on the inner side of the sterno-cleido-mastoideus muscle. On raising the margin of this muscle, the omo-hyoideus could be distinctly seen crossing the sheath of the vessels, and the nervus descendens noni was also brought into view. The sterno-cleido-mastoideus was now separated from the omo-hyoideus, when the jugular vein was seen. This vessel became so distended at every expiration as to cover the artery. When the vein was drawn to one side, the par vagum was manifest, lying between that vessel and the carotid artery, but a little to the outer side of the artery. The nerve was easily avoided.

A double ligature was then conveyed under the artery with a blunt iron probe. The lower ligature was immediately tied, and the upper one was also drawn tight, as soon as about an inch of the artery had been separated from the surrounding parts above the first ligature, so as to allow the second to be tied at this height. A needle and thread were passed through the vessel below one ligature, and above the other. The artery was then divided. In a little more than nine weeks, the wound was quite healed, and the patient entirely recovered.—(See *Med. Chir. Trans. vol.* 1.)

Another successful instance, in which the carotid was tied for the cure of an aneurism, is related in a work to which I always have the greatest pleasure in referring.—(See *Hodgson's Treatise on the Diseases of Arteries, p.* 329.)

Mr. Travers tied the carotid artery in a woman, who had an aneurism by anastomosis in the left orbit. The disease had pushed the eye out of its socket. Two small ligatures were applied, which came away on the twenty-first and twenty-second days. No hemorrhage, nor impairment of the function of the brain took place, and the disease in the orbit was effectually cured.—(See *Med. Chir. Trans. vol.* 2.)

Another highly interesting example, in which an aneurism by anastomosis in the orbit was effectually cured by tying the carotid artery, is recorded by Mr. Dalrymple, surgeon at Norwich. This gentleman performed the operation on the 12th of November, 1812. The patient was a female, aged 44. The protrusion of the eye was relieved in proportion as the swelling

diminished. The violent headaches also subsided; but the eyesight was irrecoverably lost.—(See *Med. Chir. Trans. vol.* 6, *p.* 111.)

The carotid artery has sometimes been tied, with the view of enabling the surgeon to cut away swellings from the neck and side of the face, where, from particular circumstances in the cases there was reason to fear a fatal hemorrhage without that preliminary measure.—(See *Goodlad's and Arenat's Cases, in Med. and Chir. Trans. vols.* 7 *and* 12.)

An interesting case, in which my friend Mr. Vincent tied the carotid trunk for an aneurism, is published in the 10th vol. of the latter work.—(*P.* 212, &c.) In this example, the internal jugular vein did not appear to be at all in the way during the operation; some of the fibres of the omo-hyoideus, however, could not be conveniently drawn aside, and were therefore divided. A single ligature was applied; the pulsation in the tumour did not entirely cease, at first, when the artery was tied, but it did so two days afterward; and the swelling was rapidly diminishing. The ligature came away about three weeks after the operation, and there was every hope of a cure; but, between the fourth and fifth week, a considerable swelling occurred between the wound and the jaw, impeding deglutition, but not the breathing. This state was followed by febrile symptoms, increased difficulty of swallowing, an attack of coughing, and impeded respiration. In the hope of affording relief, an incision was made in the tumour, from which a small quantity of pus and coagulum issued; but it was in vain, for the patient was dying. On dissection, the carotid artery was found perfectly closed as far as the division of the arteria innominata. But above where the ligature had been, the vessel was open and inflamed, and pus was found in it. The most remarkable circumstance noticed was globules of air, adhering to the inner surface of the aorta, and other large arteries, and found also under the tunica arachnoidea. The bulk of the swelling in the neck depended upon effusion of serum in the cellular membrane.

In order to get at the carotid artery in the safest manner, Mr. Abernethy has recommended making an incision on that side of it which is next the trachea, where no important parts are exposed to injury, and then to pass a finger underneath the vessel. The par vagum must be carefully excluded from the ligature; for to tie it would be fatal.—(*Surgical Observations*, 1804.)

The cure of carotid aneurisms by the operation has now been so often exemplified, that even to refer to every case upon record would demand more space than I can afford. A successful instance is reported by Macaulay (*Edin. Med. Surg. Journ. April*, 1814); another by Dr. Post, who used two ligatures, and divided the artery in the space between them (*New-England Journ. of Medicine and Surgery, vol.* 3, *p.* 205, *Boston*, 1814); another by Mr. Giles Lyford, proving the sufficiency of a single ligature.—(*Med. Chir. Trans. vol.* 11, *p.* 97, &c.) The case in which Mr. Goodlad tied the carotid, in order to prevent hemorrhage in the removal of a tumour involving the parotid gland, is contained in *vol.* 7, *p.* 112, &c. of the latter book. The example in which the carotid was tied by Dr. Fricke, in the hospital at Hamburgh, for the cure of a diseased parotid, is reported in the *Lancet*, *No.* 182. Some diminution of the swelling, and increased power of swallowing followed; but suppuration took place, and the case ended fatally.

The best anatomical engravings of the parts concerned in the operation of taking up the carotid artery, are those by Tiedemann and Rosenmüller.—(See *Chirurg. Anatom. Abbildungen, th.* 1, *tab.* 7, 8, 9.)

For the particulars of a carotid aneurism cured by the ligature of the artery by M. Dumont, see *Diss. sur l'Aneurisme de l'Artère carotide, par P. J. Vanderhagen, Paris*, 1815. Walther, of Landshut, in the year 1814, tied the carotid artery for the cure of an aneurism with complete success: he applied only a single ligature.—(*Breschet, Fr. transl. of Mr. Hodgson's work, t.* 2, *p.* 83.) In this translation are reported several instances, in which Dupuytren and other continental surgeons applied a ligature to the carotid. Dr. Holscher, of Hanover, has also operated with success.—(See *Lond. Med. Repository, vol.* 16, *No.* 94.)

[Dr. Bushe has lately tied the common carotid for an aneurism situated in the fauces, with complete success. Professor Pattison, of the University of London, when resident in Baltimore, cured an immense aneurism of the internal maxillary by tying the trunk of the carotid. I witnessed this operation, and saw the successful result.—*Reese.*]

Of the plan of tying the carotid above the aneurism, when it is situated so low that the ligature cannot be applied below it, I have also spoken. The facts, by which the propriety of this practice has now been completely established, have also been noticed: they appear to me to reflect considerable credit on Mr. Wardrop, by whom this method of operating has been revived and extended. The practice of tying the carotid for the cure of aneurism of the arteria innominata will be noticed in the ensuing section.

NEW OPERATION FOR ANEURISM OF THE ARTERIA INNOMINATA.

It having been established, that aneurisms may be cured by simply lessening the impetus of the blood flowing through them, and that, although a circulation may yet continue in them for some time, the layers of coagulable lymph within the sac will augment, and ultimately bring about a complete consolidation of the swelling, it occurred to Mr. Wardrop, that in aneurism of the arteria innominata, the progress of the disease might be arrested by tying its two great branches, the carotid and subclavian. Although a certain portion of blood would still continue to pass along the innominata to those branches of the subclavian on the cardiac side of the ligature, the ligature being necessarily placed on the subclavian artery after it emerges from between the scaleni muscles, Mr. Wardrop conceived, that such would yet be the diminution of the impetus of the blood in the sac, that the future increase of the tumour would be prevented, and even a permanent obliteration of the aneurismal cavity would be accomplished.—(*On Aneurism*, *p.* 58.) The knowledge of this principle, indeed, he thinks, may be useful in the cure of many aneurisms, which have hitherto been considered beyond the reach of art. In an aneurism of the innominata, Mr. Mackelcan found that nature had nearly completed a cure of the disease on this principle. The carotid artery was plugged up, and the large aneurismal swelling was filled with a coagulum, leaving only a comparatively small channel for the passage of the blood into the subclavian artery.—(See *Appendix to Wardrop on Aneurism.*) Mr. Wardrop has seen some cases, and several are on record, which illustrate the same important pathological fact, and prove beyond a doubt, that blood can coagulate in an aneurism so as to strengthen the parietes of the sac, and ultimately fill its cavity, without the circulation in the sac being in the first instance either suddenly or entirely interrupted.

It was the knowledge of this fact that led Mr. Wardrop to perform the operation, which he has related. Nature, in the case alluded to, had already instituted a curative process by diminishing the circulation in the carotid artery; and when he found this alone not sufficient to stop the enlargement of the aneurism, he determined to place a ligature on the subclavian. In doing this, he conceived that he was strictly imitating the process which nature herself had commenced.—(*P.* 61.) The case of Mrs. Denmark, aged 45, in whom he tied the subclavian artery, and thus cured an aneurism of the arteria innominata, is highly interesting. The particulars may be read in his own publication, or in the *Lancet* for 1827. Suffice it here to state, that the disease was completely cured. In the appendix to Mr. Wardrop's publication, and in the *Lancet* for Novem ber, 1828, is another highly important case, confirming the accuracy of the principles explained by this ingenious surgeon. It is an example in which Mr. Evans, of Belper, Derbyshire, successfully treated an aneurism of the innominata and root of the carotid, by tying the latter vessel. In the end, the patient, a butcher and horse-dealer, thirty years of age, was well enough to attend regularly the markets and fairs of Derby, seven miles from his home. In the course of the case, three remarkable circumstances occurred: 1st, An obliteration of the large arteries of the right arm. 2dly, A profuse salivation. 3dly, A disposition to paralysis of the right side, supposed by Mr. Evans to have arisen from a greater quantity of blood being sent to the left hemisphere of the brain than to the right. However, as such paralysis has not attended

other operations in which the carotid was tied, the truth of the explanation seems doubtful. The palsy afterward nearly subsided.

[It affords me high gratification to record, that Professor Mott, of this city, has lately performed this operation for the first time it has been attempted in America, by tying the carotid artery for aneurism of the arteria innominata, involving the subclavian and root of the carotid. This is the first time in America in which aneurism has been treated by tying the artery on the anticardial side of the tumour. The report of the case, and its successful result, is contained in the American Journal of the Medical Sciences, No. 10, for February, 1830. Since that report was published the patient has died, and the tumour having been removed, fully establishes the success of the operation. I have had an opportunity of examining the preparation, and found the carotid entirely obliterated and impervious above the aneurismal sac, although the ligature was applied very high on that vessel. The death was occasioned by the displacement and distortion of the trachea and larynx, which are seen lying on the side of the neck, and in no wise connected with the operation, but was the consequence of the long existence of the disease before the oper tion was submitted to.—*Reese.*]

OF ANEURISMS OF THE AORTA, AND VALSALVA'S TREATMENT.

This afflicting and fatal disease is by no means unfrequent, and the arch of the aorta is its most common situation. Dr. Hunter was of opinion that the latter circumstance depended on the forcible manner in which the blood, propelled from the left ventricle of the heart, must be driven against the angle of the curvature of the vessel.

Mr. A. Burns considered aneurism of the thoracic aorta more frequent, perhaps, than that of any other vessel in the body. "I have had (says he) an opportunity of examining fourteen who had died of this disease, but have not seen more than three instances of external aneurism."—(*On Diseases of the Heart, &c. p.* 215.)

These proportions, however, would not correspond to common observation, external aneurisms, taken collectively, being supposed to be about as numerous as those of the aorta alone, a calculation long ago made by Dr. A. Monro, primus.

It was the opinion of Dr. W. Hunter that the aneurismal sac was composed of the dilated coats of the artery, which parts nature thickened and studded with ossifications after the origin of the disease, for the purpose of resisting its increase. Mr. Hodgson, also, in his late excellent publication declares his decided belief, and adduces facts to prove, that many aneurisms of the aorta are formed by dilatation. Scarpa argues, however, that the generality of aneurisms of the aorta are the consequence of a rupture of the proper coats of this large vessel; and that the cellular sheath of the artery is what becomes distended into the thickened and ossified aneurismal sac.

Dr. W. Hunter considered the ossifications of the sac as consequences of the disease: but Haller looked upon such scales of bone in the aorta as the very cause of the affection, by rendering the artery inelastic, and incapable of yielding to each pulsation of the heart.

It is unquestionably true that aneurisms of the aorta are most common in persons who are advanced in life, and it is equally well known, that the aorta of every old subject, whether affected with aneurism or not, is almost always marked in some place or another with ossifications, or rather with calcareous concretions. Such productions appear to occasion a decay or absorption of the muscular and inner coats of the vessel, so that at length the force of the blood makes the artery give way, and this fluid, collecting on the outside of the laceration or rupture, gradually distends the external sheath of the artery into the aneurismal sac, which itself becomes at last of considerable thickness, and studded with ossified specks.

"If any person who is not prejudiced in favour of the common doctrine with regard to the nature and proximate cause of this disease (says Scarpa), will examine, not hastily and superficially, but with care and by dissection, the intimate structure and texture of the aneurism of the aorta, unfolding with particular attention the proper and common coats of this artery, and in succession those which constitute the aneurismal sac, in order to ascertain distinctly the texture and limits of both, he will clearly see that the aorta, properly speaking, contributes nothing to the formation of the aneurismal sac, and that, consequently, the sac is merely the cellular membrane, which in the sound state covered the artery, or that soft cellular sheath which the artery received in common with the neighbouring parts. This cellular substance, being raised and compressed by the blood effused from the corroded or lacerated artery, assumes the form of a circumscribed tumour, covered externally, in common with the artery, by a smooth membrane, such as the pleura in the thorax and the peritoneum in the abdomen."

Scarpa then comments upon the differences of mere dilatation of an artery from aneurism, a subject which has been already fully considered in the foregoing pages.—(*Scarpa on the Anatomy, Pathology, and Surgical Treatment of Aneurism, transl. by Wishart, p.* 55, 56.)

As I have already explained in the preceding columns, the sentiments of this eminent anatomist are not adopted by the generality of surgeons; or rather, his doctrine is not carried by others to the extent which he has insisted upon; and it would be useless repetition to bring before the reader again the facts which prove that his statements are liable to many exceptions. A case, however, recited by Roux, which I have met with since the foregoing pages were printed, merits notice; it was an instance in which a popliteal aneurism, unattended with pulsation, had been mistaken for an abscess and punctured, whereby the patient lost his life. On dissecting the limb, Roux says, "the three coats of the artery participated in the dilatation, and the case was one of the clearest specimens which I have ever seen of a true aneurism."—(*Nouveaux Elémens de Méd. Opératoire, t.* 1, *p.* 517.)

All arguments brought against the possibility of a dilatation of the inner coat, and founded on the inelastic structure of that membrane, must likewise be completely refuted by another fact demonstrated by morbid preparations, collected by Dubois and Dupuytren, where the inner coat of the aorta is alone dilated, protruding through the outer tunics in the form of a distinct swelling somewhat like a hernia.—(*Roux, op. cit. p.* 49.)

In whatever manner aneurisms of the aorta are formed, there are no diseases which are more justly dreaded, or which more completely fill the surgeon as well as the patient with despair. No affliction, indeed, can be more truly deplorable; for the sufferings which are occasioned hardly ever admit even of palliation, and the instances of recovery are so very few, that no consolatory expectation can be indulged of avoiding the fatal end to which the disease naturally brings the miserable sufferer.

The existence of aneurisms of the aorta is scarcely ever known with certainty before they have advanced so far as to be attended with an external pulsation and a tumour that admits of being felt or even seen. In very thin subjects, the throbbing of the abdominal aorta is sometimes unusually plain through the integuments and viscera, and this has occasionally given rise to the suspicion of an aneurism; a circumstance which deserves to be remembered by every surgeon desirous of not pronouncing a wrong opinion. The preternatural pulsations, however, which are liable to be mistaken for those of aortic aneurisms, are of various kinds, and form a subject to which the attention of Dr. Albers, of Bremen, the late Mr. A. Burns, and others, has been very usefully directed.—(See *Abdomen.*)

While thoracic aneurisms of the aorta are accompanied with no degree of external swelling, the symptoms are all equivocal, and might depend on a disease of the heart, angina pectoris, phthisis pulmonalis, &c. However, some difference depends upon the volume, position, and nature of the aneurism. As Laennec observes, simple dilatation, when in a moderate degree, hardly produces any effect, but the most inconsiderable false aneurisms may give rise to very serious disorder. The first and most common of these effects is, the compression of the heart and lungs.—(See *Laennec on Diseases of the Chest, by Forbes, p.* 676, *ed.* 2.) Violent and irregular throbbings frequently occur between the fourth and fifth true ribs of the left side: the same irregularity of the pulse prevails as often proceeds from organic affections of the heart; a dissimilarity of the pulse in the two wrists; the respiration

is exceedingly obstructed; the voice altered; and in a more advanced period of the malady the patient is at times almost suffocated. The pressure of the internal swelling on the trachea, bronchia, and lungs, is sufficient to account for this difficulty of breathing. In many instances the irritation and compression produced by the tumour occasion an absorption of the greater part of the lungs, and abscesses and tubercles throughout the portion which remains. Even the function of deglutition suffers interruption in consequence of the pressure made on the œsophagus, which may even be in a state of ulceration. Thus, in an example recently published, we read that "the cavity of the windpipe was nearly obliterated from the pressure of the aneurism; and the extremities of four of its cartilages lay in the œsophagus, having entered that canal through an ulcer in its coat."—(*Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 3, *p.* 83.)

After what has been stated, it cannot be surprising, that ere the disease manifests itself externally, affections of the lungs or strictures of the œsophagus should often be suspected.—(*Hodgson, p.* 91.)

An aneurism of the arteria innominata, not discovered till after the patient had died of suffocation, gave rise to great difficulty of drawing air into the chest without any other symptom calculated to throw light on the nature of the disease. The aneurismal swelling was situated behind the first bone of the sternum, and pressed upon the trachea. The front of this tube was pushed in by the tumour so as to present a convex prominence on the inner surface, which, however, diminished its area in a very slight degree. Mr. Lawrence adduces this fact to prove that spasm of the air-cells may be the cause of great distress in breathing. "The termination of this case (says he) is the more remarkable, inasmuch as in another patient an aneurism rising out of the arch of the aorta, and pressing on the corresponding part of the trachea, so as to produce ulceration of the internal membrane, under which there was a slight appearance of coagulated blood, caused no affection of the breath at all. The person died of a different complaint, and the discovery of the aneurismal tumour, which was very small, and filled with firm laminated coagula, was quite accidental."—(*Med. Chir. Trans. vol.* 6, *p.* 227.)

Thus we find in thoracic aneurisms, at least previously to their attainment of a certain size, that no regularity prevails even with regard to difficulty of breathing, the symptom which, *à priori*, one might suppose would invariably be present.

Few diseases, according to Laennec, are so insidious as aneurism of the thoracic aorta. He affirms, that "it cannot be known with certainty till it shows itself externally. It can hardly be suspected even when it compresses some important organ, and greatly deranges its functions. When it produces neither of these effects, the first indication of its existence is often the death of the individual, as instantaneously as if by a pistol-bullet." One case, recorded by Mr. Pattison, confirms the same fact, for the patient had only symptoms leading to a suspicion of rheumatism in the neck, and died suddenly of apoplexy.—(*Burns on the Head and Neck, ed. by Pattison.*) Laennec has known persons cut off in this manner who were believed to be in the most perfect health. He admits that percussion will sometimes enable us to detect a tumour of large size existing within the mediastinum, or even in the back; but not to discriminate the nature of the swelling. His experience had not been sufficient to let him pronounce how far the difficulty of diagnosis was likely to be removed by the stethoscope. However, aneurisms of the abdominal aorta, he says, are recognised with the utmost facility by means of this instrument. In this case we are sensible of tremendous pulsations which painfully affect the ear, and the intensity of which is not at all recognised by the hand, even when sufficiently perceptible to the touch. As high up as the cœliac artery the contractions of the auricles are not in the least distinguishable. The sound of the pulsations is described as clear and loud.—(*Laennec on Diseases of the Chest, p.* 678, *&c.*)

I have mentioned that the symptoms of thoracic aneurisms, previously to the formation of any outward swelling, often resemble those of phthisis, and the latter is sometimes actually supposed to be the disease under which the patient is labouring. But there is one distinction between the cases, which is pointed out by Mr. Hodgson, and may be of use, in combination with other circumstances, in facilitating the diagnosis: "in phthisis, the expectoration is either puriform or thick and clotted; but in aneurisms which are not accompanied with disease in the lungs, as far as I have observed, it always consists of a thin frothy mucus.—(*On Diseases of Arteries, &c. p.* 93.)

According to Kreysig's experience, the cough comes on at irregular periods, is violent, and attended with great efforts, the expectorated matter being forced up by the vehemence. He agrees with Mr. Hodgson respecting the general quality of what is expectorated, where thoracic aneurisms are not complicated with diseased lungs; but he says that the matter coughed up also frequently consists of masses of lymph blended with brick-red particles of blood, which masses, when thrown into water, seem as if they were composed of a ball of stringy substances.—(*German transl. of the latter work, p.* 137.)

From a review of many cases of aortic aneurisms, Mr. A. Burns was inclined to think, that when the ascending aorta is aneurismal, the breathing is more affected than when the arch of the vessel is enlarged, but that in the latter case the impediment to deglutition is greatest.—(*On Diseases of the Heart, &c. p.* 244.)

According to Laennec, false aneurisms are most common in the descending aorta; and true ones in the ascending portion of the vessel and its arch. He has never met with any species of false aneurism in the latter situation, but such as is consequent to the true or simple dilatation of the artery.—(See *Laennec on the Diseases of the Chest, p.* 676, *ed. by Forbes.*)

The way in which aneurisms of the thoracic aorta prove fatal, is subject to considerable variety. These swellings do not always destroy the patient by hemorrhage; in numerous instances, the magnitude of the disease so impedes respiration, that death seems induced by suffocation, and not a drop of blood is found internally effused. Frequently (to use the description of Mr. John Bell), before the awful and fatal hemorrhage has had time to occur, the patient perishes of sufferings too great for nature to bear. The aneurismal tumour so fills the chest, so oppresses the lungs, compresses the trachea, and curbs the course of the descending blood, that the system with a poor circulation of ill-oxydated blood, is quite exhausted. And thus, though the patient is saved from the most terrible scene of all, he suffers great miseries; he experiences in his chest severe pains, which he compares with the stabbing of knives; terrible palpitations; an awful sense of sinking within him; a sound within his breast, as if of the rushing of waters; a continual sense of his condition; sudden startings during the night; fearful dreams and dangers of suffocation; until with sleepless nights, miserable thoughts by day, and the gradual decline of an ill-supported system, he grows weak, dropsical, and expires.—(See *Anatomy of the Human Body, by John Bell, vol.* 2, *edit.* 3, *p.* 234, 235.)

Mr. A. Burns saw two examples, in which the patients died instantaneously, though their aneurismal tumours were very small and had not burst. Both these patients were in the early stage of pregnancy.—(*On Diseases of the Heart, p.* 236.)

The situations in which aneurisms of the curvature of the aorta burst, are different in different cases. Sometimes the swelling bursts into the cavity of the chest, or that of the pericardium, and the patient drops suddenly down. According to Laennec, the left cavity of the pleura is by far the most frequent situation in which the thoracic aneurisms of the aorta burst.—(*On Diseases of the Chest, p.* 677.) When the coats of the aorta give way within the pericardium, where they only receive a slight external membranous covering, this is apt to be also ruptured at the same time, so as to bring on copious effusion of blood, which oppresses the action of the heart, and produces immediate death. In other examples, the blood is effused into the trachea or bronchia, and the patient, after violent coughings and ejections of blood from the mouth, expires. Sometimes, after the tumour has become closely adherent to the lungs, it bursts into the air-cells, through which the blood is widely diffused. An example of this termination of the disease was observed by Laennec; who also saw another case, in which, if the patient had lived a little longer, the same occurrence in all probability would have happened. Ehrhardt says, that he is not

aware, that this mode of rupture has been noticed by other writers.—(*De Aneurysmate Aortæ, p.* 21, 4*to. Lips.* 1820.)

The most remarkable local effects of aneurisms of the aorta are those on the vertebral column. They often destroy it to a very great depth. This is entirely the work of interstitial absorption, there never being any mark of suppuration. On the side next the vertebræ, the sac is completely destroyed, and the circulating blood is bounded by the naked bone. In certain cases, the swelling beats its way through the ribs; even the spinal marrow may be injured, and the patient suffer a species of death somewhat less violent and sudden. In one case of an enormous aneurism of the abdominal aorta, reported in No. 259 of the *Lancet*, the left leg and thigh were much wasted and quite paralytic. This seemed to arise from the pressure on the nerves of the lower extremity, and not from injury of the medulla spinalis. But, although aneurisms in the chest do sometimes protrude at the back, a circumstance that depends on the particular situation of the disease (see *Pelletan, Clinique Chir. t.* 1, *Obs.* 7, *p.* 84), they more commonly rise towards the upper part of the breast, where a throbbing tumour occurs, which has caused an absorption of the opposing parts of the ribs and sternum; and sometimes dislocated the clavicles. Corvisart saw an instance, in which an aneurism of the aorta had dislocated the sternal extremity of the clavicle; and Duverney makes mention of a case, in which, besides the displacement and injury of the clavicle, the sternum and scapula were partially destroyed. Guattani speaks of an example, in which the clavicle was bent by a large aneurism, of which a portion as large as a pigeon's egg projected above the bone.—(*Lauth, p.* 168.) And Morgagni has described a case, where the upper bone of the sternum, the sternal ends of the clavicles, and the adjoining ribs were destroyed by the pressure of a large aneurism of the front of the curvature of the aorta, and the disease presented itself externally somewhat in the form of a bile. —(*Epist.* 26, *art.* 9.)

The swelling now pulsates in an alarming way. The blood is only retained by a thin covering of livid skin, which is becoming thinner and thinner. At length a point of the tumour puts on a more conical, thin, and inflamed appearance than the rest; a slough is formed, and on this becoming loose, the patient is sometimes instantaneously carried off by a sudden gush of blood.

An extraordinary case of aneurism of the aorta is related by Dr. C. W. Wells. The disease being unattended with any external swelling, it seems, was not comprehended during the patient's lifetime.

The following is an abstract of the case. Mr. A. B., a gentleman, thirty-five years of age and temperate in his habits, became affected in 1789 with symptoms which were thought to denote the approach of pulmonary consumption. These, however, after some time entirely disappeared. In 1798 he was attacked with a slight hemiplegia, from which he also recovered, with the exception of an inconsiderable sense of coldness in the foot, which had been paralytic. In March, 1804, he complained of being frequently troubled with a noise in his ears, flatulence in his bowels, and pains in his hands and feet, sometimes attended with slight swellings in the same parts. From one or more of these symptoms he was never afterward quite free; but he did not complain of any unusual feelings in his chest. August 11, 1807, he fatigued himself considerably with walking; ate rather a hearty dinner; and, having refreshed himself with some sleep afterward, he played about with his children. While thus amusing himself, he was suddenly seized, between eight and nine o'clock, with great oppression in his chest. He soon afterward became sick, and in the matter thrown up, some streaks of blood were observed. He now went to bed; but, though the weather was warm and he was covered with bed-clothes, his skin felt cold to the attendants. At midnight he laboured under a constant cough, and expectorated mucus tinged with blood. His body was moistened with a cold sweat, and his pulse was extremely feeble; sometimes it was scarcely perceptible. About five in the morning his pulse was feeble and irregular; his breathing difficult, his skin pale and cold, and covered with a clammy sweat. He frequently tossed and writhed his body, as if he was suffering great pain or uneasiness. The mental faculties, however, seemed unimpaired. Shortly afterward he expired, having complained, just before his death, of much heat in his chest, and thrown off the bed-clothes.

The most remarkable circumstance found on opening the body is thus recorded:—"The ascending aorta was distended to about the size of a large orange. The tumour adhered to the pulmonary artery, just before its division into the right and left branches. Within the circumference of this adhesion there was a narrow hole, by means of which a communication was formed between the two arteries."

Dr. Wells concludes with observing, that though such a disease might easily have been imagined, he had found no instance of it in books, and that it had not been observed by any of the surgeons or anatomists in London. He supposed, that the communication between the aorta and pulmonary artery, took place on the evening before the patient's death, when the oppression of the chest was first felt: and that, in consequence of the superior strength of the left side of the heart, a part of the blood which was thrown into the aorta must have been forced into the pulmonary artery, from which circumstance he conjectures most of the symptoms originated.—(*Trans. of a Society for the Improvement of Med. and Chir. Knowledge, vol.* 3, *p.* 85.)

The bursting of an aneurism of the aorta into the pulmonary artery, is then another possible mode in which the disease may prove fatal.

Besides the example of this nature reported by Dr. Wells, several others are detailed by writers.—(See *Bulletin de la Faculté de Médecine, No.* 3, *in which there are two cases; Sue, in Journ. de Méd. continué, t.* 24, *p.* 124; *and in Bulletin de la Faculté, &c. t.* 17, *p.* 16.)

Aneurisms of the arch of the aorta are stated to have adhered to, and burst into, the right auricle of the heart, and thus to have produced instant death.—(See *Med. Chir. Journ. vol.* 6, *p.* 617. *Bulletin de la Société de Médecine à Paris,* 1810, *No.* 3, *p.* 38.)

The cases recorded in which aneurisms of the thoracic aorta have burst into the œsophagus, are beginning to be more numerous than formerly. Bonetus and Morgagni relate no examples of it; nor are there any in the comprehensive treatises of Scarpa and Hodgson. Corvisart speaks of an instance which had been seen by Dupuytren, of which, however, no description is given. Yet the possibility of the occurrence is not a matter of speculation or doubt.

A case of this description is noticed by Matani (*De Aneurism. Præcordiorum Morbis, p.* 120); another is alluded to by Ehrhardt, as being related by Copeland (*Comment. de Aneurismate Aortæ, p.* 22, *et Cerutti Catal. Prop. Pathol.*); an instance is described by Bertin (See *Bulletins de la Faculté de Méd.* 1810, *p.* 14); and a very interesting one, attended with disease of the spinal cord and paralysis, is given by Dr. Molison. —(See *Edin. Med. Chir. Trans. vol.* 3, *p.* 173.)

Sauvages is one of the writers who have adduced proofs of this mode of rupture: *cadavere aperto, inveni ventriculum septem vel octo libris sanguinis distensum, aortam ad brachii magnitudinem, per spatium septem vel octo pollicum dilatatam, et orificium denarii magnitudine aortæ, et œsophago continuo commune, quod tamen quinque cristæ carneæ, veluti valvulæ ex ambitu orificii oriundæ et circumpositæ potuerunt obturare. Per hoc orificium, sanguis ex aorta fluxerat in œsophagum.*—(*Nov. Method. t.* 2, *p.* 298.) A similar case has been recently published by Bricheteau.—(See *Bulletin de l'Athenée de Méd. de Paris, Dec.* 1816.) Laennec met with three examples of death from this cause.—(*On Dis. of the Chest, p.* 677, *ed. by Forbes.*) The same distinguished professor met with an aneurism of the descending aorta, where the tumour had made such pressure on the thoracic duct, that this tube was partly destroyed, and all the lymphatic vessels were found uncommonly turgid.—(*Journ. de Méd. par Corvisart, t.* 2, *p.* 15.) With the exception, perhaps, of one instance given on the authority of Lancisi (*Lauthii Collect. p.* 38), no other example of this description is upon record.

An instance is reported by Corvisart, in which the pressure of an aneurism of the ascending aorta had nearly obliterated the termination of the lower vena cava, and a fatal attack of apoplexy was the consequence.—(*Mal. du Cœur, p.* 342.)

It is well worthy of notice, that aneurisms of the

arch of the aorta may occasion a tumour so much like that of a subclavian aneurism, as to be in danger of being mistaken for the latter disease. An example of this kind is related by Mr. Allan Burns: "a case," says he, "on which several of the most distinguished practitioners of Edinburgh, and almost every surgeon in Glasgow, were consulted. The nature of the disease appeared to be so decided, and its situation in the subclavian artery so clear, that on that subject there was no difference of opinion. Some were, however, of opinion, that an operation might be performed, while others were fully convinced, that the case was hopeless. For myself, I must confess, that I was firmly persuaded, that in the early stage of the disease, an operation might have been beneficial," &c.—(*Surgical Anatomy of the Head and Neck, p.* 30.) After death the vessel which was supposed to have been most materially affected, was found perfectly healthy.—(*P.* 39.)

After detailing all the particulars of this interesting case, Mr. A. Burns observes, that "it corroborates Sir Astley Cooper's remark, that aneurism of the aorta may assume the appearance of being seated in one of the arteries of the neck: an inference drawn from the examination of a case which came under his own observation, and of which he had the goodness to transmit a short history to me, along with a sketch, illustrative of the position of the tumour. In one case, the aneurism was attached to the right side of the aortic arch, and involved a part of the arteria innominata: in Sir A. Cooper's, the tumour arose from the left side of the arch, from between the roots of the left subclavian and carotid arteries. It formed a Florence-flask-like cyst, the bulbous end of which projected at the root of the neck, from behind the sternum, and so nearly resembled aneurism of the root of the carotid artery, that the practitioner who consulted Sir A. Cooper actually mistook the disease for carotid aneurism."—(*Allan Burns, op. cit. p.* 41.)

The preceding statement has received full confirmation from the observation of an intelligent writer. "I have seen (says Mr. Hodgson) several cases of aneurism arising from the superior part of the arch of the aorta, which protruded above the sternum and clavicles, and in one instance, the space between the tumour and the sternum was so considerable, that it was proposed to tie the carotid artery for an aneurism, which dissection proved to arise from the origin of the arteria innominata and from the arch of the aorta."—(*On the Diseases of Arteries and Veins, p.* 90.)

As we have already noticed, aneurisms of the aorta are most frequent at its curvature; but they are also met with on the other portion of this vessel in the thorax, and likewise on that part of it which is below the diaphragm. In subjects, predisposed to aneurisms, such swellings are frequently seen affecting various parts of the aorta at the same time.

When the disease occurs in the abdominal aorta, a preternatural pulsation generally becomes perceptible at some particular point. The pressure of the tumour interferes with the functions of the viscera; the breathing is rendered difficult by the swelling resisting the descent of the diaphragm; the patient suffers at times excruciating internal pains; sometimes he is affected with costiveness; sometimes with diarrhœa; and not unfrequently with incontinence of the urine and feces. At length, an immense external swelling is formed, which pulsates alarmingly, and if the patient survives long enough, destroys him by a sudden external or internal effusion of blood.

Aneurisms within the thorax and abdomen, being entirely out of the reach of operative surgery, have been too commonly abandoned as unavoidably fatal, and when any thing has been done in such cases, it has generally been only with a view of palliation. Moderating the force of the circulation by bleedings and low diet, avoiding every thing that has the least tendency to heat the body, or quicken the motion of the blood, keeping the bowels well open with laxative medicines, and lessening pain with opiates, have been the means usually employed. Of late years, also digitalis, which has a peculiar power of diminishing the action of the sanguiferous system and impetus of the blood, has been prescribed with every appearance of benefit.

That the diminution of the force of the circulation will prevent the increase of an aneurism, Mr. Hodgson considers illustrated by the following circumstance: if two sacs exist in the course of the same artery, the obstruction which is caused by the passage of blood into the upper removes the force of circulation from the lower, which becomes stationary, or its cavity is obliterated with coagulum.—(*On Diseases of Arteries, &c. p.* 149.)

It was the opinion of the celebrated Valsalva, that the utility of a lowering plan of treatment might do more than merely retard the death of aneurismal patients. It was his belief, that the method might entirely cure such aneurisms as had not already made too much progress; and he put it into practice with such rigour and perseverance, that the treatment became considered as particularly his own. The plan alluded to is not described in his writings, but was published in the first volume of the Commentaries of the Academy of Bologna, by Albertini, one of his fellow-students; and several persons, who had learned this method of Valsalva, afterward imparted it to others. Thus, as Morgagni was passing through Bologna, in 1728, Stancazi, a physician of that place, is said to have informed him of Valsalva's practice.—(See on this subject *Kreysig, uber die Herzkrankheiten, b.* 2, *p.* 728.)

After taking away a good deal of blood by venesection, Valsalva used next to diminish the quantity of food gradually, till the patient at length was allowed only half a pint of soup in the morning, and a quarter of a pint in the evening, and a very small quantity of water, medicated with mucilage of quinces, or with the lapis osteocolla. When the patient had been so reduced as to be incapable of getting out of his bed, Valsalva used to give him more nourishment till this extreme debility was removed. Valsalva was sure, that some aneurisms, thus treated, had got well, because every symptom disappeared, and his conviction was verified by an opportunity which he had of dissecting the body of a person that had been cured of this disease, and afterward died of another affection; for the artery which had been dilated was found contracted, and in some degree callous.

Morgagni relates, that this method of treating aneurisms is somewhat like the plan which Bernard Gengha tried with success, as well as Lancisi, and he refers us to the 24th chapter of the 2d vol. of the Anatomy of the one, and to lib. 2, cap. 4, of the Treatise on the Heart and Aneurisms, of the other. But Sabatier tells us, that in consequence of this instruction, he examined both these works, without finding any thing on the subject. However this may be, we are informed by the latter, that he has seen the good effects of the practice in an officer, who had an alarming aneurism in front of the humeral extremity of the clavicle, in consequence of a sword-wound in the axilla. The patient, after having been bled several times, was confined to his bed, and kept to an extremely low diet. He was allowed as drink only a very acid kind of lemonade. He took pills containing alum, and the swelling was covered with a bag full of tan-mill dust, which was every now and then well wet with port wine. By a perseverance in this treatment, the swelling was reduced to a smallish hard tubercle, having no pulsation, and a perfect cure ensued.—(See *Sabatier, Médecine Operatoire, tom.* 3, *p.* 170—172.)

Guerin recommended the application of ice water or pounded ice, to aneurismal swellings; a plan which he represents as being often of itself sufficient to effect a cure. This topical employment of cold applications may be rationally and conveniently adopted in conjunction with Valsalva's practice.

The most interesting and convincing facts in proof of the efficacy of this mode of treatment, were published a few years ago by Pelletan. Indeed, upon the whole, I have no hesitation in saying, that I have never read any modern collection of surgical cases, which have appeared to me more valuable, than those which compose the Clinique Chirurgicale of this experienced writer.* The following extract from a well-written critique on this work will serve to convey to the reader some idea of the important information contained in the memoir on internal aneurisms:—"The intent in the treatment is to reduce the patient gradually to as extreme a degree of weakness as is possible, without immediately endangering life. It is done by absolute rest, a rigorous diet, and bleeding; to these means, M. Pelletan adds the external application of ice, or cold and astringent washes, &c. He has here

detailed many cases from his own practice, of partial or complete success, which cannot be too generally known, as they may be the means of creating in some, and of confirming in others, a good opinion of the only method of treatment, which has been found at all efficacious in a dreadful and not unfrequent organic disease.

Of the cases here recorded, some appear to have been cured; in others, the treatment had marked good effects. In extreme cases, at best, it afforded but partial and temporary relief. We can notice but a few of these cases, which are, in every respect, highly interesting. In one, a robust man, an aneurism at the root of the aorta, with a pulsating tumour of the size of an egg, projecting between the ribs (the edges of which were already partly absorbed), was reduced so as to recede within the ribs in the course of eight days. At the end of this time, the patient refused to submit any longer. The tumour did not appear again for nearly a year, although he returned to very drunken and irregular habits. He died in about two years and a half, with the tumour again appearing, and much increased in volume. The aneurismal sac communicated with the aorta, by a smooth and round opening, opposite to one of the sigmoid valves. There can be no doubt of the efficacy of the treatment in this case; and it is highly probable that his health and his life might have been long preserved, but for his own indiscretion. In a case somewhat similar, but not so far advanced, the patient appears to have been cured. There was a swelling on the right side of the breast, about six inches in circumference, with a very strong beating. The pulsation was accompanied with a pain which stretched towards the scapula and the occiput. It was evident that the disease was an aneurism of the great arch of the aorta. The patient was a crier, of a strong frame, who was accustomed to drink freely. In the first four days, he was bled eight times, drawing three basins, 'palettes,' in the morning, and two in the evening. On the fifth, the pains and the beating were much lessened, but the pulse was still full. He was again bled once. The pulse was in a favourable state as to strength, till the seventh day, when it again rose, and the man was twice bled.

During this time the man was kept to a most rigorous diet. A cold poultice of linseed and vinegar was placed on the tumour, and renewed when it became warm. At the end of eight days, the good effects of this plan were very evident; the pain and the pulsation were gone. The patient, though weak, was in health and tranquil. He was now allowed more food by degrees. At the end of four weeks from the commencement of the treatment, he left the Hôtel-Dieu well. He afterward led a sober life, and became fatter, without any vestige of disease, except a slight and deep pulsation at the part, in which the aorta may always be felt beating in its natural state. He died two or three years after of another complaint. His death was not known, and the body was not examined."—(See *London Med. Review*, *vol.* 5, *p.* 123.)

Pelletan also cured by similar treatment a large axillary aneurism, which was deemed beyond the reach of operative surgery. On the thirteenth day, the patient was reduced to a degree of weakness which alarmed many of the observers. From that time, all pulsation in the tumour ceased. The contents were gradually absorbed; and the patient returned to his former laborious life with his arm as strong as ever. The pulse at the wrist was lost in consequence of the obliteration of the axillary artery, and the limb only receiving blood through the branches of the subclavian artery. "*Il y a beaucoup d'exemples d'aneurismes, guéris spontanément et sans le secours de l'art* (says Pelletan); *mais on ne peut leur comparer le cas que nous venons de décrire: l'état extrême de la maladie, l'energie des moyens employés, et l'effet immédiat et successif qui en est résulté prouvent assez que le succès a été dû tout entier à l'art.*"—(*Clinique Chirurgicale*, *tom.* 1, *p.* 80.)

In this work, we find not less than three cases, in which aneurism of the aorta is stated to have been effectually cured. One instance was greatly relieved; but the disease returned the next year, in consequence of the patient's intemperate mode of life. In another example, an aneurism at the origin of the aorta was cured; but the disease recurred in another part of that vessel, farther from the heart. Even such cases as proved incurable, to the number of fourteen, all received various degrees of palliation from the treatment adopted.

In a modern work of great merit, several other instances are adduced, in which the utility and efficacy of a debilitating plan of treatment are illustrated.—(See *Hodgson's Treatise on the Diseases of Arteries*, *p.* 146, 147, *&c. &c.*) In the same publication, as I have previously explained, there are several interesting facts, which tend to prove, that when the aneurism of the aorta is lessened or cured, this great vessel itself may remain pervious. The progress of the disease is stopped by the blood coagulating in the sac, and closing the communication between the cavity of the aneurism and that of the artery.

It must be confessed, in regard to Valsalva's mode of treatment, that some experienced men do not place confidence in it. Boyer declares himself against it, as not being really efficacious; and he states, that some time ago, it was tried twice in the Hôtel-Dieu of Paris. The first trial was made on a patient with an axillary aneurism, which could not be operated upon on account of its situation; the second on a woman, who had an aneurism of the abdominal aorta. In both cases, the tumour was large, and its parietes reduced to the cellular coat, and the surrounding cellular substance. In these two aneurisms, the progress of the swelling was much more rapid, and its rupture happened precisely at the moment when the treatment had been pushed to the utmost, and there ought to have been the greatest hope.—(*Traité des Maladies Chir. t.* 2, *p.* 121.)

Sir Astley Cooper declares, that he has seen but little benefit result from the treatment of this disease. According to his experience, only two measures are useful; viz. venesection when the pulse is hard and full; and the administration of the carbonate of soda in considerable doses, which, with entire rest, seem to prevent the increase of the swelling. But he adds, that the soda is at length unavoidably given up, on account of its producing petechiæ. Sir Astley believes that the irritability and quickened pulse, produced by antiphlogistic treatment, often do as much injury as the natural force of the circulation.—(*Lectures*, *&c.*, *vol.* 2, *p.* 48.)

Roux expresses his entire disbelief in the possibility of an aneurism of the aorta being ever completely cured by Valsalva's mode of treatment, because he imagines, that such change could not happen without the tube of that great vessel becoming impervious, and of the lower parts of the body then perishing from stoppage of the circulation. But he bears witness to the utility of such treatment, and recites a case which he attended himself, where an aneurism made a considerable projection on the left side of the sternum, where the cartilages of the third and fouth ribs were raised, the throbbings very forcible, and the sense of suffocation such that the patient was obliged to keep himself constantly quiet; yet, says Roux, though the disease now exists, it forms no prominence on the chest; the pulsations can only be obscurely felt between the ribs; the respiration is but slightly oppressed; and the patient is capable of attending to his business. —(*Nouveaux Elemens de Médecine Opératoire*, *t.* 1, *p.* 510, 8*vo. Paris*, 1813. *Fr. Torti, De Aortæ Aneurysmate Observationes binæ, cum animadv. Pauli Valcarenghi*, 8*vo. Cremonæ*, 1741. *D. Sommer, Dis. sistens Aneurysmatis Aortæ Pleuritydem mentientis Casum.* 8*vo. Berol.* 1816.)

ANEURISMAL VARIX, VARICOSE, OR VENOUS ANEURISM.

By these terms, surgeons mean a tumour, arising from a preternatural communication, formed between a large vein and a subjacent artery. Thus, in venesection performed immediately over the artery at the bend of the elbow, if the lancet be carried too deeply, it may transfix the vein, and wound the artery, in which event, the arterial blood, in consequence of the proximity of the two vessels, instead of being effused into the cellular substance, will pass directly into the cavity of the vein, which will become dilated in the form of a varix by the jet of arterial blood into it.

Although Sennertus probably referred to an instance of this disease (*Op. t.* 5, *l.* 5, *cap.* 43), Dr. W. Hunter is undoubtedly the first who gave an accurate description of it. Scarpa is disposed to claim a share of the merit for his countryman Guattani; but, as Mr. Hodgson has remarked, Dr. Hunter's observations on this disease were published in the years 1757 and 1764; whereas, Guattani did not see his first patient until the

year 1769, and his book was not published until the year 1772.

"Does it ever happen in surgery," says Dr. Hunter, "that when an artery is opened through a vein, a communication, or anastomosis, is afterward kept up between these two vessels? It is easy to conceive this case, and it is not long since I was consulted about one, that had all the symptoms that might be expected, supposing such a thing to have actually happened, and such symptoms, as otherwise must be allowed to be very unaccountable. It arose from bleeding; and was of some years' standing, when I saw it about two years ago, and I understand very little alteration has happened to it since that time. The veins, at the bending of the arm, and especially the basilic, which was the vein that had been opened, were there prodigiously enlarged, and came gradually to their natural size, at about two inches above and as much below the elbow. When emptied by pressure, they filled again almost instantaneously, and this happened, even when a ligature was applied tight round the forearm, immediately below the affected part. Both when the ligature was made tight, and when it was removed, they shrunk, and remained of a small size, while the finger was kept tight upon the artery, at the part where the vein had been opened in bleeding. There was a general swelling in the place, and in the direction of the artery, which seemed larger, and beat stronger than what is natural, and there was a tremulous jarring motion in the vein, which was strongest at the part which had been punctured, and became insensible at some distance both upwards and downwards."—(*Med. Obs. and Inq. vol.* 1.)

In the second volume of this work, Dr. Hunter adds some farther remarks on the aneurismal varix.

"In the operation of bleeding, the lancet is plunged into the artery through both sides of the vein, and there will be three wounds made in these vessels, viz. two in the vein, and one in the artery, and these will be nearly opposite to one another, and to the wound in the skin. This is what all surgeons know has often happened in bleeding, and the injury done the artery is commonly known by the jerking impetuosity of the stream, while it flows from the vein, and by the difficulty of stopping it, when a sufficient quantity is drawn.

In the next place, we must suppose, that the wound of the skin, and of the adjacent or upper side of the vein, heal up as usual; but that the wound of the artery, and of the adjacent or under side of the vein, remain open (as the wound of the artery does in the spurious aneurism), and, by that means, the blood is thrown from the trunk of the artery directly into the trunk of the vein. Extraordinary as this supposition may appear, in reality it differs from the common spurious aneurism in one circumstance only, viz. the wound remaining open in the side of the vein, as well as in the side of the artery. But this one circumstance will occasion a great deal of difference in the symptoms, in the tendency of the complaint, and in the proper method of treating it: upon which account, the knowledge of such a case will be of importance in surgery.

It will differ in its symptoms from the common spurious aneurism principally thus:—

The vein will be dilated, or become varicose, and it will have a pulsating jarring motion on account of the stream from the artery. It will make a hissing noise, which will be found to correspond with the pulse for the same reason. The blood of the tumour will be altogether, or almost entirely fluid, because kept in constant motion. The artery, I apprehend, will become larger in the arm, and smaller at the wrist, than it was in the natural state; which will be found out by comparing the size, and the pulse, of the artery, in both arms, at these different places. The reason of which I will speak of hereafter; and the effects of ligatures, and of pressure upon the vessels above the elbow and below it, will be what every person may readily conceive, who understands any thing of the nature of arteries and veins in the living body.

The natural tendency of such a complaint will be very different from that of the spurious aneurism. The one is growing worse every hour, because of the resistance to the arterial blood, and, if not remedied by surgery, must at last burst. The other, in a short time, comes to a nearly permanent state; and, if not disturbed, produces no mischief, because there is no considerable resistance to the blood that is forced out of the artery.

The proper treatment must, therefore, be very different in these two cases, the spurious aneurism requiring chirurgical assistance, as much, perhaps, as any disease whatever; whereas, in the other case, I presume it will be best to do nothing.

If such cases do happen, they will no doubt be found to differ among themselves, in many little circumstances, and particularly in the shape, &c. of the tumefied parts. Thus the dilatation of the veins may be in one only, or in several, and may extend lower or higher in one case than in another, &c., according to the manner of branching, and to the state of the valves in different arms. And the dilatation of the veins may also vary, on account of the size of the artery that is wounded, and of the size of the orifice in the artery and in the vein.

Another difference in such cases will arise from the different manner in which the orifice of the artery may be united or continued with the orifice of the vein. In one case, the trunk of the vein may keep close to the trunk of the artery, and the very thin stratum of cellular membrane between them may, by means of a little inflammation and coagulation of the blood among its filaments, as it were, solder the two orifices of these vessels together, so that there shall be nothing like a canal going from one to the other; and then the whole tumefaction will be more regular, and more evidently a dilatation of the veins only. In other instances, the blood that rushes from the wounded artery, meeting with some difficulty of admission and passage through the vein, may dilate the cellular membrane, between the artery and vein, into a bag, as in a common spurious aneurism, and so make a sort of canal between these two vessels. The trunk of the vein will then be removed to some distance from the trunk of the artery, and the bag will be situated chiefly upon the under side of the vein. The bag may take on an irregular form, from the cellular membrane being more loose and yielding at one place than at another, and from being unequally bound down by the fascia of the biceps muscle. And if the bag be very large, especially if it be of an irregular figure, no doubt, coagulations of blood may be formed, as in the common spurious aneurism."

As Scarpa correctly observes, a concurrence of two circumstances is requisite for the production of an aneurismal varix: 1st, the incision in the vein, and that in the artery must be exactly in the same direction; 2d, the solution of continuity in the integuments and upper side of the vein must heal, while the wound in the deeper side of that vessel and the puncture in the upper surface of the artery remain open, and communicate so readily that the arterial blood finds greater facility in entering from the artery into the vein, than in being effused from the artery into the surrounding cellular substance.

If one of these two circumstances be wanting, either because the wounding instrument has entered the artery a little obliquely from the vein, or because the vein has not been sufficiently near to the artery, on account of the cellular substance between them, the arterial blood most frequently does not produce the aneurismal varix; or, if it does, the disease is always complicated with effusion of arterial blood into the cellular substance, or with an aneurism and aneurismal varix at the same time. In this case the small aneurismal sac serves as a short canal of communication between the artery and the vein (*Med. Facts and Obs. vol.* 4, *p.* 115); two distinct diseases in fact being formed from the same cause, and placed one over the other, viz. an aneurism and an aneurismal varix.—(*Scarpa, p.* 421, *ed.* 2.) The following marks of distinction between aneurism and aneurismal varix are pointed out by the same author: the aneurismal varix always forms a circumscribed tumour; aneurism does not always do so. The cellular substance which constitutes the sac of the aneurism does not always resist so strongly the impetus of the arterial blood as the coats of the vein do. Not unfrequently, therefore, aneurism from being *circumscribed* at first becomes *diffused*; extends along the course of the wounded artery; compresses strongly the surrounding parts; occasions acute pain and inflammation; and the parts are threatened with gangrene. On the contrary, the aneurismal varix is always *circumscribed*, increases very slowly, does not produce much pain, and, as it augments, it always extends more or less above or below the place where venesec-

tion has been done; and this extension is in proportion to the greater or less force with which the arterial blood is thrown from the artery into the vein, and the greater or less resistance made by the valves situated in the vein below the puncture, and according to the greater or less number of veins communicating with the aneurismal varix. The seat of the disease is generally the basilic vein, which appears dilated in an unusual manner, forming an oblong tumour of the size of a walnut, if the disease is recent. In the centre of the swelling is the cicatrix left by the lancet. The vein is less dilated the farther it is from this scar, and in general at the distance of two inches and a half above and below this point the vessel resumes its natural size. The small tumour, as has been explained, pulsates like an artery with a tremulous motion and hissing noise, which is sometimes so great that the patient cannot sleep if he is lying with his head low, and resting on the injured arm. The trunk of the brachial artery, from the axilla down to the place where it has been wounded with the lancet, vibrates with extraordinary force. There is no change of colour nor inflammation of the skin; and the pain is inconsiderable. The swelling is compressible and yielding; but it returns as soon as the pressure is removed from it. When the arm is kept for some time raised up towards the head, the tumour diminishes; and the same thing happens when pressure is made on the communication between the artery and vein, or when a tight tourniquet is applied near the axilla. If the disease be complicated with aneurism, a second pulsating tumour will be found lying under the aneurismal varix.—(*Scarpa, p.* 424, *ed.* 2.)

After relating two cases, illustrative of the nature of aneurismal varix, Dr. W. Hunter proceeds to inquire, "Why is the pulse at the wrist so much weaker in the diseased arm than in the other? surely the reason is obvious and clear. If the blood can easily escape from the trunk of the artery directly into the trunk of the vein, it is natural to think that it will be driven along the extreme branches with less force and in less quantity.

Whence is it that the artery is enlarged all the way down the arm? I am of opinion, that it is the consequence of the blood passing so readily from the artery into the vein, and is such an extension as happens to all arteries in growing bodies, and to the arteries of particular parts when the parts themselves increase in their bulk, and at the same time retain a vascular structure. It is well known that the arteries of the uterus grow much larger in the time of utero-gestation. I once saw a fleshy tumour upon the top of a man's head as large nearly as his head; and his temporal and occipital arteries, which fed the tumour, were enlarged in proportion. I have observed the same change in the arteries of enlarged spleens, testes, &c. so that I should suppose it will be found to be universally true in fact, and the reason of it in theory seems evident."—(See *Med. Obs. and Inq. vol.* 2.)

In thin subjects the median basilic vein is so close to the brachial artery, the track of which it crosses at a very acute angle, that it is almost impossible to open it at this point without risk of wounding the artery at the same time. The bend of the arm indeed is the very situation in which this disease is usually noticed. It is easy to conceive, however, that a venous aneurism may happen wherever an artery of a certain diameter lies immediately under a large vein. Thus, Baron Larrey informs us that his uncle, surgeon to the hospital at Toulouse, saw a case of aneurismal varix, which had been occasioned by a wound of the popliteal vein and artery, and that a history of the disease, accompanied with the pathological preparation, was sent to the former Royal Academy of Surgery at Paris. "The varicose swelling, which was as large as two fists, occupied the whole of the ham in a middle-aged man, who some years previously had been wounded with a sword in that part of the limb. At a consultation, amputation was deemed necessary, and was performed with success. At the bottom of the varicose pouch the communication between the popliteal vein and artery was observed. The sac itself was evidently composed of the vein, the parts of which, adjacent to the varicose swelling, were dilated, especially the lower continuation of the vessel. The popliteal nerve was rendered flat, like a piece of tape, and adherent to the outside of the cyst."—(See *Mém. de Chir. Mil. t.* 4, *p.* 340. *Boyer, Traité des Mal. Chir. &c. t.* 2, *p.* 177.) Two cases are likewise recorded by Mr. Hodgson. In one, the disease was caused in the thigh, about four inches below Poupart's ligament, by the point of a heated iron rod, which had passed through the femoral artery and vein. In the other example, the aneurismal varix was situated in the ham, and was the consequence of a wound in that part with a pistol-ball.—(*Treatise on the Diseases of Arteries, p.* 498.) Larrey records one example of aneurismal varix situated under the clavicle.

P. Cadrieux was wounded with a sabre in a duel, on the 20th of November, 1811: part of the attachment of the sterno-mastoid muscle was divided, the anterior scalenus, the subclavian artery and vein at a very deep point, and probably also a portion of the brachial plexus. A most violent hemorrhage took place, followed by syncope. Pressure was applied to the wound, and the patient conveyed to the hospital at Gros-Caillou. The external wound, which was small, did not bleed at all the following morning; but the clavicle was quite concealed by a large tumour, which throbbed with the arteries, particularly at its lower part. A peculiar noise, like that of the passage of a fluid through tortuous metallic tubes, could also be felt more deeply in the direction of the axillary vein. The arm was quite cold, insensible, motionless, and without any pulse even in the axillary artery itself. On the 22d, the tumour was not larger, but its throbbings were stronger; the jugular vein on the same side was considerably dilated; and the pulsation of the carotid and of the arteries of the opposite arm had augmented. A vein in the right arm was opened, and compresses dipped in camphorated vinegar, muriate of ammonia, and ice applied to the swelling. It would be superfluous here to detail the diet, bleedings, and other parts of the treatment. On the 8th day, the outer wound was quite healed. On the 10th, the veins of the limb were observed to be swelled, and sensibility and warmth were returning in it; though no pulse could yet be felt. The tumour was much smaller, and restricted to a circumscribed place behind the great pectoral muscle; but the hissing sound was still plainer. By degrees the muscles of the arm and forearm regained their power of motion. The hand, however, continued useless, and affected with pricking pains. On the 20th day, the tumour was quite gone; but the hissing sound was unaltered, and the throbbings were still evident in the veins of the neck and arm. The arm was not at all emaciated. On the 55th day, a pulse at the wrist could be slightly felt; the hissing sound had become less distinct; the veins were less turgid, and their throbbing diminished.

A second instance of aneurismal varix, or rather perhaps of a varix of all the veins of the arm, caused by a sword-wound of the axilla, is also recorded by Larrey. He mentions, however, that a pulsation was observable in the most prominent of the enlarged vessels.—(See *Mém. de Chir. Mil. t.* 4, *p.* 341, *&c.*)

Dr. Dorsey, of Philadelphia, published a case of aneurismal varix, which is in several respects interesting. A patient was wounded in the leg with buck-shot; and after the cure of the injury, an aneurismal varix was noticed just below the knee; and in a little time the superficial veins of the limb became dilated, and the hissing noise, characterizing this species of aneurism, could be plainly distinguished. The patient was seen by Dr. Dorsey twelve years after the accident; the veins were then considerably distended from the toes up to the groin, all about which latter part pain was constantly experienced, and some ulcers situated on the foot and ankle could not be healed by any of the remedies which were tried. The patient was under the care of Drs. Physick and Wistar. The enormous distention of the vessels of the leg, and the uncertainty of finding out the communication between the artery and vein, led these gentlemen to tie the first of these vessels in the middle of the thigh. Gangrene soon ensued, and in this state the patient was farther weakened by an unexpected hemorrhage from one of the distended veins; and though the vessel was secured with a ligature, the bleeding recurred, the patient became more and more enfeebled, and at length expired. When the limb was examined after death, the whole of the trunk of the femoral artery was found preternaturally dilated; while all the veins of the limb were considerably distended; a bougie could readily be passed from the popliteal into the posterior tibial artery, which participated in the dilatation, and from

this last artery the instrument could be passed into the vein, through a cyst situated on the inside of the leg below the knee.—(See *Dorsey's Elements of Surgery, vol.* 2, *p.* 210, *Philadelphia*, 1813.)

Professor Scarpa, Dr. Hunter, Mr. B. Bell, Pott, and Garneri mention cases of the aneurismal varix which remained stationary for fourteen, twenty, and thirty-five years. Several cases are related by Brambilla, Guattani, and Monteggia, of a cure having been obtained by means of compression. But as this method of cure, if it does not succeed, exposes the patient to the danger of a complication of the disease with an aneurism, it ought not to be employed, except in recent cases where the tumour is small, and in slender patients at an early period of life, and where both of the vessels can be accurately compressed against the bone.

Two cases are recorded, in which it was necessary to operate in consequence of the disease being joined with aneurism of the artery, and even bursting. The sacs were opened, and a ligature applied both above and below the aperture in the artery.—(See *Park, in Medical Facts and Obs. vol.* 4, *p.* 111; *and Physick, in Medical Museum, vol.* 1, *p.* 65.) The latter form of the disease, which is particularly noticed by Dr. Hunter, and also by my friend Mr. Hodgson, is readily understood by recollecting that the artery and vein, when punctured together, do not always unite in such a manner as to let the arterial blood have a direct passage into the vein; but they may be separated for some distance from each other, so that the blood passes from the artery into the adjacent cellular membrane, where a sac is formed, into which the blood is poured previously to its entrance into the vein.—(See *Gibson's Institutes of Surgery, vol.* 2, *p.* 158, *Philadelphia*, 1825.)

In the winter of 1819, I heard a case read to the Medical and Chirurgical Society of London, from Mr. Atkinson, of York, who had found it necessary to take up the brachial artery on account of the large and increasing size of an aneurismal varix: mortification of the limb ensued. When the aneurism, joined with an aneurismal varix, is circumscribed, but the circumstances such as to require the brachial artery to be tied, this vessel should be exposed and tied above the swelling with a single ligature. It is only when the aneurism is diffused that opening the swelling and applying a ligature both above and below the aperture in the artery are thought necessary.—(See *Scarpa on Aneurism*, *p.* 433, *ed.* 2; *also Guattani, de Cubiti flexuræ aneurysmatibus, in Lauth's Coll. Scriptorum, &c.; and P. Adelmann, Tract. Anat. Chir. de Aneurismate spurio varicoso. Wirceb.* 1824.)

ANEURISM BY ANASTOMOSIS.

This is the term which the late Mr. John Bell, of Edinburgh, applied to a species of aneurism resembling some of the bloody tumours (*nævi materni*) which appear in new-born children, grow to a large size, and ultimately bursting emit a considerable quantity of blood.

Imperfect descriptions of this disease may be traced in writers; though before the publication of Mr. John Bell's Principles of Surgery it was not classed with aneurisms. Thus Desault has recorded a case of this affection for the express purpose of proving that pulsation is an uncertain sign of the existence of an aneurism.—(See *Parisian Chirurgical Journal, vol.* 2, *p.* 73.)

Aneurism by anastomosis often affects adults, increasing from an appearance like that of a mere speck or pimple to a formidable disease, and being composed of a mutual enlargement of the smaller arteries and veins. The disease originates from some accidental cause; is marked by a perpetual throbbing; grows slowly but uncontrollably; and is rather irritated than checked by compression. The throbbing is at first indistinct, but when the tumour is perfectly formed the pulsation is very manifest. Every exertion makes the throbbing more evident. The occasionally turgid states of the tumour produces sacs of blood in the cellular substance, or dilated veins, and these sacs form little tender, livid, very thin points, which burst from time to time, and then, like other aneurisms, this one bleeds so profusely as to induce extreme weakness.

The tumour is a congeries of active vessels, and, according to Mr. John Bell, the cellular substance through which these vessels are expanded, resembles the gills of a turkey-cock or the substance of the placenta, spleen, or womb. The irritated and incessant action of the arteries fills the cells with blood, and from these cells it is reabsorbed by the veins. The size of the swelling is increased by exercise, drinking, emotions of the mind, and by all causes which accelerate the circulation.

In this peculiar disease Dupuytren regards the arteries as being in an aneurismal state; but, besides this circumstance, he says, their extreme ramifications intermix in a thousand different ways, intercepting spaces, and representing cavities like those which are found in the corpora cavernosa; and he imputes the disease to increased activity of the capillary circulation. —(*Fr. transl. of Mr. Hodgson's work, t.* 2, *p.* 300.) It is observed by Mr. Syme, that most surgeons have followed John Bell in believing this disease to consist of a morbid cellular structure through which the blood passes in its course from the arteries into the veins. However, he has long been one of those who maintain that the apparent cells are really sections of enlarged vessels.—(See *Edin. Med. Journ. No.* 98, *p.* 72.)

In the dissection of a pulsating tumour of the scalp in a patient who had died after the operation of tying the carotid artery, Dr. Maclachlan found the branches of this vessel on the head "degenerated into dilated tubes of extreme thinness and transparency; which, apparently yielding to the impetus of the blood, had become elongated, contorted, and ultimately convoluted on themselves, so as to form by this species of doubling the tumours which constituted this singular disease." They felt like placenta, and the larger portion immediately over the ear looked precisely like a bundle of earthworms coiled together.—(See *Glasgow Medical Journ. vol.* 1, *p.* 85.) Two cases are given by Pelletan, fully confirming the view taken of the nature of the disease by Dr. Maclachlan and Mr. Syme.—(See *Clinique Chir. t.* 2.) Boyer, who saw one of these cases, describes all the arteries of the swelling as being dilated, tortuous, knotty, and though very large in some places, in others contracted.—(*Traité des Mal. Chir. t.* 2, *p.* 295.) In the tumour described by Dr. Maclachlan none of the cells spoken of by Mr. John Bell were found; no parenchyma as in the spleen; the bulk of the tumour was formed almost entirely by convoluted, dilated arterial *trunks*, the veins being but little changed from their healthy state. He adds, that these arteries did not appear to communicate more freely than by their ordinary inosculations. Some of these conclusions, as it appears to me, require corroboration by a careful anatomical injection of the vessels.

In the female subject the hemorrhage from the aneurism by anastomosis is sometimes a substitute for menstruation, as the following example illustrates: Ann Vachot, of St. Maury, in Bresse, was born with a tumour on her chin, of the size and shape of a small strawberry, without pain, heat, or discoloration of the skin. As it produced no uneasiness nor inconvenience whatever, it excited little attention, particularly as it did not seem to increase with the growth of the child. For the first fifteen years there was but little alteration; but about the menstrual period it increased suddenly to double the size, and became more elongated in its form. A quantity of red blood was observed to ooze from its extremity. This flux became, in some measure, periodical, and sometimes was sufficiently abundant to produce an alarming degree of weakness. Each period of its return was preceded by a violent pain in the head and numbness.

Before and after the appearance of these symptoms there was no alteration in the size of the tumour; the only difference was a small enlargement of the cutaneous veins, with an increase of heat in the part, occasioning some degree of tenderness.

The menses at length took place, but in small quantity and at irregular periods, without influencing the blood discharged from the tumour or the frequency of the evacuation.

The breasts were not enlarged till a late period, nor did the approach of puberty seem to have its accustomed influence on those glands, &c.—(See *Parisian Chir. Journ. vol.* 2, *p.* 73, 74.)

As far as my observations extend, the true aneurism by anastomosis is a disease with which a surgeon should never tamper; and if it be decided to try any treatment at all, the only prudent plan is either a complete removal of the disease with a knife, or tying the chief arteries which supply the swelling with blood.

The first is the surest mode of relief, and should be preferred, when not forbidden by the magnitude or situation of the tumour.

In performing such an operation, as Mr. Wardrop remarks, the surgeon should avoid cutting into the substance of the tumour; for if this be done, the hemorrhage is violent; whereas, by making the incisions beyond the diseased structure, the flow of blood is much more moderate.—(*Med. Chir. Trans. vol.* 9, *p.* 212.) In a few nævi pressure may be safely tried; but all attempts to get rid of a true aneurism from anastomosis by caustic I should think by no means advisable.

"This aneurism," Mr. John Bell observes, "is a mere congeries of active vessels, which will not be cured by opening it; all attempts to obliterate the disease with caustics, after a simple incision, have proved unsuccessful, nor does the interception of particular vessels which lead to it affect the tumour; the whole group of vessels must be extirpated. In varicose veins, or in aneurisms of individual arteries, or in extravasations of blood, such as that produced under the scalp from blows upon the temporal artery, or in those aneurisms produced in schoolboys by pulling the hair, and also in those bloody effusions from blows on the head which have a distinct pulsation, the process of cutting up the varix, aneurism, or extravasation, enables you to obliterate the vessel and perform an easy cure. But in this enlargement of innumerable small vessels, in this aneurism by anastomosis, the rule is, 'not to cut into, but to cut it out.' These purple and ill-looking tumours, because they are large, beating, painful, covered with scabs, and bleeding, like a cancer in the last stage of ulceration, have been but too often pronounced cancers! incurable bleeding cancers! and the remarks which I have made, while they tend in some measure to explain the nature and consequences of the disease, will remind you of various unhappy cases, where either partial incisions only have been practised, or the patient left entirely to his fate."—(*Principles of Surgery, vol.* 1.)

That Mr. John Bell has comprised in his account of aneurism by anastomosis certain swellings called nævi cannot be doubted; nor, indeed, are the differences between this kind of aneurism and some nævi at all defined even by the best writers on surgery. To the consideration of nævi, however, I have allotted an article, in which the method of extirpating particular forms of the disease by means of a ligature will be explained.

The following case, recorded by Mr. Wardrop, affords a valuable illustration of the nature and structure of one form of this disease. A child was born with a very large subcutaneous nævus on the back part of the neck. It was of the form and size of half an ordinary orange. The tumour had been daily increasing, and when Mr. Wardrop saw it, ten days after birth, the skin had given way, and a profuse hemorrhage had taken place. The swelling was very soft and compressible; when squeezed in the hand it yielded like a sponge, and was reducible to one-third of its original size. On removing the pressure, however, the tumour rapidly filled again, and the skin resumed its purple colour. "Conceiving the immediate extirpation of the tumour the only chance of saving the infant (says Mr. Wardrop), I removed it as expeditiously as possible, and made the incision of the integuments beyond the boundary of the tumour; aware of the danger of hemorrhage, where such tumours are cut into. So profuse, however, was the bleeding, that though the whole mass was easily removed by a few incisions, the child expired.

The tumour having been injected by throwing coloured size into a few of the larger vessels, its intimate structure could be accurately examined. Several of the vessels, which, from the thinness of their coats appeared to be veins, were of a large size, and there was one sufficiently big to admit a full-sized bougie." This vessel was quite as large as the carotid artery of an infant. The boundaries of the tumour appeared distinct, some healthy cellular membrane, traversed by the blood-vessels, surrounding it. On tracing these vessels to the diseased mass, they penetrated into a spongy structure composed of numerous cells and canals, of a variety of forms and sizes, all of which were filled with the injection, and communicated directly with the ramifications of the vessels. These cells and canals had a smooth and polished surface, and in some parts resembled very much the cavities of the heart, fibres crossing them in various directions like the columnæ tendinæ. The opening in the skin, through which the blood had escaped during life, communicated directly with one of the large cells, into which the largest vessel also passed."—(*Wardrop, in Med. Chir. Trans. vol.* 9, *p.* 203.)

In the section on Carotid Aneurisms I have mentioned the cases in which Mr. Travers and Mr. Dalrymple cured aneurisms by anastomosis in the orbit by tying the common carotid artery. Professor Pattison also cured an immense anastomosing aneurism of the cheek and side of the face by taking up the carotid artery.—(See *Med. and Phys. Journ. vol.* 48, *July*, 1822.) These facts prove that aneurism by anastomosis, like many other diseases, sometimes admits of being cured on the principle of cutting off or lessening the supply of blood to the part affected.

However, surgeons must not be too confident of being always able to cure the disease by tying the main artery from which the swelling receives its supply of blood; and the great cause of failure is the impossibility of preventing in some situations the transmission of a considerable quantity of blood into the tumour, through the anastomosing vessels. A case is recorded by Maunoir, in which he applied a ligature for three days to the carotid artery, and obliterated it; yet the benefit effected seemed to be only temporary, as in a short time the tumour was as large as before.—(See *Med. and Phys. Journ. vol.* 48.) In fact, every vessel, artery, and vein around the disease seems to be enlarged and turgid; and the inosculations are so infinite that no point of the circumference of the swelling can be imagined which is free from them. Etienne Dumand was born with two small red marks on the antihelix of the right ear. Until the age of twelve years the chief inconveniences were, a sensation of itching about the part, occasional bleeding from it, and the greater size of this than of the other ear. The disease now extended itself over the whole antihelix, and to the helix and concha; and the upper part of the ear became twice as large as natural. Slight alternate dilatations and contractions began to be perceptible in the tumour, which was of a violet colour, and covered by a very thin skin. Soon afterward any accidental motion of the patient's hat was sufficient to excite copious hemorrhages, which were difficult to suppress, and at the some time that they produced great weakness, caused a temporary diminution of the tumour and its pulsations. At length the disease began to raise up the scalp for the distance of an inch around the meatus auditorius, and the hemorrhages to be more frequent and alarming. Pressure was next applied to the temporal, auricular, and occipital arteries; but as the patient could not endure it, the first two of these vessels were tied, the only benefit from which was a slight diminution in the pulsation and bulk of the swelling. This treatment did not prevent the return of hemorrhage, and therefore forty-three days after the first operation a ligature was applied to the occipital artery, which pro eeding was equally ineffectual. As the disease continued to make progress, the patient entered the Hôtel-Dieu, where, on the 8th of April, 1818, Dupuytren tried what effect tying the trunk of the carotid artery would produce on the swelling. As soon as the ligature was applied, the throbbing ceased, and the tumour underwent a quick and considerable diminution. On the 17th day, slight expansions and contractions of the diseased part of the ear were again perceptible, though the swelling had diminished one-third. An attempt was now made to compress the tumour by covering it with plaster of Paris; a plan which was somewhat painful, though it lessened the size of the disease. After being sixty-three days in the hospital, the patient was discharged, at which period the tumour was diminished one-third; the throbbings had returned, but no unpleasant noises continued to affect the ear.—(See *Breschet's tr. of Mr. Hodgson's work, t.* 2, *p.* 296.)

An infant, six weeks old, was brought to Mr. Wardrop, on account of an aneurism by anastomosis (a subcutaneous nævus) of a very unusual size, situated on the left cheek. The base of the tumour extended from the temple to beyond the angle of the jaw, completely enveloping the cartilage of the ear. At its upper part there was an ulcer, about three inches in diameter, presenting a sloughing appearance. The tumour was

soft and doughy; its size could be much diminished by pressure; there was a throbbing in it, and a strong pulsation in the adjacent vessels. The disease was daily increasing, and several profuse hemorrhages had taken place from the ulcerated part. Mr. Wardrop, knowing, from the case to which I have already adverted, the danger of attempting to extirpate so large a tumour of this nature, was led to try what benefit might be obtained by tying the carotid artery. A few hours after this operation, the tumour became soft and pliable; its purple colour disappeared, and the tortuous veins collapsed. On the second day, the skin had resumed its natural pale colour, and the ulceration continued to extend. On the third, the tumour still diminished. On the fourth, the swelling had considerably increased again; the integuments covering it had become livid, and the veins turgid. The inosculating branches of the temporal and occipital arteries had become greatly enlarged. A small quantity of blood had oozed from the ulcer. After remaining without much alteration, the tumour on the seventh day had again evidently diminished. On the ninth, the ulceration was extending itself slowly, and the tumour was lessened fully one-half. On the twelfth, the child's health was materially improving. The auricular portion of the swelling had now so much diminished, that the cartilage of the ear had fallen into its natural situation. After a poultice had been applied for two days, the central portion of the swelling, which appeared like a mass of hardened blood, was softened, and Mr. Wardrop removed considerable portions of it. On the thirteenth, the child became very ill, and died the following day, exhausted by the irritation of an ulcer, which had involved the whole surface of an enormous tumour. Mr. Wardrop thinks the advantages likely to occur from the plan of tying the main arteries supplying tumours of this nature with blood are, the diminution of the size of the disease; the lessening of the danger of hemorrhage, if the ulcerative process has commenced; and the rendering it practicable to remove the swelling with the knife, though the operation may previously have been dangerous or impracticable. —(See *Med. Chir. Trans. vol. 9, p. 206—214*, &c.) Instead of endeavouring to promote ulceration in any of these cases, my own sentiments would incline me to leave the business of removing the diseased mass quietly to the absorbents, or at most, I would only assist them with pressure, or by covering the tumour with plaster of Paris.

The next case of aneurism by anastomosis, which I shall briefly notice, was one which was under the care of my friend Mr. Lawrence, and situated on the ring finger of the right hand, in a young woman about twenty years of age. The disease was attended with painful sensations extending to various parts of the limb and the breast, and the arm was disqualified for any kind of exertion. In January, 1815, Mr. Hodgson had taken up the radial and ulnar arteries, and the consequences of the operation were an entire cessation of the beating, collapse of the swelling, and relief from pain; but these symptoms all recurred in a few days. Finding compression unavailing, and the sufferings of the patient increasing, Mr. Lawrence proposed amputation of the finger at the metacarpal joint; but as this suggestion was not approved of, he recommended the patient to try the effects of a division of all the soft parts, by a circular incision close to the palm, so as to cut off the supply of blood. This operation Mr. Lawrence performed in the presence of Mr. George Young and myself, in as complete a manner as can possibly be conceived. All the soft parts, excepting the flexor tendons, with their theca and the extensor tendon, were divided. The digital artery, which had pulsated so evidently in the palm of the hand, was fully equal in size to the radial or ulnar of an adult, and was the principal nutrient vessel of the disease. After tying this and the opposite one, we were surprised at finding so strong a jet of arterial blood from the other orifices of these two vessels, as to render ligatures necessary. I can here only add, that the whole finger beyond the cut swelled very considerably; the incision healed slowly; the swelling subsided, but did not entirely disappear; the integuments recovered their natural colour; the pulsation and pain were removed, and the patient so far recovered the use of her arm, that she could work at her needle for an hour together, and use the arm for most purposes.—(See *Wardrop's Obs. on one Species of Nævus, in Med. Chir. Trans. vol. 9, p. 216.*)

ANTHRAX (ἄνθραξ a burning coal). See *Carbuncle.*

ANTIMONIAL POWDER; PULVIS ANTIMONIALIS. (Oxidum Antimonii cum Phosphate Calcis.) In all cases where it is desirable to promote the secretions in general, and those of the kidneys, skin, and alimentary canal, in particular, it is proper to have recourse to antimonial medicines. In inflammation of the brain and its membranes, and in that of the greater number of organs of high importance in the system, antimony should be exhibited. For an adult, from two to five grains of pulv. antim. may be ordered, and the dose, if requisite, may be repeated three or four times a day. In order to increase its action on the bowels, it is frequently conjoined with calomel.

Of late, doubts have arisen concerning the efficacy of antimonial powder, Dr. Elliotson having prescribed it even in the dose of 100 gr. apparently without any effect. Mr. R. Philips has attempted to explain the circumstance by the preparation of antimony being the peroxide, which is known to be inert.—(See *Annals of Philosophy for Octob.* 1822. *Pharmacologia by Dr. Paris, p.* 357, *vol.* 2, *ed.* 5, 1822.)

ANTIMONIUM MURIATUM. (*Butter of Antimony.*) Employed as a caustic.

ANTIMONII SULPHURETUM PRÆCIPITATUM. An ingredient in the compound calomel pill, and seldom prescribed in any other form.

ANTIMONIUM TARTARIZATUM. (*Emetic Tartar.*) Of this useful medicine, the best preparation is the vinum antim. tart. every half ounce of which contains one grain of antim. tart. Tartarized antimony, in the dose of gr. ¼, will, if the skin be kept warm, promote a diaphoresis; gr. ½ will procure some stools first, and sweating afterward; and gr. j. will generally excite vomiting, then purging, and lastly perspiration. In very minute doses, as gr. 1-10 or 1-12, combined with squill and ammoniacum, it acts as an expectorant. As Dr. Paris justly remarks, it is decidedly the most manageable, and the least uncertain of all the antimonial preparations, and the practitioner would probably have but little to regret, were all the other combinations of antimony discarded from our pharmacopœias.—(See *Pharmacologia by Dr. Paris, vol.* 2, *p.* 67, *ed.* 5.)

Tartarized antimony is sometimes blended with lard or spermaceti ointment, and used for producing redness and pustules of the integuments, where counter-irritation is indicated.—(See *Unguentum.*)

ANTRUM, *Diseases of.* This cavity is liable to a variety of diseases. Sometimes its membranous lining inflames, and secretes an extraordinary quantity of mucus or pus; at other times, in consequence of inflammation or other causes, it is the seat of various excrescences, polypi, and fungi. Even the bony parietes of the antrum are occasionally affected with exostosis or caries. Sometimes it contains extraneous bodies; and it is even asserted that insects may be generated there, and cause, for many years, very afflicting pains.

COLLECTIONS OF MUCUS AND PUS.

Inflammation of the membranous lining of the antrum sometimes produces an extraordinary secretion of mucus within it, and the collected fluid being confined, the bony parietes of the cavity become expanded in a surprising degree. This disease, says Boyer, is sometimes ascribed to a blow on the cheek, to caries of the teeth, or the projection of one of their fangs into the antrum. But in general, the case takes place unpreceded by any of these causes, and without there being the least ground for suspecting what has given rise to the disorder. It is remarked, however, that collections of mucus within the antrum are most frequent in young subjects: of three patients seen by Boyer, the eldest was not more than twenty.—(*Traité des Mal. Chir. t.* 6, *p.* 139.) As Mr. Hunter has noticed, whether the obliteration of the duct leading to the nose, be a cause or only an effect of the disease, is not easily determined; but from some of the symptoms, there is great reason to suppose it an attendant. "If it be a cause, we may suppose that the natural mucus of these cavities, accumulating, irritates, and produces inflammation for its own exit, in the same manner as an obstruction to the passage of the tears through the ductus ad nasum produces an abscess of the lachrymal sac."—(See *Hunter's Natural Hist. of the Teeth, p.* 174, *ed.* 3.) The most interesting example of the effects of the lodgement of mucus in the antrum is that recorded by Dubois: a boy, between seven and eight years of age, was observed to have at the base of the ascending process of the upper jaw-bone, on the left side, a small, very hard tumour of the size of a nut. As it gave no pain, and did not appear to increase, his parents did not give themselves any concern about it. When he was about sixteen, however, the swelling began to increase, and to be somewhat painful. Before he was eighteen, its augmentation was so considerable that the floor of the orbit was raised up by it; the eye thrust upwards; the palpebræ very much closed; the arch of the palate pushed down in the form of a tumour; and the nostril almost effaced. Below the orbit the cheek made a considerable prominence; while the nose was thrown towards the opposite side of the face, and the skin at the upper part of the tumour, below the lower eyelid, was of a purple red colour and threatening to burst. The upper lip was drawn upwards, and behind it all the gums on the left side were observed to project much farther than those on the opposite side of the face, and at this point alone the thinness of the bony parietes of the antrum was perceptible. The patient spoke and breathed with great difficulty; he slept uneasily, and his mastication was painful. The case was first supposed by Dubois, Sabatier, Pelletan, and Boyer, to be a fungus of the antrum, and an operation was considered advisable. In proceeding to this measure, the first thing which attracted the notice of Dubois was a sort of fluctuation in the situation of the gum behind the upper lip; a circumstance which led him to give up the idea of the

case being a fungus, though he expected that, on making an opening, merely a small quantity of ichorous matter would escape, affording no kind of information. In this place, however, he determined to make an incision along the alveolary process, whereby a large quantity of a glutinous substance like lymph, or what is found in cases of ranula, was discharged. A probe was now introduced, with which Dubois could feel a cavity equal in extent to the forepart of the tumour, and in moving the instrument about, with the view of learning whether any fungus was present, it struck against a hard substance, which felt like one of the incisor teeth, near the opening that had been made. Five days after this first operation, Dubois extracted two incisors and one grinder, and then removed the corresponding part of the alveolary process. As the hemorrhage was profuse, the wound was now filled with dressings, which in two days came away, and enabled Dubois to see with facility all the interior of the cavity. At its upper part, he perceived a white speck, which he supposed was pus, but on touching it with a probe, it turned out to be a tooth, which was then extracted, in doing which some force was requisite. The rest of the treatment merely consisted in injecting lotions into the cavity, and applying common dressings. In about six weeks all the hollow disappeared; but the swelling of the cheek and palate, and the displacement of the nose, still continued. In the course of another year and a half, however, every vestige of deformity was entirely removed.—(*Dubois, Bulletin de la Faculté de Méd. an* 13, *No.* 8.)

With respect to the treatment of collections of mucus in the antrum, by means of injections, thrown into that cavity through the natural opening in it, while the head is inclined to the opposite side, for the purpose of facilitating the escape of the collected fluid, as proposed by Jourdain in 1765 (*Mem. de l'Acad. de Chir. t.* 4, *p.* 357), Deschamps and Boyer are of opinion, that the method is objectionable: not only because it is difficult to find the aperture, which, ere the disease forms an outward swelling, is probably obliterated, but also because the thickness of the mucus collected would make it impossible for the surgeon to wash it out with injections. Hence, Boyer approves of the practice of opening the tumour in an eligible place, and to an extent sufficient for the discharge of the mucus.—(*Deschamps, Traité des Maladies des Fosses Nasales, et de leur Sinus, p.* 231, 8*vo. Par.* 1804; *Boyer, Traité des Mal. Chir. t.* 6, *p.* 145, 8*vo. Paris*, 1818.) Indeed, that Jourdain's proposal was attended with too much difficulty for common practice, was the sentence long ago pronounced upon it by a committee of the Royal Academy of Surgeons in France, nominated for the express purpose of inquiring into the merits of the suggestion. The method of making an opening into the antrum, will be considered in the sequel of this article. As a general rule, I may here remark, that except when a tumour or fungus requires to be extirpated, or a foreign body to be extracted from the antrum, it is quite unnecessary to remove any part of the alveolary process, or cut away any of the bony parietes of the antrum: the drawing of one of the teeth situated below this cavity, and making a perforation in this situation, being the only kind of opening required. This aperture may be preserved as long as necessary, by the introduction of a piece of elastic gum catheter, which is to be fastened to the adjacent teeth, and through which the secretion in the antrum may escape, or lotions be injected.—(See *Deschamps, Traite des Mal. des Fosses Nasales, &c. p.* 234.) However, as Hunter remarks, if the forepart of the bone has been destroyed, even though the case be merely a collection of mucus or pus, an opening may be made on the inside of the lip; but on account of the difficulty of maintaining such an aperture, he still inclines to the practice of drawing one of the teeth.—(*Natural Hist. of the Teeth, p.* 176, *ed.* 3.)

Of all the above cases, abscesses are by far the most common. Violent blows on the cheek, inflammatory affections of the adjacent parts, and especially of the pituitary membrane lining the nostrils, exposure to cold and damp, and, above all things, bad teeth, may bring on inflammation and suppuration within the hollow of the upper jaw-bone. The first symptom is a sensation of pain at first imagined to be a toothache, particularly if there should be a carious tooth at this part of the jaw. Such pain, however, extends more into the nose, than that usually does which arises from a decayed tooth: it also affects, more or less, the eye, the orbit, and the situation of the frontal sinuses.—(See *Hunter on the Teeth, p.* 175, *ed.* 3.) But even these symptoms are insufficient to characterize the disease, the nature of which is not unequivocally evinced till a much later period. The complaint is, in general, of much longer duration than one entirely dependent on a caries of a tooth, and its violence increases more and more, until, at last, a hard tumour is perceptible below the cheek-bone. By degrees the swelling extends over the whole cheek; but it afterward rises to a point, and forms a very circumscribed hardness, which may be felt above the back grinders. This symptom is accompanied with redness, and sometimes with inflammation and suppuration of the external parts. It is not uncommon, also, for the outward abscess to communicate with that within the antrum.

The circumscribed elevation of the tumour, however, does not occur in all cases. There are instances in which the matter makes its way towards the palate, causing the bones of this part to swell, and at length rendering them carious, unless timely assistance be given. There are other cases in which the matter escapes between the fangs and sockets of the teeth. Lastly, there are certain examples, in which the matter formed in the antrum makes its exit at the nostril of the same side, when the patient is lying with his head on the opposite one in a low position. If this mode of evacuation should be frequently repeated, it prevents the tumour both from pointing externally and bursting, as it would do if the purulent matter could find no other vent. But this evacuation of pus from the nostril is not very common; for, according to Mr. Hunter, the opening between the antrum and cavity of the nose is generally stopped up. He even seems inclined to think, as I have already observed, that the disease may sometimes be occasioned by the impervious state of this opening, in consequence of which, the natural mucus of the antrum collects in such quantity, as to irritate and inflame the membrane with which it is in contact, just as an obstruction in the ductus nasalis hinders the passage of the tears into the nose, and causes an abscess in the lachrymal sac. This is a point, however, on which even Mr. Hunter would not venture to speak with certainty; for it is by no means impossible, that the impervious state of the opening is rather an effect than the cause of the disease, since inflammation in the antrum is often manifestly produced by causes of a different kind, and since the opening in question is not invariably closed.

Abscesses in the antrum require a free exit for their contents, and if the surgeon neglects to procure such opening, the bones become more and more distended and pushed out, and finally carious. When this happens, the pus makes its appearance, either towards the orbit, the alveoli, the palate, or, as is mostly the case, towards the cheek. The matter having thus made a way for its escape, the disease now becomes fistulous.

In all cases, whether the pus be simply confined in the antrum, or whether the case be conjoined with a carious affection of the bones, the principal indication is to discharge the matter.

The ancients seem to have known very little about the treatment of diseases of the antrum. Drake, an English anatomist, is reputed to be the first proposer of a plan for curing abscesses of this cavity.—(*Anthropologia Nova. Londini*, 1727.) However, Meibomius was much earlier in proposing, with the same intention, the extraction of one or more of the teeth, in order that the matter might have an opening for its escape through the sockets. This plan may be employed with success. The pus frequently has a tendency to make its way outwards towards the teeth; it often affects their fangs; and, after their extraction, the whole of the abscess is seen to escape through the sockets. But this very simple plan will not suffice for all cases, as there are numerous instances in which there is no communication between the alveoli and the antrum.

Drake, and perhaps before him, Cowper, took notice of the insufficiency of Meibomius's method, and hence they proposed making a perforation through the socket into the antrum with an awl, for the purpose of letting out the matter, and injecting into the cavity such fluids as were judged proper.

M. Jourdain recommended to the French Academy of Surgery, the injection of detergent lotions into the

natural opening of the antrum, by means of a curved pipe introduced into the nostril; but, without dwelling upon the difficulty of putting this method in practice, especially where the opening is closed, many assert on the authority of the French surgeons themselves, that the mere employment of injections is not in these cases an effectual mode of treatment.—(See *Dict. des Sciences Med. t.* 51, *p.* 383.)

In the treatment of abscesses of the antrum, the extraction of one or more teeth, and the perforation of the alveoli, being generally essential steps, we must consider what tooth ought to be taken out in preference to others.

A caries, or even a mere continual aching, of any particular tooth, in general, ought to decide the choice. But if all the teeth should be sound, which is not often the case, writers direct us to tap each of them gently, and to extract that which gives most pain on this being done. When no information can be thus obtained, other circumstances ought to guide us.

All the grinding teeth, except the first, correspond with the antrum. They even sometimes extend into this cavity, and the fangs are only covered by the pituitary membrane. The bony lamella which separates the antrum from the alveoli, is very thin towards the back part of the upper jaw. Hence, when the choice is in our power, it is best to extract the third or fourth grinder, as in this situation the alveoli can be more easily perforated. Though, in general, the first grinder and canine tooth do not communicate with the antrum, their fangs approach the side of it, and from their socket an opening may readily be extended into that cavity.

When one or more teeth are carious, they should be removed, because they are both useless and hurtful. The matter frequently makes its escape as soon as a tooth is extracted, in consequence of the fang having extended into the antrum, or rather in consequence of its bringing away with it a piece of the thin partition between it and the sinus. Perhaps a discharge may follow from the partition itself being carious. If the opening thus produced be sufficiently large to allow the matter to escape, the operation is already completed. But as it can easily be enlarged, it ought always to be so when there is the least suspicion of its being too small. However, when no pus makes its appearance after a tooth is extracted, the antrum must be opened by introducing a pointed instrument in the direction of the alveoli. Some use a small trocar or awl, others a gimlet for this purpose.

The patient should sit on the ground in a strong light, resting his head on the surgeon's knee, who is to sit behind him. Immediately the instrument has reached the cavity, it is to be withdrawn. Its entrance into the antrum is easily known by the cessation of resistance. After the matter is discharged, surgeons advise the opening to be closed with a wooden stopper, in order to prevent the entrance of extraneous substances.

The stopper is to be taken out several times a day, to allow the pus to escape. This plan soon disposes the parts affected to discontinue the suppuration, and resume their natural state. Sometimes, however, the pus continues to be discharged for a long time after the operation, without any change occurring in regard to its quality or quantity. In such instances, the cure may often be accelerated by employing injections of brandy and water, lime-water, or a solution of the sulphate of zinc.

Some surgeons prefer a silver cannula, or a piece of elastic gum catheter, instead of the stopper, as it can always be left pervious except at meals. The examples on record, where the extraction of a tooth and the perforation of the bottom of the antrum were the means of curing abscesses of that cavity, are very numerous.—(See *Farmer's Select Cases, No.* 9; *Gooch's Cases, p.* 63, *new edition*; *Palfyn, Anatomie, &c.*)

If no opening were made in the antrum, the matter would make its way sometimes towards the front of this cavity, which is very thin; sometimes towards the mouth; and fistulous openings and caries would inevitably follow.

When the bones are diseased, the abov plan will not accomplish a cure until the affected pieces of bone exfoliate. A probe will generally enable us to detect caries in the antrum. The fetid smell and ichorous appearance of the discharge, also, leave little doubt that the bones are diseased; and in proportion as the bones free themselves of any dead portions, the discharge has less smell and its consistence becomes thicker.

When there are loose pieces of dead bone or other foreign bodies to be extracted, it is requisite to make a larger opening in the antrum than can be obtained at its lower part. Instances also occur where patients have lost all the grinding teeth and the sockets are quite obliterated, so that a perforation from below cannot be effected. Some practitioners object to sacrificing a sound tooth. In these circumstances, it has been advised to make a perforation in the antrum above the alveolary processes: a method first suggested by Lamorier. It consists in making a transverse incision below the malar process and above the root of the third grinder. Thus the gum and periosteum are divided, and the bone exposed. A perforating instrument is to be conveyed into the middle of this incision, and the opening in the antrum made as large as requisite.—(See *Mem. de l'Acad. de Chir. t.* 4, *p.* 351; *Gooch's Obs. append. p.* 138.) There are some extensive exfoliations of the antrum, where it is absolutely necessary to expose a great part of the surface of the bone, and to cut away the dead pieces which are wedged, as it were, in the livingones. A small trephine may sometimes be advantageously applied to the malar process of the superior maxillary bone.

Surgeons formerly treated carious affections of the antrum in the most absurd and unscientific way; introducing setons through its cavity, and even having recourse to the actual cautery. The moderns, however, are not much inclined to adopt this sort of practice. It is now known, that the detachment of a dead portion of bone, in other terms the process of exfoliation, is nearly, if not entirely, the work of nature, in which the surgeon can act a very inferior part. Indeed, he should limit his interference to preventing the lodgement of matter, maintaining strict cleanliness, and removing the dead pieces of bone as soon as they become loose. But it is to be understood, that examples occasionally present themselves, in which the dead portions of bone are so tedious of separation, and so wedged in the substance of the surrounding living bone, that an attempt may properly be made to cut them away.

TUMOURS OF THE ANTRUM.

Ruysch, Bordenave, Desault, Abernethy, Weinhold, and others, have recorded cases of polypous, fungous, and cancerous diseases of the antrum, and examples of this cavity being affected with exostosis.

The indolence of any ordinary fleshy tumour in the antrum, while in an incipient state, certainly tends to conceal its existence; but such a disease rarely occurs without being accompanied with some affection of the neighbouring parts; and hence, its presence may generally be ascertained before it has attained such a size as to have altered, in a serious degree, the natural shape of the antrum. This information may be acquired, by examining whether any of the teeth have become loose, or have spontaneously fallen out; whether the alveolary processes are sound, and whether there are any fungous excrescences making their appearance at the sockets; whether there is any habitual bleeding from one side of the nose; any sarcomatous tumour at the side of the nostril, or towards the great angle of the eye. When the swelling, however, has attained a certain size, the bony parietes of the antrum always protrude, unless the body of the tumour should be situated in the nostril, and only its root in the antrum. This case, however, is very uncommon.

As soon as a tumour is certainly known to exist in the antrum, the front part of this cavity should be opened, without waiting till the disease makes farther progress. In a few instances, indeed, we may avail ourselves of the opening which is sometimes found in the alveolary process, and enlarge it sufficiently to allow the tumour to be extirpated. If the front of the antrum were freely opened, it would in general be better to cut away the disease in its interior.

A swelling of the parietes of the antrum, in consequence of an abscess, or a sarcomatous tumour in its cavity, may lead us to suppose the case an enlargement of the bones, or an exostosis. The symptoms of the first two affections have been already detailed. One sign of an exostosis, besides the absence of the symptoms characterizing an abscess or a sarcoma, is

the thickened parietes of the antrum forming a solid resistance; whereas, in cases of mere expansion, the dimensions of the surface of the bone being increased, while its substance is rendered proportionally thinner, the resistance is not so considerable.

When such an exostosis depends upon a particular constitutional cause, and especially upon one of a venereal nature, it must be attacked by remedies suited to this affection. But when the disease resists internal remedies, and its magnitude is likely to produce an aggravation of the case, a portion of the bone may be removed with a trephine or a cutting instrument. Such operations, however, require a great deal of delicacy and prudence.

Mr. B. Bell, vol. 4, describes a kind of exostosis of the upper jaw, very different from what I have mentioned, since, instead of its being distinguishable from other diseases of the antrum by the greater firmness of the tumour, the substance of the bone gradually acquires such suppleness and elasticity, that it yields to the pressure of the fingers, and immediately resumes its former plumpness when the pressure is discontinued. If the bone be cut, it is found to be as soft as cartilage, and in an advanced stage of the disease, its consistence is almost gelatinous. The swelling increases gradually, and extends equally over the whole cheek, without becoming prominent at any particular point, or only so in the latter periods of the malady, when the soft parts inflame, and become affected. The complaint is described as totally incurable. Cutting and trephining the tumour, as recommended in other cases of exostosis, only aggravate the patient's unhappy condition.

Mr. Abernethy published an account of a very singular disease of the antrum. The patient, who was thirty-four years of age when the account was written, perceived, when about ten years old, a small tumour on his left cheek, which gradually attained the size of a walnut, and then remained for some time stationary. About a year afterward, the tumour having again enlarged, a caustic was applied to the integuments, so as to expose the bone. The actual cautery was next applied, and an opening thus made into the antrum. After the exfoliation, the antrum became filled with a fungus, which rose out upon the cheek, and could not be restrained by any applications. Part of the fungus also made its way into the mouth, through the socket of the second tricuspid tooth, the other teeth remaining natural. The disease continued in this state nine years, occasionally bleeding in an alarming way. When the patient was in his twentieth year, the whole fungus sloughed away during a fever, and never returned. After this, the sides of the aperture in the bone began to grow outwards, forming an exostosis, which rapidly attained a great magnitude. A small exostosis took place in the mouth, but became no larger than a horse-bean. The exostosis of the maxillary bone was of an irregular figure, and projected from the whole circumference of the aperture a great way directly forwards. Mr. Abernethy compared its appearance, when he was writing, with that of a large tea-cup fastened upon the face, the bottom of which may be supposed to communicate with the antrum. The diameter of the cup, formed by the circular edge of the bone, was three inches and a half; the depth two inches and seven-eighths. The general height of the sides of the exostosis, from the basis of the face, was two inches; its walls were not thick, and terminated in a thin circular edge. The integuments, as they approached this edge, became thinner, and they extended over it into the cavity. The exostosis now reached to the nose in front, and to the masseter muscle behind; above, it included the very ridge of the orbit, and below, it grew from the edge of the alveolary process. A line, that would have separated the diseased from the sound bone, would have included the orbit and nose, and indeed one-half of the face. Mr. Abernethy saw no means of affording the man relief.—(*Trans. of a Soc. for the Improvement of Med. and Chir. Knowledge, vol.* 2.) See also a case related by Harrison.—(*New-Lond. Med. Journ. vol.* 1, *p.* 1.)

In a case of fungus, which had distended the antrum, hindered the tears from passing down into the nose, raised the lower part of the orbit, caused a protrusion of the eye, made two of the grinding-teeth fall out, and occasioned a carious opening in the front of the antrum, through which opening a piece of the fungus projected, Desault operated as follows: the cheek was first detached from the os maxillare, by dividing the internal membrane of the mouth, at the place where it is reflected over this bone. Thus the outer surface of the bone was denuded of all the soft parts. A sharp perforating instrument was applied to the middle of this surface, and an opening made more forwards than the one already existing. The plate of bone situated between the two apertures, was removed with a little falciform knife, which, being directed from behind forwards, made the division without difficulty. The opening thus obtained being insufficient, Desault endeavoured to enlarge it below, by sacrificing the alveolary process. This he endeavoured to accomplish with the same instrument, but finding the resistance too great, he had recourse to a gouge and mallet. A considerable piece of the alveolary arch was thus detached, without any previous extraction of the corresponding teeth, three of which were removed by the same stroke. In this manner an opening was procured in the external and inferior part of the antrum, large enough to admit a walnut. Through this aperture a considerable part of the tumour was cut away with a knife, curved sideways, and fixed in its handle. A most profuse hemorrhage took place, but Desault, unalarmed, held a compress in the antrum for a short time; this being removed, the actual cautery was applied repeatedly to the rest of the fungus. The cavity was dressed with lint, dipped in powdered colophony.

On the eighteenth day, the swelling was evidently diminished, the eye less prominent, and the epiphora less visible. But, at this period, a portion of fungus made its appearance again. This was almost entirely destroyed by applying the actual cautery twice. It appeared again, however, on the twenty-fifth day, and required a third and last recourse to the cautery. From this time, the progress of the cure went on rapidly. Instead of fungous excrescences, healthy granulations were now formed in the bottom of the sinus. The parietes of the antrum gradually approaching each other, the large opening made in the operation was reduced to a small aperture, hardly capable of admitting a probe. Even this little opening closed in the fourth month, at which time no vestiges of the disease remained, except the loss of teeth, and a very obvious depression just where they were situated.

In all fungous diseases of the antrum, making a free exposure of them is an essential part of the treatment: if you neglect this method, how can you inform yourself of the size, form, and extent of the tumour? How could you remove the whole of the fungus, through a small opening, which would only allow you to see a very little portion of the excrescence? How could you be certain that the disease was extirpated to its very root? Even when the antrum is freely opened, this circumstance can only be learned with difficulty; and how could it be ascertained, when only a point of the cavity is opened? A portion, left behind, very soon gives origin to a fresh fungus, the progress of which is more rapid, and the character more fatal, in consequence of being irritated by the surgical measures adopted.—(*Œuvres Chir. de Desault, par Bichat, t.* 2.) See also other cases, recorded by Canolles (*Recueil Periodique de la Soc. de Méd. t.* 2, *No.* 9); Eichorn (*Diss. de Polypis in Antro Highmori, Goett.* 1814); Sandifort (*Museum Anat. vol.* 2, *tab.* 30); Leveillé (*Recueil de la Soc., &c. t.* 1, *p.* 24); Weinhold (*Von den Krankheiten der Gesichtsknochen, p.* 27, 4*to. Halle*, 1818).

I imagine, that English surgeons, unaccustomed to use the actual cautery, will peruse with a degree of aversion this means, so commonly employed in France. Nor can I expect that they will altogether approve the use of the mallet and gouge for making a free opening into the antrum. Perhaps it might be better to trephine this cavity with a small instrument for the purpose, and then cut the fungus away. After removing as much of it as possible in this manner, some instrument of suitable shape might be used to scrape the part where the tumour has its root. However, if there be any case in which potent and violent measures, like those of Desault, are allowable, it is the one of which we have just been treating. Inveterate diseases demand powerful means, and tampering with them is generally more hurtful than useful. I have lately been informed of one or two cases, in which the use of the cautery was found necessary in this country, for the stoppage of the bleeding after the removal of fungi from the antrum.

There is an interesting case of a fungus in the maxillary sinus, related in the first vol. of the Parisian Chir. Journal. It was at last cured by opening the antrum, applying the cautery, and tying the portion of the tumour which had made its way into the nose. In the second volume of the same work is an excellent case, exhibiting the dreadful ravages which the disease may produce when left to itself.

Professor Pattison, a few years ago, suggested the expedient of tying the carotid artery, as likely to bring about the dispersion of fungous diseases of the antrum, without the necessity of meddling with the tumour itself. He adverts to three cases, the results of which were, on the whole, favourable to the practice.—(See *Burns on Anat. of the Head, &c. ed. by Pattison.*) I consider that this proposal merits further trials, inasmuch as the operation of taking up the carotid artery is an infinitely less severe proceeding than that of extirpating the disease in the cheek, in the manner practised by Desault.

INSECTS IN THE ANTRUM.

It is said, that insects in this cavity may sometimes make it necessary for the surgeon to open it. This case, however, must be exceedingly rare; and even what we find in authors (*Pallas, de insectis Viventibus intra viventia*) appears so little authentic, that I should hardly have mentioned the circumstance, if there were not, in a modern work (*Med. Comm. vol.* 1), a fact which appears entitled to attention. Mr. Heysham, a medical practitioner at Carlisle, relates, that a strong woman, aged sixty, in the habit of taking a great deal of snuff, was subject, for several years, to acute pains in the antrum, extending over one side of the head. These pains never entirely ceased, but were more severe in winter than summer, and were always subject to frequent periodical exacerbations. The patient had taken several anodyne medicines, and others, without benefit, and had twice undergone a course of mercury, by which her complaints had been increased. All her teeth on the affected side had been drawn. At length, it was determined to open the antrum with a large trocar, though there were no symptoms of an abscess, nor of any other disease in this cavity. For four days, no benefit resulted from the operation. Bark injections and the elixir of aloes, were introduced into the sinus. On the fifth day, a dead insect was extracted, by means of a pair of forceps, from the mouth of the cavity. It was more than an inch long, and thicker than a common quill. The patient now experienced relief for several hours; but the pains afterward recurred with their former severity: oil was next injected into the antrum, and two other insects, similar to the former, were extracted. No others appeared, and the wound closed. The pains were not completely removed, but considerably diminished for several months, at the end of which time they became worse than ever, particularly affecting the situation of the frontal sinus.

Bordenave has published, in the twelfth and thirteenth volumes of the *Mem. de l'Acad. de Chir.* edit. 12mo. two excellent papers on diseases of the antrum. In the thirteenth volume, he relates the history of a case, in which several small whitish worms, together with a piece of fetid fungus, were discharged from the antrum, after an opening had been made on account of an abscess of this cavity, attended with caries.—(*P.* 381.) But, in this instance, the worms had probably been generated after the opening had been made in the cavity; for when they made their appearance, the opening had existed nine months. Deschamps refers to another case, in which M. Fortassin, his colleague at La Charité, found in the antrum of a soldier, whom he was dissecting, a worm of the ascaris lumbricus kind, four inches in length.—(*Traité des Mal. des Fosses Nasales, &c. p.*107.) Such an example is also recorded in one of the volumes of the *Journ. de Méd.* Were a case of this description to present itself in a living subject, it would be advisable to inject oil into the cavity of the antrum, and then endeavour to wash out the extraneous substances, by throwing into the sinus warm water, by means of a syringe.—See *Précis d'Observations sur les Maladies du Sinus Maxillaire, par M. Bordenave, in Mém. de l'Acad. Royale de Chirurgie, t.* 12, *edit. in* 12*mo. Also, Suite d'Observations on the same subject, by M. Bordenave, t.* 13, *of the said work; L. H. Halle*, 1808. *Also, an account of a Malignant Tumour removed from the Antrum, by T. Irving, in Edin. Med. Journ. Nos.* 83 *and* 84.

[A case of aneurism by anastomosis, situated in the branches of the internal maxillary artery, and cured by tying the carotid, is recorded by Professor Pattison, of the London University. The centre of the tumour occupied the antrum; but the sides of this cavity having been destroyed, the swelling made its way out of it in every direction; upwards into the orbit, from which it had displaced the eye; laterally into the nostril, which it completely filled; and against the septum narium, so as to produce a considerable distortion of the nose. It was as large as a new-born child's head, and attended with profuse and sometimes nearly fatal hemorrhages. Immediately after the performance of the operation, the appearance of the tumour in the nostril underwent a remarkable change; just before the ligature was applied, it seemed ready to burst from distention; but as soon as the direct circulation was stopped, its distention ceased, and its surface became shrivelled. The pulsatory movement, previously perceptible in it, now could not be detected. A daily improvement in the expression of the countenance followed. The swelling entirely disappeared, and the cheek-bone and zygoma, which had been quite concealed by it, again became evident. At the end of two years and a half from the operation, there had been no return of the disease, and the disfigurement was so trifling that it was scarcely perceptible.—(See *A. Burn's Surgical Anatomy of the Head and Neck, p.* 463, *ed.* 2, *with additions by G. S. Pattison, Glasgow*, 1824.) In the same edition the efficacy of tying the carotid for the cure of fungous diseases of the antrum is proved by several interesting cases. This is a subject which seems to me to demand the earnest attention of surgical practitioners.—*Pref.*]

ANUS. The lower termination of the great intestine named the rectum, is so called, and its office is to form an outlet for the feces.

The anus is furnished with muscles which are peculiar to it, viz. the sphincter, which keeps it habitually closed, and the *levatores ani*, which serve to draw it up into its natural situation, after the expulsion of the feces. It is also surrounded, as well as the whole of the neighbouring intestine, with muscular fibres, and a very loose sort of cellular substance. It is subject to various diseases, in which the aid of surgery is requisite: of these we shall next treat.

IMPERFORATE ANUS.

As it is of the utmost consequence that this and other malformations should not remain long unknown,

one of the earliest duties of an accoucheur after delivery should be an examination of all the natural outlets of new-born infants.

The place in which the extremity of the rectum, or the anus, ought to be, may be entirely or partly shut up by a membrane or fleshy adhesion. In other instances, no vestige of the intestine can be found, as the skin retains its natural colour over the whole space between the parts of generation and the os coccygis, without being more elevated in one place than another. In these cases, the intestine sometimes terminates in one or two culs-de-sac, about an inch upwards from the ordinary situation of the anus.—(See *Baillie's Engravings, fasc.* 4, *tab.* 5.) Sometimes it does not descend lower than the upper part of the sacrum; sometimes it opens into the bladder or vagina. Dr. Palmer dissected a case where the colon, after reaching the vicinity of the left kidney, began, as it descended, to form a sigmoid flexure; but previously to its arrival at the concavity of the left ileum, made a sudden turn to the right; and crossing the psoas muscle, reached the projection of the sacrum, where it terminated, *without at all entering the pelvis.* With this malformation was combined an imperforate meatus urinarius, and other considerable deviations of the genital organs from their natural structure.—(See *Medico-Chir. Journ. vol.* 1, 8vo. *Lond.* 1816.)

Sometimes the colon terminates in a sac, and the rectum is entirely deficient.—(See *Beauregard, in Journ. de Méd.* 1, 66.) Instances are also upon record where the rectum opened into the urethra.—(*Bresl. Samml.* 1718, *p.* 702; *Hist. de l'Acad. Royale des Sciences*, 1752, *p.* 113; *Hochstetter, in Med. Wochenblatt*, 1780, *No.* 18; 1783, *No.* 19; *Kretschmar, in Horn's Archiv. b.* 1, *p.* 350.)

When a surgeon is consulted he must not lose much time in deliberation; for if a speedy opening be not made for the feces, the infant will certainly very soon perish, with symptoms similar to those of a strangulated hernia. Mr. C. Hutchison thinks it, however, advantageous not to operate till the expiration of from twenty-four to sixty hours after birth, as within this period no great inconvenience will arise, and the distention of the rectum with meconium is a guidance to the surgeon in making the incisions.—(See *Obs. in Surgery, ed.* 2.) After ascertaining the complaint, which is an easy matter, the surgeon should endeavour to learn whether the anus is merely shut by a membrane or fleshy adhesion, or whether the anus is altogether wanting, in consequence of the lower portion of the cavity of the gut being obliterated or the rectum not extending sufficiently far down.

When a membrane or production of the skin closes the opening of the rectum, the part producing the obstruction is somewhat different in colour from the neigbouring integuments. It is usually of a purple or livid hue, in consequence of the accumulation of the meconium on its inner surface. The meconium, propelled downwards by the viscera above, forms a small roundish prominence, which yields like dough to the pressure of the fingers; but immediately projects again when the pressure is removed. When a fleshy adhesion closes the intestine, the circumstance is obvious to the eye, if the part protrude, as is generally the case. The finger feels greater hardness and resistance than when there is a mere membrane, and the livid colour of the meconium cannot be seen through the obstructing substance.

These last signs alone are enough to convince the surgeon of the necessity of the operation; but they do not clearly show whether the intestine descends as far as it ought in order to form a proper kind of anus. Complete information on this point can only be acquired after the membrane or adhesion has been divided; or else after the child's death, when the operation has proved ineffectual. Though there be no mark to denote where the anus ought to be situated, and no degree of prominence, yielding like soft dough to the pressure of the fingers, and rising again when such pressure is removed; yet it may happen, especially on our being consulted immediately after the child is born, that, notwithstanding the absence of such symptoms, denoting the presence of the meconium, and the natural extent of the intestine, as far as where the anus ought to be, the gut may exist and have a cavity as far as the membrane or adhesion closing it.

When the anus is simply covered with skin, and its place indicated by a prominence arising from the contents of the rectum, we have only to make an opening with a knife, sufficient to let out the meconium. Levret recommends a circular incision in the membrane; but a transverse one is sufficient. A small tent of lint is afterward to be introduced, in order to keep the opening from closing. If the anus be only partly closed by a membrane, the opening may be dilated with tents or bougies; but if the aperture be very small, it is preferable to use the bistoury for its enlargement.

When no external appearance denotes where the situation of the anus ought to be, the case is much more serious and embarrassing; and this, whether the intestine be stopped up by a fleshy adhesion or the coalescence of its sides, or whether a part of the gut be wanting.

However, it is the surgeon's duty to do every thing in his power to afford relief. For this purpose, an incision an inch long or rather more is to be made in the situation where the anus ought to be, and the wound is to be carried more and more deeply in the natural direction of the rectum. The cuts are not to be made directly upwards, nor in the axis of the pelvis, for the vagina or bladder might thus be wounded. On the contrary, the operator should cut backwards, along the concavity of the os coccygis, where there is no danger of wounding any part of importance. In all cases of this kind the surgeon's finger is the best director. The operator, guided by the index finger of his left hand, introduced within the os coccygis, is to dissect in the direction above recommended, until he reaches the feces, or has cut as far as he can reach with his finger. If he should fail in finding the meconium, as death must unavoidably follow, one more attempt ought to be made by introducing, upon the finger, a middle-sized trocar, in the direction best calculated to reach the rectum without danger to other parts, viz. upwards and backwards. The cannula of the trocar may be left in the puncture, and secured there by tapes, so as to afford an outlet for the feces. In some observations on this subject, addressed to the Medical and Chirurgical Society by Mr. Copland Hutchison, he recommends an elastic gum catheter to be substituted for the cannula after a week, and when the tube can be dispensed with, a sponge tent or piece of bougie to be worn 12 out of the 24 hours.—(See also *Obs. in Surgery, ed.* 2, 1826.)

In a very interesting case, recorded in Langenbeck's new Surgical Bibliotheca, the imperforate state of the anus was not discovered till the evening of the 12th day from the child's birth, when hiccough and convulsions had come on. M. Wolff found the abdomen protuberant, hard, and painful when handled, and nausea, vomiting, and great depression of strength prevailed. Next day, he introduced a large lancet a few lines in front of the os coccygis to the depth of an inch without finding the rectum. The puncture was then carried to the depth of two inches, but without effect. With a pharyngotomus, however, he now succeeded in piercing the rectum; and a glyster was administered, which brought away some meconium. Under the use of glysters and tents the child soon recovered.

By such proceedings many infants have been preserved, which would otherwise have been devoted to certain death. Hildanus, La Motte, Roonhuysen, Mr. Copland Hutchison, and others have successfully adopted the practice. Mr. B. Bell met with two cases, in which the intestine was very distant from the integuments, and he was so successful as to form an anus, which fulfilled its office tolerably well for several years; but he found it exceedingly difficult to keep the passage sufficiently pervious. As soon as he removed the dossils of lint, and other kinds of tents, used for maintaining the necessary dilatation, such a degree of contraction speedily followed, that the evacuation of the intestinal matter became very difficult for a long while afterward. He employed, at different times, tents made of sponge, gentian root, and other substances, which swell on being moistened. But they always produced so much pain and irritation that it was impossible to persevere in their use.

Tents of very soft lint, dipped in oil, or rolls of bougie-plaster, cause less irritation than those composed of any other materials.

Though keeping the opening dilated may seem simple and easy to such men as have had no opportunities of seeing cases of this description, it is far otherwise in practice. Mr. B. Bell assures us, that he never met with any disease that gave him so much trouble and

embarrassment as he experienced in the two cases of this sort which occurred in his practice. Although in both instances he made the openings at first sufficiently large, it was only by very assiduous attention for eight or ten months, that the necessity for another operation, and even repeated operations, was prevented. When only the skin has been divided, the rest of the treatment is doubtless more simple; for then nothing more is requisite than keeping a piece of lint for a few days in the opening made with the knife. But when the extremity of the rectum is at a certain distance, though we may generally hope to effect a cure, after having succeeded in giving vent to the intestinal matter, yet the treatment after the operation will always demand for a long while a great deal of attention and care on the part of the surgeon. In a highly interesting example, recorded by Mr. Miller, of Methven, such was the tendency to closure of the new opening, that he was obliged to repeat the operation ten times before the child was eight months old.—(See *Edin. Med. Journ. No.* 98, *p.* 62.) Notwithstanding all these operations, and another one of two hours and three-quarters' duration, performed several years afterward for the extraction of an alvine concretion equal in size to a turkey's egg, the power of the sphincter was perfect. The difficulty of success may be considered as in some measure proportioned to the depth of the necessary incision. In a case like that recorded by Dr. Palmer, to which I have above adverted, the inutility of any attempt to discharge the feces by an operation in the usual site of the anus must be sufficiently obvious.—(*Medico-Chir. Journ. vol.* 1, *p.* 181.)

Sometimes, while the anus appears pervious and well formed, infants suffer the same symptoms as if there were no anus at all. The reason of this depends upon the intestine being occasionally closed by a membranous partition situated more or less upwards, above the aperture of the anus (*Courtial, Nouvelles Obs. sur les Os, p.* 147; *John Wayte, in Edin. Med. and Surgical Journ. April*, 1821; *and Cases in Hutchison's Obs. in Surgery, ed.* 2), and sometimes the symptoms are owing to the termination of the gut in a cul-de-sac. This erroneous formation may always be suspected when an infant, whose anus is externally open, does not void any excrement for two or three days after its birth, and especially when urgent symptoms arise, such as swelling of the belly, vomiting, &c. We are now to endeavour to ascertain whether the rectum is impervious above the anus, by attempting to inject glysters or to introduce a probe. If the gut be shut up there is nothing to be done but having recourse to the method described above, and forming a communication by means of a bistoury guided on the finger, or else with a pharyingotomus. If the obstacle should only consist of a transverse membrane, the operation will be easy and its success highly probable. But if there should be a strangulation or obstruction of the intestine, the case is infinitely more serious.

In the case recorded by Mr. Wayte, the membranous septum was felt by the finger about an inch from the verge of the anus. It was pierced with a pointed probe which was followed by a hydrocele trocar, and afterward by a bougie of larger dimensions. On withdrawing the latter, much meconium, mixed with feces, escaped and continued to be frequently discharged. In a week, however, the opening closed, and a fresh puncture was made, which was maintained by the frequent introduction of bougies. The child proceeded tolerably well until the end of another week, when the passage was again much contracted and the abdomen proportionably distended. On the 20th day from birth, a full-sized trocar was used for restoring the opening, which, however, again had a tendency to close, but was afterward dilated by introducing twice a day bougies, which were increased in size until a rectum bougie of middle size could be passed. The boy now rapidly improved, and every hope of a perfect recovery was entertained, but disease of the os coccygis ensued, and at the end of six months the little patient died hectic.—(See *Edin. Med. and Surg. Journ. vol.* 17.)

When the anus is imperforate, the intestine sometimes opens into the vagina or bladder.—(*Dumas, in Recueil Periodique de la Soc. de Méd. t.* 3, *No.* 13. *L'Eveillé, Rapport des Travaux de la Soc. Philom. vol.* 1, *p.* 145. *Murray, Diss. Atresis Ani vesicalis, Ups.* 1794. *Act. Nat. Cur. vol.* 8, *Obs.* 24, *vol.* 9, *Obs.* 11. *Roestel, in Mursinna's Journ. fur die Chir. b.* 1, *p.* 547. *Obs. Med. Decad.* 2, *No.* 2.) The first case is the least dangerous of such malformations. The intestine may also terminate at two places at the same time, viz. at the usual place, so as to form a proper anus more or less perfect; and also in the vagina.

If these two openings should be ample enough for the easy evacuation of the excrement, nothing can be done at so tender an age; for though voiding the feces through the vagina is a most unpleasant inconvenience, yet there is no effectual means of closing the opening of the intestine in this situation, nor could one be devised which would not seriously incommode the infant.

But when the two openings are exceedingly small, and the alvine evacuations cannot readily pass out, even with the aid of glysters, the opening of the anus ought to be dilated by cannulæ of different sizes. If this method should not avail, the knife must be employed, and the wound dressed as already explained.

For the most part the intestine has only one opening in the vagina. In this circumstance, as in the instance in which the feces have no vent at all, we must make an incision in that place which the anus ought to occupy. The natural course of the feces being opened by this operation, which in such a case is not at all perilous, much less excrement will pass out of the vagina, and of course the infirmity will be diminished. By the introduction of a tube into the new anus, the communication between the rectum and vagina might possibly be obliterated, and a perfect cure accomplished. The opening between the intestine and vagina may also be too small for the easy evacuation of the feces, and even expose the infant to the same sort of dangerous symptoms as would occur if the rectum had no opening at all.

In male infants the rectum sometimes opens into the bladder, and in this circumstance there is generally no anus. The case is easily known by the meconium being blended with the urine, which acquires a thick greenish appearance, and is voided almost continually, though in small quantities. Only the most fluid part of the meconium is thus discharged. The thicker part not getting from the rectum into the bladder, nor from the bladder into the urethra, greatly distends the intestines and bladder, and produces the same symptoms as take place in cases of total imperforation. Hence, without the speedy interference of art to form an anus capable of giving vent to the feces, with which the urinary organs cannot remain obstructed, the infant will inevitably die. This case must, therefore, be treated like the foregoing examples. Though we can hardly hope to prevent altogether the inconveniences resulting from the rectum opening into the bladder, since even a new passage will not completely hinder the feces from following the other course; yet we shall thus afford the child a very good chance of preservation, and the only one which its situation will allow.

In cases in which an outlet for the feces cannot be procured by any of the methods pointed out above, it has been proposed by Littre to make an opening above one of the groins, find out a portion of intestine, open it, fix it in this situation with a few stitches, and thus form an artificial anus. Sabatier was only acquainted with one case in which this proceeding had been actually done, viz. the example where Duret, a French naval surgeon, operated. This gentleman cut into the abdomen at the lower part of the left iliac region, and having opened the sigmoid flexion of the colon, he fixed it near the wound. The child was saved by the formation of an artificial anus; but at the age of twenty-five months it continued to be troubled with a sort of prolapsus of the lining of the bowel.—(See *Recueil Périodique de la Soc. de Méd. t.* 4, *No.* 19; *and Sabatier, Méd. Opératoire, t.* 3, *p.* 336, *edit.* 2.)

An instance has been published by Mr. Pring, in which he made an opening in the colon, near its sigmoid flexure, in a lady, who, in consequence of a scirrhous disease of the rectum, was afflicted with an obstinate and perilous obstruction of the intestinal canal. The patient survived the operation nearly sixteen months, at the end of which time she fell a victim to the disease of the rectum.—(See *London Medical and Physical Journal, vols.* 45 *and* 47.) I should be reluctant to offer any remarks encouraging the repetition of this practice, against which various considerations present themselves, particularly in cases where, besides a mere difficulty of emptying the bowels, another dis-

case exists, which is itself likely to destroy the patient, and is of a nature not capable of receiving any effectual benefit from the bold operation practised in the example related by Mr. Pring.

Callisen conceives that the descending colon may be most conveniently got at by making an incision in the left lumbar region along the edge of the quadratus lumborum muscle; and he prefers this mode of operating to that of making the incision above the groin.—(*Syst. Chir. Hodiernæ, t.* 2, *p.* 688, 689, *ed.* 1800.) Its advantages, however, are not obvious.—(See *Sabatier, Médecine Opératoire, t.* 3, *p.* 330. *Pappendorf, de Ano infantum imperforato, Leipz.* 1783. *Remarques sur Différens Vices de Conformation que les Enfans apportent en naissant, par M. Petit, in Mém. de l'Acad. Royale de Chir. t.* 2, *p.* 236, *edit. in* 12*mo. H. A. Wrisberg, de præternaturali et raro Intestini Recti cum vesica urinaria coalitu, et independente Ani defectu,* 4*to. Wayte, in Edin. Med. Journ. vol.* 17. *Lancet, vol.* 1, *p.* 434. *A. C. Hutchison, in Pract. Obs. in Surgery, ed.* 2, 1826. *Miller, in Edin. Med. Journ. No.* 98, *p.* 61. *Jolliet, in Journ. de Méd. par Leroux, t.* 32, *p.* 272.)

ABSCESSES OF THE ANUS.—FISTULA IN ANO.

The custom of giving the appellation of *fistula* to every collection of matter formed near the anus, has, by conveying a false notion of them, been productive of such methods of treating them, as are diametrically opposite to those which ought to be pursued.

A small orifice or outlet from a large or deep cavity, discharging a thin gleet or sanies, made, as Mr. Pott has explained, a considerable part of the idea which our ancestors had of a fistulous sore, wherever seated. With the term fistulous they always connected a notion of callosity; and therefore, whenever they found such a kind of opening yielding such sort of discharge, and attended with any degree of induration, they called the complaint a *fistula*. Imagining this callosity to be a diseased alteration made in the very structure of the parts, they had no conception that it could be cured by any means but by removal with a cutting instrument, or by destruction with escharotics; and therefore they immediately attacked it with knife or caustic, in order to accomplish one of these ends; and very terrible work they often made.

That abscesses formed near the fundament do sometimes, from bad habits, from extreme neglect, or from gross mistreatment, become fistulous, is certain; but the majority of them have not at first any one character or mark of a true fistula; nor can, without the most supine neglect on the side of the patient, or the most ignorant management on the part of the surgeon, degenerate or be converted into one.

Collections of matter from inflammation (wherever formed), if they be not opened in time and in a proper manner, do often burst. The hole through which the matter finds vent is generally small, and not often situated in the most convenient or most dependent part of the tumour: it therefore is unfit for the discharge of all the contents of the abscess; and instead of closing contracts itself to a smaller size, and becoming hard at its edges, continues to drain off what is furnished by the undigested sides of the cavity.

When an abscess near the anus bursts, the smallness of the accidental orifice; the hardness of its edges; its being found to be the outlet from a deep cavity; the daily discharge of a thin, gleety, discoloured kind of matter; and the induration of the parts round about, have all contributed to raise and confirm the idea of a true fistula.

Abscesses about the anus present themselves in different forms.

Sometimes the attack is made with symptoms of high inflammation; with pain, fever, rigor, &c., and the fever ends as soon as the abscess is formed.

In this case a part of the buttock near the anus is considerably swollen, and has a large circumscribed hardness. In a short time the middle of this hardness becomes red and inflamed; and in the centre of it matter is formed.

This (in the language of our ancestors) is called in general a *phlegmon;* but when it appears in this particular part, a *phyma.*

The pain is sometimes great, the fever high, the tumour large and exquisitely tender; but however disagreeable the appearances may have been, or however high the symptoms may have risen before suppuration, yet when that end is fairly and fully accomplished, the patient generally becomes easy and cool; and the matter formed under such circumstances, though it may be plentiful, is good.

On the other hand, the external parts, after much pain, attended with fever, sickness, &c., are sometimes attacked with considerable inflammation, but without any of that circumscribed hardness which characterized the preceding tumour; instead of which the inflammation is extended largely, and the skin wears an erysipelatous kind of appearance. In this the disease is more superficial; the quantity of matter small, and the cellular membrane sloughy to a considerable extent.

Sometimes instead of either of the preceding appearances, there is formed in this part what the French call *une suppuration gangreneuse;* in which the cellular and adipose membrane is affected in the same manner as it is in a carbuncle.

In this case, the skin is of a dusky red or purple kind of colour; and although harder than when in a natural state, yet it has, by no means, that degree of tension or resistance, which it has either in phlegmon or in erysipelas.

The patient has generally, at first, a hard, full, jarring pulse, with great thirst, and very fatiguing restlessness. If the progress of the disease be not stopped, or the patient relieved by medicine, the pulse soon changes into an unequal, low, faltering one; and the strength and the spirits sink in such manner, as to imply great and immediately impending mischief. The matter formed under the skin, so altered, is small in quantity, and bad in quality; and the adipose membrane is gangrenous and sloughy throughout the extent of the discoloration. This generally happens to persons, whose habit is either naturally bad, or has been rendered so by intemperance.

Sometimes the disease makes its first appearance in the induration of the skin, near to the verge of the anus, but without pain or alteration of colour; which hardness gradually softens and suppurates. The matter, when let out, in this case, is small in quantity, good in quality; and the sore is superficial, clean, and well-conditioned. On the contrary, it now and then happens, that although the pain is but little, and the inflammation apparently slight, yet the matter is large in quantity, bad in quality, extremely offensive, and proceeds from a deep crude hollow.

The place also where the abscess points, and where the matter, if let alone, would burst its way out, is various and uncertain. Sometimes it is in the buttock, at a distance from the anus; at other times, near its verge, or in the perinæum; and this discharge is made sometimes from one orifice only, sometimes from several. In some cases there is not only an opening through the skin externally, but another through the intestines into its cavity: in others, there is only one orifice, and that either external or internal.

Sometimes the matter is formed at a considerable distance from the rectum, which is not even laid bare by it; at others, it is laid bare also, and not perforated: it is also sometimes not only denuded, but pierced; and that in more places than one.

All consideration of preventing suppuration is generally out of the question: and our business, if called at the beginning, must be to moderate the symptoms; to forward the suppuration; when the matter is formed, to let it out; and to treat the sore in such manner as shall be most likely to produce a speedy and lasting cure.

When there are no symptoms which require particular attention, and all that we have to do is to assist the maturation of the tumour, a soft poultice is the best application. When the disease is fairly of the phlegmonoid kind, the thinner the skin is suffered to become before the abscess is opened, the better; as the induration of the parts about will thereby be the more dissolved, and, consequently, there will be the less to do after such opening has been made. This kind of tumour is generally found in people of full, sanguine habits; and who, therefore, if the pain be great, and the fever high, will bear evacuation, both by phlebotomy and gentle cathartics: which is not often the case of those, who are said to be of bilious constitu-

tions; in whom the inflammation is of a larger extent, and in whom the skin wears the yellowish tint of the erysipelas; persons of this kind of habit, and in such circumstances, being in general seldom capable of bearing large evacuation.

When the inflammation is erysipelatous, the quantity of matter formed is small, compared with the size and extent of the tumour; the disease is rather a sloughy, putrid state of the cellular membrane than an imposthumation; and, therefore, the sooner it is opened the better: if we wait for the matter to make a point, we shall wait for what will not happen; at least, not till after a considerable length of time: during which the disease in the membrane will extend itself, and, consequently, the cavity of the sinus or abscess be thereby greatly increased.

When, instead of either of the preceding appearances, the skin wears a dusky purplish-red colour; has a doughy unresisting kind of feel, and very little sensibility; when these circumstances are joined with an unequal, faltering kind of pulse, irregular shiverings, a great failure of strength and spirits, and inclination to doze, the case is formidable, and the event generally fatal.

The habit, in these circumstances, is always bad: sometimes from nature, but much more frequently from gluttony and intemperance. What assistance art can lend must be administered speedily; every minute is of consequence; and if the disease be not stopped, the patient will sink. Here (says Pott) is no need for evacuation of any kind: recourse must be immediately had to medical assistance; the part affected should be frequently fomented with hot spirituous fomentations; a large and deep incision should be made into the diseased part, and the application made to it should be of the warmest, most antiseptic kind.

This also is a general kind of observation, and equally applicable to the same sort of disease in any part of the body. Our ancestors have thought fit to call it in some a carbuncle, and in others by other names: but it is (wherever seated) really and truly a gangrene of the cellular and adipose membrane: it always implies great degeneracy of habit, and, most commonly, ends ill.

Strangury, dysury, and even total retention of the urine are no very uncommon attendants upon abscesses in the neighbourhood of the rectum and bladder: more especially if the seat of them be near the neck of the latter.

They sometimes continue from the first attack of the inflammation, until the matter is formed, and has made its way outwards: and sometimes last a few hours only.

The two former most commonly are easily relieved by the loss of blood, and the use of gum arabic, with nitre, &c. But in the last (the total retention), they who have not often seen this case, generally have immediate recourse to the catheter: but the practice is essentially wrong.

The neck of the bladder does certainly participate, in some degree, in the said inflammation. But the principal part of the complaint arises from irritation, and the disease is, strictly speaking, spasmodic. The manner in which an attack of this kind is generally made; the very little distention which the bladder often suffers; the small quantity of urine sometimes contained in it, even when the symptoms are most pressing; and the most certain as well as safe method of relieving it; all tend to strengthen such opinion.

But whether we attribute the evil to inflammation or to spasmodic irritation, whatever can, in any degree, contribute to the exasperation of either, must be manifestly wrong. The violent passage of the catheter through the neck of the bladder (for violent in such circumstances it must be) can never be right.

If the instrument be successfully introduced, it must either be withdrawn as soon as the bladder is emptied, or it must be left in it: if the former be done, the same cause of retention remaining, the same effect returns; the same pain and violence must again be submitted to, under (most likely) increased difficulties. On the other hand, if the catheter be left in the bladder, it will often, while its neck is in this state, occasion such disturbance that the remedy (as it is called) will prove an exasperation of the disease, and add to the evil it is designed to alleviate. Nor is this all; for the resistance which the parts while in this state make, is sometimes so great that if any violence be used, the instrument will make for itself a new route in the neighbouring parts, and lay the foundation of such mischief as frequently baffles all our art.

The true, safe, and rational method of relieving this complaint (says Pott) is by evacuation and anodyne relaxation: this not only procures immediate ease, but does, at the same time, serve another very material purpose; which is that of maturating the abscess. Loss of blood is necessary; the quantity to be determined by the strength and state of the patient: the intestines should also be emptied, if there be time for so doing, by a gentle cathartic; but the most effectual relief will be from the warm bath or semicupium, the application of bladders with hot water to the pubes and perinæum, and, above all other remedies, the injection of glysters, consisting of warm water, oil, and opium. There may have been cases which have resisted and baffled this method of treatment; but Pott never met with them.

A painful tenesmus is no uncommon attendant upon an inflammation of the parts about the rectum.

If a dose of rhubarb, joined with the confect. opii, does not remove it, the injection of thin starch and opium or tinct. thebaic. is almost infallible.

The bearing down in females, as it proceeds, in this case, from the same kind of cause (viz. irritation), admits of relief from the same means as the tenesmus.

In some habits, an obstinate costiveness attends this kind of inflammation, accompanied, not unfrequently, with a painful distention and enlargement of the hemorrhoidal vessels, both internally and externally While a large quantity of hard feces is detained within the large intestines, the whole habit must be disordered; and the symptomatic fever which necessarily accompanies the formation of matter, must be considerably heightened. And while the vessels surrounding the rectum (which are large and numerous) are distended, all the ills proceeding from pressure, inflammation, and irritation must be increased. Phlebotomy, laxative glysters, and a low, cool regimen must be the remedies: while a soft cataplasm applied externally serves to relax and mollify the swollen, indurated piles, at the same time that it hastens the suppuration.

When the abscesses have formed, and are fit to be opened, or when they have already burst, they may be reduced to two general heads, viz.

1. Those in which the intestine is not all interested: and,

2. Those in which it is either laid bare or perforated.

In making the opening, the knife or lancet should be passed in deep enough to reach the fluid; and when it is in the incision should be continued upwards and downwards in such manner as to divide all the skin covering the matter. By these means, the contents of the abscess will be discharged at once; future lodgement of matter will be prevented; convenient room will be made for the application of proper dressings; and there will be no necessity for making the incision in different directions, or for removing any part of the skin composing the verge of the anus.

Notwithstanding all these collections of matter are generally called *fistulæ*, and are all supposed to affect the rectum, the abscess is sometimes really at such a distance from the gut, that it is not at all interested by it; and none of these cases either are or can be originally *fistulæ*.

In this state of the disease, we have no more necessarily to do with the intestine than if it were not there; the case is to be considered merely as an abscess in the cellular membrane.

A short time ago, some interesting remarks on fistula in ano were published in France by Dr. Ribes, whose opinions, however, like those of many other valuable writers, are not invariably free from error; and I have no hesitation in extending this observation to one of his statements, though what he has said is alleged to be deduced from the dissection of not less than 75 persons who had died with fistulæ. No man who has seen much of this part of surgery, can doubt that the most frequent form of the disease is that in which the abscess has only an external opening, and does not perforate the rectum at all, from which, indeed, the matter is sometimes more or less distant. Nor can any experienced surgeon question the truth of Mr. Pott's account respecting the diversity of the

nature of the cases of fistulæ, some being phlegmonous, some erysipelatous, and others more like the carbuncle in their origin, progress, and consequences. But besides these circumstances, another one worthy of notice is, that the presence of fistula in ano by no means implies the previous or present existence of piles. However, notwithstanding these considerations, the doctrine started by Dr. Ribes is, that a fistula is formed by the bursting of an internal pile into the rectum, and the consequent passage of a portion of the contents of the bowel into the orifice. He farther asserts that such orifice is *always* within five or six lines above the junction of the internal membrane of the bowel with the external skin, and that it may usually be seen, if the patient forces the gut gently down, as in going to stool. The only correct part of these statements is, I believe, the account of the common situation of the internal opening, when the abscess communicates with the bowel, which is not always the case.—(See *Recherches sur la Situation de l'Orifice interne de la Fistule de l'Anus, &c. Quarterly Journ. of Foreign Med. No.* 8. *Oct.* 1820.) This part of the account is confirmed by the observations of Larrey.—(*Mém. de Chir. Mil. t.* 3, *p.* 415.)

Suppose a large and convenient opening to have been made by a simple incision; the contents of the abscess to have been thereby discharged; and a sore or cavity produced, which is to be filled up.

The term *filling up*, and the former opinion, that the induration of the parts about is a diseased callosity, have been the two principal sources of misconduct in these cases.

The old opinion, with regard to hollow and hardness, was that the former is caused entirely by loss of substance; and the latter, by diseased alteration in the structure of the parts.

The consequence of which opinion was, that as soon as the matter was discharged, the cavity was filled and distended, in order to procure a gradual regeneration of flesh; and the dressings, with which it was so filled, were most commonly of the escharotic kind, intended for the dissolution of hardness.

On the other hand, the surgeon who regards the cavity of the abscess as being principally the effect of the gradual separation of its sides, with very little loss of substance, compared with the size of the said cavity; and who looks upon the induration round about, as nothing more than a circumstance which necessarily accompanies every inflammation, will, upon the smallest reflection, perceive that the dressings applied to such cavity ought to be so small in quantity, as to permit nature to bring the sides of the cavity towards each other, and that such small quantity of dressings ought not by their quality either to irritate or destroy.

If the hollow, immediately it is opened, be filled with dressings (of any kind), the sides of it will be kept from approaching each other, or may even be farther separated. But if this cavity be not filled, or have little or no dressings of any kind introduced into it, the sides immediately collapse, and, coming nearer and nearer, do, in a very short space of time, convert a large hollow into a small sinus. And this is also constantly the case, when the matter, instead of being let out by an artificial opening, escapes through one made by the bursting of the containing parts.

True, this sinus will not always become perfectly closed; but the aim of nature is not therefore the less evident; nor the hint, which art ought to borrow from her, the less palpable.

In this, as in most other cases, where there are large sores, or considerable cavities, a great deal will depend on the patient's habit, and the care that is taken of it; if that be good, or if it be properly corrected, the surgeon will have very little trouble in his choice of dressings; only to take care that they do not offend either in quantity or quality: but if the habit be bad, or injudiciously treated, he may use the whole farrago of externals, and only waste his own and his patient's time.

By light, easy treatment, large abscesses formed in the neighbourhood of the rectum will sometimes be cured, without any necessity for meddling with the said gut. But it much more frequently happens, that the intestine, although it may not have been pierced or eroded by the matter, has yet been so stripped or denuded, that no consolidation of the sinus can be obtained, but by a division; that is, by laying the two cavities, viz. that of the abscess and that of the intestine, into one.

When the intestine is found to be separated from the surrounding parts by the matter, the operation of dividing it had better (on many accounts) be performed at the time the abscess is first opened, than be deferred to a future one. For, if it be done properly, it will add so little to the pain, which the patient must feel by opening the abscess, that he will seldom be able to distinguish the one from the other, either with regard to time or sensation; whereas, if it be deferred, he must either be in continual expectation of a second cutting, or feel one at a time when he does not expect it.

The intention in this operation is to divide the intestine rectum from the verge of the anus up as high as the top of the hollow in which the matter was formed; thereby to lay the two cavities of the gut and abscess into one; and by means of an open, instead of a hollow or sinuous sore, to obtain a firm and lasting cure.

For this purpose, the curved, probe-pointed knife, with a narrow blade, is the most useful and handy instrument of any. This, introduced into the sinus, while the surgeon's fore-finger is in the intestine, will enable him to divide all that can ever require division; and that with less pain to the patient, with more facility to the operator, as well as with more certainty and expedition, than any other instrument whatever. If there be no opening in the intestine, the smallest degree of force will thrust the point of the knife through, and thereby make one: if there be one already, the same point will find and pass through it. In either case, it will be received by the finger in ano; will thereby be prevented from deviating; and being brought out by the same finger, must necessarily divide all that is between the edge of the knife and the verge of the anus: that is, must by one simple incision (which is made in the smallest space of time imaginable) lay the two cavities of the sinus and of the intestine into one.

Authors make a very formal distinction between those cases in which the intestine is pierced by the matter, and those in which it is not; but although this distinction may be useful when the different states of the disease are to be described, yet in practice, when the operation of dividing the gut becomes necessary, such distinction is of no consequence at all: it makes no alteration in the degree, kind, or quantity of pain which the patient is to feel; the force required to push the knife through the tender gut is next to none, and when its point is in the cavity, the cases are exactly similar. In this statement every man of experience and discernment must agree, notwithstanding the prohibition to the operation, delivered by Dr. Ribes, in every case, in which the internal opening cannot be found: a piece of advice (as it seems to me) fully admitting the occurrence of cases which could not be formed in the manner in which he conceives all fistulæ in ano to be produced, viz. by the bursting of a pile, and the entrance of feces into the orifice.

Immediately after the operation, a soft dossil of fine lint should be introduced (from the rectum) between the divided lips of the incision; as well to repress any slight hemorrhage, as to prevent the immediate reunion of the said lips; and the rest of the sore should be lightly dressed with the same. This first dressing should be permitted to continue, until a beginning suppuration renders it loose enough to come away easily; and all the future ones should be as light, soft, and easy as possible; consisting only of such materials as are likely to promote kindly and gradual suppuration. The sides of the abscess are large; the incision must necessarily, for a few days, be inflamed; and the discharge will, for some time, be discoloured and gleety: this induration, and this sort of discharge, are often mistaken for signs of diseased callosity and undiscovered sinuses; upon which presumptions, escharotics are freely applied, and diligent search is made for new hollows: the former of these most commonly increase both the hardness and the gleet; and by the latter new sinuses are sometimes really produced. These occasion a repetition of escharotics, and, perhaps, of incisions; by which means, cases which at first, and in their own nature, were simple and easy of cure, are rendered complex and tedious.

To quit reasoning, and speak to fact only: In the

great number of these cases, which must have been in St. Bartholomew's Hospital, within these ten or twelve years, *I do aver* (says Pott), *that I have not met with one, in the circumstances before described, that has not been cured by mere simple division, together with light, easy dressings: and that I have not, in all that time, used, for this purpose, a single grain of precipitate, or any other escharotic.*

Let us now suppose the case in which the matter is fairly formed; has made its point, as it is called; and is fit to be let out.

Where such point is, that is, where the skin is most thin, and the fluctuation most palpable, the opening most certainly ought to be made, and always with a cutting instrument, not caustic, as was formerly done.

When a discharge of the matter by incision is too long delayed or neglected, it makes its own way out, by bursting the external parts somewhere near to the fundament, or by eroding and making a hole through the intestine into its cavity; or sometimes by both. In either case, the discharge is made sometimes by one orifice only, and sometimes by more. Those in which the matter has made its escape by one or more openings through the skin only are called *blind external fistulæ*; those in which the discharge has been made into the cavity of the intestine, without any orifice in the skin, are named *blind internal*; and those which have an opening both through the skin and into the gut are called *complete fistulæ*.

Thus, all these cases are deemed fistulous, when hardly any of them ever are so; and none of them necessarily. They are still mere abscesses, which are burst without the help of art; and, if taken proper and timely care of, will require no such treatment as a true fistula may possibly stand in need of.

The most frequent of all are what are called the *blind external*, and the *complete*. The method whereby each of these states may be known is, by introducing a probe into the sinus by the orifice in the skin, while the fore-finger is within the rectum: this will give the examiner an opportunity of knowing exactly the true state of the case, with all its circumstances.

Whether the case be what is called a complete fistula or not, that is, whether there be an opening in the skin only, or one there and another in the intestine, the appearance to the eye is much the same. Upon discharge of the matter, the external swelling subsides, and the inflamed colour of the skin disappears; the orifice, which at first was sloughy and foul, after a day or two are passed, becomes clean and contracts in size; but the discharge, by fretting the parts about, renders the patient still uneasy.

As this kind of opening seldom proves sufficient for a cure (though it sometimes does), the induration, in some degree, remains; and if the orifice happens not to be a depending one, some part of the matter lodges, and is discharged by intervals, or may be pressed out by the fingers of an examiner. The disease, in this state, is not very painful; but it is troublesome, nasty, and offensive: the continual discharge of a thin kind of fluid from it creates heat, and causes excoriation in the parts above; it daubs the linen of the patient; and is, at times, very fetid: the orifice also sometimes contracts so as not to be sufficient for the discharge; and the lodgement of the matter then occasions fresh disturbance.

The means of cure proposed and practised by our ancestors were three, viz. caustic, ligature, and incision.

The intention in each of these is the same, viz. to form one cavity of the sinus and intestines by laying the former into the latter. The first two are now completely, and most properly, exploded.

Hitherto we have considered the disease either as an abscess, from which the matter has been let out by an incision, made by a surgeon; or from which the contents have been discharged by one single orifice, formed by the bursting of the skin somewhere about the fundament. Let us now take notice of it, when, instead of one such opening, there are several.

This state of the case generally happens when the quantity of matter collected has been large, the inflammation of considerable extent, the adipose membrane very sloughy, and the skin worn very thin before it burst.—It is, indeed, a circumstance of no real consequence at all; but from being misunderstood, or not properly attended to, is made one of additional terror to the patient, and additional alarm to the inexperienced practitioner; for it is taught, and frequently believed, that each of these orifices is an outlet from, or leads to, a distinct sinus, or hollow: whereas, in truth, the case is most commonly quite otherwise; all these openings are only so many distinct burstings of the skin covering the matter; and do all, be they few or many, lead and open immediately into the one single cavity of the abscess: they neither indicate, nor lead to, nor are caused by, distinct sinuses; nor would the appearance of twenty of them (if possible) necessarily imply more than one general hollow.

If this account be a true one, it will follow, that the treatment of this kind of case ought to be very little, if at all, different from that of the preceding; and that all that can be necessary to be done, must be to divide each of these orifices in such manner as to make one cavity of the whole. This the probe-knife will easily and expeditiously do; and afterward, if the sore, or more properly its edges, should make a very ragged, uneven appearance, the removal of a small portion of such irregular angular parts will answer all the purposes of making room for the application of dressings, and for producing a smooth even cicatrix after the sore shall be healed.

When a considerable quantity of matter has been recently let out, and the internal parts are not only in a crude undigested state, but have not yet had time to collapse and approach each other, the inside of such cavity will appear large; and if a probe be pushed with any degree of force, it will pass in more than one direction into the cellular membrane by the side of the rectum. But let not the unexperienced practitioner be alarmed at this, and immediately fancy that there are so many distinct sinuses; neither let him, if he be of a more hardy disposition, go to work immediately with his director, knife, or scissors: let him enlarge the external wound by making his incision freely; let him lay all the separate orifices open into that cavity; let him divide the intestine lengthwise by means of his finger in ano; let him dress lightly and easily; let him pay proper attention to the habit of the patient; and wait and see what a few days, under such conduct, will produce. By this he will frequently find, that the large cavity of the abscess will become small and clean; that the induration round about will gradually lessen; that the probe will not pass in that manner into the cellular membrane; and, consequently, that his fears of a multiplicity of sinuses were groundless. On the contrary, if the sore be crammed or dressed with irritating or escharotic medicines, all the appearances will be different: the hardness will increase, the lips of the wound will be inverted, the cavity of the sore will remain large, crude, and foul; the discharge will be thin, gleety, and discoloured; the patient will be uneasy and feverish; and, if no new cavities are formed by the irritation of parts and confinement of matter, yet the original one will have no opportunity of contracting itself, and may very possibly become truly fistulous.

Sometimes the matter of an abscess, formed juxta anum, instead of making its way out through the skin externally near the verge of the anus, or in the buttock, pierces through the intestine only. This is what is called a *blind internal fistula*.

In this case, after the discharge has been made, the greater part of the tumefaction subsides, and the patient becomes easier. If this does not produce a cure, which sometimes though very seldom happens, some small degree of induration generally remains in the place where the original tumour was; upon pressure on this hardness, a small discharge of matter is frequently made per anum; and sometimes the expulsion of air from the cavity of the abscess into that of the intestine may very palpably be felt and clearly heard; the stools, particularly if hard, and requiring force to be expelled, are sometimes smeared with matter; and although the patient, by the bursting of the abscess, is relieved from the acute pain which the collection occasioned, yet he is seldom perfectly free from a dull kind of uneasiness, especially if he sits for any considerable length of time in one posture. The real difference between this kind of case and that in which there is an external opening (with regard to method of cure), is very immaterial; for an external opening must be made, and then all difference ceases. In this, as in the former, no cure can reasonably be expected until the cavity of the abscess and that of the rectum are made

one; and the only difference is, that in the one case we have an orifice at or near the verge of the anus, by which we are immediately enabled to perform that necessary operation; in the other, we must make one.

We come now to that state of the disease, which may truly and properly be called *fistulous*. This is generally defined, *sinus angustus, callosus, profundus: acri sanie diffluens:* or, as Dionis translates it, "*Un ulcère profond, et caverneux, dont l'entrée est étroite, et le fond plus large; avec issue d'un pus acre et virulent; et accompagné de callosités.*"

Various causes may produce or concur in producing such a state of the parts concerned as will constitute a fistula, in the proper sense of the word; that is, a deep hollow sore, or sinus; all parts of which are so hardened or so diseased, as to be absolutely incapable of being healed while in that state; and from which a frequent or daily discharge is made, of thin discoloured sanies, or fluid.

These are divided into two classes, viz. those which are the effect of neglect, distempered habit, or bad management, and which may be called, without any great impropriety, local diseases; and those which are the consequence of disorders whose origin and seat are not in the immediate sinus or fistula, but in parts more or less distant, and which, therefore, are not local complaints.

The natures and characters of these are obviously different by description; but they are still more so in their most frequent event; the former being generally curable by proper treatment, the latter frequently not so by any means whatever.

Under the former are reckoned all such cases as were originally mere collections of matter within the coats of the intestine rectum, or in the cellular membrane surrounding the said gut; but which, by being long neglected, grossly managed, or by happening in habits which were disordered, and for which disorders no proper remedies were administered, suffer such alteration, and get into such state, as to deserve the appellation of *fistulæ*.

Under the latter are comprised all those cases in which the disease has its origin and first state in the higher and more distant parts of the pelvis, about the os sacrum, lower vertebræ of the loins, and parts adjacent thereto; and are either strumous, or the consequence of long and much distemperate habits; or the effect of, or combined with, other distempers, local or general; such as a diseased neck of the bladder or prostate gland, or urethra, &c. &c. &c.

Among the very low people, who are brought into hospitals, we frequently meet with cases of the former kind: cases which, at first, were mere simple abscesses; but which, from uncleanliness, from intemperance, negligence, and distempered constitutions, become such kind of sores as may be called *fistulous*.

In these the art of surgery is undoubtedly, in some measure, and at some time, necessary; but it very seldom is the first or principal fountain from whence relief is to be sought: the general effects of intemperance, debauchery, and diseases of the habit are first to be corrected and removed, before surgery can, with propriety, or with reasonable prospects of advantage, be made use of.

The surgery required in these cases, consists in laying open and dividing the sinus or sinuses, in such a manner that there may be no possible lodgement for matter, and that such cavities may be fairly opened lengthwise into that of the intestine rectum: if the internal parts of these hollows are hard, and do not yield good matter, which is sometimes the case, more especially where attempts have been made to cure by injecting astringent liquors, such parts should be lightly scratched or scarified with the point of a knife or lancet, but not dressed with escharotics; and if, either from the multiplicity of external orifices, or from the loose, flabby, hardened, or inverted state of the lips and edges of the wound near to the fundament, it seems very improbable that they can be got into such a state as to heal smoothly and evenly, such portions of them should be cut off as may just serve that purpose. The dressings should be soft, easy, and light; and the whole intent of them to produce such suppuration as may soften the parts and bring them into a state fit for healing.

If a loose fungous kind of flesh has taken possession of the inside of the sinus (a thing much talked of and very seldom met with), a slight touch of the lunar caustic will reduce it sooner, and with better effect on the sore, than any other escharotic whatever.

Modern writers also speak of a smooth adventitious membrane, which is found to line old fistulæ, and frequently to hinder the success of the operation (see *Quarterly Journ. of Foreign Medicine, &c. No.* 8); a complication which would undoubtedly justify the recourse to measures for the extirpation of such membrane. But I ought to mention my own belief, that a case hindered from getting well by this cause is very rare in comparison with others, in which the cure is prevented by the matter being still more or less confined, and not having as free an outlet as circumstances demand.

The method and medicines by which the habit of the patient was corrected, must be continued (at least in some degree) through the whole cure; and all the excesses and irregularities which may have contributed to injure it must be avoided.

By these means, cases which at first have a most disagreeable and formidable aspect are frequently brought into such state as to give very little trouble in the healing.

If the bad state of the sore arises merely from its having been crammed, irritated, and eroded, the method of obtaining relief is so obvious as hardly to need recital.

A patient who has been so treated has generally some degree of fever; has a pulse which is too hard, and too quick; is thirsty, and does not get his due quantity of natural rest. A sore which has been so dressed, has generally a considerable degree of inflammatory hardness round about; the lips and edges of it are found full, inflamed, and sometimes inverted; the whole verge of the anus is swollen; the hemorrhoidal vessels are loaded; the discharge from the sore is large, thin, and discoloured; and all the lower part of the rectum participates in the inflammatory irritation, producing pain, bearing down, tenesmus, &c. *Contraria contrariis* is never more true than in this instance: the painful, uneasy state of the sore and of the rectum is the great cause of all the mischief, both general and particular; and the first intention must be to alter that state. All escharotics must be thrown out and disused; and in lieu of them, a soft digestive should be substituted, in such manner as not to cause any distention, or to give any uneasiness from quantity; over which a poultice should be applied: these dressings should be renewed twice a day; and the patient should be enjoined absolute rest. At the same time, attention should be paid to the general disturbance which the former treatment may have created. Blood should be drawn off from the sanguine; the feverish heat should be calmed by proper medicines; the languid and low should be assisted with the bark and cordials; and ease in the part must, at all events, be obtained by the injection of anodyne clysters of starch and opium.

If the sinus has not yet been laid open, and the bad state of parts is occasioned by the introduction of tents imbued with escharotics, or by the injection of astringent liquors (the one for the destruction of callosity, the other for the drying up gleet and humidity), no operation of any kind should be attempted until both the patient and the parts are easy, cool, and quiet; cataplasms, clysters, rest, and proper medicines must procure this; and when that is accomplished, the operation of dividing the sinus, and (if necessary) of removing a small portion of the ragged edges, may be executed, and will, in all probability, be attended with success. On the contrary, if such operation be performed while the parts are in a state of inflammation, the pain will be great, the sore for several days very troublesome, and the cure prolonged or retarded, instead of being expedited.

Abscesses and collections of diseased fluids are frequently formed about the lumbar vertebræ, under the psoas muscle, and near to the os sacrum; in which cases, the said bones are sometimes carious, or otherwise diseased. These sometimes form sinuses, which run down by the side of the rectum, and burst near to the fundament.

The treatment of such sores and sinuses can have little influence on the remote situation where the collection of matter is originally formed.—(See *Lumbar Abscess.*)

Fistulous sores, sinuses, and indurations about the

anus, which are consequences of diseases of the neck of the bladder and urethra, called fistulæ in perinæo, require separate and particular consideration.—(See *Fistula in Perinæo.*)

A few years ago M. Roux published a critique on the preference which English surgeons invariably give to Pott's method of operating for the fistula in ano. The chief peculiarity in the French plan, on which he bestows unqualified praise, consists in the use of a kind of director called a gorget, which is usually made of ebony wood, and intended to be introduced within the rectum, with its concavity turned towards the fistula. A steel inflexible director, slightly pointed and without a cul-de-sac, is then passed through the fistula till the point comes into contact with the wooden gorget. A long, narrow, sharp-pointed, straight bistoury is now introduced along the groove of the steel director, till its point meets the groove of the ebony gorget, by cutting upon which all the parts are divided which lie between the internal opening of the fistula and the anus. It may be objected to this method, that it is not always easy to make a director pass at once through the fistula into the rectum. This is acknowledged by Richerand, who adds, that in this circumstance the point of the director may be forced into the rectum without lessening the chance of the success of the operation.—(*Nosogr. Chirurg. t.* 3, *p.* 463, 464, *edit.* 4.) Why then does it matter so much that the surgeon sometimes pierces the rectum with the point of his curved bistoury? Surely th s is as good an instrument for making the puncture as the pointed director. Besides, it appears to me that a flexible silver director is more likely to follow the track of the fistula into the rectum than an unbending iron instrument. I shall say nothing of the awkwardness of using the other wood n director: the finger of the surgeon can always do the office of all such contrivances with greater safety and convenience. M. Roux also censures us for not *cramming* the wound with charpie; for he is not content with merely introducing into it a dossil of lint.—(See *Parallèle de la Chir. Angloise, &c. p.* 296, *&c.*) His countryman Pouteau, however, knew better long ago: for he has expressed his decided conviction of the inutility of cramming the wound with dressings to its very bottom after the third day, when superficial dressings, and the renewal of them as often as cleanliness requires, will be fully sufficient.

For information relative to former opinions concerning *fistula in ano*, refer to *Celsus; Heister's Surgery; Le Dran's Operations; Sharpe's Operations; La Faye's Notes on Dionis. H. Bass, De Fistula Ani feliciter curanda, in Halleri Disp. Chir.* 4, 463. *J. L. Petit, Traité des Mal. Chir. t.* 1 *and* 2, *p.* 113. *Petit is an advocate for making an early opening, like Pott, and all the best writers on this disease. In Kirkland's Medical Surgery, vol.* 2, *may be found an account of the opinions and practice of many former celebrated practitioners. The best modern practical remarks are contained in Pott's Treatise on the Fistula in Ano, in which he has offered also an excellent critique on some opinions of Le Dran, De la Faye, and Cheselden. The reader may also consult with advantage Sabatier's Médecine Opératoire, t.* 2. *J. Howship, Practical Obs. on the Diseases of the Lower Intestines, &c. chap.* 6, *ed.* 3, *Lond.* 1824. *T. Augsb.* 1816. *Into the consideration of these plans of curing fistulæ by the introduction of a ligature through them and tying them, I have not judged it advisable to enter, because every method of this kind is most justly banished from the practice of surgery in this country.*

ANUS, PROLAPSUS OF.

Prolapsus ani, technically called also *exania*, or *archoptosis*. In this case the rectum protrudes at the anus, either from mere relaxation of the internal membrane of the bowel, or from a real displacement and inversion of its upper portion, which presents itself as an external tumour. The first form of the disease is that which is most common. The inner coat of the rectum being connected to the muscular by a very loose elastic cellular substance, naturally forms several folds, the use of which is to let this bowel dilate sufficiently for the retention of the excrement. The swelling occasioned by the protrusion of the inner coat of the rectum, or by the actual displacement of the greater part of this bowel, is subject to considerable variety in respect to length and thickness; when small resembling a mere ring; when large and reaching far downwards, having an oblong globular form. The tumour sometimes admits of reduction with ease; sometimes it cannot be returned without difficulty. The disease occurs in persons of all ages; but it is most common in infants and elderly subjects. Such examples as are combined with thickening and relaxation of the inner coat of the rectum, internal hemorrhoids, or other tumours, are sometimes attended with a copious discharge from the anus, and from the prolapsed bowel, of a serous and mucous fluid mixed with blood. The disease may originate from various causes:

1. From circumstances tending to relax and weaken the parts which retain the rectum or its inner membrane in its situation.

2. From various kinds of irritation and pressure on the bowel itself, having the effect of increasing the powers by which it is liable to be forced outwards.

3. From any disease or irritation in the adjacent parts, and affecting the rectum sympathetically.

Hence, a prolapsus ani may be caused by long habitual crying, and great exertions of the voice; violent coughing; sitting long at stool; hard dry feces, and much straining to void them; obstinate diarrhœa in infants, kept up by dentition; dysentery; chronic tenesmus; various diseases of the rectum itself; the abuse of aloetic medicines and emollient clysters; hemorrhoids; excrescences and thickenings of the inner membrane of the rectum; difficulty of making water; the efforts of parturition; the stone in the bladder; paralysis of the sphincter and levatores ani; and prolapsus vaginæ.

Considering the degree of the disease, and the occasional closeness of the stricture, the symptoms are sometimes mild, the rectum generally bearing pressure, exposure to the air, and other kinds of irritation better than any other bowel. But the urgency and danger of a prolapsus ani are greater when the swelling is large, recent, and conjoined with violent pain, inflammation, and febrile symptoms. When complicated with strangulation, the consequences may be a stoppage of the feces, severe pain, swelling, inflammation, and even gangrene within the cavity of the abdomen. In short, all the evils may arise which attend strangulated hernia. The prognosis, therefore, varies according to the different degree, species, cause, and complication of the disease. The recent, small, moveable prolapsus ani, the cause of which admits of being at once removed, may be effectually and radically cured. It should always be recollected, however, that when once the rectum has been affected with prolapsus, a tendency to protrusion from any slight occasional cause generally remains. The habitual prolapsus, which has existed for years, and comes on whenever the patient goes to stool, is the case which is most difficult of relief.

The treatment of prolapsus ani embraces three principal indications:

1. The speedy reduction of the prolapsed part.

2. The retention of the reduced bowel.

3. The removal and avoidance of the causes by which the disease is induced.

In general, when the case is recent and the tumour not of immoderate size, the reduction may be accomplished with tolerable ease, by putting the patient in a suitable posture, with the buttocks raised and the thorax depressed, and by making gentle and skilful pressure either with the palm of the hand or fingers. When difficulty is experienced, the patient, if young or robust, may be bled, and the part be fomented. The

large intestines may also be emptied by means of a mild unirritating clyster, and half an ounce of the oleum ricini should be exhibited. In the habitual prolapsus ani the patient himself is generally accustomed to reduce the part, or it goes up of itself when he lies down. When, however, the inflammation and swelling are urgent, the part ought on no account to be irritated by repeated attempts at reduction. The practitioner should rather have recourse to the antiphlogistic plan, especially leeches, fomentations, or cold washes, and the exhibition of the oleum ricini; and when the swelling has been lessened the reduction may be again attempted. When the reduction is prevented by a spasmodic resistance, the use of an anodyne poultice or fomentations, a clyster of the same quality, the warm bath, and the internal use of opium, are the best means. Should the complaint not give way to the preceding remedies, and the symptoms become more and more pressing, the particular situation of the stricture should be examined with a probe, and divided either with a knife and director or with a concealed bistoury. Some writers speak of the employment of a speculum ani; but on account of the globular form of the disease, it must be difficult of application. Cases are recorded in which the protruded part, either in the state of gangrene or of chronic hardness, thickening, and elongation, has been removed with a knife or ligature.—(See *Cheselden's Anatomy*, &c. 1741; *Kerstens, Historia Sedis prociduæ, resectione feliciter sanatæ*, *Kilon*, 1779; *Whately, in Med. Tracts and Observ. vol.* 8, *No.* 16.)

However, I should apprehend that in the circumstance of gangrene, the measures best calculated for stopping its course, detaching the sloughs, and keeping up the patient's strength, must always be more prudent than such an operation.

The reduction having been effected, it is proper to introduce the fore-finger up the rectum in order to ascertain that no intussusception exists above the anus within the sphincter. The bowel is then to be kept in its place by quietude and the recumbent posture, and if there be a great tendency to relapse it will be proper to apply to the fundament a piece of sponge or compresses, supported with the T bandage. But if such means should not answer, and an habitual prolapsus ani should recur again and again, which is not unfrequent when the disease has been neglected, or its causes have long remained unremoved, the apparatus described by Mr. Gooch may be tried with more hope of success.—(*Chir. Works, vol.* 2, *p.* 150, *edit.* 1792.) Others have used perforated balls of ivory. Callisen found the introduction of a piece of sponge within the rectum, fastened to a silver probe, give effectual support. In France, instruments made of elastic gum have been employed with advantage for supporting the rectum.—(*Richerand, Nosogr. Chir. t.* 3, *p.* 444, *ed.* 4.)

On account of the elasticity and unirritating quality of this substance, I conceive it is better calculated than any other material for the construction of such instruments. It cannot be denied, however, that all foreign bodies in the rectum create serious annoyance. In the female sex, a vaginal pessary, rather prominent behind, usually hinders the recurrence of a prolapsus ani.

The late Mr. Hey published some highly interesting remarks on the cure of the procidentia ani in adults. In one gentleman the disease took place whenever he had a stool, and continued for some hours, the gut gradually retiring, and at last disappearing, until he had occasion to go to the privy again. After each stool, he used to place himself in a chair, and obtain a little relief by making pressure on the prolapsed part; and he then was in the habit of going to bed, where the intestine by degrees regained its natural situation. While the bowel was down there was a copious discharge from it of a thin mucous fluid blended with blood. When the part was up, the anus was constantly surrounded by a thin, pendulous flap of integuments, generally hanging down to the extent of three-fourths of an inch. Around the anus there were also several soft tubercles of a bluish colour, situated at the basis and at the inner part of the pendulous flap. These were evidently formed by the extremity of the rectum. The patient, previously to the establishment of these habitual attacks of prolapsus ani, had been afflicted for several years with pain after each stool, protuberances at the extremity of the rectum, and discharge of blood and mucus. For these complaints he applied to Mr. Sharp, who gave him an ointment to be applied after each stool, some soapy pills to be taken, and recommended the use of a clyster a little before the time of going to stool. The latter remedy, however, could not be adopted, and no material benefit was derived from the others. Some years afterward, when Mr. Hey was consulted, the foregoing symptoms continued; in addition to which there was the grievance of the prolapsus, which came on at every time of going to stool, and lasted for several hours. This judicious surgeon at first advised the patient to wash the prolapsed part with a lotion composed of an infusion of oak-bark, lime-water, and spirit of wine, and keeping on the tumour compresses, wet with this fluid, and supported by the T bandage. The disease, however, was too obstinate to be cured by this treatment. Nor could Mr. Hey succeed in reducing the bowel when it came down. "Although (says he) the prolapsed part of the intestine consisted of the whole inferior extremity of the rectum, and was of considerable bulk, yet the impediment to reduction did not arise from the stricture of the sphincter ani; for I could introduce my finger with ease during the procidentia; but it seemed to arise from the relaxed state of the lowest part of the intestine and of the cellular membrane which connects it with the surrounding parts. My attempt proved vain as to its immediate object, yet it suggested an idea which led to a perfect cure of this obstinate disorder. The relaxed state of the part which came down at every evacuation, and the want of sufficient stricture in the sphincter ani, satisfied me that it was impossible to afford any effectual relief to my patient unless I could bring about a more firm adhesion to the surrounding cellular membrane, and increase the proper action of the sphincter. Nothing seemed so likely to effect these purposes as the removal of the pendulous flap and the other protuberances which surrounded the anus." This operation was performed on the 13th of November. On the 15th the gut protruded and did not gradually retire as it used to do. Mr. Hey attempted to procure ease by means of opiates and fomentations, and avoided immediately trying to reduce the prolapsed part. However, the prolapsus continued so long that the appearance of the part began to alter, and therefore, on the 16th he made an attempt at reduction, and succeeded with great ease. However, as a good deal of pain in the hypogastrium was still complained of, the patient was bled in the evening, and gently purged with the oleum ricini. These means gave relief; but as some pain in the belly yet continued, an opiate was given. A low diet, linseed tea, lac amygdalæ, &c. were ordered, and a little of the oleum ricini every morning, or every other morning, with an opiate after a stool had been procured. "By proceeding in this manner for some days, regular stools were procured without any permanent inconvenience. My patient recovered very well, and was freed from this distressing complaint, which had afflicted him so many years.—(See *Hey's Pract. Obs. p.* 438, *&c. ed.* 2.)

This and some other cases which this gentleman has related, convincingly exemplify the necessity of paying attention to the removal of excrescences, hemorrhoids, and other tumours, situated about the lower part of the rectum, in cases of prolapsus ani; for unless this object be accomplished, the disease may resist every other treatment. Mr. Howship prefers the ligature for the extirpation of the protuberances; but heartily commends the principle of the treatment proposed by Mr. Hey.—(*Pract. Obs. on Diseases of the Lower Intestines, p.* 163, *ed.* 3.) An elderly gentleman, whom I know, was troubled for many years with a prolapsus ani, which used to come on several times a week, sometimes at the privy, and sometimes on other occasions. Several of the first surgeons were consulted, who failed in affording permanent benefit, because they omitted to extirpate some hemorrhoidal excrescences, situated at the lower part of the rectum; for, when these were afterward removed, the prolapsus ani entirely disappeared.

Dupuytren, finding that the excision of piles, which so often accompany prolapsus ani, commonly prevented the return of the latter complaint, was led to cut off more or less considerable portions of the internal membrane of the rectum. However, as in one case a profuse hemorrhage took place, and, in another, a tedious suppuration, he has subsequently adopted the plan of

removing a certain number of the projecting folds, which may be seen converging from the circumference to the margin of the anus. He takes hold of them with ligature-forceps, a little flattened at one end, and cuts them off with scissors curved on their flat side. This practice is similar to that employed by the late Mr. Hey. Dupuytren, in his first method, used to cut away the mucous membrane itself; in the last, only the folds of skin at the margin of the anus are removed. A woman had had a constant prolapsus ani for ten years; when she was in the upright posture, the swelling was ten inches in one diameter, and seven in the other; it hindered her from walking, and continually discharged a mixture of blood and mucus. Dupuytren removed five or six of the projecting folds from without inwards. The patient, who used to have more than twenty stools a day, now went six days without one; on the seventh, however, an abundant evacuation took place, and the prolapsus never returned. Merely simple dressings are needed.—(See *Journ. Universel des Sciences Méd. No.* 81, *Sept.* 1822.)

The last indication in the treatment is the removal and avoidance of all such causes as are known to have a tendency to bring on the complaint. In infants, a fresh protrusion of the rectum may sometimes be prevented by making them sit on a high close-stool, with their feet hanging freely down. Every thing tending to cause either diarrhœa or costiveness should be avoided. In the generality of cases, however, there is an inclination to costiveness, which must be obviated by the mildest means. For this purpose, Mr. Hey used to prescribe half an ounce of the oleum ricini, which is to be taken every morning, or every other morning, as circumstances may require. The same practitioner sometimes also employed, in addition to this medicine, a clyster composed of a pint of water-gruel, and a large spoonful of treacle. The tone of the relaxed intestine is to be restored by the continued use of cold clysters, made with the decoction of oak-bark, alum, and vinegar. In one obstinate case, under the care of Mr. Hey, he recommended the following lotion for washing the part during the state of prolapsus, and he also advised its application to the anus in the intervals, by means of a thick compress, supported by the T bandage. ℞. Aquæ calcis simplicis ℔ij. Cort. quercûs contus. ℥iv. f. infusum per hebdomadam, et colaturæ adde sp. vini rect. ℥iv. ft. lotio.—(See *Hey's Pract. Obs. p.* 442, *ed.* 2.)

Irritability of the rectum may be lessened with opium.

The intussusception of the higher part of the bowel, especially of the colon, or cœcum, causing a protrusion at the anus, is always incurable, as it is not in the power of art to rectify the displacement. Some extraordinary cases prove, however, that large portions of the intestinal canal thus inverted, may be separated and voided, and the patients recover.—(See *Intussusception.*)

According to Mr. Travers, when an artificial anus is complicated with prolapsus, the case very rarely admits of cure.—(See *Inquiry into the Process of Nature in repairing Injuries of the Intestines, p.* 374.)

Surgical writers have been too much in the habit of confounding together prolapsus ani and intussusception. In the latter disease, they have even fallen into the error of supposing, that the whole of the rectum becomes everted, in consequence of the relaxation of the sphincter and levatores ani, and that it then draws after it other portions of the intestinal canal. But they ought to have been undeceived by the strangulation, which sometimes occurs under such circumstances, and which not only throws a great obstacle in the way of the reduction of the displaced part, but even sometimes brings on mortification. Besides, the connexions of the rectum with the neighbouring parts, by means of the cellular substance, which surrounds it, and the attachment of this intestine to the posterior surface of the urinary bladder, render the above origin of the complaint impossible. Such an explanation could only be admitted with regard to those protrusions of the rectum which come on in a very slow manner. It could not apply to certain cases, in which the everted intestine presents itself in the form of an enormous tumour. Fabricius ab Aquapendente met with cases of prolapsus of the rectum, where the tumour was as long as the forearm, and as large as the fist. In the *Mélanges des Curieux de la Nature*, is the description of a tumour of this sort, which was two feet long, and occurred in a woman from parturition. Nor is a more satisfactory reason assigned for these cases, by supposing, that they originate from a relaxation of the villous coat of the rectum, and its separation from the muscular one. We are not authorized to imagine, that such a separation can take place to a considerable extent, nor so suddenly as to give rise to the phenomena sometimes remarked in this disease.

Accurate observations long ago removed all doubt upon this subject. In the *Mémoires de l'Académie de Chirurgie, t.* 11, *ed. in* 12*mo.* is an account of a pretended prolapsus of the rectum, which, after death, was discovered to be an eversion of the cœcum, the greater part of the colon being found at the lower end of this intestine, and most of the rectum at its upper part. This eversion began at the distance of more than eleven inches from the anus, and terminated about five or six from this opening, the tumour formed by the disease having been reduced some time before the child's death. It was impossible to draw back the everted part, in consequence of the adhesions which it had contracted. Another dissection evinced the same fact. A child, having suffered very acute pain in the abdomen, after receiving a blow, had a prolapsus of intestine through the anus, about six or seven inches long. This was taken for a prolapsus of the rectum. After death, the termination of the protruded bowel was found to be the cœcum, which had passed through the colon and rectum.—(See *Intussusception.*)

ANUS ARTIFICIAL.

This signifies an accidental opening in the parietes of the abdomen, to which opening some part of the intestinal canal tends, and through which the feces are, either wholly or in part, discharged.

An artificial anus is always preceded by an injury of the intestinal canal, either a penetrating wound of the abdomen, ulceration of the bowel, and the bursting of an abscess externally; an operation, in which the preternatural opening is purposely made, with the view of saving life, in particular cases of imperforate anus; an accidental wound of the gut in the operation for hernia; or, lastly, and most commonly, mortification of the bowel, the effect of the violence and long continuance of the strangulation of the part. All these cases are farther divisible into such as are attended with a destruction of a portion of the intestinal tube; and into those which are not accompanied with any such loss of substance.

Whatever may be the kind of injury which the bowel has sustained, one thing here invariably happens, viz. the adhesion of the two divided portions of the intestine to the edge of the opening in the parietes of the abdomen. This occurrence, which has the most salutary effect in preventing extravasation of the contents of the bowel in the cavity of the abdomen, is produced by inflammation, which precedes gangrene, and follows wounds.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 352—354.)

When, in strangulated hernia, the case is not relieved by the usual means, or when the necessary operation has not been practised in time, the protruded bowel sloughs; the adjoining part of it adheres to the neck of the hernial sac; and the gangrenous mischief spreads from within outwards. If the patient live long enough, and an incision in the tumour be not now practised, one or more openings soon form in the integuments, and, through these apertures, the feces are discharged until the separation of the sloughs gives a freer vent to the excrement. But when an incision is made, the feces are more readily discharged, and, as

Mr. Travers has related, this is sometimes the best mode of relief.

"In the ordinary situation of hernia (as this gentleman has correctly explained), the portions of intestine embraced by the stricture occupy a position nearly parallel. Their contiguous sides mutually adhere; in the remainder of their circumference they adhere to the peritoneum, lining or forming the stricture. The existing adhesion of the contiguous sides, strengthened by the adhesion of the parts in contact, ensures a partial continuity upon the separation of the sphacelated part. The line of separation is the line of stricture. It commences on that side of the gut which is in direct contact with the stricture. As the separation advances, the opposite adhering sides may perhaps recede somewhat, and a little enlarge the angle of union. But it is ever afterward an angle; and, where the peritoneum is deficient, the canal is simply covered in by granulations from the cellular membrane of the parietes, coalescing with those of the external or cellular surface of the peritoneum."—(*On the Process of Nature in repairing Injuries of the Intestines*, *p.* 360.) It must be confessed, that few surgeons have entertained sufficiently accurate ideas of the changes which happen around the wounded or mortified portion of intestine, when an artificial anus is produced; and, though Desault's account was excellent, as far as it went, it was not until the year 1809, when Scarpa published his valuable work on Hernia, that the whole process of nature on such occasions was completely elucidated. The hernial sac (says he) does not always partake of gangrene with the viscera contained in a hernia, and even when it does slough, since the separation of the dead parts happens on the outside of the abdominal ring, there almost always remains in this situation a portion of the neck of the hernial sac perfectly sound. It may be said, therefore, that in all cases, immediately after the detachment of the mortified intestine, whether it happen within or on the outside of the ring, the two orifices of the gut are enveloped in the neck of the hernial sac, which, soon becoming adherent to them by the effect of inflammation, serves for a certain time to direct the feces towards the external wound, and to prevent their effusion in the abdomen. In proportion as the outer wound diminishes, the external portion of the neck of the hernial sac also contracts; but, *that part which embraces the orifices of the intestine gradually becomes larger, and at length forms a kind of membranous, funnel-shaped, intermediate cavity, which makes the communication between the two parts of the bowel.* However, according to Scarpa's investigation, this adhesion of the neck of the hernial sac, round the two orifices of the gut, does not hinder the latter from gradually quitting the ring, and becoming more and more deeply placed in the cavity of the abdomen. The base of the above-described funnel-shaped membranous cavity corresponds to the bowel, and its apex tends towards the wound or fistula.

But in relation to this part of the subject, there are some other circumstances, which every surgeon should well understand, and his ignorance of them would not be excusable, on the ground of their not having been, like the funnel-shaped membranous cavity, forming the communication between the two orifices of the bowel, only a discovery of recent date; for they were fully explained many years ago. I here allude to the exact position of the two portions of the bowel, with respect to each other, the direction of their orifices, the angle or ridge between them, and the difference in their diameters. The first of these circumstances, viz. the position of the two parts of the bowel, was correctly described by Morand, and, as we have seen, is pointed out by Mr. Travers, who represents them as occupying a position nearly parallel, and cites an interesting observation recorded by Pipelet. The patient was a woman, 56 years old; the loop of spoiled gut was from five to six inches long; the contents of the bowel were discharged through the wound for a considerable time, and an artificial anus was established. Some accidental obstruction occurred; a purgative was given, which operated in the natural way; and, in fifteen days, the wound was healed. She lived in perfect health to the age of 82, when she died of a disease not connected with this malady. Pipelet examined the body, and has given a figure representing the union. The line of the intestine formed an acute angle, where it adhered to the peritoneum, opposite to the crural arch. The cylinder is evidently much contracted. Pipelet particularly dwells upon the angular position and constriction of the tube at the point of union. The lower continuation of the intestinal tube was also remarked to be more contracted than the upper portion; a circumstance correctly referred, by Mr. Travers, to the undilated state of the bowels, situated between the artificial and the natural anus.—(See *Mém. de l'Acad. de Chir. t.* 4, *p.* 164; *and Travers on Injuries of the Intestines*, *p.* 364.) The two ends of the bowel, as Scarpa has observed, are always found lying in a more or less parallel manner by the side of each other; the upper, with its orifice open, and directed towards the external wound by the feces, which issue from it, while the lower, which gives passage to nothing, becomes less capacious, and is retracted farther into the abdomen. Hence, the breach in the intestinal canal is never repaired by the orifices of the upper and lower portions of the bowels reuniting, coalescing, and running, as it were, into each other. Indeed, they meet at a very acute angle; the axis of one does not correspond to that of the other; and their orifices never lie exactly opposite each other. It is in short by means of the funnel-shaped cavity, formed by the remains of the hernial sac, that the two parts of the bowel communicate, and the feces, in order to get from the upper into the lower continuation of the intestine, must first pass in a semicircular track through that funnel-shaped cavity; there being between the orifices of the bowel, directly opposite to the communication between the cavity of the intestine and that of the funnel-shaped membrane, *a considerable projection, or jutting angle, forming a material additional obstacle to the direct passage of the feces from the upper into the lower portion of the intestinal tube.*—(*Scarpa sull' Ernie Memorie, Nat. Chirurgiche, Milano*, 1809.)

Desault, after noticing the efficiency of the adhesions, between the injured part of the bowel and the edge of the opening in the parietes of the abdomen, in preventing extravasation, remarks, that if such adhesions were entire, the abdominal parietes would form a substitute for the portion of the canal which has been destroyed, and the contents of the bowel would continue to pass as usual towards the anus, if the portions of the intestine, separated and adherent to the neighbouring parts, did not form such an acute angle as obstructs the passage of the intestinal matter. The more acute this angle is, the greater is the obstruction; when the two parts of the bowel lie nearly parallel, the entrance into the lower portion of the canal is completely prevented; but, if they meet at a right angle, then more or less of the contents of the upper portion may be transmitted into the lower. The first disposition chiefly happens, when a considerable part of the intestinal canal has been destroyed, or when the tube has been completely divided; while the second posture is principally remarked in all cases where the injury has been less extensive. And it is plain, that the possibility of a cure depends materially on the kind of angle at which the two portions of bowel meet, and that the projection of the internal frænum, or jutting membranous ridge between the two orifices, is always a greater or less obstacle to the cure.

With respect to the diminution which occurs in the diameter of the part of the intestinal canal between the artificial opening and the natural anus, Desault admits the correctness of the observation, but entirely dissents from such authors as have spoken of the change as sometimes proceeding so far, that an obliteration of that portion of the intestinal tube is the consequence. The mucus secreted within it suffices for preventing this obliteration; a secretion which, in these cases, is copious, and is partly voided from the rectum in the form of white flakes. And if any farther proof were needed, that the bowels between the artificial and natural anus remain pervious, it is furnished by the fact, that in cases of artificial anus, the lower continuation of the tube frequently becomes inverted, and protrudes. On the other hand, the kind of obliteration above spoken of, has never been demonstrated by dissection; it was not observed by Lecat, in the examination of the body of a person, who died twelve years after the entire cessation of the passage of feces *per anum;* nor was it found to exist by De-

sault, when he opened a patient who died of marasmus in the Hôtel-Dieu, in consequence of an artificial anus, which communicated with the ileum, and had lasted two years.—(*Œuvr. de Desault*, *t.* 2, *p.* 354—356.)

However proper the formation of an artificial anus may be, in many cases, in which the patient's life depends upon the event, it must be confessed that the consequence is a most afflicting and disgusting infirmity. This truth cannot be denied; though the feces which are discharged, from not having been so long retained in the bowels, may not be so fetid as those which are evacuated in the ordinary way. As the opening, which gives vent to the excrement, is not endued with the same organization as the lower end of the rectum, and as, in particular, it is not furnished with any sphincter capable of contracting and relaxing itself as occasion requires, the feces are continually escaping without any knowledge of the circumstance on the part of the patient. Hence the uncleanly state of the parts around the external opening; and their frequently excoriated fungous state. Some persons in this state, among the number of those whose histories are on record, made use of a metal box, in which their excrement was received. Schenckius relates the case of an officer, who was wounded in the belly, and who allowed his feces to escape into a vessel made for the purpose. Dionis mentions a similar case.

Moscati also communicated to the Academy of Surgery the history of a wounded man, in whom an artificial anus took place, in consequence of a wound in the abdomen below the right hypochondrium. His excrement used to be received in a tin box, fastened to him with a belt. The wound received a leaden cannula, to which the tin box was accommodated.

Uncleanliness is not the only inconvenience of an artificial anus. Persons have been known to be quite debilitated by the affliction, and even ultimately to die in consequence of it. This is liable to happen, whenever the intestinal canal is opened very high up, so that the aliment escapes before chylification is completed, and the nutritious part of the food has been taken up by the lacteals. In this circumstance, the patient becomes emaciated, and sometimes perishes, as Desault had an opportunity of observing; and examples of which are also recorded by Hoin and Le Blanc. In cases of this description, the matter voided has little fetor, and is frequently sourish. In all instances, the matter is evacuated involuntarily, because there is nothing like a sphincter. But when the opening only interests the lower convolutions of the ileum, or, what is more frequent, when it has occurred in the large intestines, the danger is less serious, and patients in this state are often noticed performing all their functions very well; and, with the exception of colic, to which they are subject, enjoying as good health as they did previously to their having the present disease. In such examples, the matter voided is more fetid, its discharge does not follow so quickly its introduction into the stomach, and it is retained for a longer time.

Many patients afflicted with an artificial anus void no feces at all from the rectum; but occasionally, a thick whitish substance, which is the mucous secretion of the portion of the large intestines nearest to the anus. Under certain circumstances, the quantity of this mucus discharged is more copious.—(*Desault*, *vol. cit. p.* 359.)

The most grievous occurrence to which persons with an artificial anus are exposed, is a prolapsus of the bowel, similar to what sometimes happens through the anus, with respect to the rectum. The descent of the bowel is sometimes simple, only affecting a portion of the intestinal canal just above or below the opening. On other occasions the complaint is double, the bowel both above and below the opening being prolapsed. This descent of the intestine forms a tumour, the dimensions of which vary considerably in different subjects. When the protrusion is caused by the upper part of the intestinal canal, the feces are voided at the extremity of the tumour, and when the swelling consists of the lower portion of the bowel, the excrement is evacuated at the base of the prolapsed part. By observing this evacuation when the tumour is double, it is easy to know to which end of the intestinal canal each protruded portion belongs. This consequence of an artificial anus is very serious, because it greatly increases the inconvenience which the patient suffers. Sometimes the tumour is exquisitely sensible; and occasionally, when the eversion of the intestine is considerable, a strangulation is produced, which puts the patient's life in danger.

I apprehend no well-informed surgeon of the present day can doubt that formerly the frequency of artificial ani after hernia was seriously increased by the absurd measures sometimes adopted for the express purpose of preventing them; and as Mr. Travers has rightly observed, the cases reported by the old surgeons, if they prove any thing, prove this: "that the canal had been very generally restored, when the artificial anus was reckoned upon as inevitable, and that where an officious solicitude had been at work to prevent it, showing itself in an active interference with the arrangements of nature, the case has terminated in artificial anus; so that the event either way has been a matter of surprise to the surgeon. The fear of doing too little, or too much, applies only to the pernicious customs of dilating the stricture, displacing, amputating, and sewing the intestine; the general adoption of which practice fully accounts to my mind for the number of artificial ani, which are the sequelæ of hernia."—(*Op. cit. p.* 367.)

The treatment of an artificial anus is either palliative or radical. The first consists in obviating the habitual uncleanliness produced by the involuntary discharge of the intestinal matter, and in relieving such bad symptoms as may arise from the disorder.

The first indication is fulfilled by the employment of silver or tin machines, which are either kept applied to the external opening by means of a spring, or form receptacles placed more or less off the artificial anus, from which the intestinal matter is transmitted through a tube, kept constantly in the opening. In general, says Desault, as elastic gum is supple, light, and capable of taking any shape, it is the best material for the construction of such instruments, which, however, rarely answer their purpose completely, and always give the patient a great deal of trouble.

As for the second indication, Richter, with the view of hindering the too quick escape of the intestinal matter, and the death of the patient from this cause, proposed covering the opening for a certain time with a piece of sponge, supported by an elastic bandage or truss. But Loeffler found this method objectionable, as it was apt to bring on colic, constipation, and an inflamed excoriated state of the skin.

When the outer opening is disposed to contract too much, and inconveniences arise from this change, Sabatier is an advocate for preventing such closure by means of a tent, or skein of silk, introduced into the aperture, and changed very often for the sake of cleanliness; while others prefer a ring of ivory for the purpose. But the irritation produced by the matter imbibed by this sort of tent, and in particular the liability of the bowel to protrude, and be strangulated in the opening of the ivory ring, are found strong objections to these practices; and according to Desault, the sponge employed by Richter also occasions a great deal of excoriation by the irritation of the fluid which is lodged in it.

For the purposes of hindering a protrusion of the gut, of keeping the opening sufficiently pervious, of relieving any uneasiness and tenesmus, of hindering the intestinal matter from escaping in the intervals of dressing, and confining it long enough for the adequate nourishment of the patient, Desault preferred a linen tent or stopper covered by a pad of charpie, compresses, and a tight bandage. At first, says he, the patient feels some uneasiness from this plan, and slight colics may be the consequence of it: but, by degrees, the parts become habituated to their new state, and every thing goes on well. With respect to the employment of tents and plugs with the views above indicated, I am disposed to think the practice can rarely be advisable; and that any necessity for it may be obviated by attention to diet, and the occasional exhibition of laxative medicines and clysters, as will be hereafter noticed. When the gut protrudes, its reduction is to be effected in the same way as a common prolapsus ani; but serious difficulty will occur when the protruded part is inflamed, thickened, and of considerable size. Indeed, surgeons have usually regarded the reduction as impracticable in these circumstances; but according to Desault this is not the case, as compression with a bandage, kept up for some days, will succeed. Care must be taken, however, to leave a sufficient opening

for the passage of the feces. Whatever may be the size of the protrusion, Desault argues, that it should be the invariable rule of the surgeon to endeavour to return the part by the means here suggested.—(See *Œuvres Chir. de Desault*, *t.* 2, *p.* 361, *&c.*)

The radical cure is what is next to be considered. The business of the surgeon is to prevent, if possible, the formation of an artificial anus; but when the event has occurred, and particularly, when the whole or the greater part of the stools is discharged in this way, no attempt must be made to stop up the opening without a great deal of consideration; for any effort of this kind, made under circumstances which do not justify it, may be the means of exposing the patient's life to the most alarming danger. Sometimes, indeed, without any interference of the surgeon, the outward opening contracts, and the issue of the intestinal matter being obstructed, pain and tenesmus are excited; and the same consequences may be produced by any swelling and enlargement of the projecting ridge, situated between the two portions of the bowel. In two cases Puy found this swelling take place in such a degree, that the patients fell victims to the complete stoppage of the intestinal contents. The symptoms which arise are then similar to those which happen in strangulated hernia. Hoin, Le Blanc, and Sabatier also cite instances, in which the patients lost their lives by gangrene, brought on by this species of strangulation.—(*Desault*, *vol. cit. p.* 360.)

There is a period (says Mr. Travers), at which the function of the lower portion of the canal, with a little assistance, may be restored. The natural order of events connected with this recovery has been mistaken and inverted. Practitioners have closed the wound instead of conducting the matter by purgatives and clysters into the large intestines. Now, the wound will never fail to heal, when the matter recovers its accustomed route; but this condition cannot be reversed. The restoration is safest when most gradual; when there is evidence of an existing sympathy between the repair of structure and the return of function. According to the same gentleman, there is reason to believe, that the well-timed exhibition of a single purgative might often prove effectual. "If the food is rapid and little changed in its passage, it should be pultaceous and nutritive, and given in moderate quantity at short intervals; while injections of the same kind should be administered at least twice in twenty-four hours, and retained as long as possible." He states that by such means patients may be nourished for many weeks. If the discharge is sparing, and does not readily escape, he recommends an occasional purgative in less than ordinary quantity. He disapproves of other medicines, especially stimulants, and all such food as is difficult of digestion, giving a general preference to animal food in a gelatinous form. He bestows just praise on strict attention to cleanliness, and, in opposition to Desault and Sabatier, condemns the employment of tents and sponges.—(*Op. cit. p.* 371. 373.)

Numerous cases on record furnish abundance of proof, that the feces, after being voided for several months from the wound produced by the operation for hernia, frequently resume their natural course. Facts of this kind, which in general may be said to be common when the intestine is without loss of substance, are not very rare even when more or less of the bowel has been destroyed by gangrene; and many illustrations of this remark may be found in the writings of De la Peyronie, Louis, Petit, Pott, Le Dran, &c. The greater number of these instances of success, as already stated, were the result of the most simple, unofficious treatment, or rather of the undisturbed, and very little assisted, efforts of nature.

In the radical cure of an artificial anus, the following are the general indications laid down by Desault: 1. To reduce the gut when it protrudes and is everted. 2. To prevent the issue of the feces from the wound, so that they may be obliged to pass on towards the rectum, at the same time that the healing of the external opening is to be promoted. 3. To obviate any internal impediments to the passage of the matter into the lower part of the intestinal canal.

How the first of these objects is to be accomplished in the case of greatest difficulty, that is, when the parietes of the bowel are thickened, has been already explained. Experience proves, says Desault, that the second indication cannot be fulfilled by means of sutures. The best thing for this purpose he represents to be the linen stopper, above spoken of as a means for preventing the protrusion of the bowel. Here it answers the double object of hindering such a protrusion, and filling up the fistulous opening, so as to make the contents of the bowel tend towards the anus. Desault argues that the surgeon need not be apprehensive of the tent doing harm by keeping the wound from healing. The first aim, he says, should be to determine the feces to take their natural route; and when this has been done by closing the external opening, the tent may be removed, and this opening will spontaneously close.

However, when the internal impediment is too great, it must be overcome ere such treatment can be successful. According to Desault, the most frequent impediment here alluded to, is the angle formed by the two portions of the intestine, and it must be enlarged, and rendered less acute, in order that the feces may continue their route. This desirable change he recommends to be effected by introducing long dossils of charpie into the two ends of the bowel, and gradually altering their direction so as to bring it into one same straight line. When the dilatation is sufficient, and the inner angle or ridge is effaced, the long dossils need not be continued. The linen tent, with the precaution of not introducing it too deeply, lest it obstruct the course of the feces itself, will then suffice. When this plan is skilfully managed, Desault says, there will be a great chance of its succeeding, and its beneficial effect will be denoted by a rumbling in the bowels, and frequently by slight colics. At first wind is discharged from the rectum, and soon afterward, the feces begin to come away. On the contrary, if they should not pass with facility, the colic be violent, and an accumulation happen in the upper portion of the intestinal canal, the tent must be withdrawn, and the other cause of obstruction be considered, and, if possible, removed.—(*Vol. cit. p.* 365, *&c.*)

In the preceding columns, I have given a full explanation of the impediment made to the passage of the feces into the lower orifice of the intestinal canal, by the projecting septum or ridge between the two parts of the bowel, and the matter having to traverse the funnel-shaped membranous cavity in quite a semicircular track. A representation of this septum may be seen in Scarpa's work, tab. 9, fig. 1, and also in the sixth plate of Mr. Traver's Inquiry. In one example in which this septum was plainly visible in the wound, Dupuytren introduced into the orifice of the upper part of the bowel a curved needle, and passing it through the projecting septum, brought it out again through the orifice of the lower portion of the gut. Thus he included a considerable part of the septum in a ligature, which was daily made thicker with a view of first exciting inflammation in the two layers of this septum, and thus ensuring their adhesion together, and his next plan consisted in making a division through the part embraced by the ligature, whereby the passage for the feces into the lower portion of the bowel was made quite free. But as the section made by the ligature was too superficial, Dupuytren completed the division of the septum with a knife; but peritonitis and the death of the patient ensued. According to Dr. Breschet, the ligature also proved ineffectual, because its operation was so slow, that adhesions and cicatrization took place behind it as fast as it made its way through the rest of the septum. Hence, the expectation that the feces would sufficiently pass through the aperture made by the ligature was not realized; and in one case quoted by Breschet, though some amendment followed the operation, still the cure was far from being accomplished, as only some of the feces passed out of the natural anus, while the remaining and greater part of them still came through the fistula.—(See *Graefe's Journ. b.* 2, *p.* 300.) In another case, Dupuytren tried to render the layers of the septum adherent by compressing them between the blades of a pair of forceps of particular construction, and afterward he effected the division of the part by augmenting the compression by means of a screw traversing the handles of the instrument. In a case which followed the operation for bubonocele, attended with mortification of the bowel, Dupuytren began with dilating the outer opening with a bistoury, and after ascertaining the position of the septum, between the two orifices of the bowel, he in-

troduced one of the blades of the forceps into each portion of the gut, and closed the instrument with the screw. The part of the instrument situated externally to the ridge or septum, he covered with charpie and a compress. The constriction was soon followed by colic pains and tendency to vomit, complaints which were quickly removed by fomenting the belly. They recurred, however, the instrument became loose, and some discharge ensued. On examination, the septum was found to be partially divided. After the breadth of the instrument had been lessened it was applied again; but when the screw was turned, the patient began to suffer such violent pain over the whole of the abdomen, that it was necessary to diminish the pressure; and as the instrument was afterward separated from the parts in a fit of vomiting, it was withdrawn. A trial was now made to determine the feces towards the rectum by pressure on the external opening; but the plan could not be endured, and the hindrance to the egress of the intestinal matter was so oppressive that it was discontinued. As the forceps used on the foregoing occasion did not take sufficient hold of the septum, nor divide it properly, the instrument was somewhat altered. A particular description of its improved make has been inserted by Breschet in *Graefe's Journal*, *b.* 2, *p.* 302. Dr. Reisinger has published three cases in which it was successfully employed by Dupuytren. In the first of these examples, when the instrument had been applied, it embraced the septum so well, that it could not be displaced from it. The colic attacks, vomiting thirst, furred tongues, and loss of appetite, which ensued, soon gave way after the belly had been fomented; the constriction was then increased, and found to produce less and less indisposition. On the 29th, very little of the feces came out of the artificial anus, and after a short time, five natural evacuations took place. The blades of the instrument were now completely closed, and on taking it out, a slough of membrane was found between the blades; a proof that the septum was destroyed. On the 30th, the patient's health was undisturbed. Clysters were now administered with the view of promoting evacuations in the natural manner; and the next day, the patient had a proper motion without any assistance, and a very small quantity of the feces passed out of the fistulous opening. This aperture was now merely covered with charpie; but as some high granulations were rising, the powder of colophonium was sprinkled on them, and compresses and a bandage were applied. The use of clysters was also daily continued, though the patient voided his feces in the natural way. On discontinuing the external pressure, the quantity of discharge from the fistulous opening increased; and, therefore, on the first of October, the compresses were again applied, and kept on the part with a spring truss. The treatment ended in a perfect cure.

In another case, Dupuytren enlarged the lower angle of the outer opening with a bistoury, and after feeling with his finger that both orifices of the bowel were close to that opening, he applied the forceps. In the evening, the constriction was increased, which was followed by severe colic pains over the whole abdomen. They subsided, however, the following day. From the outer opening, a great deal of slimy excrement was discharged. The constriction was not augmented. On the 5th day, the patient was attacked in the night with pain and vomiting. The following night he was also very restless. Though the belly was not tense, it could not bear to be touched. On the 11th, and 12th days, the patient was nearly free from pain, and by means of clysters, two natural motions were procured; and on the 13th, as the patient was easy, Dupuytren began to make pressure on the fistulous opening. On the 26th, the edges of the aperture were touched with lunar caustic; and on the 28th, a compress supported by a spring truss was applied. The patient was kept constantly in the horizontal posture; the feces began to be voided the natural way regularly, and the opening contracted in the most favourable manner.

I think the generality of surgeons will agree with Dr. Reisinger, that the foregoing treatment cannot be indiscriminately adopted in all descriptions of patients without danger. It should never be tried too soon after the formation of an artificial anus; but time should be allowed for the irritability and sensibility of the gut, and especially of the septum, to be lessened by the effect of the air and the pressure of the feces. Nor should the trial ever be made ere it has been fully ascertained that nature cannot herself bring about the cure. Breschet mentions an example in which the foregoing method could not have been practised, in consequence of the mouth of the lower portion of the bowel having been obliterated by the pressure of a large tent three inches long, which had been worn by the patient two years, and the projecting ridge could not be detected.—(See *Graefe's Journ. der Chir. b.* 2, *p.* 298.) Many other interesting observations on this new proposal may be perused in the memoir by Dr. Breschet, and in Dr. Reisinger's tract, the title of which is given in the list of works at the end of the present article. In order not to incur the risk of extravasation of the feces in the abdomen, the constriction of the septum should never be increased with imprudent haste before the adhesive inflammation has had time to be produced between the layers of which that part is composed.

In cases of artificial anus, the appearance of the mucous coat of the bowel undergoes some change, in consequence of exposure to the air and the contact of extraneous bodies; it becomes redder and less villous, but does not cease to secrete a great quantity of mucus: this is one of the principal reasons why it is so difficult to close the fistulous opening, even when the passage for the feces has been restored. The skin around an artificial anus is also generally very irritable, and rendered exceedingly painful by the contact of the excrement.—(*Breschet, in Graefe's Journ. b.* 2, *p.* 303.)

If after the destruction of the septum, and the re-establishment of a free communication between the two portions of the bowel, the external fistula were not to admit of being healed by pressure and other ordinary means, no doubt could be entertained of the propriety of resorting to the plan of attempting to cure it by paring off the edges and bringing them together with sutures, as is sometimes done by Dupuytren, or on the Taliacotian principles, as successfully exemplified by Mr. G. F. Collier.—(See *Med. and Physical Journ. for June*, 1820.) Dupuytren, for the purpose of making the sides of the fistula remain in contact, or making them approach each other, occasionally applies an ingenious little instrument consisting of two pads, which by means of a screw can be made to embrace the part. An engraving of it may be seen in *Graefe's Journ. b.* 3, *taf.* 3, *fig.* 9. For the closure of the fistula, Dupuytren also sometimes has recourse to the actual cautery.

I shall conclude with the relation of an interesting case of artificial anus complicated with prolapsus, as recorded by my friend Mr. Lawrence.

"If the complaint (a mortified hernia) terminates in the formation of an artificial anus, we must endeavour to alleviate those distressing inconveniences which arise from the involuntary discharge of wind and feces through the new opening, by supplying the patient with an apparatus in which these may be received as they pass off. An instrument of this kind, the construction of which appears very perfect, is described by Richter (*Anfangsgr. der Wundarzn. vol.* 5), from the *Traité des Bandages* of Juville. The patient will be best enabled to adapt any contrivance of this sort to the particular circumstances of his own case. It has been found in some instances, that a common elastic truss with a compress of lint under the pad, has been more serviceable than any complicated instrument (*Parisian Journal, vol.* 1, *p.* 193) in preventing the continual flow of feculent matter from the artificial opening."—(*Treatise on Hernia, p.* 206.)

"I know," says Mr. Lawrence, "a patient with an artificial anus, in whom the gut often protrudes to the length of eight or ten inches, at the same time bleeding from its surface. This is attended with pain, and compels him to lie down; in which position the intestine recedes. The patient has now discharged all his feces at the groin for fifteen years, and has enjoyed tolerable health and strength during that time. His evacuations are generally fluid, but sometimes of the natural consistence. Whenever he retains his urine after feeling an inclination to void it, a quantity of clear inoffensive mucus like the white of an egg, amounting to about four ounces, is expelled from the anus; and this may occur two or three times in the day."—(*P.* 208.)

When the protruded intestine is strangulated, an operation may become necessary for the removal of the stricture.—(*Schmucker, Vermischte Chirurgische Schriften, t.* 2.) Two cases which terminated fatally from this cause are mentioned by Sabatier, in a memoir in the 5th tom. de l'Acad. de Chir. Mr. Lawrence also refers to Le Blanc.—(*Precis d'Opérations de Chir. tom.* 2, *p.* 445.) We should always endeavour to prevent such protrusions when a disposition to their formation seems to exist, by the use of a steel truss, which should indeed be worn by the patient independently of this circumstance. If the tumour has become irreducible by the hand, an attempt may be made to replace it by keeping up a constant pressure on the part, the patient being at the same time confined to bed. By these means, as we have already noticed, Desault (*Parisian Journ. vol.* 1, *p.* 178) returned a very large prolapsus, and by pressure on the opening, the feces were made to pass entirely by the anus, although for four years they had been voided only through the wound.—(*Lawrence, p.* 209, 210.)

In cases of mortified hernia, the wound sometimes closes, except a small fistulous opening which discharges a thin fluid and cannot be healed. Mr. Lawrence has related, in his excellent treatise on hernia, a case in which the feces came from the wound some time after an operation, although the bowel did not appear gangrenous when this proceeding was adopted. —(*P.* 211.)

In the appendix to this work, the author adds some farther account of the case of artificial anus which he has related.—(*P.* 208.) The man is sixty years of age, and appears to be healthy, active, and even younger than he really is. He had had a scrotal hernia which ended in mortification, and involved the testicle of the same side and a large portion of the integuments in the destruction. It is now nearly seventeen years since this event, and the feces have during all this time been discharged from the groin. He has never made use of a truss, nor taken any step, except that of always keeping a quantity of tow in his breeches.

The prolapsed portion of intestine varies in length and size at different times. It was four inches long when Mr. Lawrence saw it, and the basis, which is the largest part, measured nearly six inches in circumference. The prolapsus never recedes entirely, and it has occasionally protruded to the length of eight or ten inches, being as large as the forearm, and emitting blood. This occurrence is painful, and only comes on when the bowels are out of order. Warm fomentations and a recumbent position afford relief and accomplish a reduction of the bowel.

The projecting part is of a uniform red colour, similar to that of florid and healthy granulations. The surface, although wrinkled and irregular, is smooth, and lubricated by a mucous secretion. It feels firm and fleshy, and can be squeezed and handled without exciting pain. The man has not the least power of retaining his stools. When these are fluid, they come away repeatedly in the course of the day, and with considerable force. When of a firmer consistence, there is only one stool every one or two days, and the evacuation requires much straining. Such feces are not broader than the little finger. When the patient is purged, the food is often voided very little changed. This is particularly the case with cucumber. In this state he is always very weak. Ale is sometimes discharged five minutes after taken, being scarcely at all altered. The bowels are strongly affected by slight doses of purgatives.

All irritating plans were avoided. Scarpa represents the artificial ani which follow wounds, as far more difficult of cure than those which are the consequence of hernia with mortification; yet I have known many of the first description of cases cured.*

AORTA. Aneurisms of this vessel have already been treated of; but there are a few other particulars relating to it which merit notice in a dictionary of surgery.

WOUND OF THE AORTA NOT ALWAYS FOLLOWED BY INSTANTANEOUS DEATH.

A case exemplifying this fact was recorded by M. Pelletan. In the month of May, 1802, a young man was brought to the Hôtel-Dieu. In a duel, he had been run through with a foil, which penetrated above the right nipple, and came out at the left loin. The most alarming symptoms were apprehended; but several days elapsed without any serious complaints taking place. The patient was bled twice, and kept on a very low regimen. Every thing went on quietly for a fortnight. He now complained of severe pains in his loins, and he was relieved by the warm bath. He seemed to be recovering, got up, and went to walk in the garden allotted for the sick; but the pain in his loins quickly returned, attended with difficulty of breathing, constipation, and wakefulness. He now became very impatient, and out of temper with the surgeons for not relieving him.

On the 15th of July, two months after the accident, a deformity of the spine was remarked about the eighth dorsal vertebra. The patient grew rapidly worse, and died in the utmost agony, saying that he felt suffocated; and tearing off his shirt, that his chest might be free from the pressure of all kinds of clothing.

On the body being opened, the right side of the chest was found full of blood, coagulated in various degrees, and an opening, the diameter of which was equal to that of a writing pen, was detected in the aorta above the crura of the diaphragm. All the adjacent cellular substance was injected with blood, and three of the dorsal vertebræ were found carious. No mark of injury was perceptible in any of the thoracic or abdominal viscera.—(*Pelletan, Clinique, Chir. t.* 1, *p.* 92—94.)

THICKENING AND CONSTRICTION OF THE AORTA.

Meckel met with two cases in which the aorta was thickened and considerably constricted just below its arch; yet in both subjects there was every reason to believe that the abdominal viscera and lower extremities had been duly supplied with blood.

This fluid, which could only pass from the heart with great difficulty and in small quantities, had, by regurgitating, lacerated the semilunar valves.—(*Mém. de l'Acad. Royale de Berlin,* 1756. *Obs.* 17 *and* 18.) A similar example is recorded by Stoerck.—(*Ann. Med.* 11, *p.* 171.) An instance, in which a stricture was met with in the aorta opposite to the termination of the canalis arteriosus, is described by Sir Astley Cooper. The little finger could hardly pass through the constriction, which impeded the course of the blood through the heart and lungs, and was attended with a considerable dilatation of the right ventricle.—(*Surgical Essays, vol.* 1, *p.* 103, *8vo. Lond.* 1818.)

OBLITERATION OF THE CAVITY OF THE AORTA.

It is observed by Professor Scarpa, that the whole body may be regarded as an anastomosis of vessels, a vascular circle; and he contends that this remark is so true, that even an obliteration of the aorta itself, immediately below its arch, may take place, without the general circulation of the blood in the body being stopped. Such a disease of the aorta was seen by Paris in the body of a woman. While she lived, the

blood which was expelled from the heart was transmitted into the trunk of the aorta below the constriction, and it got there by passing through the subclavian, axillary, and cervical arteries, into the mammary, intercostal, diaphragmatic, and epigastric arteries. From these latter arteries the blood passed into the vessels of the thoracic and abdominal viscera and those of the lower extremities.—(See *Desault's Journal, t.* 2, *p.* 107. *Brasdor, in Recueil Périodique de la Soc. de Méd. t.* 3, *No.* 18.)

Dr. Graham, of Glasgow, published another example, in which the aorta was completely obstructed, just below the canalis arteriosus. The particulars are detailed in the *Med. Chir. Trans. vol.* 5, *p.* 287.

Dr. Goodison, of Wicklow, in examining the dead body of a woman in the Hospice de la Pitié at Paris, and endeavouring to trace the origin of the inferior mesenteric artery, discovered a hard tumour placed upon the aorta, and accompanied with an obliteration of that vessel from the origin of the inferior mesenteric artery downwards the remainder of its length; the left iliac being also rendered impervious down to its bifurcation, and the right for more than one-half of its length. The corpora sesamoidea of the semilunar valves of the aorta were considerably enlarged, and the mitral and tricuspid valves presented the appearances termed by Corvisart "vegetations." The arch of the aorta was greatly enlarged, and internally was studded with patches of bone. The vessels given off from the trunk, and especially the lumbar arteries, were all noticed to be considerably increased in size. At the obliterated part of the abdominal aorta, there was a firm bony sheath, covering the vessel for about two inches, and filled with a hard fleshy substance which extended farther upwards, and was firmly adherent to the coat of the artery. It was the inner coat itself which was ossified. For a particular account of the vessels which were chiefly enlarged for the purpose of continuing the circulation, I must refer to Dr. Goodison's description. The general appearance of the body was not unhealthy; and the lower extremities, which were not emaciated, must have been well supplied with blood. The history of the case could not be traced. Mr. Crampton having carefully compared Dr. Goodison's narrative with the preparation taken from this subject, refers the obliteration of the aorta to the effects of the process by which an aneurism had been spontaneously cured; in which particular this case is quite different from those reported by M. Paris and Dr. Graham.—(See *Dublin Hospital Reports, vol.* 2, *p.* 193, *&c.* 8*vo.* 1813.)

The next case which I shall notice is one of the most memorable in the annals of surgery, since it was nothing less than an operation in which a ligature was applied to the aorta of a living subject, under circumstances which, at a time when the successful repetition of Brasdor's operation had not been made (see *Wardrop on Aneurism*, 1829), perhaps warranted even this desperate attempt to preserve life. Sir Astley Cooper had often placed ligatures round the aorta in dogs, and found that the blood was readily carried by the anastomoses to their posterior extremities (see *Med. Chir. Trans. vol.* 2, *p.* 158), and he has ascertained, that if the aortic plexus be tied with the artery, the lower extremities are rendered paralytic, and the animal ultimately dies; but if care be taken to include only the vessel in the ligature, these consequences do not take place.—(See *Lancet, vol.* 2, *p.* 47.)

A porter, aged thirty-eight, was admitted into Guy's Hospital, April 9, 1817, for an aneurism in the left groin, situated partly above and partly below Poupart's ligament. The swelling was considerably diffused, and pressure upon it gave a great deal of pain. On the third day from his entrance into the hospital, the tumour increased to double its former size, and the pulsation became less distinct. The blood could be felt in a fluid state within the sac, which was so large that no operation was practicable without opening the peritoneum. Sir Astley Cooper therefore waited, in order to let the man have the chance of a spontaneous cure. Notwithstanding the practice of venesection and compression, the swelling continued to increase, and, on the 20th of June, a bleeding took place from a point of the tumour, where a slough had formed. The bleeding recurred from time to time, and on the 25th he was so much exhausted by loss of blood that his feces passed involuntarily, and his immediate death was only prevented by pressure on the opening. At nine o'clock in the evening, this experienced surgeon made a small incision into the sac above Poupart's ligament, and introducing his finger, tried if it was practicable to pass a ligature round the external iliac artery within the cavity; but the thing was found impossible, as instead of the vessel, "only a chaos of broken coagula" could be perceived. At the moment of withdrawing the finger, two students compressed the aorta against the spine, and the incision was then closed with a dossil of lint. Sir A. Cooper now determined to apply a ligature to the aorta itself. "I made (says he) an incision three inches long into the linea alba, giving it a slight curve to avoid the umbilicus. One inch and a half was above, and the remainder below the navel," the cut being inclined towards the left side. "Having divided the linea alba, I made a small aperture into the peritoneum, and introduced my finger into the abdomen; and then with a probe-pointed bistoury, enlarged the opening into the peritoneum to nearly the same extent as that of the external wound. Neither the omentum nor the intestines protruded; and during the progress of the operation only one small convolution projected beyond the wound." With his finger-nail he scratched through the peritoneum on the left side of the aorta, and then gently moving his finger from side to side, he gradually passed it between the aorta and spine, and again penetrated the peritoneum on the right side of the aorta. A blunt aneurismal needle, armed with a single ligature, was next conveyed under that vessel, and tied, with the precaution of excluding the intestines from the noose. The wound was then closed by means of the quilled suture and adhesive plaster. During the operation the feces were discharged involuntarily, and the pulse both immediately and for an hour after the operation was 144. An opiate was given, and the involuntaty passage of feces soon ceased. The sensibility of the right leg was very imperfect. In the night, the patient complained of heat in the abdomen; but he felt no pain upon pressure; and the lower extremities, which had been cold a little while after the operation, were regaining their heat, but their sensibility was very indistinct. At six o'clock the following morning, the sensibility of the limbs was still imperfect; but at eight o'clock the right one was warmer than the left, and its sensibility returning. At noon the temperature of the right limb was ninety-four; that of the left or aneurismal one, eighty-seven and a half. At three o'clock, an enema was ordered. The heat of the right leg was now ninety-six; that of the left or diseased limb, eighty-seven and a half. It is unnecessary here to detail all the various circumstances which preceded the patient's death. Vomiting, pain in the abdomen and loins, involuntary discharge of urine and feces, a weak pulse, cold sweats, &c. were some of the most remarkable symptoms. At eight o'clock on the second morning after the operation, the aneurismal limb appeared livid and cold, more particularly round the aneurism; but the right leg was warm; and between one and two o'clock the same day, the patient died. On opening the abdomen, there was not the least appearance of peritoneal inflammation, except at the edges of the wound; and the omentum and intestines were of their natural colour. The ligature, which included no portion of intestine or omentum, was placed round the aorta about three-quarters of an inch above its bifurcation. When the vessel was opened, a clot of more than an inch in extent filled it above the ligature; and below the bifurcation another clot an inch in extent occupied the right iliac artery, while the left contained a third, which extended as far as the aneurism. The neck of the thigh-bone was also found broken within the capsular ligament, and not united; an accidental complication. As there were no appearances of inflammation of the viscera, Sir Astley Cooper refers the cause of the man's death to the want of circulation in the aneurismal limb, which never recovered its natural heat, nor any degree of sensibility, though the right leg was not prevented from doing so: hence, says this experienced surgeon, "in an aneurism similarly situated, the ligature must be applied before the swelling has acquired any considerable magnitude."—(*Surgical Essays, vol.* 1, *p.* 114, *&c.*)

Indeed the most important conclusions from this case are:—First, that where no other impediment exists, the circulation will continue in the lower extremities though the abdominal aorta be tied or suddenly obstructed. Secondly, that suffering aneurismal swell-

ings to become very large before the operation is done, exposes the patient to considerable disadvantage, on account of the pressure of the disease upon the surrounding anastomoses, whereby the continuance of the circulation is rendered less certain than it would be were the operation done at an earlier period.

Sir Astley Cooper mentions, that if he were to perform the operation again, he would cut off the two portions of the ligature close to the knot on the vessel, because the irritation of the bowels by them seems to him a source of considerable danger.

[This formidable operation of tying the aorta has again been performed by Mr. James, of Exeter, Eng., very lately, with the hope of preserving the life of an individual afflicted with aneurism, not admitting of the common mode of treatment; but, like the former, it was unsuccessful.

"For cases in which aneurismal tumour is so situated as not to admit of a ligature being applied to the artery leading to the disease, Brasdor's proposal, and the facts and arguments in its favour related by Mr. Wardrop and others, and noticed in the article *Aneurism* of this Dictionary, deserve serious reflection.

In weighing the various reasons both for and against this practice, as well as those either in favour or condemnation of the desperate expedient of tying the aorta, the judicious surgeon will always regard the occasional spontaneous cures of aneurisms as facts of much importance."—*Pref.*

The numerous cases in which the aorta has been found obliterated has emboldened Sir Astley Cooper, Mr. James, and others, to advocate the propriety of tying this vessel in certain cases, and to maintain that it will yet succeed. It should be recollected, however, that in all these cases the obliteration of the vessel was *gradually* produced by disease, and the anastomosing branches became enlarged by a slow and safe process, because one that is perfectly natural. The case, however, is very different when the vessel is *suddenly* closed by a ligature; and this want of parallel in the cases very obviously vitiates the argument drawn from analogy.

Professor Jamieson, of Baltimore, in a valuable paper on traumatic hemorrhage, published in the American Med. Recorder for January, 1829, has detailed a number of experiments performed on inferior animals, in some of which he passed a seton through large vessels, with a view of obstructing their circulation, and thus effecting their gradual obliteration. His success was certainly encouraging, and Dr. Webster, of Philadelphia, has repeated these experiments with similar results. The latter gentleman, in the late Philadelphia edition of "Cooper's First Lines," has introduced some highly interesting and practical remarks on this subject in a note on the subject of aneurism, to which reference may be had, as containing hints of the most invaluable importance.

Future experiments, however, will be necessary to enable the surgeon to arrive at definite conclusions on this most interesting subject.—*Reese.*]

RUPTURE OF THE AORTA WITHIN THE PERICARDIUM.

The surgical writings of Scarpa in relation to the formation of aneurisms have now gained extensive celebrity in the world. It is well known that this author maintains the doctrine, that in all aneurisms the internal and muscular coats of the artery are ruptured, and that the aneurismal sac is not formed of these tunics, but of the dilated cellular sheath which surrounds the vessel. When a large aneurism bursts, there is always a double rupture; one of the artery, another of the aneurismal sac. The last is that which is the immediate cause of the patient's destruction, by altering the *circumscribed* state of the aneurism into the *diffused*.

There are some exceptions, however, to the foregoing statement, and Scarpa has not failed to point them out. When the internal and muscular coats of the aorta are ruptured in a situation where the outside of the vessel is only covered by a thin, tense, closely adherent membrane, such membrane may be ruptured at the same time with the proper coats of the artery, and sudden death be occasioned by the effusion of blood in the cavity of the thorax. These events are liable to happen whenever the proper coats of the aorta are ruptured within the pericardium, where the vessel is only covered by a thin layer reflected from this membranous bag. Waller has recorded one example of this kind, and Morgagni several others. A similar case is related by Scarpa.—(See *Haller, Disput. Chir. tom.* 5. *Acta Medic. Berlin, vol.* 8, *p.* 86. *Morgagni de Sed. et Causis Morb. Epist.* 26, *art.* 7. 17. 21. *Epist.* 27, *art.* 28. *Scarpa on Aneurism, transl. by Wishart, p.* 81. *Also, Hodgson on the Diseases of Arteries and Veins.*)

STEATOMATOUS TUMOURS OF THE AORTA.

Two steatomatous tumours were noticed by Stenzel in the body of a male subject. They were situated in the substance in the membranes of the aorta, immediately below its arch. Notwithstanding these swellings rendered the vessel almost impervious, the man had the appearance of strength and of having been well nourished. *Hæc corpora fere cor magnitudine æquabant ut omnem propemodum exeunti e sinistri cordis thalamo sanguini spatium præcluderent.* De Steatomatibus in principio arteriæ aortæ, &c. Wittemb. 1723.

This is another striking fact, illustrating the great power of the inosculations to carry on the circulation.

APHÆRESIS. (From ἀφαιρέω, to remove.) This term was formerly used in the schools of surgery to signify that part of the art which consists in taking off any diseased or preternatural portion of the body.

APONEUROSIS. Matter often collects under aponeuroses, particularly under those which cover the muscles of the thigh, leg, and forearm. Abscesses are also sometimes met with under the temporal, the palmar, and the plantar fasciæ; in the tendinous thecæ, which include the flexor tendons of the fingers; and occasionally also in the aponeurotic sheath, in which the rectus abdominis muscle is situated.

One particular effect of an aponeurosis, or any kind of tendinous expansion lying between a collection of matter and the skin, is materially to retard the progress of the pus towards the surface of the body. Hence, if the case be allowed to take its own course, the quantity of matter increases, the pus spreads extensively under the aponeurosis in every possible direction, separates the muscles from such fascia and the muscles from each other, and the abscess does not burst till a vast deal of mischief has been produced, together with more or less sloughing of the fascia, tendons, &c. These circumstances cannot happen without a considerable degree of constitutional disturbance, and a permanent loss of the use of certain muscles. Even when a spontaneous opening is formed, and some of the matter escapes, it is often only a very imperfect discharge; for the aperture generally occurs, not in a depending situation, nor over in the main collection of pus, but at a part where the aponeurosis is thinnest, and consequently where the matter has the least resistance to overcome in going to the surface of the body.

In all such cases the chief indication is to make an early and a depending opening with a lancet, so as to prevent the extension of the abscess, and to let the matter escape as fast as it is formed. If a spontaneous opening should have occurred in an unfavourable place, a new aperture must be made in a proper situation; or if the former should be sufficiently depending and near the principal accumulation of matter, but too small, it must be rendered larger with a curved bistoury and a director. Whenever any black dead pieces of fascia or tendons present themselves at the opening, they must be taken hold of with a pair of forceps and extracted.

APPARATUS. Every thing necessary in the performance of an operation, or in the application of dressings. The apparatus varies according to circumstances. Instruments, machines, bandages, tapes, compresses, pledgets, dossils of lint, tents, sponges, basins of water, towels, &c. &c. are parts of the apparatus, as well as any medicinal substances used.

It is a rule in surgery to have the apparatus ready before an operation is begun. All preparations of this kind should be made, if possible, out of the patient's room and presence, as they might agitate and render him timid.

We have been lately censured by a French surgeon for our too common neglect of what has been here recommended. "In France (observes M. Roux) we are careful not to let a patient who is to undergo a serious operation see any of the requisite preparations for it.

We hasten as much as possible the immediate preparatory measures, in order not to prolong unnecessarily the restlessness and moral agitation which the expectation of an operation, and sometimes of the slightest one, always produces. These precautions are neglected by the English surgeons, at least by most of those whom I saw operate. They even neglect them in private practice, where, more commonly than in hospitals, we have to deal with pusillanimous individuals, who are easily alarmed, and whose extreme susceptibility it is of importance to spare. It was in the very room where the patient lay, of course under his eyes, that the table and all the necessary instruments for lithotomy were arranged, at an operation which I saw done in London, during my stay in that capital, by a gentleman at the head of his profession."—(See *Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise*, p. 105.)

M. Roux, in his visit to London, had also too good reason to complain of the slovenly, objectionable practice of leaving the application of the tourniquet and the dressing of the wound, after a surgical operation, to mere novices and students. I entirely coincide with him, that, in respect to the dressings in particular, a surgeon is bound to extend his attention and solicitude a little beyond the moment when the operation terminates.

APPARATUS MINOR; APPARATUS MAJOR; APPARATUS ALTUS. Three ways of cutting for the stone.—(See *Lithotomy*.)

AQUA PICIS LIQUIDÆ. *Dubl.* Take of tar two pints; water a gallon. Mix them with a wooden rod for a quarter of an hour, and after the tar has subsided let the liquor be strained, and kept in well-corked bottles. This lotion is often used in porrigo and ulcers surrounded with scorbutic redness.—(See *Liquor*.)

ARGENTI NITRAS. (*Nitrate of silver, lunar caustic.*) One of the best caustics. Its utility in stimulating indolent ulcers, and keeping granulations from rising too high, is well known to every surgeon.

Mr. Hunter sanctions the use of the argentum nitratum on the first appearance of a chancre, before absorption can be supposed to have taken place. He directs the caustic to be scraped to a point, like a black lead pencil; so that when it is applied every part of the surface of the chancre may be touched with it; and he advises the repetition of this process till the last slough which is thrown off leaves the sore florid and healthy.

This treatment, when the sore is very small, may sometimes be advisable as a means of lessening the chance of the constitution being infected by absorption. In general, surgeons combine with the plan the moderate use of mercury.

The important use of the argentum nitratum, in the cure of numerous diseases, we shall have occasion to remark in various articles of this work; particularly *Cornea, ulcers of; Iris, prolapsus of; Ulcers; Urethra, strictures of*, &c.

The argentum nitratum is often used in the form of a solution, in the proportion of a drachm of the caustic to an ounce of distilled water. In general, this application ought to be at first more or less diluted with distilled water. Cancerous ulcers and sores about the nose and neighbouring parts of the face, being examples of *lupus*, or *noli me tangere*, are often considerably benefited by the argentum nitratum, both in the solid and fluid state. The solution agrees also very well with certain sores which occur round the roots of the nails of the fingers and toes. The lotion is sometimes applied with a camel-hair pencil; but in general by dipping little soft bits of lint in the fluid, laying them on the part, and covering them with a pledget.

ARSENIC is the chief ingredient in a secret remedy which has long possessed very great celebrity in Ireland for the cure of cancer, and is now well known among surgeons by the name of Plunket's caustic. This application consists of the ranunculus acris, the greater crow-foot, the flammula vulgaris, and the less crow-foot, in the proportion of an ounce of each, bruised and mixed with a drachm of the white oxide of arsenic and five scruples of sulphur. The whole is to be beaten into a paste, formed into balls, and dried in the sun. When required for use, these balls are beaten up with yolk of egg and spread upon a piece of pig's bladder. The use of the ranunculus is to destroy the cuticle, upon which the arsenic would have no effect; for it is to be observed, that Plunket's caustic was employed for the dispersion of tumours as well as for the relief of ulcerated cancers. The application is to remain on the part twenty-four hours, at the end of which time the slough is to be dressed with any simple unirritating ointment. When arsenic was first recommended as an application for cancers, it used generally to be blended with opium. When Plunket's caustic is employed so as to form an eschar over a scirrhous tumour, I conjecture, that if it ever do good, it is not by any specific effect of this arsenical application, but simply as a slough or issue formed near the disease in any other manner. It is highly probable, also, that the swellings which have been thus dispersed, have never been complicated with the structure characteristic of true scirrhi. With respect to cancerous ulcers, Pulnket's caustic sometimes evidently produces a degree of amendment, which, however, rarely lasts for any considerable time; but there are many inveterate ulcerations and anomalous sores which derive permanent benefit from the application, and are even completely cured by it. Some examples of lupus, ulcerations about the roots of the nails, and reputed carcinomatous sores of the lips are of this description.

At Paris an arsenical paste is often used by Dubois and other surgeons of that capital for cancerous sores of the penis and other malignant ulcers. It is composed of seventy parts of cinnabar, twenty-two of sanguis draconis, and eight of the white oxide of arsenic formed into paste with saliva at the time when it is to be employed. "The pain and inflammation that succeed the use of it (says Mr. Cross) cannot be equalled by the severest operation with the knife."—(*Sketches of the Medical Schools of Paris*, p. 45, 8vo. 1815.) Even death may be occasioned by the absorption of the poison, as appears from the two annexed facts; the first of which is recorded by M. Roux in his *Médecine Opératoire*. "The day after the paste was applied, the patient complained of colic and severe vomiting, and in two days perished in convulsions, *et les plus vives angoisses*. The body went quickly into putrefaction. The internal coat of the stomach and a great part of the intestinal canal were inflamed and marked here and there with dark spots." Just before I visited Paris (adds Mr. Cross), I dissected in London a woman who died under similar circumstances, and where the same morbid appearances were presented, &c.—(*Op. cit.*)

Justamond's applications to cancer were generally combinations of arsenic and sulphur. One formula was an ounce of yellow arsenic with half that quantity of Armenian bole, and sometimes as much red precipitate. He also employed a sulphuret of arsenic and a combination of this sulphuret with crude antimony. The arsenical preparation selected for use, was scraped and laid on the middle of the sore, the edges of which were moistened with a combination of the muriate of iron and muriate of ammonia. In some instances we learn that the effects of the treatment were the correction of the fetid smell, melioration of the appearance of the sore, and separation of the cancerous part.

In the Pharmacopœia Chirurgica, Justamond's arsenical caustic is directed to be made in the following manner. ℞. Antimonii pulverizati ℥j. Arsenici pulverizati ℥ij. These are to be melted together in a crucible. The application may be reduced to any degree of mildness by blending with this pulverized caustic a quantity of opium in the form of powder, which was also supposed to act specifically in diminishing pain.

The powder of white oxide of arsenic, unmixed with other substances, has sometimes been sprinkled upon cancerous and other inveterate ulcers, but the practice is now abandoned by every judicious surgeon, on account of the violent pain resulting from it, and the not unfrequently fatal consequences of its absorption. Could I suppose, that a man so rash and ignorant as to revive this murderous practice yet existed in the profession, I should feel disposed to lengthen these remarks; but I am persuaded, that in this country at least, more judgment and knowledge every where prevail. The white oxide of arsenic, however, may be applied with more prudence in other forms; either in one of those already specified, or as a lotion, composed of eight grains of the oxide and the same quan-

tity of subcarbonate of potash dissolved in four ounces of distilled water; or as an ointment, formed by rubbing together one drachm of the oxide and twelve drachms of spermaceti ointment.—(See *A. T. Thomson's Dispensatory*, *p.* 51.)

Feburc's celebrated remedy consisted of ten grains of the white oxide of arsenic dissolved in a pint of distilled water; to which were then added an ounce of the extractum conii, three ounces of the liquor plumbi subacetatis, and a drachm of laudanum. With this fluid the cancer was washed every morning. Febure likewise gave arsenic internally; and his prescription was two grains of the white oxide, a pint of distilled water, syrup of chichory q. s. and half an ounce of rhubarb. Of this mixture a table-spoonful was given every night and morning with half a drachm of the syrup of poppies. Each dose contained about one-twelfth of a grain of arsenic; but in proportion as the patient was able to bear an increased quantity, the dose was gradually augmented to six table-spoonfuls of the solution.

The arseniate or rather superarseniate of potash, is an excellent preparation for internal exhibition. The Dublin Pharmacopœia directs it to be made as follows: take of white oxide of arsenic, nitrate of potassa, each an ounce. Reduce them separately to powder; then having mixed them, put them into a glass retort and place it in a sand-bath exposed to a gradually raised heat, until the bottom of the retort becomes obscurely red. The vapours arising from the retort should be transmitted through distilled water by means of a proper apparatus, in order that the nitrous acid extricated by the heat may be disengaged. Dissolve the residue in four pounds of boiling distilled water, and after due evaporation, set it apart in order that crystals may form. This preparation has long been known under the name of Macquer's arsenical neutral salt. It may be given in the following way: ℞. Potassæ superarseniatis gr. ij. Aq. menthæ viridis ℥iv. Spir. vinosi tenuioris ℥j. M. et cola.

Dosis drachmæ duæ ter quotidie.

The following is Dr. Fowler's method of preparing arsenic for internal use: take of the white oxide of arsenic and pure subcarbonate of potash, each sixty-four grains. Boil them gently in a Florentine flask or other glass vessel, with half a pound of distilled water, until the arsenic is dissolved. To this solution, when cold, add half an ounce of the compound spirit of lavender, and as much water as will make the whole equal to a pint, or fifteen ounces and a half in weight. The dose of this solution, of which the liquor arsenicalis L. P. is an imitation, is as follows: from two years old to four, M. ij or iij to v; from five to seven, M. v to vij; from eight to twelve, M. vij to x; from thirteen to eighteen, M. x to xii; from eighteen upwards, M. xii. These doses may be repeated every eight or twelve hours, the medicine being diluted with thick gruel or barley-water. As the preparation is decomposed by the infusion and decoction of cinchona, it should never be ordered with either of these medicines.

The white oxide of arsenic may be given in the form of pills, made by mixing one grain of it with ten of sugar, and then beating up the mixture with a sufficient quantity of the crumb of bread to form ten pills, one of which is a dose. It will only be in my power to specify here a few of the numerous surgical cases in which the internal employment of arsenic has been proposed. The following are particularly worthy of attention: tetanic affections; cancer; lupus; elephantiasis; inert cases of lepra (See *Bateman's Pract. Synopsis of Cutaneous Diseases*, *p.* 33, *ed.* 3); various unnamed malignant ulcers; certain forms or sequelæ of the venereal disease, or other unintelligible diseases which cannot be subdued by mercury; different cutaneous affections, &c. A longer list of diseases for which a trial of arsenic is suggested, may be seen in some papers published by Mr. Hill.—(*Edin. Med. and Surg. Journ. vols.* 5, 6.)

Arsenic has also been recommended by Dr. J. Hunter for the prevention of hydrophobia.—(See *Trans. of a Society for the Improvement of Med. and Chir. Knowledge*, *vol.* 1.) Later trials of the medicine, however, in this particular case, do not appear to entitle it to any confidence. Dr. Marcet found it quite unavailing, though not less than three drops of Fowler's solution were taken every other hour in two drachms of peppermint or sweetened water.—(See *Med. Chir. Trans. vol.* 1, *p.* 141. 156.) After the symptoms of hydrophobia have once began, arsenic is decidedly useless.

But although it fails in hydrophobia, some facts published by Mr. Ireland, and certain observations and experiments detailed in Dr. Russel's work on Indian serpents, make it appear a truly valuable remedy for the effects of the bites of serpents.—(See *Med. Chir. Trans. vol.* 2, *p.* 393.)

In cases of poison by arsenic, practitioners universally agree respecting the first indication, which is to empty the stomach as quickly as possible with the stomach pump or an emetic. In this country the common practice is to exhibit an emetic of sulphate of zinc or sulphate of copper, which (it is said) ought to be preferred; first, because they do not require much dilution for their action; a circumstance of no small importance where poisons act by being absorbed; and secondly, because they are extremely expeditious; a dose of fifteen or twenty grains producing almost instantaneous vomiting, without exciting that previous stage of nausea which so frequently characterizes other emetics, and which produces a state of the vascular system highly favourable to the functions of absorption.—(See *Pharmacologia, by Dr. Paris*, *p.* 232, *vol.* 1, *ed.* 5.)

On the other hand, instead of the use of violent emetics like antimon. tart. and sulphate of zinc, which Orfila says always increase the irritation created by the poison, he prefers exciting vomiting by making the patient drink large quantities of warm water, milk, water containing sugar or honey, linseed tea, and other mucilaginous fluids, the experiment of tickling the throat with a feather or finger not being omitted. After as much of the poison has been discharged by vomiting as can be thus evacuated, the stomach may be mechanically washed out with the stomach pump; a plan first proposed by Boerhaave and afterward improved by MM. Dupuytren and Renault.—(See *Orfila, Toxicologie Générale*, *t.* 1, *p.* 132, *ed.* 2, 1818. *See also Mr. Jukes's Obs. on this subject in Med. and Phys. Journ. for Nov.* 1822, *and June*, 1823; *also Lancet*, *vol.* 1.) By this means, the contents of the stomach may either be pumped out at once, or any fluid may be first injected and then drawn out again. As arsenic produces its fatal effects chiefly by being absorbed, an important indication, according to this principle, is to administer only such liquids as are least liable to dissolve the arsenic in the stomach. On this account lime-water has been recommended as proper to be drunk after the stomach has been emptied by vomiting. It is remarked by Orfila, that lime-water with milk offers no particular advantage in cases of poison with the solid arsenical acid; but where this acid is fluid, he admits the great utility of lime-water, as in this circumstance, an insoluble arsenite of lime is formed, the action of which is very weak. This last observation is confirmed by experiments on dogs.—(*Toxicologie Générale*, *t.* 1, *p.* 233.)

When inflammation of the abdomen and alarming nervous symptoms prevail, the means of relief are, leeches, venesection, the warm bath, fomentations, emollient clysters and antispasmodic narcotic medicines.

It should also never be forgotten, that the success of the treatment will depend, in a great measure, upon the regimen observed during the patient's convalescence, which is usually tedious; and he should be chiefly nourished with milk, gruel, cream, rice, and beverages of a softening mucilaginous nature.—(See *Orfila*, *t. cit. p.* 235.)

[There can be little doubt that *arsenic* is the basis of the active ingredients of most of the popular nostrums of the day which are set forth in our public papers as infallible remedies for the cure of cancerous affections, as they are termed; and hence the manifold evils which we often witness from such practice. So long ago as in 1786, Dr. Rush favoured the public with an exposition of the nature of the famous cancerous powder of Dr. Martin; its base was arsenic, though like the specifics of our own time it was alleged to be of a vegetable nature. The consequences arising from applications of this character might be noticed at greater length than our author has seen fit to do; and the caution to be deduced from facts of this sort might operate more forcibly if they were better understood. The external application of arsenic ought to be had recourse to only after the severest scrutiny into the peculiar character of the case and constitution affected. Even in small quantities it has produced apoplexy, mental aberration, organic lesion of the stomach, paralysis,

loss of motion, enlargement of the joints, fatal petechiæ, &c. Arsenic, in fact, may be enumerated among that class of poisons which induces nearly the same effects externally applied as well as when taken inwardly. The experiments of Brodie, as well as those of other philosophers, demonstrate, that its influence on the system is no less rapid and dangerous when had recourse to as an external application to denuded surfaces than when applied directly to the stomach. Another peculiarity of its action deserves also farther to be stated: according to Professor Francis (*Lectures on Forensic Medicine*), in *some cases*, even while favourable anticipations from the operation of this powerful agent locally applied are indulged, of a sudden the general health yields, and death *ensues rapidly and unexpectedly*; an occurrence of much consideration in the investigations of the juridical physician.—*Reese.*]

ARTERIOTOMY. (From ἀρτηρία, an artery, and τέμνω, to cut.) The operation of opening an artery, for the purpose of taking away blood for the relief of diseases.—(See *Bleeding.*)

ARTERIES. The process by which a divided or punctured artery is healed is particularly considered under the word *Hemorrhage*; while the general principles, which ought to be observed in the application of the means for the stoppage of bleeding, may be collected partly from the remarks contained in that part of the work, and partly from what is stated in the articles *Amputation*, *Aneurism*, and *Ligature*. As the condition of a bleeding patient admits of no delay, and the preservation of his life entirely depends upon proper measures being immediately taken, no man ought to be suffered to profess surgery who is not competent to the treatment of wounded arteries, whether injured by accident or in a surgical operation. As Langenbeck observes, an ignorant practitioner, when called to a case of serious hemorrhage, is thrown into such consternation, as actually deprives him of the power of rendering prompt assistance. Pale as a corpse, and trembling, he beholds the jet of blood; and, for the sake of appearing to do something, perhaps he applies spirit of wine, or a very tight bandage, and cries out for farther aid; while simple pressure of the thumb upon a certain point in the vicinity of the injury would prevent all this confusion, and a dangerous loss of blood. No part of surgery, in fact, is of higher importance than the treatment of wounded arteries; and it deserves, therefore, to be earnestly studied by every practitioner, whether he move in the higher or the lower sphere of the profession. And as a proof of the necessity of country surgeons making themselves acquainted with the subject, he recites the case of a turf-cutter, who let the instrument with which he worked fall against the lower part of his leg, whereby the posterior tibial artery was wounded. The blood gushed out profusely, and the surgeon who was sent for applied a tourniquet to the popliteal artery, and thus stopped the bleeding for a time; but, unfortunately, the tourniquet was kept so long on the limb, that the foot mortified and sloughed away.—(*Bibl. für die Chir. b.* 1, *p.* 231, 232, *Gött.* 1806.) From the explanations, delivered in the article *Hemorrhage*, it will be seen, that in all bleedings from considerable arteries, nothing is equal to the ligature, as a means of preventing the farther loss of blood; and it may be laid down as a standing rule, that each extremity of the wounded vessel should be tied as nearly as possible to the wound in its coats. As Mr. Hodgson has remarked, "the necessity of tying both ends of a wounded artery is evident from the fact, that the anastomoses in all parts of the body are so extensive, as to furnish a supply of blood, which may pass through the lower extremity of the wounded vessel in a sufficient stream to produce an alarming, and, in some instances, a fatal hemorrhage."—(*On Diseases of Arteries, &c. p.* 469.) This correct observation is followed by a case, in which the bleeding from the lower end of a divided brachial artery caused the patient's death. Of course the inference is, that both extremities of the vessel ought to have been tied directly after the receipt of the wound. With regard to tying the trunk of an artery in a part of the limb where it cannot be exposed with facility, when it is difficult to secure its bleeding extremities, as Mr. Hodgson remarks, the practice "was falsely deduced from a knowledge of the fact, that the ligature of an artery at a distance from the disease will effect the cure of an aneurism. But a more intimate acquaintance with the condition of a limb after such an operation, and the processes by which the cure of an aneurism is effected after the modern operation, afford a complete illustration of the inefficacy and danger of this mode of treating a wounded artery; for it is now fully proved, that when an artery is tied, a stream of blood continues to pass through it below the ligature."—(*P.* 471.) This well-informed surgeon is aware, however, that instances do occur, in which only the upper end of a wounded artery is tied, and yet the patient recovers without hemorrhage from the lower orifice, which is closed by the natural processes.

In the year 1814, in Holland, I took up the femoral artery, in the middle of the thigh, in a case in which the popliteal artery had given way, ten days after the passage of a musket-ball through the ham. I employed only one smallish ligature, which was applied with the precaution of not detaching the artery from its natural connexions. The hemorrhage was effectually stopped, and the wound healed in the most favourable manner. Here, no doubt, the inflammation in the ham had obliterated the portion of the artery immediately below the point at which it had sloughed or ulcerated, and there might even have been from the same cause some deposition of lymph within the upper portion of the popliteal artery, contributing to the success of the operation. But, no doubt, it was the diminution of the impulse of the circulation by the ligature of the femoral artery, which enabled nature to complete the obliteration of the wounded part of the vessel. Sometimes, says Mr. Hodgson, when hemorrhage takes place, a few days after the bleeding from a wounded artery has been stopped by compression, one extremity of the vessel will be pervious, while the other will have closed by the natural processes. Cases have even occurred, in which the upper end of the artery has been closed by the natural processes, while those processes failed in effecting the obliteration of the lower extremity of the vessel, from which a serious hemorrhage took place.—(*Hodgson, op. cit.* 475; *and Guthrie, in New Med. and Phys. Journ. vol.* 4, *p.* 177.) Indeed, in the example in which I took up the femoral artery myself, it was impossible to say positively, whether the blood came from the part of the popliteal artery above or below the slough in it, as no incision was made into the ham.

The principle, respecting the application of a ligature to each end of every large divided artery, is to be extended also to punctured arteries, one ligature being placed above and the other below the opening in the vessel.

From some observations in the article *Aneurism*, p. 125, it will be seen, that when the impulse of the circulation has been lessened by the ligature of the main trunk of an artery, some distance above the wound, the hemorrhage from the more remote portion of the vessel may sometimes be effectually restrained by pressure, which, previously to the stoppage of one great current of blood to the part had proved unavailing. This fact is worth remembering, in cases in which the arteries of the hand or foot are wounded.

Mortification is observed to be more frequent after the ligature of an artery for a wound, than for an aneurism. In wounds, Mr. Hodgson very correctly, I think, refers the difference to the frequent injury of the surrounding parts, and particularly of the veins and nerves, and to the loss of blood, and want of quietude and proper care after the accident. The principal anastomosing vessels are also sometimes divided.—(*P.* 479.)

Having given, in the article *Aneurism*, the necessary directions, how to cut down to and tie many of the principal arteries, I shall conclude the present subject with a few instructions how to take up the arteries of the forearm and leg, as delivered by Scarpa, Mr. C. Bell, Mr. Hodgson, and others. Some directions how to act in a case of wounded axillary artery are likewise subjoined.

In order to lay bare the radial artery at the upper third of the forearm, a finger is to be put on the insertion of the tendon of the biceps. A little below this insertion, an incision, about two inches and a half in length, is to be made in the integuments, in the oblique direction, denoted by the inner edge of the supinator radii longus. The subjacent fascia is then to be divided, and the inner edge of the supinator muscle drawn a little from the outer side of the arm: in the space between that muscle and the flexor carpi ra-

dialis the radial artery immediately presents itself, passing over the tendon of the pronator radii teres and the flexor longus pollicis, and it then runs down between the latter-named tendon and the flexor carpi radialis.—(See *Camper's Demons. Anat. Pathol. lib.* 1, *tab.* 1, *fig.* 2.) A branch of the musculo-spiral nerve lies on the radial side of the artery.

At the wrist, the radial artery may be taken up by making an incision a little way from the ulnar margin of the flexor carpi radialis. Here the artery is covered by a fascia, over which a small branch of the external cutaneous nerve runs; but the vessel is now unaccompanied with the musculo-spiral nerve, which quits it, and passes under the supinator radii longus, a little below the middle of the forearm.

After the radial artery leaves the forepart of the wrist, it may be taken up by making an incision "on the outside of the insertion of the extensor primi internodii pollicis, and the inside of the extensor tertii internodii pollicis. Between these tendons the artery lies very deep, and over it is the extreme branch of the muscular spiral nerve. We find the artery going close to the notch, between the os scaphoides and trapezium."—(*C. Bell, Op. Surgery, vol.* 2, *p.* 373.)

For bringing into view the ulnar artery at the upper third of the forearm, the situation and breadth of the flexor carpi ulnaris muscle must first be ascertained. An incision is then to be made from above downwards, beginning two inches below the inner condyle of the humerus, and following the course of the inner margin of the above muscle to the extent of two inches and a half. The fascia is then to be divided: the flexor carpi ulnaris is to be drawn a little away from the flexor sublimis. In this opening, rather under the margin of the latter muscle, the ulnar artery will be felt with the finger, continuing its course over the flexor profundus. The ulnar nerve is situated on the ulnar side of the artery.

Below the middle of the forearm, the ulnar artery is more superficial, and may easily be taken up by making an incision upon the radial side of the flexor carpi ulnaris, between the tendon of which muscle and that of the flexor profundus digitorum the vessel is situated. The artery, however, will not be reached until a thin aponeurosis under the fascia of the forearm has been divided. The nerve is rather more under the tendon of the flexor carpi ulnaris than the artery. When the ulnar artery arises from the brachial above the elbow, it runs above the fascia, and is easily taken up in any part of its course.

The anterior tibial artery passes forwards between the bones of the leg, about an inch below the upper head of the fibula. In order to take up the vessel in this situation, a free cut must be made through the fascia, extended between the heads of the tibia and fibula. The incision is then to be continued more deeply at the edge of the peronæus longus, following the fascia between this muscle and the origin of the extensor digitorum communis. The artery will be met with on the interosseous ligament.—(*C. Bell, vol.* 2, *p.* 376.)

In order to lay bare the anterior tibial artery, a little above the middle of the leg, the finger is to be passed along the outer side of the spine of the tibia, and the breadth of the tibialis anticus muscle is to be ascertained. Along the outer margin of this muscle, an incision is to be made through the integuments and fascia, two inches and a half in length. The knife is then to be introduced between the outer margin of the tibialis anticus muscle and the extensor longus of the great toe. In this space, at the depth of about an inch, the anterior tibial artery is situated.—(See *Haller's Icon. Anat. fasc.* 5, *tab.* 4.) Cutting down to this artery, near the tarsus, where the vessel passes out between the tendons of the tibialis anticus and extensor muscle of the toes, is an easy operation.

The laying bare of the posterior tibial artery, behind the malleolus internus, is also quite easy: an incision, about two inches long, is to be made between the internal malleolus and the tendo achillis, down to the posterior surface of the tuberosity of the tibia. At this depth, the tendon of the tibialis posticus muscle, and that of the flexor communis digitorum pedis, run as in a furrow. Along with these two tendons, but a little nearer to the os calcis, the posterior tibial artery descends to the sole of the foot.

On the contrary, the depth of the posterior tibial artery at the middle or in the upper third of the leg, makes it very difficult to take up the vessel in these situations. And the difficulties are increased by the spasmodic contractions of the gastrocnemius and soleus muscles. When necessary, however, the artery may be exposed and tied above and below the wound in it, by proceeding as follows: an incision is to be made three or four inches in length, along the inner side of the crest of the tibia, and the origins of the soleus muscle are to be detached from it to the same extent, and reflected. Under the soleus muscle is found the aponeurosis, which separates the muscle of the calf of the leg into superficial and deep-seated. When this fascia has also been divided, the posterior tibial artery may be seen, or felt, deeply situated, running on the tibialis posticus and flexor muscle of the toes.—(See *Haller, Icon. Anat. fasc.* 5, *tab.* 5.)

In taking up the axillary artery when it is wounded, Scarpa believes that nothing tends more to embarrass the surgeon, than an injudicious smallness of the first incision through the skin and such other parts as conceal the wound in the artery. An assistant must compress the vessel, from above the clavicle, as it passes over the first rib. When the weapon has penetrated, from below upwards, directly into the axilla, the surgeon is to make a free dilatation of the wound upon a director or his finger. This must be done to a sufficient height to expose a considerable portion of the artery, and the precise situation of the wound in it.

When the weapon has pierced obliquely, or from above downwards, through a portion of the great pectoral muscle, into the axilla, Scarpa advises the surgeon to cut through the lower edge of this muscle, and enlarge the wound, on a director, or his finger, so as to bring fairly into view the injured part of the artery. The thoracic arteries, divided in this operation, must be immediately tied. The clots of blood are then to be removed, and the bottom of the wound cleaned with a sponge, by which means the opening in the axillary artery will be more clearly seen. As this vessel lies imbedded in the brachial plexus of nerves, the surgeon must take care to raise it from these latter parts with a pair of forceps, before he ties it. Two ligatures will be required; one above, the other below, the wound of the arteries.

ASTRINGENTS. Substances which possess the power of making the living fibres become contracted, condensed, and corrugated. They are employed in the practice of surgery chiefly as external applications, either for restoring diminished tonic power, or checking various discharges. Astringent lotions are deemed eligible local remedies for phlegmonous inflammation.

ATHEROMA. (From ἀθήρα, pap.) An encysted tumour, so named from its pap-like contents.—(See *Tumours, Encysted.*)

AUSCULTATION. Mediate auscultation, or the method of judging of the nature and conditions of various diseases by the particular sound which they communicate to the ear, through the medium of the instrument called the *stethoscope*. Thus, in diseases of the lungs and pleura, the practitioner may derive important information respecting the condition of those organs, by attending minutely to the changes in the sound of respiration, to the sound of the voice and coughing within the chest, and to what is called the *rattle*, and other sounds occasionally heard in the same situation. The stethoscope, then, in many ambiguous cases, must be deemed an instrument of great use in practice. For a particular description of it, however, I refer to Laennec's invaluable work on diseases of the chest, in the translation and improvement of which, by numerous instructive notes, Dr. Forbes has rendered himself a benefactor to medical science. In surgery, the stethoscope is usefully employed in detecting the real nature of various doubtful swellings, particularly those of an aneurismal character. By M. Lisfranc it has been found of considerable service in enabling him to judge with more accuracy of the collision of the sound against calculi, or other substances in the bladder, in the operation of sounding. M. de Kergaradec has used the stethoscope with much success for ascertaining pregnancy, where the history was obscure. It has also been found of great utility in determining the existence and state of various collections of fluids, and particularly of pus; and it has enabled practitioners to ascertain with certainty the communications occasionally existing between abscesses of the liver and the interior of the lungs, as well as the occasional communication of pulmonary abscesses with the abdominal cavity. In

cases of fracture, where the crepitus is obscure, the stethoscope removes all ambiguity. In all diseases about the heart, and large blood-vessels near this organ, much useful information may be derived from the application of the stethoscope; but the method of using it, and the circumstances by which it affords instruction, must be gathered from a careful perusal of Laennec's work.

B

BALSAMUM COPAIBÆ. Exhibited by surgeons principally in cases of gonorrhea, gleet, fluor albus, and piles. The common dose is from ten drops to half a drachm, two or three times a day. Mr. Brande gives the following formula: R. Mucil. acaciæ ℥ iss. Copaibæ ℥ ss. tere simul et adde gradatim aq. menth. vir. ℥ j. Tinct. capsici mv. gutt. ft. Haustus bis vel ter quotidie sumendus.—(See *Manual of Pharmacy*, *p.* 70.)

BANDAGE. The use of bandages is to keep dressings, compresses, remedies, &c. in their proper situation; to compress blood-vessels, so as to restrain hemorrhage; to rectify certain deformities by holding the deranged parts in a natural position; and to unite parts in which there is a solution of continuity. As the application of bandages is an important branch of surgery, authors have not neglected it. Much has been written on the subject, and almost every writer has devised new bandages, perhaps without much benefit to the art. Unfortunately, it is next to impossible to give clear ideas of the numerous sorts of bandages by a printed description of them. The surgeon can only acquire all the necessary instruction from experience and practice. Hence, we shall confine ourselves to a general account of the subject.

Bandages should be made of materials possessing sufficient strength to fulfil the end proposed in applying them, and at the same time they should be supple enough to accommodate themselves to the parts to which they are applied.

Bandages are made of linen, cotton, or flannel. If possible, they should be without a seam or selvage, which sometimes causes unequal and painful pressure.

There are cases in which the bandage should have a degree of firmness that does not belong to the materials usually employed. This circumstance is obvious in hernia, and in all those examples in which there is occasion for elastic bandages. As we have already observed, linen, flannel, and cotton (calico) are the common materials. The first employment of flannel bandages is imputed to the Scotch surgeons, who preferred them to linen ones, in consequence of their being better calculated for absorbing moisture, while, being more elastic, they yield in a greater degree in cases requiring this property; as in the swelling subsequent to dislocations, fractures, &c. It has been asserted, that linen is better than flannel, because more cleanly; but neither one nor the other will continue clean, unless care be taken to change it often enough. Where the indication is to keep the parts warm, flannel is of course preferable both to linen and calico.

In applying a bandage, care must be taken, that it be put on tight enough to fulfil the object in view, without running any risk of stopping the circulation, or doing harm in any other way. If it be not sufficiently tight to support the parts in a proper manner, it is useless; if it be too tense, it will produce swelling, inflammation, and even mortification.

In order to apply a roller skilfully, the part which is to be covered, must be put in its proper situation; the head of the roller held in the surgeon's hand, and only so much unrolled as is necessary for the commencement of the application.

In general, the bandage should be applied in such a manner as will admit of its being most conveniently removed, and allow the state of the subjacent parts to be examined, as often as occasion may require, with the least possible disturbance of them.

For this reason, in fractures of the leg and thigh, the eighteen-tailed bandage is generally preferred to a simple roller. The former may be loosened and tightened, at pleasure, without occasioning the smallest disturbance of the affected limb; a thing which could not be done were a common roller to be employed.

As soon as the bandage has fulfilled the object for which it is applied, and it has become useless, its employment should be discontinued; for, by remaining too long on parts, it may obstruct the circulation, diminish the tone of the compressed fibres and vessels, and thus do harm.

Bandages are either *simple* or *compound*. They are also sometimes divided into *general* and *particular*. The latter often derive their names from the parts to which they are usually applied.

A simple bandage is a long piece of linen or cotton, of an indefinite length, and from three to six inches in breadth. When about to be applied, it is commonly rolled up, and the roller part is termed its *head*. When rolled up from each end, it is called a *double-headed roller* or *bandage*.

The chief of the simple bandages are the *circular*, the *spiral*, the *uniting*, the *retaining*, the *expellent*, and the *creeping*.

The *circular* bandage is the simplest; consisting merely of a few circles of a roller covering or overlapping each other.

The *spiral* bandage is the most frequently used of all; for it is this which is seen in such common employment on the limbs, in cases of ulcers, varices, &c. In applying a common roller to the whole of a limb, the bandage must be carried round the part spirally: for otherwise the whole member cannot be covered. When the leg is the part, the surgeon is to begin by surrounding the foot with a few turns. Then carrying the head of the bandage over the instep, he is to convey it backwards, so as to make the bandage unroll, and apply itself just above the heel. The roller may next be brought over the inner ankle; thence again over the instep, and under the sole; and the surgeon then brings the bandage spirally upwards once more to the outer part of the leg. After this, every circle of the roller is to be applied, so as to ascend up the limb in a gradual, spiral form, and cover about one-third of the turn of the roller immediately below it. The unequal diameter of the limb is one great cause which brings into view the unskilfulness of a surgeon in this common operation; for it prevents the roller from lying smoothly, although spirally applied, unless a particular artifice be dexterously adopted. The plan alluded to is, to double back the part of the roller that would not be even, were the application to be continued in the common spiral way, without this manœuvre. When the bulk of the limb increases very suddenly, it is sometimes necessary to fold, or, as it is termed, *reverse* every circle of the bandage in the above manner, in order to make it lie evenly on the limb. It is manifest, that the pressure of the roller will be greatest where the duplicatures are situated; and hence, when it is an object to compress any particular part, the surgeon should contrive to reverse the turns of the bandage just over the situation where most pressure is desirable.

When a roller is to be applied to the forearm, it is best to put a few of the first turns of the bandage round the hand.

Care must be taken not to make the bandage very tight, if it be intended to wet it afterward with any lotion; for moisture always renders it still more tense.

Mr. John Bell describes the principal purposes for which a roller is employed as follows: "Although in recent wounds it is with plasters and sutures that we unite the parts point to point, yet it is with the bandage that we support the limb, preserve the parts in continual and perfect contact with each other, and prevent any strain upon the sutures, with which the parts are immediately joined; and we often unite parts by the bandage alone. But it is particularly to be observed, that, in gun-shot wounds, and other bruised wounds, though it would be imprudent to sew the parts, since it is impossible that they should altogether unite, yet the gentle and general support which we give by a compress and bandage, prevents them from separating far from each other, unites the deep parts early, and lessens the extent of that surface which must naturally fall into suppuration.

In the hemorrhagy of wounds we cannot always

find the artery; we dare not always cut parts for fear of greater dangers; we are often alarmed with bleedings from uncertain vessels, &c., or from veins as well as arteries: these hemorrhages are to be suppressed by the compress; which compress, or even the sponge itself, is but an instrument of compression, serving to give the bandage its perfect effect. Frequently, in bleedings near the groin or the armpit, or the angle of the jaw, wherever the bleeding is rapid, the vessels uncertain, the cavity deep, and the blood not to be commanded by a tourniquet, and where the circumstances forbid a deliberate and sure operation, we trust to compress and bandage alone.

Bandage is very powerful in suppressing bleeding. At one period of surgery, it took place of every other method, &c. If a compress be neatly put upon the bleeding arteries, if there be a bone to resist the compress, or even if the soft parts be firm below, and the bandage be well rolled, the patient is almost secure. But such a roller must be applied smoothly from the very extremities of the fingers or toes; the member must be thoroughly supported in all its lower parts, that it may bear the pressure above. It is partial stricture alone that does the harm, creates intolerable pain and anxiety, or brings on gangrene. Hemorrhagy requires a very powerful compression, which must therefore be very general, &c. It must not be made only over the bleeding arteries, which is all that the surgeon thinks of in general, &c.

In abscesses, where matter is working downwards along the limb, seeking out, as it were, the weak parts, undermining the skin, and wasting it, insulating and surrounding the muscles, and penetrating to the bones, the bandage does every thing. The expelling bandage, the propelling bandage, the defensive bandage, were among the names which the older surgeons gave to the roller, when it was applied for these particular purposes; and these are properties of the roller which should not be forgotten."—(*Principles of Surgery*, *vol.* 1.)

Soon after this description of some of the chief surgical uses of the roller, Mr. John Bell proceeds to explain in what manner this most simple of all bandages may be put on a limb.

"Practice will convince you that the firmness and neatness of a bandage depend altogether upon these two points; first, upon the turns succeeding each other in a regular proportion; and, secondly, upon making reverses wherever you find any slackness likely to arise from the varying form of the limb. Thus, in rolling from the foot to the ankle, leg, and knee, you must take care, first, that the turns, or, as the French call them, *doloires*, of the roller lie over one another by just one-third of the breadth of the bandage; and, secondly, that at every difficult part, as over a joint, you turn the roller in your hand, make an angle, and lay the roller upon the limb, with the opposite flat side towards it: you must turn the bandage so as to reverse it, making what the French call a *renversée* of the roller at the ankle, at the calf of the leg, and at the knee. You must be careful to roll your bandage from below upwards, and support the whole limb by a general pressure. That you may be able to support the diseased part with a particular pressure, you must lay compresses upon the hollows and upon the bed of each particular abscess, and change the place of these compresses from time to time, so as now to prevent matter sinking into a particular hollow, now to press it out from a place where it is already lodged, and again to reunite the surface of an abscess already completely formed, from which the matter has been discharged."—(*Principles of Surgery*, *vol.* 1.)

In the article *Joints* we have taken notice of the good effects of the pressure of the roller in the cure of some diseases of the knee. Here we shall just introduce Mr. John Bell's sentiments upon the subject: "In a diseased bursa, as in a relaxation of the knee-joint, that disease which, with but a little indulgence, a very little encouragement of fomentations, poultices, bleeding, and low diet, would end in whites welling of the knee, may be stopped even by so simple a matter as a well-rolled bandage."—(*Vol.* 1, *p.* 127.)

The *uniting bandage*, or *spica descendens*, used in rectilinear wounds, consists of a double-headed roller, with a longitudinal slit in the middle of three or four inches long. The roller, having one head passed through the slit, enables the surgeon to draw the lips of the wound together. The whole must be managed so that the bandage may act equally. When there are sutures, this bandage supports the stitches, and prevents their tearing through the skin. When the wound is deep, writers advise a compress to be applied on each side, in order to press the deeper part of its sides together. When the wound is very long, two or three bandages should be employed, and great care taken that the pressure be perfectly equable.

Heister, Henckel, and Richter describe a sort of uniting bandage that allows the surgeon to see the wound, over which only small ligatures cross. This contrivance will be best understood by reference to an engraved representation of it in *Richter's Elements*, *b.* I.

When we make use of a single-headed roller as a *retentive bandage* only, we should remember always to begin the application of it on the side opposite the wound. The obvious reason for so doing is to prevent a farther separation of the lips of the wound, as the contrary manner of applying the roller would tend directly to divide them.—(*Gooch*, *vol.* 1, *p.* 143.)

The intention of the *expellent bandage* is to keep the discharge sufficiently near the orifice of the wound to prevent the formation of sinuses. In general, a compress of unequal thickness is necessary; the thinner part of the compress being placed next, and immediately contiguous to, the orifice of the wound; the thicker part below. Before the bandage is applied the pus must be completely pressed out, and the rolling begin with two or three circular turns on the lower part of the compress. The bandage must then be carried spirally upwards, but not quite so tightly as below. It is afterward to be rolled downwards to the place where it began.

The *creeping* is a simple bandage, every succeeding turn of which only just covers the edge of the preceding one. It is employed in cases in which the object is merely to secure the dressings, and not to make any considerable or equable pressure.

A bandage is termed *compound* when several pieces of linen, cotton, or flannel are sewed together in different directions, or when the bandage is torn or cut so as to have several tails. Such are the T bandage, the suspensory, the capistrum, &c.

The *eighteen-tailed bandage* is one of the most compound. It is now in general use for all fractures of the leg and thigh, sometimes for those of the forearm, and frequently for particular wounds. Its great recommendation is the facility with which it can be undone so as to allow the parts to be examined, and its not creating on such an occasion the smallest disturbance of the disease or accident.

The eighteen-tailed bandage consists of a longitudinal portion of a common roller, and a sufficient number of transverse pieces or tails, to cover as much of the part as is requisite.

Each of the cross-pieces is to be proportioned in length to the circumference of the part of the limb to which it is to be applied; so that in making this sort of bandage for the leg or thigh, the upper tails will be twice as long as the lower ones. After laying the long part of the bandage on a table, fix the upper end of it in some way or another. Then arrange the tails across it in sufficient number to cover such part of the limb as requires the bandage. Each tail must be long enough to extend about two inches beyond the opposite one, when they are both applied. The tails being all arranged across the longitudinal band, they are to be stitched in this position with a needle and thread. When the bandage is intended for the leg, a piece of the longitudinal part of the roller below is to extend beyond the tails. This is usually brought under the sole of the foot, and then applied over the inner ankle directly after the bandage has been put under the limb. Then the surgeon lays down the first of the lower tails and covers it with the next. In this way he proceeds upwards till all the cross-pieces are applied, the uppermost one of which he fastens with a pin. This bandage has a very neat appearance. The tails are said to lie better when placed across the longitudinal piece a little obliquely.—(*Pott.*)

The T *bandage* is for the most part used for covering parts of the abdomen and back, and especially the scrotum, perinæum, and parts about the anus. Its name is derived from its resemblance to the letter T, and it is, as Mr. John Bell remarks, the peculiar bandage of the body. If the breast or belly be wounded, we make the transverse piece which encircles the body very broad; and having split the tail part into two portions, one of

these is to be conveyed over each side of the neck and pinned to the opposite part of the circular bandage, so as to form a suspensory for the latter, and prevent its slipping down. But, says Mr. John Bell, if we have a wound, or disease, or operation near the groin or private parts, the tail part then becomes the most important part of the bandage: then the transverse piece which is to encircle the pelvis is smaller, while the tail part is made very broad. When the disease is in the private parts, perinæum, or anus, we often split the tail according to circumstances; but when the disease is in one groin we generally leave the tail part of the bandage entire and broad.

The *scissum linteum*, or *split-cloth*, is a bandage applied occasionally to the head, and consists of a central part and six or eight tails or heads, which are applied as follows:

When the cloth has six heads, the middle or unsplit part of the cloth is applied to the top of the head. The two front tails go round the temples and are pinned at the occiput; the two back tails go also round the temples, and are pinned over the forehead; the two middle tails are usually directed to be tied under the chin; but, as Mr. John Bell observes, this suffocates and heats the patient, and it is better to tie them over the top of the head or obliquely so as to make pressure upon any particular point.—(*Principles of Surgery, vol.* 1, *p.* 131.)

The old surgeons usually split this middle tail into two parts, a broad and narrow one. In the broad one, they made a hole to let the ear pass through. This broad portion was tied under the chin, while the narrow ends were tied obliquely over the head. As Mr. John Bell has observed, though this gave the split-cloth the effect of eight tails, yet the ancient surgeons did not name it the split-cloth with eight tails. When they split the cloth into eight tails, and especially when they tied the eight tails in the following particular manner, they called the bandage *cancer*, as resembling a crab in the number of its legs. The *cancer*, or *split-cloth of eight tails*, was laid over the head in such a manner that four tails hung over the forehead and eyes, while the other four hung over the back of the head. They were tied as follows: first, the two outermost tails on each side in front were tied over the forehead, while the two middle tails in front were left hanging over the knot. Then the two outermost or lateral tails behind were tied round the occiput. Next the middle tails were tied, the two anterior ones being made to cross over each other and pass round the temples, to be pinned at the occiput; while the two middle tails behind were made to cross each other and pass round the temples so as to be pinned over the ears or near the forehead.—(See *John Bell's Principles, vol.* 1, *p.* 132.)

The *triangular bandage* is generally a handkerchief doubled in that form. It is commonly used on the head, and now and then as a support to the testicles when swelled. The French term it *couvre-chef en triangle*.

The *nodose bandage*, called also *scapha*, is a double-headed roller, made of a fillet four yards long, and about an inch and a half broad. It must be reversed two or three times, so as to form a knot upon the part which is to be compressed. It is employed for the stoppage of hemorrhage, or for securing the compress after the performance of arteriotomy in the temples.

The most convenient bandage for the forehead, face, and jaws, is the *four-tailed one*, or *single split-cloth*.

It is composed of a strip of cloth about four inches wide, which is to be torn at each end, so as to leave only a convenient portion of the middle part entire. This unsplit middle portion is to be applied to the forehead if the wound be there, and the two upper tails are carried backwards and tied over the back part of the head, while the two lower ones are to be tied either over the top of the head or under the chin, as may seem most convenient.

When the wound is on the top of the head, the middle of the undivided part is to be applied to the dressings. The two posterior tails are to be tied forwards, and the two anterior ones are to be carried backwards, so as to be tied behind the head. This is sometimes called *Galen's bandage*. It is curious, that writers on bandages should use the terms *head* and *tail*, synonymously; and hence this *four-tailed bandage* is often called the *sling* with *four heads*. Such confusion of language is highly reprehensible, as it obstructs the comprehension of any, the most simple subject.

If the upper lip be cut, and a bandage needed, which is seldom the case, it is almost superfluous to say, that this bandage will serve the purpose. It serves also in cuts of the lower lip, though in them also we trust rather to the twisted suture than a bandage.

The single split-cloth is particularly useful for supporting a fractured lower jaw, and in such cases, is the only one employed in modern surgery. This bandage, when used for this particular purpose, namely, supporting the lower jaw, is named *capistrum* or *bridle*, because it goes round the part somewhat like a bridle.

"In some cases (says Mr. John Bell), the circumstances require us to support the chin particularly, and then the unslit part of the bandage is applied upon the chin with a small hole to receive the point; but where the jaw is broken, we pad up the jaw-bone into its right shape with compresses pressed in under the jaw, and secured by this bandage. When we are in fear of hemorrhage after any wound or operation near the angle of the jaw, we can give the sling a very remarkable degree of firmness. For this purpose, we tear the band into three tails on each side, and we stitch the bandage at the bottom of each slit, lest it should give way when drawn firm," &c.—(*Principles of Surgery, vol.* 1.)

We have already described one way of applying a handkerchief as a bandage to the head, in our notice of the *triangular one*, or *couvre-chef en triangle*. The other manner of applying the handkerchief, called the *grand couvre-chef*, is as follows:

You take a large handkerchief, and fold it, not in a triangular, but a square form. You let one edge project about three finger-breadths beyond the other, in order to form a general border for the bandage. You lay the handkerchief upon the head, so as to make the lower fold to which the projecting border belongs lie next the head; while the projecting border itself is left hanging over the eyes till the bandage is adjusted. The two corners of the outermost fold are first to be tied under the chin; the projecting border is then to be turned back and pinned in a circular form round the face, while the corners of the fold next the head are to be carried backwards and tied.

After the outer corners of this bandage have been tied under the chin; after the inner corners have been drawn out and carried round the occiput; and after the border has been turned back and pinned; the doubling of the handkerchief over each side of the neck hangs in a loose, awkward manner. It remains, therefore, to pin this part of the handkerchief up above the ear as neatly as can be contrived.—(See *J. Bell's Principles.*)

The grand couvre-chef has certainly nothing to recommend it, either in point of utility or elegance. A common nightcap must always be infinitely preferable to it. In the event, however, of a cap not being at hand, it is proper that the surgeon should know what contrivances may be substituted to fulfil the objects in view.

Having, in the numerous articles of this Dictionary, noticed the mode of applying bandages in particular cases, and allotted a few separate descriptions for such bandages as are not here mentioned, but which are often spoken of in books, we shall conclude for the present with referring the reader for farther information to *Rees's Cyclopædia; John Bell's Principles of Surgery, vol.* 1. *Dict. des Sciences Méd. art. Bandage. Galen and Vidus Vidius are reckoned the best of the old writers on the subject; M. Suc, Thillaye, Heister, Juville, Lombard, Bernstein, and J. Bell, of the modern ones.*

BARK, *Peruvian.* See *Cinchona.*

BELLADONNA. (*Deadly Nightshade.*) A powerful sedative and narcotic. The leaves were first used externally for discussing scirrhous swellings, and they have been subsequently given internally in scirrhous and cancerous diseases, amaurosis, &c. Five grains of them dried are reckoned a powerful dose: one is enough to begin with. At present the extract in doses of one grain gradually increased to five, is more commonly prescribed.

It is said, that the recent leaves powdered, and made into an ointment with an equal weight of lard, more effectually prevent priapism and relieve chordee, when rubbed on the penis, than any other application.—(*Paris's Pharmacologia, vol.* 2, *p.* 110, *ed.* 5.)

From the power which belladonna is known to possess of lowering the action of the whole arterial sys-

tem, it seems to be a fit medicine in many surgical cases where that object is desirable, particularly in examples of aneurism.

Belladonna has the power of producing a dilatation of the pupil, when applied to the eyebrow and eyelids. The late Mr. Saunders was in the habit of employing belladonna a good deal for this express purpose. A little while before undertaking the operation for the congenital cataract, he was accustomed to introduce some dissolved extract of belladonna between the eyelids, or rub the eyebrow and skin about the eye freely with the same application. The consequence was, that if there were no adhesions of the iris to other parts, a full dilatation of the pupil was produced in less than an hour, and the whole of the cataract was distinctly brought into view. This was unquestionably a considerable improvement in practice, as the iris was kept out of danger, and the operation materially facilitated. I allude here more particularly to Mr. Saunders's own method, in which he introduced the needle through the cornea in front of the iris, and then conveyed it to the cataract through the enlarged pupil. Belladonna was also externally applied by Mr. Saunders after the operation, with the view of preventing the edge of the iris from becoming adherent to the edges of the torn capsule. In iritis the same plan is an important part of the treatment. Whenever the state of the eye behind the pupil requires to be minutely examined, the plan of dilating this aperture by means of belladonna very materially facilitates the examination. Stramonium is found to have the same effect upon the iris as belladonna. Some experiments, in which the fact is clearly proved, were detailed many years ago, by a namesake of my own in the United States.—(See *A Dissertation on the Properties and Effects of the Datura Stramonium, &c. by Samuel Cooper, Philadelphia*, 1797. *C. Himbly, De la Paralysie de l'Iris par une application locale de Jusquiame, &c. 2d ed. 12mo. Altona*, 1805. *J. Bailey, Observations relative to the Use of Belladonna in painful Disorders of the Head and Face, 8vo. Lond.* 1818.)

BINOCULUS. (From *binus*, double, and *oculus*, the eye.) A bandage for keeping dressings on both eyes. Its application will easily be understood by referring to *Monoculus*.

BISTOURY. (*Bistoire*, French.) Any small knife for surgical purposes.

BLADDER, *Puncture of.* The making of an artificial outlet for the urine is an operation to which we are obliged to have recourse, after having in vain employed all the other means indicated for the prevention of the bad, and even fatal consequences of a stoppage of the evacuation of this fluid, and distention of the bladder. Various accidents and diseases, both acute and chronic, may occasion this dangerous state, as will be more particularly noticed in the article *Urine, Retention of.*

The bladder, which can conveniently hold about a pint and a half of urine, is no sooner dilated, so as to contain two pints, than uneasy sensations are experienced. The desire of discharging the water now becomes urgent, and if the inclination be not gratified, and the bladder is suffered to be dilated beyond its natural state, it loses all power of contraction, and becomes paralytic. The desire, indeed, continues, and the efforts are renewed in painful paroxysms; but the power is lost, and the bladder becomes more and more distended. When this viscus is dilated in the utmost degree, and neither its own structure nor the space in the abdomen can allow a farther distention, either the bladder must be lacerated, which it never is, so equally is it supported by the pressure of the surrounding parts, or its orifice must expand and the urine begin to flow. After the third day of the retention, the urine often really begins to flow, and whatever descends from the kidneys is evacuated in small quantities from time to time; and at this period, the bladder is distended in as great a degree as it ever can be, however long the patient may survive. This dribbling of the urine, which begins when the bladder is dilated to the utmost, and continues till the eight or tenth day, or till the bladder sloughs, has long been understood, and is named by the French, "*urine par régorgement.*" To practitioners who do not understand it, the occurrence is most deceitful. The friends felicitate themselves, that the urine begins to flow; the surgeon believes it; basins and cloths wet with urine are easily produced; but the patient lies unrelieved. The continued distention of the bladder is followed by universal inflammation of the abdomen. The insensibility and low delirium of incipient gangrene are mistaken for that relief which was expected from the flow of urine, till either hiccough comes on, and the patient dies of fever and inflammation, or the urine gets into the abdomen through an aperture formed by mortification. Let no surgeon, therefore, trust to the reports of nurses and friends, but lay his hands upon the hypogastric region, and tap with his finger, in order that he may distinguish the distended bladder and the fluctuation of urine. As the bladder suffers no farther distention after the third day, why should it burst? Not from laceration; for it is supported by the uniform pressure of the surrounding viscera; not by yielding suddenly, for it is distended to its utmost on the third day of the retention, and yet seldom gives way before the tenth; not by attenuation, for it becomes thickened. The term *laceration* was never more wrongly applied than in this instance; for when there is a breach in the bladder, it is found on dissection to be a small round hole, such as might be covered with the point of the finger. The rest of the viscus and the adjacent bowels are red and inflamed, while this single point is black and mortified! Delay is more dangerous than even the worst modes of making an opening into the bladder, and while life exists, the patient should have his chance.—(See *John Bell's Principles of Surgery, vol. 2, part 1, p. 262, &c.*)

That many patients die after paracentesis of the bladder is an undoubted truth, and this circumstance has rather intimidated practitioners against the operation. It appears to me, however, that in general death may be more fairly ascribed to the effects of the disease than to the puncture of the bladder, and that if this last measure, or the making of an outlet for the urine in some way or another, were not deferred so long as it often is, the recoveries would be more numerous.

Hence, when relief cannot be obtained by the treatment described in the article *Urine, Retention of*; when no urine at all has come away at the end of the third day; or when it only does so in a dribbling manner after this period, while the bladder continues distended, and no catheter can be introduced; the operation should not be delayed. Indeed, in urgent cases, one should rather operate earlier.

No doubt, a man who is exceedingly skilful in the use of the catheter, and knows how to practice with science and judgment all the other means for relieving the retention of urine, will not frequently find it necessary to have recourse to the operation of puncturing the bladder. This is said to have been so much the case with the eminent Desault, that in the course of ten years, he had occasion only once to perform such an operation in the Hôtel-Dieu, where diseases of the urethra are always extremely numerous.—(See *Œuvres Chir. de Desault, par Bichat, tom. 2, p. 316.*) When, however, this superior manual dexterity with the catheter is not the acquirement of the practitioner, the timely performance of the paracentesis of the bladder, or, at all events, the making of an outlet for the urine in some way or another, should not be neglected. It is gratifying to know, however, that at the present day, the absolute necessity for puncturing the bladder is rendered less frequent, not only by the treatment of diseases of the urethra being better understood than formerly, but also by the very great perfection to which the construction of elastic gum catheters is brought; instruments, from which the most essential assistance may frequently be derived. Strictures in the urethra, and enlargement of the prostate gland, are the two cases most frequently producing a retention of urine: and in both of them Sir Astley Cooper considers the operation of puncturing the bladder (with very few exceptions) entirely unnecessary; an opinion with which my own observations lead me fully to concur. In cases of enlarged prostate gland, a skilful surgeon will almost always succeed in introducing a catheter of proper shape and length; and in examples of retention from stricture when relief cannot be afforded by ordinary means, the best plan, generally, is, not to puncture the bladder, but to make a small opening in the part of the urethra between the stricture and neck of the bladder; a part which is most commonly much dilated. I shall next treat of the three modes of puncturing the bladder.

1. *Puncture through the Perinæum.*

This operation is said to have been first done by M. Tolet, a French surgeon, the author of a valuable treatise, entitled, "*Traité de Lithotomie, ou de l'Extraction de la Pierre hors de la Vessie, troisième édition, Paris*, 1681." According to Sabatier, it was customary at the time of Dionis to make the opening with a narrow pointed scalpel, about four or five inches long, which was plunged into the bladder at the place where the incision in the apparatus major terminated.—(See *Lithotomy.*) The escape of the urine indicated when the surgeon had reached the bladder. A straight probe was conducted along the knife, and then a cannula was passed over the probe into the bladder, where it was allowed to remain as long as necessary, care being taken to fix it by means of tapes put through the rings at the broad part of the instrument. The opening was then closed with a linen tent. Dionis first suggested the method of opening the bladder on one side of the perinæum, at the part where Frère Jacques used to perform lithotomy. Dionis conceived that this mode of operating had advantages, because neither the urethra nor the neck of the bladder was injured; a narrow scalpel was first introduced, so as to make a passage for the probe, and along this the cannula was guided into the bladder. The idea of substituting for these unsuitable instruments a trocar of convenient length was exceedingly simple, and for this improvement, which took place in 1721, surgery is indebted to Juncker (see *Conspectus Chirurgiæ, tab.* 97, *p.* 674), unless the following passage be correct: "In the year 1717 or 1718, M. Peyronie showed in the king's garden a long trocar which he had successfully employed in a similar puncture."—(*Desault's Parisian Chir. Journ. vol.* 2, *p.* 267.)

The patient having been placed in the same position as for lithotomy, an assistant is to press with his left hand on the region of the bladder above the pubes, in order to propel that viscus as far downward into the less pelvis as possible, while with his right hand he supports the scrotum. The surgeon is then to introduce the trocar at the middle of a line drawn from the tuberosity of the ischium to the raphe of the perinæum, two lines more forwards than the verge of the anus. The instrument is first to be pushed in a direction parallel to the axis of the body: and its point is afterward to be turned a little inwards. Here, according to Bichat, there is no occasion to convey the cannula so far into the bladder as is done when the operation is performed above the pubes. The portion of this viscus that is pierced, being incapable of changing its position with regard to the other parts in the perinæum, if the cannula only project a few lines into its cavity, it will not be liable to slip out. It would be wrong indeed to carry it in farther; for the pressure of its end against the posterior parietes of the bladder would do harm. Lastly, the cannula is to be fixed in its place, by means of the T bandage.—(See *Œuvres Chir. de Desault, t.* 3, *p.* 320.) A silver cannula, when kept introduced too long, becomes covered with a thick incrustation, which renders its extraction very difficult and painful: care should be taken to prevent the inconvenience, either by withdrawing it entirely, or substituting another for it, according as the circumstances of the case may demand. When Dr. Ehrlich visited London, Mr. Chandler tapped the bladder through the perinæum, and introduced a cannula, which, after remaining in the puncture three weeks, was so thickly covered with an incrustation, that its extraction produced considerable laceration of the parts, and a great deal of inflammation, followed by a urinary fistula.—(See *Dict. des Sciences Méd. t.* 26, *p.* 205.)

Some writers recommend the introduction of the left index finger into the rectum, in order to draw this intestine out of the way; but Sabatier thinks it better to use this finger for pressing on the part of the perinæum where the puncture is about to be made, so as to make the skin tense, and assist in the guidance of the trocar.—(*Médecine Opératoire, t.* 2, *p.* 126.)

The parts divided in the puncture are, the skin, a good deal of fat and cellular substance, the levator ani muscle, and that portion of the lower part of the bladder which is situated on one side of its neck.

The following is the judgment which Bichat has passed upon this method: In the track which the trocar has to pass, there is no part the puncture of which must of necessity give rise to bad symptoms. A surgeon moderately exercised in the practice of this operation is tolerably sure of piercing the bladder, which is opened in the most depending situation, and at a point which constantly bears the same relation to the perinæum. But the position in which the patient is placed for the operation is a great deal more disagreeable than that for the puncture above the pubes. Several assistants are required to fix him, and one is necessary for compressing the bladder in the hypogastric region. There is a possibility of wounding the vessels of the perinæum, and of pricking the nerves which accompany them. If the point of the trocar be carried too much outwards, it may glide over the external side of the bladder. If it be inclined forwards, it may slip between this viscus and the pubes. If it be turned too much inwards, it may pierce the prostate gland. If directed too much backwards, it may wound the vasa deferentia, the rectum, the extremity of the ureter, and the vesiculæ seminales. Also, while the cannula is introduced, the patient can neither walk about nor sit down; but must continually keep himself in bed. Lastly, this mode of operating is frequently counter-indicated by tumours or other common diseases in this part of the body in consequence of retentions of urine.—(*Œuvres Chir. de Desault, par Bichat, t.* 3, *p.* 321.)

The puncture of the bladder from the perinæum is now almost universally abandoned by British surgeons. "We may esteem it fortunate," says Desault, "if the trocar penetrates directly into the bladder, after piercing the fat and the muscles situated between the tuberosity of the ischium and the anus; and as this viscus is subject to much variation in its form, the surgeon will often be defeated, unless he be perfectly clear in his ideas respecting its situation and figure. This disappointment is not without example, and there is sufficient cause to deter a practitioner from performing this operation, independently of the danger of wounding with the trocar the vasa deferentia, vesiculæ seminales, ureter," &c.—(*Parisian Chir. Journ. vol.* 2, *p.* 267.)

If there be now any practitioners who are not averse to the total relinquishment of this method, I think the following caution, given by Sabatier, may be of service to them: perhaps the operation would be more safe if the surgeon were to begin with making a deep incision in the perinæum, as is practised in the lateral way of cutting for the stone, and if he were to desist from plunging the trocar into the bladder until he has assured himself of the situation of this viscus, and felt the fluctuation of the urine.—(*Médecine Opératoire, t.* 2, *p.* 127.) Sir Astley Cooper, in describing this method, also directs an incision to be made in the perinæum as in lithotomy; the bulb of the penis to be pushed towards the patient's right side; the knife then carried within the branch of the ischium till it reaches the prostate gland, which is likewise to be pushed towards the patient's right side; and lastly, the instrument to be passed obliquely upwards into the bladder, the operator's finger resting on the prostate gland.—(*Lectures, &c. vol.* 2, *p.* 314.)

As in cases of inveterate strictures the urethra between the obstruction and the bladder is always dilated, I think, with Mr. C. Bell, that it may sometimes be better practice to cut into such distended portion of the passage than puncture the bladder. On this point many useful remarks may be found in this gentleman's *Surgical Observations, part* 5, *&c.*, the tenor of which I have more particularly considered in the 5th ed. of the *First Lines of the Practice of Surgery.* The practice of opening the urethra behind the stricture, in preference to puncturing the bladder, is also successfully adopted and highly commended by Sir Astley Cooper.—(See *Lectures, &c. vol.* 2, *p.* 315.)

2. *Puncture above the Pubes.*

The invention of the method of tapping the bladder above the pubes was suggested by the possibility of extracting calculi from that viscus by what is usually denominated the high operation. The first performers of the puncture above the pubes are said to have employed a straight trocar, the very same instrument as was used for tapping the abdomen in cases of dropsy. The consequence was, that when such a trocar was too long, its cannula was apt to hurt the opposite parietes of the bladder, so as to occasion inflammation and a slough, on the separation of which the urine was liable to insinuate itself either into the abdomen or rectum, as happened in a case mentioned by Mr. Sharp, where no more urine was discharged through the can-

nula, and the patient died of a sort of diarrhœa. When the trocar is short, the bladder, on subsiding and contracting itself, gradually quits the cannula, which becomes useless, and a necessity for making another puncture may be produced. Whatever pains may be taken to direct the trocar obliquely downwards and backwards, so that the cannula may be, in some degree, parallel to the axis of the bladder, one or the other of these accidents cannot always be prevented.

Their prevention, however, may be effected by merely employing, instead of a straight trocar, a curved one, which will naturally take a suitable direction. This improvement was embraced by Frère Côme, the inventor of the lithotome caché, who also devised a curved trocar for the paracentesis of the bladder, very superior to the instrument of the same shape previously in use.

To this way of operating Mr. Sharp was partial, and Mr. Abernethy has recommended it under certain circumstances. The former remarks that it is an operation of no difficulty to the surgeon, and of little pain to the patient, the violence done to the bladder being at a distance from the parts affected. It is equally applicable, whether the disorder be in the urethra or the prostate gland; and when there are strictures, the use of bougies may be continued, while the cannula remains in the bladder.—(*Critical Inquiry, p.* 125, *ed.* 4.)

Some writers recommend making an incision about two inches long through the linea alba a little way above the pubes, and then introducing a trocar into the bladder. Others deem this preliminary incision quite useless, asserting that the operation may be performed with equal safety and less pain to the patient by puncturing at once the skin, the linea alba, and the bladder. When the trocar has been introduced, the stilet must be withdrawn, and the cannula kept in its position by a riband passed through two little rings, with which it should be constructed, and fastened round the body. The orifice of the cannula should be stopped up with a little plug, so as to keep the urine from dribbling away involuntarily, and taken out as often as may be necessary.—(*Encyclopédie Méthodique: part. Chirurg. art. Paracentèse de la Vessie.*)

The trocar should be introduced in a direction obliquely downwards and backwards: for as this corresponds with the axis of the bladder, the instrument will be less likely to injure the opposite side of that organ.

Nearly all writers advise the puncture to be made an inch or an inch and a half above the pubes. The reasons for so doing are the following: "If the puncture be made close to the os pubis, the bladder in that part, often rising with an almost perpendicular slope, leaves a chasm between it and the abdominal muscles, or, to speak more strictly, a certain depth of membrana cellularis only, so that if the trocar penetrate but a little way, it possibly may not enter into the bladder. If it penetrates considerably, it may pass through the bladder into the rectum, or if not in the operation itself, some days afterward, when by the course of the illness and confinement the patient is more wasted. For the abdominal muscles, shrinking and falling in, occasion the extremity of the cannula to press against the lower part of the bladder, and in a small time to make a passage into the rectum."—(*Sharp, in Critical Inquiry, p.* 127.) Though the reasons here adduced seem at first as formidable as they are numerous, does not the danger of injuring the peritoneum form an objection to plunging in a trocar at the above distance from the pubes? Certain it is, peritonitis would be more apt to be induced by such practice, than by introducing the instrument immediately above the pubes. Richerand decidedly condemns the plan, principally because the higher the puncture is made, the more apt the bladder will be to quit the cannula on the urine being discharged. —(See *Nosogr. Chir. t.* 3, *p.* 472, *ed.* 2.) In Desault's works by Bichat, the puncture is also advised to be made immediately above the pubes.—(*T.* 3, *p.* 318.) Some of Mr. Sharp's objections are removed by taking care to pass the trocar into the bladder in the axis of this viscus, and employing one which is somewhat curved, as Hunter, Frère Côme, Sabatier, &c. have advised. Mr. Sharp confirms the danger of using too long a cannula, by mentioning an accident which occurred in his own practice. Though he introduced the instrument more than an inch and a half above the os pubis, yet having pushed it full two inches and a half below the surface of the skin, its extremity in six or seven days insinuated itself into the rectum.—(*Critical Inquiry, p.* 127.) The instrument, says an excellent writer, should be more or less long, according as the patient is fat or otherwise; but the ordinary length should be about four inches and a half. The curvature should be uniform, and form the segment of a circle, about eight inches in diameter.—(*Œuvres Chir. de Desault, par Bichat, t.* 3, *p.* 317.)

A catheter left in the bladder longer than ten days may gather such an incrustation from the urine, as not only to render the extraction of it painful, but even impracticable. Surgeons, therefore, should never leave the cannula in the bladder quite a fortnight; or if it must be kept introduced so long, Mr. Sharp advises a second one to be introduced, made with an end like that of a catheter.—(*Critical Inquiry, p.* 129.)

Mursinna, however, has reported one example in which a cannula was kept in for a long time without inconvenience.—(*Hecker, Annales der Ges. Medicin.* 1810, *Jul. p.* 39.) I have seen one myself, and two other examples of the same kind are mentioned by Sir Astley Cooper.—(*Lancet, vol.* 2, *p.* 410.)

Mr. Abernethy makes an incision between the pyramidales muscles, passes his fingers along the upper part of the symphysis pubis, so as to touch the distended bladder, and introduces a common trocar of the middle size in a direction obliquely downwards. On withdrawing the stilet, he passes a middle-sized hollow elastic catheter through the cannula into the bladder. The cannula is withdrawn, and the catheter left in till the urine passes through the urethra. After a week, as the instrument begins to be stopped up with mucus, it is taken out, and a new one introduced.—(*Surgical Observations*, 1804.) It might be objected to this plan of employing a hollow bougie, that as it is smaller than the wound, the urine is not kept from passing between the instrument and parts into which it is introduced, as well as through the tube itself. This happened in Mr. Abernethy's case, and though no urine in this instance got into the cellular membrane, it might sometimes do so, because it is not till after inflammation has taken place, that the cavities of the cellular substance are closed with coagulating lymph. After a day or two, however, the cannula of the trocar might be withdrawn and the hollow bougie employed, which would be less likely than the silver one to cause ulceration of the posterior part of the bladder.

The following is one of Sir E. Home's conclusions: "When the puncture is made above the pubes, the cannula which encloses the trocar is not to be removed till the surrounding parts have been consolidated by inflammation, so as to prevent the urine in its passage out from insinuating itself into the neighbouring parts; for wherever the urine lodges mortification takes place. Any advantage, therefore, which may arise from a more flexible instrument remaining in the bladder, is more than counterbalanced by its not filling completely the aperture through the coats of the bladder, and allowing the urine to escape into the cellular membrane."—(*Trans. of a Soc. for Med. and Chir. Knowledge, vol.* 2.)

There is much truth in the following passage: The abdomen is inflamed; the preliminary incisions, which prepare for the introduction of the trocar, sometimes pass through several inches of fat and cellular substance; the incisions must be wide in proportion to their depth; the cannula is no sooner lodged here than it is displaced, in some degree, by the contraction of the bladder, which, when emptied, subsides under the pubes. The cannula stands so obliquely, that the urine never flows with ease, but by running out upon the wound, and by being injected among the cellular substance, it causes the wound to inflame; the wound by its proximity to the inflamed peritoneum soon mortifies, and thus, notwithstanding the temporary relief produced by the emptying of the bladder, the patient dies on the third or fourth day.—(*John Bell's Principles of Surgery, vol.* 2, *p.* 271.)

That this operation is infinitely better than that of making the puncture in the perinæum, is indisputable. There are even now some good surgeons, who seem to prefer it to the method of tapping the bladder from the rectum. In the *Œuvres Chirurgicales de Desault, t.* 3, *p.* 324, it has received the preference; and at *p.* 319 of the same book, a high encomium is bestowed on it in the following terms: "This operation is easy. The little thickness of the parts which are to be

wounded, renders it quick and triflingly painful. The surgeon has occasion for no assistance. The patient is neither intimidated nor fatigued with the posture in which he is put. It is almost impossible to miss the bladder except it be exceedingly contracted. There is no risk of piercing the cavity of the abdomen. Anatomy proves, that here the bladder is in immediate contact with the recti muscles, and that when this viscus is distended with urine, it pushes the peritoneum upwards and backwards, under which membrane it enlarges, and thus makes the point of the trocar become more and more distant from the cavity of the abdomen. The patient may easily lie on his side or abdomen, so as to discharge all the urine contained in the bladder. There are here no nerves nor vessels of which the injury can be dangerous. No difficulty is experienced in fixing the cannula, and the presence of this instrument does not hinder the patient from sitting, standing up, or even walking about in his chamber. When the cannula also is introduced to the lower part of the bladder, this viscus cannot possibly quit it. Lastly, the wound heals with more facility, than that made in any other method."

Respecting this advice to push the cannula so far into the bladder, it is highly objectionable, for the reason already explained. The writer of the preceding commendation seems to me rather too partial. He has told us of the little thickness of the wounded parts, and yet a little before bestowing these praises, he has acknowledged, "*il est rare, que dans cette ponction, on traverse directement la ligne blanche: on passe presque toujours sur ses côtés, et l'on divise le peau, l'aponéurose des muscles larges du bas-ventre, les muscles droits, quelquefois l'un des pyramidales, et la paroi antérieure de la vessie.*"—(*T.* 3, *p.* 318.)

This operation (according to Sir Astley Cooper) is very easily performed; it is not liable to the objections which were formerly made to it, and it is in general safe. In the female it is the only proper one in cases of retention of urine from retroversio uteri, and from an obliteration of the meatus urinarius by cancerous disease; for (says he) opening the bladder through the vagina is a very unsafe and disastrous operation, as the urine afterward dribbles into that passage, where it occasions the highest degree of excoriation, attended with dreadful suffering and constitutional irritation. "It is an operation which ought never to be performed."—(See *Lancet*, *vol.* 2, *p.* 410.)

According to my own judgment, the plan which is about to be described is the safest and best, when the circumstances of the case afford a choice; and I think, that it would be for the benefit of the afflicted if the puncture above the pubes were only performed in cases in which the enormous enlargement of the prostate gland and disease in the rectum prevent it from being safely made from the rectum.

3. *Puncture from the Rectum.*

This method is more generally applicable than either of the two plans above related. It is not, like the puncture in the perinæum, liable to the objection, that the wound is made in diseased or inflamed parts which afterward become gangrenous. Nor is it, like the puncture above the pubes, attended with a chance of the urine diffusing itself in the cellular membrane. It has also the advantage of emptying the bladder completely. The puncture is made sufficiently far from the neck of the bladder not to increase any inflammation existing in that situation; and the operation is really attended with little pain, since there is no skin nor muscles to be wounded; merely the coats of the bladder and rectum, at a point where these viscera lie in contact with each other. In cases of enlarged prostate gland and of disease of the rectum, however, some other method should be chosen, though I am of opinion, that in the first of these cases, puncturing the bladder at all can seldom be absolutely necessary, as the catheter may almost always be introduced by a surgeon who understands the nature of the disease and its alteration of the course of the urethra.

We read in the *Philosophical Transactions* for 1776, of a case of total retention of urine from strictures, where the bladder was successfully punctured from the rectum. The plan was suggested to Mr. Hamilton, who did the operation by his feeling the bladder exceedingly prominent in the rectum when his finger was in the bowel.

The patient was placed in the same position as that for lithotomy; a trocar was passed along the finger into the anus, and pushed into the lowest and most projecting part of the swelling, in the direction of the axis of the bladder. A straight catheter was immediately introduced through the cannula, lest the bladder by contracting should quit the tube, which was taken away, and as soon as the water was discharged the catheter was also removed. Notwithstanding the puncture, the bladder retained the urine as usual until a desire to make water occurred. Then the opening made by the instrument seemed to expand, and the water flowed in a full stream from the anus. The urine came away in this manner two days, after which it passed the natural way with the aid of a bougie, which had been passed through the urethra into the bladder, and which was used till all the disease in this canal was cured.

The method is said to have been originally proposed, in 1750, by M. Fleurant, surgeon of the hospital *La Charité* at Lyons; and Pouteau, in 1760, published an account of it and three cases in which Fleurant had operated. It was also the feel of the bladder on the introduction of a finger *intra anum*, which led the latter surgeon to make the puncture in this situation. The urine was immediately discharged and the cannula supported in its place with the T bandage, until the natural passage was rendered pervious again. But as the cannula was left in the rectum, it annoyed the patient when he went to stool, and the inconvenience was vastly increased by the continual dribbling of the urine from the mouth of the instrument. Hamilton avoided both these inconveniences by withdrawing the cannula at first. In another instance, however, Fleurant left the cannula in the anus and bladder thirty-nine days, without the least inconvenience.

In order to lessen the tenesmus and other inconveniences attending the presence of the cannula, Fleurant suggested that it would be better to employ a tube made of a flexible substance, and some of the moderns approve the plan of passing a flexible catheter through the silver one into the bladder, and withdrawing the latter instrument.

In the first volume of the *Mem. of the Medical Society of London* two cases are related, in which, after tapping the bladder from the rectum, the cannula was immediately withdrawn without any bad effect; and a similar fact is recorded in the *Medical Communications*, *vol.* 1.

A curved trocar, of sufficient length, is the best for performing the operation, and was recommended by Pouteau. As the trocar with a lancet-point may cut blood-vessels which would bleed freely, some authors express their preference to one made with a triangular point.—(*Howship*, *p.* 215.) It should be introduced into the prominence made by the distended bladder, a little beyond the prostate gland, exactly in the centre of the front of the rectum; but not imprudently far up the intestine, lest the peritoneum be injured. For some useful cautions on this head, the profession are indebted to Mr. Carpue, who has very properly adverted to the very low point to which the portion of peritoneum reflected over the rectum descends.—(*Hist. of the High Operation*, *&c. p.* 178, *8vo. Lond.* 1819.)

The trocar should be introduced in the direction of the axis of the bladder, or nearly in an imaginary line drawn from the spot to be punctured to the middle point between the navel and the symphysis pubis.

The patient should be placed nearly in the same posture as that adopted in lithotomy; but the hands and feet need not be bound together, it being sufficient to let the assistants support the legs. The left fore-finger, smeared with oil, is to be introduced up the rectum, where a portion of the distended bladder will be felt behind the prostate gland and between the converging vasa deferentia. The vesiculæ seminales, which are on the outside of the vasa deferentia, are less exposed to injury. Behind the prostate gland, as Sir Astley Cooper correctly explains, there is a triangular space which affords room for the instrument. In the forepart it is bounded by the meeting of the vasa deferentia, which forms the apex of the triangle; the sides are formed by the vasa deferentia, which diverge as they pass from the prostate backwards; while the basis of the triangle is formed by the peritoneum, which is reflected from the posterior part of the bladder to the rectum. Taking advantage of this space of the bladder, which is not

covered by the peritoneum, the trocar is introduced through it into the bladder about three-quarters of an inch behind the prostate gland. The instrument must not be introduced directly behind the prostate, as the vas deferens on one side or the other would certainly be wounded. If the trocar be carried three-quarters or half of an inch behind the prostate, the vasa deferentia will be safe.—(*Lectures, &c. vol.* 2, *p.* 311.) Here the surgeon is to let the end of his finger continue, until, with his right hand, and under the guidance of the left fore-finger, he has brought to the same point the extremity of the curved trocar, the concavity of which is to be kept forwards. Great care must also be taken not to let the stilet project out of the cannula too soon; that is to say, before the end of the tube has been placed exactly upon the spot at which the puncture is to be made.

It is not necessary to retain the cannula in the puncture after the inflammation has consolidated the sides of the wound, and there is no danger of the aperture closing up before another passage is made for the urine. Sir E. Home thinks that after about thirty-seven hours the cannula may be taken out.—(*Trans. of a Soc. for Med. and Chir. Knowledge, vol.* 2.) Indeed, I am not acquainted with any fact showing the ill effect of removing the cannula early; for here the urine has only to pass through a mere opening without any longitudinal extent, like what remains after puncturing above the pubes. The general safety and simplicity of tapping the bladder from the rectum will always recommend this method to impartial practitioners. The wound is made at a distance from the peritoneum, passes through no thickness of parts, and is quite unattended with any chance of the urine becoming extravasated in the cellular substance. Whether the bladder be morbidly contracted and thickened; whether the neck of the bladder be inflamed, it is equally applicable.

I am happy to join the experienced and judicious Mr. Hey with the advocates for this mode of performing the operation; and as his opinion on this subject must have considerable influence, I shall quote the following passage from his valuable work, particularly as the observations confirm some other points adverted to in the present article. "It is sometimes impossible, from various causes, to make a catheter pass through the urethra. The puncture of the bladder then becomes necessary, if the retention of urine continues. This operation may be performed either above the pubes or through the rectum. I have seen it performed in both these methods, but give the preference to the latter. It is more easy to the surgeon, and less painful to the patient. Pouteau's curved trocar is a very convenient instrument, and may be used with safety for puncturing the bladder through the rectum; but the operator should cautiously avoid wounding an artery, which may be felt running towards the anus where the bladder is most protuberant. The finger which is introduced into the rectum to guide the trocar, may be conveniently placed a little on either side of this vessel. It is not always necessary to leave the cannula in the bladder, as the urine sometimes begins to flow through the penis within a few hours after the bladder is emptied. Perhaps this event may be the most frequent when the introduction of the catheter has been prevented by a stricture in the urethra. If the wound becomes closed before the power of expelling the urine is regained, recourse must be had to a repetition of the operation, which gives very little trouble to the patient; neither is he much incommoded by suffering the cannula to remain two or three days in the bladder. This is sometimes necessary, and seldom improper."—(*Hey's Practical Observations in Surgery, p.* 430, 431, *ed.* 2.)

The objections made to the puncture through the rectum are three: first, the annoying tenesmus sometimes produced by the presence of the cannula; secondly, the irritation and ulcerated state of the rectum occasionally resulting from the dribbling of the urine through it; and thirdly, the possibility of a sinus being formed between this bowel and the bladder.—(*A. Bonn, Bemerkungen ueber der Harnverhalt, &c. Leipz.* 1794.) It seems that Sir Astley Cooper knows of some cases in which such inconveniences have followed, and, in particular, one instance in which the patient died of the subsequent diseased state of the rectum. Hence the puncture of the bladder from the rectum is not a practice on which he bestows any commendation.—(See *Lancet, vol.* 2, *p.* 412.)

In the foregoing columns I have briefly adverted to the proposal of cutting into the urethra behind the obstruction, instead of puncturing the bladder. Mr. Grainger, of Birmingham, a few years ago also recommended cutting into the urethra immediately in front of the prostate, and relieving the bladder by the introduction of a female catheter through the gland, or (if that could not be accomplished) by the division of its substance with a scalpel.—(*Med. and Surg. Remarks, &c.* 8*vo. Lond.* 1815.)

Women rarely stand in need of paracentesis of the bladder; an occasional impossibility of introducing the catheter from a retroversion of the womb, and an obliteration of the meatus urinarius by disease, being almost the only cases ever placing them in this condition. The only method applicable to them is the puncture above the pubes, with the exception of the plan of introducing the trocar directly from the vagina into the bladder; a practice which Sir Astley Cooper strongly condemns on account of its leading to the formation of an incurable urinary fistula in the vagina, and a great deal of disease and irritation in that passage from the contact of the urine.

BLADDER. *Tumour extirpated from.* Mr. Warner has recorded a case in which an excrescence, growing from the inside of a young woman's bladder, was successfully removed. The patient, on the 24th of June, 1747, strained herself in endeavouring to lift a great

weight, and she was immediately seized with a pain in the small of her back, and a total retention of urine. In April, 1750, she applied to Mr. Warner, who found that she had never been able, from the moment of the accident, to void a drop of urine without the assistance of the catheter; that she was in continual pain, and had lately been much weakened by having several times lost considerable quantities of blood, occasioned by the force made use of in introducing the instrument into the bladder.

Mr. Warner, upon examining the parts with his forefinger, which he had great difficulty in introducing into the meatus urinarius, discovered a considerable tumour, which seemed to be of a fleshy substance, and took its rise from the lower part of the bladder near its neck. When the patient strained to make water, and the bladder was full, the excrescence protruded a little way out of the meatus urinarius; but upon ceasing to strain it presently returned.

A purgative having been given the day before the operation, and the rectum opened by means of an emollient clyster, Mr. Warner directed the patient to strain so as to make the swelling project. He then hindered it from returning into the bladder by passing a ligature through it, and endeavoured to draw it farther out. The latter object was found impracticable on account of the size of the tumour. Seeing this, Mr. Warner dilated the meatus urinarius on the right side by cutting it upwards about half way towards the neck of the bladder, when, by pulling the swelling forwards, he was enabled to tie its base, which was very large.

For three days after the operation, a good deal of pain was felt in the abdomen. On the sixth day the tumour dropped off. From the first day the urine came away without assistance, and the patient got quite well. The tumour resembled a turkey's egg in shape and size.—(See *Warner's Cases in Surgery, edit.* 4, *p.* 303.)

Perhaps in this example tying the tumour was preferable to cutting it away, even though its base was large; for had the knife been used, there would have been some danger of the bladder becoming filled with blood.

For an account of other tumours of the bladder, I refer the reader to "*A Practical Treatise on the most important Complaints affecting the Secretion and Excretion of Urine, by J. Howship, 8vo. Lond.* 1823."

[A case, in which large quantities of hair, mixed with calculous matter, were from time to time extracted from the bladder through the meatus urinarius, The disease produced severe pain in making water, and other complaints resembling those of stone. At length, Delpech, suspecting that the hairs were formed in some cyst, communicating with the bladder, determined to divide the meatus urinarius. Previously to this measure, every information which could be derived from sounding was obtained; and by manual examination, a tumour, as large as an egg, was felt at the point where the bladder and uterus touch each other. With the lithotome caché, the meatus was cut in the direction towards the symphysis pubis, care being taken not to divide the corpus cavernosum of the clitoris; and, on introducing the finger, a calculus of the shape of a pigeon's egg was felt, which was easily extracted. A large mass of hair and calculous matter was also detected, projecting at the back and right part of the bladder from an opening, the edges of which were so hard and contracted that the extraneous substances required the polypus forceps for their extraction. After thus clearing the aperture of the cyst, Delpech passed his finger into it, when a large quantity of fetid pus gushed out of the meatus. It was also now discovered, that the swelling made a considerable prominence within the bladder, and that it had a circular neck which might be tied. This was afterward done with a piece of silver wire, conveyed round the part by means of the ring at the end of the catheter. Five days afterward, what had been tied sloughed away, and to the surprise of Delpech was of very trivial size, and without any cavity. In short, the ligature had only destroyed the top of the cyst, and the finger could now be passed into a larger opening, and through it into a cavity, corresponding to the swelling felt between the bladder and uterus. The cyst was found in a state of complete suppuration, and Delpech conceived, that the best chance of cure would result from letting an injection pass from a height of six feet, through a pipe, into the cyst, so as to wash it out with some force. This plan created pain in the abdomen, and fever, so that it could not be continued; but, after the discharge of more hair and calculous matter, and a substance as large as a hen's egg, which was covered by scalp and contained a molar tooth, the patient got well. This substance in fact had been the product of conception, and the sac in which it lay extended to the uterus. The case is highly interesting to the practitioner.—(*Delpech, Chirurgie Clinique, t.* 2, *p.* 521, *et seq.*) —*Pref.*]

Bladder, *Hernia of.* See *Hernia.*

Bladder, *Insects discharged from.* The instances in which worms are stated to have been discharged from the bladder are very numerous. Many cases of this kind are referred to in *Voigtel's Handbuch der Pathologischen Anatomie, b.* 3, *p.* 337—342. A few years ago, an interesting example was recorded by Mr. Lawrence.—(See *Med. Chir. Trans. v.* 2, *p.* 382, *&c.*)

Bladder, *Deficiency of.* Numerous examples in which this deviation from the natural structure has occurred are recorded by medical writers. The publications, however, which, as far as I know, contain the most ample information on the subject, are, a Gottingen inaugural dissertation, entitled "*De Vesicæ Urinariæ Prolapsu Nativo,*" by Dr. Roose, late professor in Brunswick, and a paper called "*An attempt towards a systematic account of the appearances connected with that malconformation of the Urinary Organs, in which the ureters, instead of terminating in a perfect bladder, open externally on the surface of the Abdomen,*" *by A. Duncan, jun. in Edin. Med. and Surg. Journal, vol.* 1. In this last production, may be seen references to all the most noted cases on record, both male and female.—(See also *Handbuch der Pathologischen Anatomie von J. F. Meckel, b.* 1, *p.* 650, 8*vo. Leip.* 1812.)

Bladder, *Wounds of.* See *Gun-shot Wounds.* Many cases of rupture of the bladder from blows or falls are recorded, followed by fatal extravasation of urine in the abdomen. Two such instances have been recently detailed by Dr. Cusack.—(See *Dub. Hospital Reports, vol.* 2, *p.* 312, *&c.* 8*vo.* 1818. *Also, C. Montague in Med. Communications, vol.* 2, *p.* 284, 1790.)

BLEEDING. By this operation is understood the taking away of blood for the relief of diseases. Bleeding is called *general*, when practised with a view of lessening the whole mass of circulating blood; *topical*, when performed in the vicinity of the disease, for the express purpose of lessening the quantity of blood in a particular part.

General Blood-letting is performed with a lancet, and is subdivided into two kinds; viz. the opening of a vein, termed *phlebotomy*, or *venesection*; and the opening of the temporal artery, or one of its branches, termed *arteriotomy.*

Topical Blood-letting is performed, either by means of a cupping-glass and scarificator, or leeches, or by dividing the visibly distended vessels with a lancet, as is frequently done in cases of ophthalmy.

[In the Southern and Western States, bleeding is very generally performed by the *spring* lancet, while in the North and East, the *thumb* lancet is almost universally in use. The choice of instruments must of course in every case be left with the operator, although, as a matter of convenience, it may sometimes be proper to yield in this respect to the wishes of a sensitive patient, and hence many surgeons have both at hand, whether they individually prefer one or the other. The use of the thumb lancet is thought by some to require less tact than the other, and hence they advise ignorant and awkward operators to use it; but confiding in their own skill in the use of the spring lancet, they give this the preference in their own hands. From what I have seen, however, in the South, where the spring lancet is in almost every body's hands, and in the North, where it is seldom seen or used at all, I incline to an opposite opinion, although from long habit I employ the spring lancet myself exclusively, when the prejudice of the patient does not forbid. In the hands of an ignorant or awkward phlebotomist, I conceive the *thumb* lancet to be a more dangerous instrument. There is first the risk of transfixing the vein, and then the hazard of wounding the artery beneath it, both the one and the other being greater than with the spring lancet. This latter accident of wounding the artery in the act of bleeding in the median basilic vein, is known to be a very rare occurrence in those parts of the

country where the spring lancet is indiscriminately employed by the most illiterate and awkward. Almost every southern plantation has one or more negro bleeders who employ this instrument, and yet the artery is scarcely ever wounded; while the thumb lancet will be found to be the guilty instrument in almost every case of aneurism from this cause, and hence we find this accident much more frequent in the Northern and Eastern states.

That the thumb lancet is more surgical will not be questioned, but that it is equally safe in the hands of the uninitiated I cannot believe. And the reasons are very obvious: 1st, The cephalic and median cephalic veins are easily accessible with a spring lancet, in those cases where the basilic or median basilic would be preferred with the thumb lancet, because close to the skin, and often much larger. 2d, Even when the latter vein is near the artery the oblique direction generally preferred for the incision secures it from being punctured; and, 3dly, The spring lancet will seldom if ever transfix a vein, for so soon as it enters the cavity of the vein, the non-resistance of the contained blood protects the inferior coat of the vessel, and this yields without being wounded by the force of the spring.

The only accident to which the use of the spring lancet subjects us is, the occasional fracture of the lancet by the force of the spring, by which it is sometimes left in the arm, and thus produces disastrous consequences. I have more than once had to remove the fleam, as the cutting part of a spring lancet is called, from the arm, it having entered the vein, and passed up to the next valve, requiring the slitting up of the vein itself to effect its removal. This accident, however, never occurred under my notice, except with a German fleam, such as is found in the brass lancets as imported; and being made to sell, should always be displaced from the instrument, and substituted by a new one made sufficiently strong.—*Reese.*]

PHLEBOTOMY, OR VENESECTION.

The mode of bleeding most frequently practised is that of opening a vein; and it may be done in the arm, ankle, jugular vein, frontal vein, veins under the tongue, on the back of the hand, &c. In whatever part, however, venesection is performed, it is always necessary to compress the vein, between the place where the puncture is made and the heart. Thus the return of blood through the vein is stopped, the vessel swells, becomes conspicuous, and when opened bleeds much more freely than would otherwise happen. Hence, according to the situation of the part of the body where the vein is to be opened with regard to the heart, the bandage, or other means for making the necessary pressure must be applied either above or below the puncture.

All the apparatus essential for blood-letting, on the part of the patient, is a bandage or fillet, two or more small pieces of folded linen for compresses, a basin to receive the blood, and a little clean water and a towel. The bandage ought to be about a yard in length, and nearly two inches broad, a common riband or garter being frequently employed. The compresses are made by doubling a bit of linen rag, about two inches square. On the part of the surgeon, it is necessary to have a good lancet of proper shape. He should never bleed with lancets with which he has been in the habit of opening any kind of abscesses, as very troublesome complaints have been the consequence of doing so. The shape of the instrument is also a matter of some importance. If its shoulders are too broad, it will not readily enter the vein, and when it does enter, it invariably makes a large opening, which is not always desirable. If the lancet be too spear-pointed, an incautious operator would often run the risk of transfixing the vein, and wounding the artery beneath it. More, however, certainly depends on the mode of introducing the lancet than on its shape.

In blood-letting the patient may lie down, sit down, or stand up, each of which positions may be chosen according to circumstances. If the patient be apt to faint from the loss of a small quantity of blood, and such fainting can answer no surgical purpose, it is best to bleed him in a recumbent posture. But when the person is strong and vigorous, there is little occasion for this precaution, and a sitting posture is to be preferred, as the most convenient both for the surgeon and patient. This, indeed, is the common position. In some cases, however, particularly those of strangulated hernia, it is frequently an object to produce fainting, in order that the bowels may be more easily reduced. In this circumstance the patient may be bled in an erect posture, and the wound made large, as a sudden evacuation of blood is particularly apt to bring on the wished-for swoon. For the same reason, if we wish to avoid making the patient faint, we should then make only a small puncture.

Every operator should be able to use the lancet with either hand, and thus bleed the patient in the right or left arm, as circumstances may render most eligible.

At the bend of the arm there are several veins in which a puncture may be made, viz. the basilic, cephalic, median basilic, and median cephalic. The median basilic vein, being usually the largest and most conspicuous, is that in which the operation is mostly performed; but surgeons should never forget, that it is under this vessel that the brachial artery runs, with the mere intervention of the aponeurosis sent off from the tendon of the biceps muscle. In very thin persons, indeed, the median basilic vein lies almost close to the artery, and nothing is then more easy than to transfix the first of these vessels and wound the last. Hence Richerand advises all beginners to prefer opening the median cephalic, or even the trunk of the cephalic itself, to puncturing either the basilic, or the median basilic, which last are internally situated, and nearer the brachial artery.—(*Nosographie Chirurgicale, t.* 3, *p.* 38, *edit.* 2.)

In fat subjects, the large veins at the bend of the arm are sometimes totally imperceptible, notwithstanding the fillet is tightly applied, the limb is put in warm water, and every thing done to make those vessels as turgid as possible. In this circumstance, if the surgeon has not had much experience in the practice of venesection, he will do well to be content with opening one of the veins of the back of the hand, after putting the member for some time in warm water, and applying a ligature round the wrist. In children, a sufficient quantity of blood cannot always be obtained by venesection; and in this event the free application of leeches, and occasionally the puncture of the temporal artery, are the only effectual methods.

With respect to the choice of a vein in the arm, the most experienced operators give the preference to one which rolls least under the skin. Such a vessel, though sometimes less superficial than another, may commonly be opened with greater facility. The surgeon, however, is always to fix the vein as much as he can, by placing the thumb of his left hand a little below the place where he intends to introduce the lancet.

In bleeding in the arm, the fillet is to be tied round the limb, a little above the elbow, with sufficient tightness to intercept the passage of the blood through all the superficial veins; but never so as to stop the flow of blood through the arteries, which would tend to prevent the veins from rising at all. The veins being thus rendered turgid, the surgeon must choose the one which seems most conveniently situated for being opened, and large enough to furnish as much blood as it may be proper to take away.

Before applying the fillet round the arm, however, the operator should always feel where the pulsation of the artery is situated; and, if equally convenient, he should not open the vein immediately over this part. It is also prudent to examine where a pulsation is situated, on account of the occasional varieties in the distribution of the arteries of the arm. The ulnar artery is sometimes given off from the brachial very high up; and in this case it frequently proceeds superficially over the muscles which arise from the internal condyle, instead of diving under them in the ordinary manner.

When the external jugular vein is to be opened, the surgeon generally makes the necessary pressure with his thumb. The orifice should be made in the direction of the fibres of the platysma myoides muscle; and the vein is not so apt to glide out of the way, when the surgeon makes the puncture just where it lies over a part of the sterno-cleido-mastoideus muscle.

When blood is to be taken from the foot, the ligature is commonly applied a little above the ankle.

The fillet having been put on the arm, the operator

is to take the blade of the lancet, bent to a somewhat acute angle, between the thumb and fore-finger, and, steadying his hand upon the other three fingers, he is to introduce the lancet in an oblique direction into the vessel, till the blood rises up at the point of the instrument. Then bringing up the front edge in as straight a line as possible, the wound in the skin will be made of just the same size as that in the vein. The operator next takes away the thumb of his left hand, with which he steadied the vessel, and allows the blood to escape freely, till the desired quantity is obtained. The arm ought to be kept in the same position while the blood is escaping, lest the skin should slip over the orifice of the vein, keep the blood from getting out, and make it insinuate itself into the cellular substance.

When the blood does not issue freely, most surgeons direct the patient to move his fingers, or turn something round and round in his hand. This puts the muscles of the arm into action, and the pressure which they then make on the veins makes the blood circulate more briskly through these vessels.

The proper quantity of blood being discharged, the fillet is to be untied. The flow of blood now generally ceases; though sometimes, when the orifice is large and the circulation very vigorous, it still continues. In this circumstance, the operator may immediately stop the bleeding, by placing the thumb of his left hand firmly on the vessel, a little below the puncture.

The blood is next to be all washed off the arm, the sides of the wound placed in contact, and the compresses applied and secured with a fillet, put round the elbow in the form of a figure of 8, and regularly crossing just over the compresses.

The patient should be advised not to move his arm much till the fillet is removed, which may be done after twenty-four hours.

In order to open the external jugular vein, the patient's head is to be laid on one side and properly supported. Then the operator is to press upon the lower part of the vein with his thumb, so as to make the part above swell, and then the lancet is to be pushed at once into the vessel, with the cautions already stated.

There is commonly no difficulty in stopping the bleeding, after the pressure is removed. Some practitioners divide the integuments with a scalpel, before the vein itself is opened; but this is quite unnecessary. In this country, the fashion of opening the jugular vein has considerably declined. In fact, the operation is more troublesome, and less certain of succeeding, than venesection in the arm; while the principle which recommended the practice to the old surgeons, namely, that of more effectually discharging, in this manner, blood from the sinuses of the brain, is erroneous; for it is only the external jugular vein that can be safely opened, and this does not receive the blood from the interior of the head.

Blood-letting in the feet is executed on the same principle as in other parts; but as the blood from the veins in this situation generally does not flow with much celerity, it is customary to immerse the feet in warm water to promote the bleeding.

ARTERIOTOMY.

The only arteries of any size from which blood is ever taken in practice, are the trunk and branches of the temporal artery, which lie in such a situation, that they may easily be compressed against the subjacent bones, and the bleeding stopped. When the vessel which the surgeon chooses to open lies very near the surface, or can be ascertained by feeling, or even seeing its pulsation, it may be opened at once with a lancet. But in many instances it is so deeply situated, that it becomes necessary in the first place to make a cut in the skin, and then puncture the vessel.

The bleeding generally stops without any trouble, and may always be suppressed with a compress and bandage. In a very few cases, the blood bursts forth from time to time, and more is lost than is necessary. When this happens, notwithstanding pressure, it is recommended to divide the vessel completely across, which facilitates the process of nature in closing the end of the vessel. Sometimes an aneurism follows, which must be treated on the principles explained in a foregoing article.—(See *Aneurism.*) Cavallini cured the disease by dividing the vessel and compression.—*Collez. di Casi Chir. t.* 2, *Firenze*, 1762.)

TOPICAL BLEEDING.—CUPPING.

This is done by means of a scarificator and a glass shaped somewhat like a bell. The scarificator is an instrument containing a number of lancets, sometimes as many as twenty, which are so contrived that when the instrument is applied to any part of the surface of the body, and a spring is pressed, they suddenly start out and make the necessary punctures. The instrument is so constructed, that the depth to which the lancets penetrate may be made greater or less, at the option of the practitioner. As only small vessels can be thus opened, a very inconsiderable quantity of blood would be discharged, were not some method taken to promote the evacuation. This is commonly done with a cupping-glass, the air within the cavity of which is rarified by the flame of a little lamp containing spirit of wine, and furnished with a thick wick. This plan is preferable to that of setting on fire a piece of tow dipped in this fluid, and put in the cavity of the glass; "a clumsy expedient, adding unnecessarily to the sufferings of the patient by cauterizing the skin; doing harm also by rarifying the air more than necessary within the glass, in consequence of which the edges of the cup compress the cutaneous vessels so much as to obstruct the influx of blood. The larger the glass, if properly exhausted, the less pain does the patient suffer, and the more freely does the blood flow."—(See *Mapleson's Treatise on the Art of Cupping*, *p.* 63—65, 12*mo. Lond.* 1813.) When the mouth of the glass is placed over the scarifications, and the rarified air in it becomes condensed as it cools, the glass is forced down on the skin, and a considerable suction takes place.

This professor of the said art remarks, that when the operation is about to be done, a basin of warm water, a piece of fine sponge, and a lighted candle should be provided. As many of the cupping-glasses as may be judged necessary are to be put in the basin. If sixteen or twenty ounces of blood are to be taken away, four glasses, of a size adapted to the surface to which they are to be applied, will generally be required. Each glass is then to be held for an *instant* over the flame of the spirit-lamp, and immediately placed upon the skin. Upon the quickness with which this is done, the neatness and efficacy of the operation will depend. If dry cupping be only intended, the glasses may be allowed to remain on the skin for a few moments, and be replaced five or six times, with a little variation of their position, in order to prevent the skin from being hurt by their pressure. If the intention be to scarify and take away blood, the glass ought not to remain more than a minute, when the scarificator is to be *instantly* applied; for by the quickness with which the application of the scarificator succeeds the removal of the glass, the patient is saved a degree of pain, which he would otherwise suffer from the making of the punctures. When the glasses are so full as to be in danger of falling off, or the blood is coagulated in them, they should be removed, emptied, and applied again. For the sake of neatness, care should be taken to insert the nail under the upper part of the glass, and remove it so as to keep its bottom downwards, the scarifications being at the same time wiped with a sponge wet in warm water. The glasses also, previously to each application, should be rinsed in warm water, but not dried. For these, and some other useful directions, see *Mapleson's Treatise*, *p.* 64, &c.

Trials have been made of syringes calculated for exhausting the air from cupping-glasses; but the plan is not found so convenient as that above described.

A common pledget, or bit of rag, is usually applied as a dressing for the punctures made with a scarificator.

If a little smarting be not minded, Mr. Mapleson prefers the application of arquebusade water or spirits of wine, as it immediately stops the oozing of blood, and prevents subsequent itching.—(*P.* 69.)

LEECHES.

Leeches are often preferable to cupping, which is attended with more irritation than many surfaces, under particular circumstances, can bear, especially when the topical bleeding is to be frequently repeated; and they can be used in cases in which it would not be safe or convenient to employ the lancet.

Formerly medicinal leeches were very abundant in England, but owing to their now being in greater request, and to the draining and cultivation of waste lands, it is necessary to import large supplies from the

continent, chiefly from Bourdeaux and Lisbon. As much imposition prevails in this branch of commerce, it should be understood, that unless a leech be marked with yellow rings or spots, or with variegated lines running the whole length of the back, it will generally be found useless.—(See *A Treatise on the Medicinal Leech, by J. R. Johnson, p.* 133, 8vo. *Lond.* 1816.) When leeches are to be kept in any considerable quantity, this gentleman recommends them to be placed in a large vessel provided with a false bottom, so perforated as to allow them a ready passage. "This false bottom should be raised from three to six inches above the real bottom, or to such an extent as will admit of a turf of nearly equal dimensions being placed between them It should fit closely to the sides, that the earth may not be disturbed by the frequent introduction of fresh water. It is necessary that the vessel be also furnished with a stop-cock, in order that the water may be drawn off as often as may be considered expedient. But previously to our placing the leeches in this vessel, they should be singly examined. If, on being handled, they contract, and feel hard and firm, it affords the best indication of their being healthy; but should they feel flabby, or exhibit protuberances, or white ulcerous specks on the surface, they should be kept in jars by themselves, the water and the turf of which should be frequently renewed."—(*Op. cit. p.* 138.)

Sometimes leeches cannot be easily made to fix on the part to which they ought to be applied; but they will do so if the place be first cooled with a cloth dipped in cold water, or if it be moistened with cream or milk, and they be confined in the situation with a small glass.

According to Dr. Johnson, the part on which they are intended to fix should be as clean as possible; it should, therefore, be first washed with soap and water, and afterward with water alone, which will be more necessary should any liniment or embrocation have been used. Leeches are often found to bite better when removed from the water at least an hour previously to their application. In the common practice of putting as many of them as may be required into a wine-glass, and inverting it upon the part affected, there is the disadvantage that they frequently retire to the upper part of the glass, and cannot be got down again without some risk of displacing those which have already fastened. To remedy this inconvenience, Dr. Johnson recommends glass vessels of various sizes and figures, but none of them more than an inch deep. But in his own practice he prefers applying leeches with his hand. "Bring a leech towards the part whereon you intend to fix it, and as soon as it begins to extend the head to seek an attachment, endeavour that it may affix itself to the place required." When it evinces no disposition to bite, a little puncture may be made with a lancet, when the animal will fix itself. "When the patient is fearful of the lancet, and one leech only shall have bitten where several are required, it may be of use to remove it, which is readily done by inserting the nail of the finger between its mouth and the skin. The blood then flowing from the orifice will induce the remainder to bite with the greatest avidity. As soon as the leeches are gorged they drop off; this usually happens within ten or fifteen minutes. Sometimes they remain affixed a considerable time, and become indolent; but they are quickly aroused from this state by sprinkling them with a few drops of cold water."—(*Johnson, op. cit. p.* 141.) When they fall off, the bleeding may be promoted, if necessary, by fomenting the part. When the bleeding continues longer than is desirable, a slight compress will usually stop it; but in more troublesome cases the compress must be dipped in brandy or spirits of wine. In young infants the hemorrhage from the bites of leeches has sometimes proved fatal, and the same thing may happen in adults. An example of each fact is related by Beauchene (*Gazette de Santé, Sept.* 1815). When the bleeding is very troublesome, Autenrieth advises pieces of charpie to be pushed into the orifices of the bites; a method which he assures us is perfectly effectual.—(*Tubingen Blätter, b.* 2, *st.* 1, *p.* 57.)

In order to make a leech disgorge, it is usual to throw a little salt upon it: in a few seconds the blood is ejected, the leech assumes a coiled form, and is seldom found fit for use again before the end of four or five days. As salt, however, frequently blisters the leech, it has been proposed to empty the animal by regular and uniform pressure; but though Dr. Johnson considers this plan better than the other, he admits that it is scarcely practicable without injuring the internal structure of the leech. He says, the best method, and that from which the animal suffers the least inconvenience, is pouring a small quantity of vinegar upon its head. Leeches which have been recently applied should always be kept by themselves, and allowed to retain for their nourishment about one-third of the blood which they extract. For a great deal of valuable information respecting leeches, see Dr. Johnson's work, the title of which is above specified.

When leeches are very scarce, their tails may be snipped off while they are sucking, and the blood will then flow, drop by drop, from the artificial opening, as fast as the animals suck it; or, with the same view, an incision may be made with a lancet close to the tail. —(*Johnson, op. cit. p.* 144.)

SCARIFICATION WITH A LANCET

is mostly done in cases of inflamed eyes. An assistant is to raise the upper eyelid, while the surgeon himself depresses the lower one, and makes a number of slight scarifications where the vessels seem most turgid, trying particularly to cut the largest completely across.

ILL CONSEQUENCES SOMETIMES FOLLOWING BLEEDING IN THE ARM.

1. *Ecchymosis.*

The most common is the thrombus, or ecchymosis, a small tumour around the orifice, and occasioned by the blood insinuating itself into the adjoining cellular substance at the time when it is flowing out of the vessel. Changing the posture of the arm will frequently hinder the thrombus from increasing in size, so as to obstruct the evacuation of the blood. But, in some instances, the tumour suddenly becomes so large that it entirely interrupts the operation, and prevents it from being finished. In these cases, however, the most effectual method of preventing the tumour from becoming still larger is to remove the bandage. By allowing the bandage to remain, a very considerable swelling may be induced, and such as might be attended with great trouble. If more blood be required to be taken away, it ought to be drawn from another vein, and, what is still better, from a vein in the other arm.

The best applications for promoting the absorption of these tumours, are those containing spirit, vinegar, or the muriate of ammonia. Compresses wetted with any lotion of this sort may be advantageously put on the swelling and confined there with a slack bandage.

2. *Inflammation of the integuments and subjacent cellular substance.*

According to Mr. Abernethy, the inflammation and suppuration of the cellular substance in which the vein lies, are the most frequent occurrences. On the subsidence of this inflammation, the tube of the vein is free from induration. Sometimes the inflammation is rather indolent, producing a circumscribed and slowly suppurating tumour. Sometimes it is more diffused, and partakes of the erysipelatous nature. On other occasions it is phlegmonous.

When the lancet has been bad, so as rather to have lacerated than cut the parts; when the constitution is irritable, and especially when care is not taken to unite the edges of the puncture, and the arm is allowed to move about, so as to make the two sides of the wound rub against each other, inflammation will most probably ensue. The treatment of this case consists in keeping the arm perfectly at rest in a sling, applying the saturnine lotion, and giving one or two mild saline purges. When suppuration takes place, a small poultice is the best application.

3. *Absorbents inflamed.*

Sometimes, particularly when the arm is not kept properly quiet after bleeding, swellings make their appearance about the middle of the arm, over the large vessels, and on the forearm, about the mid-space between the elbow and wrist, in the integuments covering the flexor muscles. The swelling at the inner edge of the biceps is sometimes as large as an egg. Before such swellings take place, the wound in the vein often inflames, becomes painful, and suppurates, but without any perceptible induration of the venal tube, either at this time, or after the subsidence of the inflammation. Pain is felt shooting from the orifice in the vein, in

lines up and down the arm, and upon pressing in the course of this pain, its degree is increased. On examining the arm attentively, indurated absorbents may be plainly felt, leading to the tumour at the side of the biceps muscle.

The pain and swelling often extend to the axilla, where the glands also sometimes enlarge. Cord-like substances, evidently absorbents, may sometimes be felt, not only leading from the puncture to the swelling in the middle of the arm, but also from this latter situation up to the axillary glands, and from the wound in the vein down to the enlarged glands at the mid-space between the elbow and wrist, over the flexor muscles of the hand.

The enlarged glands often proceed to suppuration, and the patient suffers febrile symptoms. It may be suspected that the foregoing consequences arise from the lancet being envenomed, and from the absorption of the virulent matter; but the frequent descent of the disease to the inferior absorbents militates against this supposition.

When the absorbents become inflamed, they quickly communicate the affection to the surrounding cellular substance. These vessels, when indurated, appear like small cords, perhaps of one-eighth of an inch in diameter: this substance cannot be the slender sides of the vessels, suddenly increased in bulk, but an induration of the surrounding cellular substance.

The inflammation of the absorbents, in consequence of local injury, is deducible from two causes: one, the absorption of irritating matter; and the other, the effect of the mere irritation of the divided tube. When virulent matter is taken up by the absorbents, it is generally conveyed to the next absorbent gland, where its progress being retarded, its stimulating qualities give rise to inflammation, and, frequently, no evident disease of the vessel through which it has passed can be distinguished.

When inflammation of the absorbents happens, in consequence of irritation, the part of the vessel nearest the irritating cause generally suffers most, while the glands, being remotely situated, are not so much inflamed.

The treatment of the preceding case consists in keeping the arm perfectly quiet in a sling, dressing the puncture of the vein with any mild simple salve, covering the situation of the inflamed lymphatics with linen wet with the saturnine lotion, and giving some gently purging medicine.

When the glandular swellings suppurate, poultices should be applied, and if the matter does not soon spontaneously make its way outwards, the surgeon may open the abscess.—(See *Abernethy's Essays on this subject.)*

4. *Inflammation of the Vein.*

When the wound does not unite, the vein itself is very likely to inflame. This affection will vary in its degree, extent, and progress. One degree of inflammation may only cause a slight thickening of the venal tube, and an adhesion of its sides. Abscesses, more or less extensive, may result from an inflammation of greater violence, and the matter may sometimes become blended with the circulating fluids, and produce dangerous consequences, or the matter may be quite circumscribed, and make its way to the surface. When the vein is extensively inflamed, a good deal of sympathetic fever is likely to ensue, not merely from the excitement which inflammation usually produces, but also from the irritation continued along the membranous lining of the vein towards the heart. If, however, the excited inflammation should fortunately produce an adhesion of the sides of the vein to each other at some little distance from the wounded part, this adhesion will form a boundary to the inflammation, and prevent its spreading farther. The effect of the adhesive inflammation in preventing the extension of inflammation along membranous surfaces, was originally explained by Mr. Hunter. In one case Mr. Hunter applied a compress to the inflamed vein above the wounded part, and he thought that he had thus succeeded in producing an adhesion, as the inflammation was prevented from spreading farther. When the inflammation does not continue equally in both directions, but descends along the course of the vein, its extension in the other direction is probably prevented by the adhesion of the sides of the vein to each other.—(See *Obs. on the Inflammation of the internal coats of Veins, in Trans. of a Soc. for the Improvement of Med. and Chir. Knowledge, vol.* 1, *p.* 18, *&c.)* More information on this subject will be found under the head of *Veins.*

Mr. Abernethy mentions his having seen only three cases in which an inflammation of the vein succeeded venesection. In neither of these did the vein suppurate. In one about three inches of the venal tube inflamed, both above and below the puncture. The integuments over the vessel were very much swollen, red, and painful, and there was a good deal of fever, with a rapid pulse and furred tongue. The vein did not swell when compressed above the diseased part. In another instance, the inflammation of the vein did not extend towards the heart, but only downwards, in which direction it extended as far as the wrist.

The treatment is to lessen the inflammation of the vein by the same means which other inflammations require, and to keep the affection from spreading along the membranous lining of the vessel towards the heart, by placing a compress over the vein a little way above the puncture, so as to make the opposite sides of the vessel adhere together.

Mr. Abernethy conceives a case possible in which the vein may even suppurate, and a total division of the vessel be proper, not merely to obviate the extension of the local disease, but to prevent the pus from becoming mixed with the circulation. Were such a proceeding deemed right, I think Mr. Brodie's method of cutting the vessel would be best. However, I have never heard of any case in which the practice has been adopted. As for the scheme of tying the vein above the diseased part of it, the severe effects frequently following this method must, as Mr. Dunn has reminded me, render it less eligible than an incision. In the case of an inflamed vein, Dr. Chapman states that nothing is so efficacious as blisters; a practice said to have been first suggested by Dr. Physick.—(See *a fatal case of Inflammation of the vessel from Venesection, in Philadelphia Journ. Feb.* 1824.) I was lately favoured by Mr. Howship with a view of the state of the parts in a case where a lady had died after an inflammation of the veins of the arm, brought on by venesection: they were considerably thickened, and in some cases quite solid and impervious.—(See *Veins.*)

5. *Inflammation of the Fascia of the Forearm, or diffuse inflammation of the cellular membrane.*

Sometimes, in consequence of the inflammation arising from the wound of the lancet in bleeding, the arm becomes very painful, and can hardly be moved. The puncture often remains unhealed, but without much inflammation of the surrounding integuments. The forearm and fingers cannot be extended without great pain. The integuments are sometimes affected with a kind of erysipelas; being not very painful when slightly touched, but when forcibly compressed, so as to affect the inferior parts, the patient suffers a good deal. The pain frequently extends towards the axilla and acromion; no swelling, however, being perceptible in either direction. These symptoms are attended with considerable fever. After about a week, a small superficial collection of matter sometimes takes place a little below the internal condyle: this being opened, a very little pus is discharged, and there is scarcely any diminution of the swelling or pain. Perhaps, after a few days more, a fluctuation of matter is distinguished below the external condyle; and this abscess being opened, a great deal of matter gushes from the wound, the swelling greatly subsides, and the patient's future sufferings are comparatively trivial.

The last opening, however, is often inadequate to the complete discharge of the matter, which is sometimes originally formed beneath the fascia, in the course of the ulna, and its pointing at the upper part of the arm depends on the thinness of the fascia in this situation. The collection of pus descends under the lower part of the detached fascia, and a depending opening for its discharge becomes necessary. This being made, the patient soon gets well.

In these cases the vein is not inflamed; but sometimes the glands of the armpit and just above the elbow swell. The integuments are not much affected, and the patient complains of a tightness of the forearm. Matter does not always form, and the pliability of the arm after a good while gradually returns again.

Mr. Watson relates a case which was followed by a

permanent contraction of the forearm. Mr. Abernethy is of opinion that a similar contraction of the forearm, from a tense state of the fascia, may be relieved by detaching the fascia from the tendon of the biceps, to which it is naturally connected. Mr. Watson seems to have obtained success in his first case by having cut this connexion.

In the treatment of an inflammation of the fascia, or of an extensive quantity of the cellular membrane, in consequence of venesection, general means for the cure of inflammation should be employed, especially numerous leeches, cupping, purgatives, &c. The limb should be kept quiet, and the inflamed part relaxed. As soon as the inflammation abates, the extension of the forearm and fingers ought to be attempted and daily performed, to obviate the contraction which might otherwise ensue.

Mr. C. Bell objects to calling the affection an inflammation of the fascia, because he sees no proof of this part being inflamed; and he conceives that the symptoms proceed from the inflammation spreading in the cellular membrane and passing down among the muscles and under the fascia. On this point I believe him to be quite correct, and that the disorder partakes of the character of diffuse inflammation of the cellular membrane so well described by Dr. Duncan.—(See *Edin. Med. Chir. Trans. vol.* 1.) To this subject, however, I shall return in the article *Erysipelas*. The fascia acts as a bandage, and from the swelling of the parts beneath it binds the arm, but is not itself inflamed and contracted. When necessary to divide the fascia, Mr. Charles Bell thinks it would be better to begin an incision near the inner condyle of the humerus, and to continue it some inches down the arm, rather than perform the nice if not dangerous operation of cutting the fascia at the point where the expansion goes off from the round tendon of the biceps.

When the elbow-joint and forearm continue stiff after all inflammation is over, Mr. C. Bell recommends frictions with camphorated mercurial ointment, &c., and the arm to be gradually brought into an extended state by placing a splint on the forepart of the limb.—(*Operative Surgery, vol.* 1, *p.* 65.)

6. *Ill Consequences of a Wounded Nerve.*

Mr. Pott used to mention two cases in which the patients suffered distracting pains, followed by convulsions and other symptoms, which could only be ascribed to nervous irritation, arising from a partial division of the nerve, and he recommended its total division, as a probable remedy. Dr. Monro related similar cases in which such treatment proved successful.

Hence, it is highly necessary to know the characteristic symptoms of the case, particularly, as all the foregoing cases would be exasperated by the treatment just now alluded to. It is to Mr. Abernethy that we are indebted for several valuable remarks elucidating this subject. He informs us, that the two cutaneous nerves are those which are exposed to injury. Most frequently all their branches pass beneath the veins at the bend of the arm; but sometimes, although the chief rami go beneath these vessels, many small filaments are detached over them, which it is impossible to avoid wounding in phlebotomy.

Mr. Abernethy thinks the situation of the median nerve renders any injury of it very unlikely. If, however, a doubt should be entertained on this subject, an attention to symptoms will soon dispel it. When a nerve is irritated at any part between its origin and termination, a sensation is felt as if some injury were done to the parts which it supplies. If, therefore, the cutaneous nerves were injured, the integuments of the forearm would seem to suffer pain; if the median nerve, the thumb and next two fingers would be painfully affected.

What are the ills likely to arise from a wounded nerve? If it were partially cut, would it not, like a tendon or any other substance, unite? It seems probable that it would do so, as nerves as large as the cutaneous ones of the arm are very numerous in various situations of the body, and are partially wounded in operations, without any peculiar consequences usually ensuing. The extraordinary pain sometimes experienced in bleeding, may denote that a cutaneous nerve is injured. The situation of the nervous branches is such, that they must often be partially wounded in the operation, though they probably unite again, in almost all cases, without any ill consequences. Yet, says Mr. Abernethy, it is possible that an inflammation of the nerve may accidentally ensue, which would be aggravated if the nerve were kept tense, in consequence of its partial division. The disorder, he thinks, arises from inflammation of the nerve in common with the other wounded parts. This gentleman supposes, that an inflamed nerve would be very likely to communicate dreadful irritation to the sensorium, and that a cure would be likely to arise from intercepting its communication with that organ.

The general opinion is, that the nerve is only partially divided, and that a complete division would bring relief. Mr. Pott proposed enlarging the original orifice. It is possible, however, that the injured nerve may be under the vein, and if the nerve be inflamed, even a total division of it at the affected part would perhaps fail in relieving the general nervous irritation, which the disease has occasioned. To intercept the communication of the inflamed nerve with the sensorium, however, promises perfect relief. This object can only be accomplished by making a transverse incision above the orifice of the vein. The incision need not be large, for the injured nerve must lie within the limits of the original orifice, and it need only descend as low as the fascia of the forearm, above which all the filaments of the cutaneous nerves are situated. As the extent of the inflammation of the nerve is uncertain, Mr. Abernethy suggests even making a division of the cutaneous nerve still farther from the wound made in bleeding.

Examples are recorded, in which not only extraordinary pain was occasioned by the prick of the lancet, but erysipelas of the skin, ending in gangrene of the whole limb, and the death of the patient.—(*Richerand, Nosogr. Chir. t.* 2, *p.* 390, *ed.* 2.) A case in which the greater part of the integuments of the arm had been destroyed by erysipelas thus produced, I once saw under the care of Mr. Vincent, in St. Bartholomew's Hospital.

In former times, it was customary to refer many of the bad symptoms occasionally following venesection to a puncture of the tendon of the biceps; but this doctrine is now in a great measure renounced, the experiments of Haller having completely proved that tendons and aponeuroses are, comparatively speaking, parts endued with little or no sensibility.

In the foregoing account, the various ill consequences occasionally arising from venesection are represented separately: no doubt, in some cases, they may occur together.

BLEEDING. See *Hemorrhage* and *Arteries*.

BLENORRHAGIA, or *Blennorrhœa*. (From βλέννα, mucus, and ῥέω, to flow.) A discharge of mucus. Swediaur, who maintains that gonorrhœa is attended with a mucous, and not a purulent discharge, prefers the name of blenorrhagia for the disease. However, in treating of gonorrhœa, we shall find, that this last appellation is itself not altogether free from objections.

BLEPHAROPTOSIS. (From βλέφαρον, the eyelid, and πτῶσις, a falling down.) Called also *ptosis*. An inability to raise the upper eyelid.—(See *Ptosis*.)

BLEPHAROTIS. An inflammation of the eyelids.

BLINDNESS. This is an effect of many diseases of the eye. See particularly, *Amaurosis; Cataract; Cornea, opacities of; Glaucoma; Gutta Serena, Hydrophthalmia; Leucoma; Ophthalmy; Pterygium; Pupil, closure of; Staphyloma, &c.*

BLISTERS. Applications which, when put on the skin, raise the cuticle in the form of a vesicle, filled with a serous fluid. Various substances produce this effect; but the powder of cantharides is what operates with most certainty and expedition, and is now invariably made use of for the purpose. The blister plaster is thus composed: ℞. *Cantharidis in pulv. subtillissimum tritæ* ℔j. *Emplastri ceræ* ℔iss. *Adipis præp.* ℔ss. The wax plaster and lard being melted, and allowed to become nearly cold, the powdered cantharides are afterward to be added.

When it is not wished to maintain a discharge from the blistered part, it is sufficient to make a puncture in the cuticle to let out the fluid; but when the case requires a secretion of pus to be kept up, the surgeon must remove the whole of the detached cuticle with a pair of scissors, and dress the excoriated surface in a particular manner. Practitioners used formerly to mix powder of cantharides with an ointment, and dress the part with this composition. But such a dressing not unfrequently occasioned very painful affections of the bladder, a scalding sensation in making water, and most afflicting stranguries. An inflammation of the bladder, ending fatally, has been thus excited. The treatment of such complaints consists in removing every particle of cantharides from the blistered part, which is to be well fomented, and administering freely mucilaginous drinks. Camphor is now suspected to prove more hurtful than useful.

These objections to the employment of salves, containing cantharides, for dressing blistered surfaces, led to the use of mezereon, euphorbium, and other irritating substances, which, when incorporated with ointment, form very proper compositions for keeping blisters open, without the inconvenience of irritating the bladder.

The favourite application, however, for keeping open blisters is the powder of savine, which was brought into notice by Mr. Crowther, in the first edition of his book on the White Swelling. He was led to the trial of different escharotic applications in the form of ointment, in consequence of the minute attention which caustic issues demand; and, among other things, he was induced to try powdered savine, from observing its effects in the removal of warts. Some of the powder was first mixed with white cerate, and applied as a dressing to the part that had been blistered; but the ointment ran off, leaving the powder dry upon the sore, and no effect was produced. Mr. Crowther next inspissated a decoction of savine, and mixed the extract with the ointment, which succeeded better, for it produced a great and permanent discharge. At last, after various trials, he was led to prefer a preparation analogous to the unguentum sambuci P. L. The following formula answers every desirable purpose: ℞. *Sabinæ recentis contusæ* ℔ij. *Ceræ flavæ* ℔j. *Adipis suillæ* ℔iv. *Adipe et cera liquefacta, incoque sabinam et cola.*

The difference of this formula from that which Mr. Crowther published in 1797, only consists in using a double proportion of the savine leaves. The ceratum sabinæ of Apothecaries' Hall, he says, is admirably made: the fresh savine is bruised with half the quantity of lard, which is submitted to the force of an iron press, and the whole is added to the remainder of the lard, which is boiled until the herb begins to crisp; the ointment is then strained off, and the proportion of wax ordered, being previously melted, is added. On the use of the savine cerate, immediately after the cuticle raised by the blister, is removed, it should be observed, says Mr. Crowther, that experience has proved the advantage of using the application lowered by a half or two-thirds of the unguentum ceræ. An attention to this direction will produce less irritation and more discharge, than if the savine cerate were used in its full strength. He found fomenting the part with flannel wrung out of warm water, a more easy and preferable way of keeping the blistered surface clean, and fit for the impression of the ointment, than scraping the part, as has been directed by others. An occasional dressing of the unguentum resinæ flavæ, he found very useful in rendering the sore free from an appearance of slough, or rather dense lymph, which is sometimes so firm in its texture, as to be separated by the probe with as much readiness as the cuticle is detached after blistering. As the discharge diminishes, the strength of the savine dressing should be proportionally increased. The ceratum sabinæ must be used in a stronger or weaker degree, in proportion to the excitement produced on the patient's skin. Some require a greater stimulus than others for the promotion of the discharge, and this can only be managed by the sensations which the irritation of the cerate occasions.

Mr. Crowther tried ointments containing the flowers of the clematis recta, the capsicum, and the leaves of the digitalis purpurea. The first two produced no effect; the last was very stimulating. He also tried caustic potassa mixed with spermaceti cerate, in the proportion of one drachm to an ounce: it proved very stimulating, but produced no discharge. One grain of the oxymuriate of mercury, blended with two ounces of the above cerate, proved so intolerably painful, that at the end of two hours it became necessary to remove the dressing; and the patient was attacked with a severe ptyalism.—(*Practical Obs. on the White Swelling, &c. 2d ed.* 1808.)

Instead of keeping a blister open, it is frequently a judicious plan to renew the application of the emplastrum cantharidis, after healing up the vesication first produced, and to continue in this manner a succession of blisters, at short intervals, as long as the circumstance of the case may demand. Where the skin is peculiarly irritable, and particularly in young children, where the emplastrum cantharidis sometimes acts so violently as to produce sloughing, or, in any cases, where the plaster produces strangury and irritation of the urinary organs, I am informed, that the inconvenience may be avoided, and the cuticle raised very well, if a piece of silk paper be interposed between the plaster and the integuments. Dr. A. T. Thomson recommends for the same purpose a piece of thin gauze wet with vinegar, and applied smoothly and closely over the plaster.—(*Dispensatory, p. 717, ed. 2.*) For infants, a proportion of opium has sometimes been added to the plaster, in order to render its action less violent; a proposal made, I believe, by the late Mr. Chevalier. Others recommend the plan of not letting the blister continue so long applied to children as to other patients.—(See *Paris's Pharmacologia, vol. 2, p. 186, ed. 5.*)

BOUGIE is a smooth flexible instrument which is introduced into the urethra for the cure of diseases of that passage (see *Urethra*); and is so named from its generally containing wax in its composition, and bearing some resemblance to a wax taper, in French, bougie. However, the kinds of bougies are various, and some of them employed in modern surgery, so far from having any similitude to a wax taper, are formed altogether of metal. They admit of being divided into those which are solid, and others which are hollow, and are more commonly named catheters.—(See *Catheter.*)

The exact period when bougies were first used, is a doubtful point in the history of surgery. By Andrew Lacuna, a Spanish physician, the invention is ascribed to a Portuguese empiric; and in 1551, the same author

published what had been communicated to him upon this subject. In the year 1554, Amatus Lusitanus published a work, in which he refers to several witnesses to prove, that the empirical practitioner above alluded to, had learned from him the use of bougies, while, on the other hand, he candidly owns, that he himself was indebted to Aldereto, of Salamanca, for a knowledge of these instruments. In 1553, however, Aiph. Ferri, of Naples, endeavoured to show, that his acquaintance with the utility of bougies reached as far back as 1548, and, of course, that he had anticipated Lacuna, and perhaps even Aldereto. But, instead of representing himself as the original inventor of bougies, he mentions that they were known to Alexander of Tralles, which, if true, carries back the invention to the sixth century. A. Ferri, also before describing bougies and escharotic ointments, mentions various means of examining the state of the urethra, and, among other things, cylinders made of flexible lead and of different sizes. Escharotic ointments for what were termed *carnosities* of the urethra, and bougies, were also described by Petronius in 1565, and afterward by A. Paré. The oldest bougies, which were wicks of cotton or thread, covered with wax and escharotic plasters, were in time succeeded by those composed of linen smeared with wax. This change was made with the view of letting them have a hollow construction; an improvement which was first noticed by Fabricius ab Aquapendente.—(*Op. Chir.* 1617.)

In the middle of the 17th century, the manner of making and using bougies was well known to Scultetus, as appears from his *Armamentarium Chirurg. tab.* 13, *fig.* 9, 10.

The making of bougies has now become so distinct a trade, that it may be considered superfluous to treat of the subject in this Dictionary. However, though a surgeon may not actually choose to take the trouble of making bougies himself, he should understand how they ought to be made. Swediaur recommends the following composition: ℞. Ceræ flavæ ℔j. Spermatis ceti ℥iij. Cerussæ acetatæ ℥v. These articles are to be slowly boiled together, till the mass is of proper consistence. Mr. B. Bell's bougie plaster is thus made: ℞. Emplastri lythargyri ℥iv. Ceræ flavæ ℥iss. Olei olivæ ℥iij. The last two ingredients are to be melted in one vessel and the litharge plaster in another, before they are mixed. In Wilson's Pharmacopœia Chirurgica, I observe this formula: ℞. Olei olivæ ℔iss. Ceræ flavæ ℔j. Minii ℔iss. Boil the ingredients together over a slow fire till the minium is dissolved, which will be in about four or six hours. The composition for bougies is now very simple, as modern surgeons place no confidence in the medicated substances formerly extolled by Daran. The linen, which may be considered as the basis of the bougie, is to be impregnated with the composition, which is generally wax and oil, rendered somewhat firmer by a proportion of resin. Some saturnine preparation is commonly added, as the urethra is in an irritable state, and the mechanical irritation might otherwise increase it. Of whatever composition bougies are made, they must be of different sizes, from that of a knitting-kneedle to that of a large quill, and even larger. Having spread the composition chosen for the purpose on linen rag, cut this into slips from six to ten inches long, and from half an inch to an inch or more in breadth. Then dexterously roll them on a glazed tile into the proper cylindrical form. As the end of the bougie, which is first introduced into the urethra, should be somewhat smaller than the rest, the slips must be rather narrower in this situation, and when the bougies are rolled up, that side must be outwards on which the plaster is spread.

Daran and some of the older writers, attributed the efficacy of their bougies to the composition used in forming them. On the contrary, Mr. Sharp apprehended that it was chiefly owing to the pressure which was made on the affected part; and Mr. Aikin adds, that as bougies of very different compositions succeed equally well in curing the same diseases in the urethra, it is plain that they do not act from any peculiar qualities in their composition, but by means of some common property, probably their mechanical form.

As the healthy as well as the diseased parts are exposed to the effects of bougies made of very active materials, modern surgeons always prefer such as are made of a simple unirritating composition.

Plenck recommended bougies of catgut, which may be easily introduced into the urethra, even when it is greatly contracted, their size being small, their substance firm, and dilatable by moisture. It is objected to catgut, however, that it sometimes expands beyond the stricture, and gives great pain on being withdrawn. Formerly, catgut bougies were sometimes coated with elastic gum, a valuable material, of which I shall next speak.

The invention of elastic bougies and catheters originated with Bernard, a silversmith at Paris, who in the year 1779 presented some instruments of this kind to the Academy of Surgery, which period was prior to the claim made by Professor Pickel of Wurzburg to the discovery.—(See *Journ. de Méd. an* 1785.)

For the composition of bougies, elastic resin or gum is thought to be very desirable, as it unites firmness and flexibility. Mr. Wilson, in his *Pharmacopœia Chirurgica*, is inclined to think that the art of making these instruments consists in finding a suitable solvent for the Indian gum. As this substance, if dissolved in ether, completely recovers its former elasticity upon the evaporation of this fluid, it is supposed that ether, though rather too expensive, would answer.

I find it positively asserted, however, in a modern work of great repute, that the idea of elastic gum being the substance really employed is a mistake, as the material used is nothing more than linseed oil boiled for a considerable time, and used as a varnish for the silk, linen, or cotton tube.—(See *Dict. des Sciences Méd. art. Bougie.*)

Very cheap and good elastic gum bougies are made by Feburier, No. 51 Rue du Bac, at Paris, who has twelve different sizes. His elastic gum catheters are also well made, though for smoothness and regularity I think they are not equal to some which are now constructed in London; but I believe Feburier's smallest size is rather less than any which are made in this city; an advantage which no doubt our artists will soon be able to give their productions. This ingenious mechanic does not employ catgut in the composition of the elastic gum bougies, for which he is so celebrated. These bougies are most excellent when you can get them to pass; for they dilate the stricture with the least possible irritation. But sometimes they cannot be introduced when a wax bougie can; and from the trials which I have made of them, I conceive this arises from their elasticity and continual tendency to become straight when they reach the perinæum, so that the point presses on the lower surface of the urethra. Hence, when the obstruction is on that side, it must be very difficult to get the end of the bougie over it.

A few years ago, Mr. Smyth discovered a metallic composition of which he formed bougies, to which some practitioners impute very superior qualities. These bougies are flexible, have a highly polished surface of a silver hue, and possess a sufficient degree of firmness for any force necessary in introducing them for the cure of strictures of the urethra. The advocates for the metallic bougies assert, that such instruments exceed any other bougies which have yet been invented, and are capable of succeeding in all cases in which the use of a bougie is proper. They are either solid or hollow, and are said to answer extremely well as catheters; for they not only pass into the bladder with ease, but may also be continued there for any convevient space of time, and thus produce essential benefit. —(*W. Smyth, Brief Essay on the Advantages of Flexible Metallic Bougies*, 8vo. *Lond.* 1804.) The greatest objection which has been urged against them is, that they are attended with a risk of breaking. I have heard of an eminent surgeon being called upon to cut into the bladder, in consequence of a metallic bougie having broken, and a piece of it passing into that organ, where it became a cause of the severe symptoms which are commonly the effect of a stone in the bladder. For the particulars of an interesting case, in which a metallic bougie broke in the urethra, the reader may consult *London Med. Repository, vol.* 9, *No.* 51. The manufacture of metallic bougies, however, is now brought to such perfection, that though they are used to a great extent in modern practice, we rarely hear of their breaking; but it is most prudent not to be too bold with those of small diameter.

The bougie, with its application, says Mr. Hunter, is perhaps one of the greatest improvements in surgery

which these last thirty or forty years have produced. "When I compare the practice of the present day with what it was in the year 1750, I can scarcely be persuaded that I am treating the same disease. I remember, when about that time I was attending the first hospitals in the city, the common bougies were either a piece of lead or a small wax candle; and although the present bougie was known then, the due preference was not given to it nor its particular merit understood, as we may see from the publications of that time."

Daran was the first who improved the bougie and brought it into general use. He wrote professedly on the diseases for which it is a cure, and also of the manner of preparing it; but he has introduced much absurdity into his descriptions of the diseases, the modes of treatment, and the powers and composition of his bougies.

When Daran published his observations on the bougie, every surgeon tried to discover the composition, and each conceived that he had found it out, from the bougies which he composed producing the effects described by Daran. It was never suspected, that any extraneous body of the same shape and consistence would do the same thing.—(See *A Treatise on the Venereal Disease, p.* 116. *Sharp's Critical Inquiry, ch.* 4. *Aikin on the External Use of Lead. BRONCHOCELE. (From βρόγχος, the windpipe, and κήλη, a tumour.) The Swiss call the disease *goitre* or *goître.* Heister thought it should be named *tracheocele.* Prosser, from its frequency in the hilly parts of Derbyshire, called it the *Derbyshire neck;* and not satisfied respecting the similitude of this tumour to that observed on the necks of women on the Alps, the *English Bronchocele.* By Alibert the disease is called *Thyrophraxia.*

1. The simple bronchocele or thyrophraxia is the most common form of the disease, and is a mere enlargement of the thyroid gland. The integuments covering the part are quite unchanged. Women are observed to be more subject to it than men. It is also well known to be in general free from danger, the office of the thyroid gland not being of such importance in the animal economy as to be essential to the continuance of life. Alibert has seen one example in which the tumour became cancerous, and destroyed the mother of a family.

2. The compound bronchocele is that which presents the greatest variety, and astonishes every beholder. Sometimes a more or less voluminous cyst is formed round it, filled with a pultaceous or purulent matter. Sometimes in compound bronchoceles, calcareous and other heterogenous substances are found. In two cases Alibert found on the outside of the enlarged gland a yellow fatty mass; and in a third instance the gland itself formed a true sarcoma.—(*Nosologie Naturelle, t.* 1, *p.* 464, 465, *folio, Paris,* 1817.)

The term *bronchocele* always signifies in this country an enlargement of the thyroid gland, which, with the disease of the surrounding parts, sometimes not only occupies all the space from one angle of the jaw to the other, but forms a considerable projection on each side of the neck, advancing forwards a good way beyond the chin, and forming an enormous mass, which hangs down over the chest. The swelling, which is more or less unequal, in general has a soft, spongy, elastic feel, especially when the disease is not in a very advanced state; but no fluctuation is usually perceptible, and the part is exceedingly indolent. The skin retains nearly its ordinary colour; but when the tumour is of very long standing and great size, the veins of the neck become more or less varicose.

According to Prosser, the tumour generally begins between the eighth and twelfth years. It enlarges slowly during a few years; but at last it augments rather rapidly, and forms a bulky pendulous tumour. Women are far more subject to the disease than men, and the tumour is observed to be particularly apt to increase rapidly during their confinement in childbed. Sometimes bronchocele affects the whole of the thyroid gland, that is to say, the two lateral lobes and the intervening portion; and it is in this kind of case, that it is not unusual to remark three distinct swellings, for the most part of unequal size. Frequently only one lobe is affected; while in many other cases the three portions of the thyroid gland are all enlarged and so confounded together, that they make, as it were, only one connected globular mass. Finally, in some dissections the thyroid gland has been found quite unchanged, the whole of the tumour having consisted of a sarcomatous disease of the adjacent lymphatic glands and cellular membrane.—(*Postiglione, p.* 21.) When only one lobe of the thyroid gland is affected, it may extend in front of the carotid artery, and be lifted up by each diastole of this vessel, so as to have the pulsatory motion of an aneurism.—(*A. Burns's Surgical Anatomy of the Head and Neck, p.* 195, *and Parisian Chirurgical Journ. vol.* 2, *p,* 292, 293.) Alibert believes that he first made the remark that the right lobe was more frequently enlarged than the left.—(*Nosol. Nat. t.* 1, *p.* 465.) The same thing was invariably noticed in every case seen by Mr. Rickwood in the neighbourhood of Horsham in Sussex.—(See *Med. and Phys. Journ. for Aug.* 1823.)

The ordinary seat of bronchocele, as Flajani remarks, is the thyroid gland; but sometimes cysts are formed in the cellular membrane.—(*Collez. d'Oss. t.* 3, *p.* 277.) And Postiglione also observes, that the swelling is sometimes encysted, and filled with matter of various degrees of consistence, resembling honey, &c.; in some cases it is emphysematous, or filled with air; and in other instances it is sarcomatous, having the consistence of a gland, which is enlarged, but not scirrhous. These different characters prove, says he, that the treatment ought not to be the same in all cases.—(*Memoria sulla Natura del Gozzo, p.* 20.)

Bronchocele is common in some of the valleys of the Alps, Apennines, and Pyrences. Indeed, there are certain places where the disease is so frequent, that hardly an individual is totally exempt from it. Larrey, in travelling through the valley of Maurienne, noticed that almost all the inhabitants were affected with goitres of different sizes, whereby the countenance was deformed, and the features rendered hideous.—(*Mem. de Chir, Mil. t.* 1, *p.* 123.) And Postiglione remarks that in Savoy, Switzerland, the Tyrol, and Carinthia there are villages in which all the inhabitants without exception have these swellings, the position and regularity of which are there considered as indications of beauty. —(*Memoria sulla Natura del Gozzo, p.* 22.) In many the swelling is so enormous, that it is impossible to conceal it by any sort of clothing. A state of idiotism is another affliction which is sometimes combined with *goître,* in countries where the latter affection is endemic. However, all who have the disease are not idiots, or cretins, as they have been called; and in Switzerland and elsewhere it is met with in persons who possess the most perfect intellectual faculties. When bronchocele and cretinism exist together, Foderé and several other writers ascribe the affection of the mind to the state of the thyroid gland.—(See *Traité sur le Goitre et le Crétinisme,* 8*vo. Paris, an* 8.) However, this opinion appears to want foundation, since the mental faculties are from birth weak, and in many the idiotism is complete where there is no enlargement of the thyroid gland, or where the tumour is not bigger than a walnut, so that no impediment can exist to the circulation to or from the brain.—(*Burns on the Surgical Anatomy of the Head and Neck, p.* 192.) The direct testimony of Dr. Reeves also proves that in countries where cretins are numerous many people of sound and vigorous minds have bronchocele.—(See *Dr. Reeve's Paper on Cretinism, Edin. Med. and Surgical Journal, vol.* 5, *p.* 31.) Hence, as Mr. A. Burns remarked, the combination of bronchocele and cretinism must be considered as accidental; a truth that seems to derive confirmation from the fact that in some parts of this country bronchocele is frequent, where cretinism is seldom or never seen.

Bronchocele is not confined to Europe; it is met with in almost every country on the globe. Professor Barton, in his travels among the Indians settled at Oneida in the state of New-York, saw the complaint in an old woman, the wife of the chief of that tribe. From this woman Barton learned that bronchoceles were by no means uncommon among the Oneida Indians, the complaint existing in several of their villages. He found also that the disease resembled that seen in Europe, in respect to its varieties. He did not indeed himself see the pendulous bronchocele which descends over the breast; but he understood that it was not uncommon among the women on the banks of the Mohawk river, who wore a particular dress for its concealment. In North America bronchocele attacks persons of every age; but it is most frequently seen in adults; a difference from what is noticed in Europe. Bronchocele is said to be frequent in Lower Canada. Bonpland, the companion of Humboldt, informed Alibert that the disease was endemic in New Grenada, and that it prevailed in such a degree in the little towns of Honda and Monpa, on the banks of the Magdalen river, that scarcely any of the inhabitants were free from it. The blacks and those who led an active, laborious life, however, are reported to escape the complaint. Some of the natives of the isthmus of Darien are said to be terribly disfigured by it.—(*Alibert, Nosol. Nat. t.* 1, *p.* 469. *Also, Observations sur quelques phénomènes peu connus qu'offre le goitre sous les tropiques, dans les plaines et sur les plateaux des Andes, par A. de Humboldt, in Journ. de Physiologie par F. Magendie, t.* 4, *p.* 109, *Paris*, 1824.)

In European women bronchocele usually makes its appearance at an early age, generally between the eighth and twelfth year, and it continues to increase gradually for three, four, or five years, and is said sometimes to enlarge more during the last half year than for a year or two previously. It does not generally rise so high as the ears, as in the cases mentioned by Wiseman. Sometimes, however, this happens, as we see in the case of Clement Desenne, of whom Alibert has given an engraving. In this patient, a part of the tumour, as large as a hen's egg, projected into the mouth.—(*Nosol. Nat. t.* 1, *p.* 466.) The swelling extended from the ears to the middle of the breast. A seton produced a partial subsidence of it; but when it was withdrawn the orifices closed. After two years more, the swelling became painful, suppuration took place, and fifteen pints of matter were discharged; and six ounces every day after the swelling had burst, came away with the dressings for three months; but, notwithstanding all this suppuration, and more afterward, the tumour was only partially lessened. The disease, mostly has a pendulous form, not unlike, as Albucasis says, the flap or dewlap of a turkey-cock, the bottom being the largest part of the tumour. Alibert mentions a case in which the swelling hung down to the middle of the sternum, and the large mass, which was quite a burden to the patient, used to become hard and, as it were, frozen in very cold weather. This author, however, cannot be right, when he adds, that it was an inert body, *destitute of vitality*!—(*Nosol. Nat. t.* 1, *p.* 466.) In another curious instance, the tumour formed a long cylinder which reached down to the middle of the thigh, the diameter becoming gradually smaller downwards.—(*P.* 468.) The common seat of bronchocele is the thyroid gland; but frequently the surrounding cellular membrane is more or less thickened, and contributes to the swelling. Sometimes also the neighbouring lymphatic glands are affected, when its base is widened and extends from one side of the neck to the other. In this circumstance, the swelling gradually loses itself in the surrounding parts, and is not circumscribed as in ordinary instances.—(*Postiglione, Mem. sulla Natura del Gozzo, p.* 20.) It is soft, or rather flabby to the touch, and somewhat moveable; but after afew years, when it has ceased enlarging, it becomes firmer and more fixed. When the disease is very large, it generally occasions a difficulty of breathing, which is increased by the patient's catching cold or attempting to run. In some subjects the tumour is so large, and affects the breathing so much, that a loud whizzing is occasioned; but there are many exceptions to this remark. Sometimes when the swelling is of great size, patients suffer very little inconvenience; while others are greatly incommoded, though the tumour is small. In general the inconvenience is trivial. The voice is sometimes rendered hoarse, and in particular cases the difficulty of speech is very considerable.—(See *Flajani, Collez. d'Oss. t.* 3, *p.* 271.)

The difficulty of respiration, produced by the pressure of the tumour and the enlargement of other glands, as this author remarks, is the most dangerous effect of the disease, since by disordering the pulmonary circulation, it renders the pulse irregular and intermittent, and a strong throbbing is excited in the region of the heart, followed by fatal disease of the lungs themselves; consequences often not suspected to have any connexion with the bronchocele, though it is in reality the immediate cause of them.—(*Vol. cit. p.* 278.)

The causes of bronchocele are little known. To the doctrine that bronchocele is caused by the earthy impregnation of water used for drink, the following objections offer themselves: 1. The water of Derbyshire, in districts where this disease is considered endemic, contains much supercarbonate of lime; but that in common use about Nottingham, where the disease is also prevalent, is impregnated with sulphate of lime. However, that the disease is not produced by water impregnated by sulphate of lime is evident; for, as Alibert observes, the waters of Saint Jean, Saint Sulpice, and Saint Pierre, where bronchocele is frequent, contain much less of this earth than the waters of Upper Maurienne, where the disease is hardly ever noticed, though the houses are built upon a vast quarry of gypsum. The same fact was observed by Bonpland in New Grenada.—(*Nosol. Nat. t.* 1, *p.* 471.) Nor, as Foderé explained, can the cause of the disease be correctly referred to the use of any particular kind of food. Certain localities, however, seem to contribute to its frequency; for this author observes, that the disease is not prevalent in very high places nor in open plains; but that it becomes more and more common as we descend into deep valleys made by torrents, where there is a good deal of marsh, and abundance of fruit-trees. The air is here constantly humid. 2. Abstinence from unboiled water does not diminish or interrupt the gradual progress of the disease. 3. Patients are cured of the disease, who still continue to drink water from the same source as before, without taking any precaution, as boiling, &c. 4. The disease in this country is less frequently found among men. 5. Many instances may be related of a swelling in the neck, sometimes very painful, and generally termed bronchocele, being produced very suddenly, by difficult parturition, violent coughing, or any other unusually powerful effort.—(See *Edin. Med. and Surgical Journ. vol.* 4, *p.* 279.) When the gland is suddenly enlarged during a violent exertion, the distention is said to be produced by the passage of air from the trachea into the substance of the thyroid gland and surrounding cellular membrane. But whether this statement be a fact or not, it is unquestionably true, that in many patients the tumour always increases when they speak loud, sing, or make any effort.—(*Flajani, Collez. d'Oss. &c. t.* 3, *p.* 276; *and Postiglione, p.* 24.) The disease is sometimes seen in scrofulous subjects; but there is every reason to believe that it is quite independent of the other disorder, as Prosser, Wilmer, and Kortum have particularly explained. The following are some points of difference between bronchocele and scrofula, as indicated by Dr. Postiglione. 1. The true bronchocele is simply a local disease of the neck, the constitution being unaffected. On the contrary, scrofula extends its effects to the whole system, attacking not only the lymphatic glands, but also the muscles, cellular membrane, ligaments, cartilages, and bones. 2. Both diseases chiefly occur in young subjects; but bronchocele often begins at a later age than scrofula, and does not, like the latter, spontaneously disappear as the patient approaches puberty and gains strength. 3. Scrofulous glands often suppurate and ulcerate; bronchocele rarely undergoes these changes. 4. The thickening of the upper lips of scrofulous subjects is not an attendant on bronchocele; and while the former patients generally enjoy their mental faculties in perfection as long as they live, the latter disease in certain countries is often joined with cretinism. Scrofula is likewise always hereditary, while bronchocele is not so; no healthy persons become scrofulous by living a long while among scrofulous patients, but many individuals contract bronchocele by going from a country where this disease is unknown, and taking up their residence in places where it abounds. 5. Nature alone often cures

scrofula, while art is rarely successful; on the contrary, bronchocele is seldom cured by nature, but very frequently by art. 6. The muriate of lime, recommended by Fourcroy for the cure of scrofula, is always useless; but in bronchocele it proves a valuable remedy.—(*Postiglione, Memoria sulla Natura del Gozzo, &c. p.* 25.) The error of confounding bronchocele with scrofula is now generally acknowledged. At the Hospital St. Louis, says Alibert, scrofulous patients are numerous, while those with bronchocele are very rare. (*Nosol. Nat. t.* 1, *p.* 465.) In Derbyshire, Genoa, and Piedmont, bronchocele has been attributed to drinking water cooled with ice. To this theory many of the objections concerning the earthy impregnation of water stand in full force; with this additional reflection, that "in Greenland, where snow-water is commonly used, these unsightly protuberances are never met with, nor (says Watson) did I ever see one of them in Westmoreland, where we have higher mountains and more snow than in Derbyshire, in which country they are very common. But what puts the matter beyond a doubt is, that these wens are common in Sumatra, where there is no snow during any part of the year."—(*Watson's Chemical Essays, vol.* 2, *p.* 157.) The above opinion was also refuted by Fodere, who remarks, that the Swiss who reside at the bottom of the glaciers are the least subject to the disease. Bronchoceles are also said to be unknown in Lapland.

Respecting the influence of particular water in bringing on the disease, Dr. Odier gives credit to the opinion, because it has appeared to him that distilled water prevented the increase of the tumour, and even tended to lessen its bulk.—(See *Manuel de Médecine Pratique*, 8vo. *Genev.* 1811.) However, that every explanation hitherto devised of the causes of bronchocele is quite unsatisfactory, is fully proved by the observations of the celebrated Humboldt. Persons afflicted with bronchocele (he remarks) are met with in the lower course of the Magdalen river (from Honda to the conflux of the Cauca); in the upper part of its course (between Neiva and Honda); and on the flat high country of Bogota, six thousand feet above the bed of the river. The first of these three regions is a thick forest, while the second and third present a soil destitute of vegetation; the first and third are exceedingly damp, the second is peculiarly dry; in the second and third regions, the winds are impetuous; in the first the air is stagnant. To these striking differences, we will add those relative to temperature. In the first and second regions, the thermometer keeps up all the year between 22 and 33 centigrade degrees; in the third, between 4 and 17 degrees. The waters drunk by the inhabitants of Mariquita, Honda, and Santa Fé de Bogota, where bronchoceles occur, are not those of snow, and issue from rocks of granite, freestone and lime The temperature of the waters of Santa Fé and Mompox, drunk by those who have this disease, varies from nine to ten degrees. Bronchoceles are the most hideous at Mariquita, where the springs which flow over granite are, according to my experiments, chemically more pure than those of Honda and Bogota, and where the climate is much less sultry, than upon the banks of the Magdalen river. Perhaps it may be thought that the atony of the glandular system (?) depends less upon the absolute temperature than upon the sudden refrigeration of the atmosphere, the difference of temperature in the night and day; but in the Magdalen valley, where the constancy of low tropical regions prevails, the extent of the scale that the thermometer pervades in the course of the whole year, is only a small number of degrees, &c.—(*Humboldt, in Journ. de Physiologie par F. Magendie, t.* 4, *p.* 116.)

The same distinguished observer confirms previous accounts of the variety of bronchoceles among the original copper-coloured natives of America and negroes. It appears, also, that in South America bronchocele is progressively extending itself from the lower provinces to the flat elevated regions of the Cordilleras; and this in so serious a degree that in 1823 the subject was adverted to in a report made to Congress by M. Restreppo, one of the Colombian ministers.

An observation lately made by an intelligent writer would lead one to conclude, that cretinism depends upon malformation of the head. Speaking of goitre, as it appears among the inhabitants of the valley of Maurienne, Baron Larrey informs us, that in many of these people, with this frightful deformity is joined that of the cranium, of which the smallness and excessive thickness are especially remarkable.—(*Mém de Chir. Milit. t.* 1, *p.* 123.) Dr. Leake thinks that tumours of this sort may be owing to the severity of the cold damp air, as they generally appear in winter, and hardly ever in the warm dry climates of Italy and Portugal. The latter part of the observation, however, is not correct, for Doct. Postiglione, and other Italian writers, assure us that the disease is extremely common in some of the warmest parts of Italy. "*Qui in Napoli, e per tutto il regno, si veggono molt gozzuti, mai non in numero tale, come in Casoria, ed in pochi altri villaggi.*" —(*P.* 21.) Prosser is inclined to consider the bronchocele as a kind of dropsy of the thyroid gland. similar to the dropsy of the ovary; and he mentions that Dr. Hunter dissected one thyroid gland which had been considerably enlarged, and contained many cysts filled with water. These, he erroneously concludes, must have been hydatids. Dr. Baillie remarks, that when a section is made of the thyroid gland affected with this disease, the part is found to consist of a number of cells containing a transparent viscid fluid.

In all probability the ordinary bronchocele is entirely a local disease, patients usually finding themselves in other respects perfectly well. The tumour itself frequently occasions no particular inconvenience, and is only a deformity. There is no malignancy in the disease, and the swelling is not prone to inflame or suppurate, though, as Dr. Hunter remarks, abscesses do occasionally form in it. Alibert's case of bronchocele becoming cancerous is singular. Mr. Gooch never knew life to be endangered by this sort of tumour, however large; a remark very much at variance with the observations of some other practitioners; but he had seen great inconvenience arise from it when combined with quinsy. In fact, the pressure of a large bronchocele may not only greatly afflict the patient, by rendering respiration difficult, but actually cause death by suffocation.—(See *Obs. sur un Goitre volumineux, comprimant la Trachée-artère; par L. Winslow, in Bulletin de l'Athénée de Méd. &c.*) "Some persons, as Alibert remarks, have the disease all their lives without suffering any inconvenience from it; some experience a suffocating oppression of the breathing; and in others there is an impediment in the circulation, and a tendency to apoplexy, arising from the strangulation which afflicts them."—(*Nosol. Nat. t.* 1, *p.* 466.) Dr. Hunter says, that the bronchocele frequently appears two or three years before or after the commencement of menstruation, and that it sometimes spontaneously disappears, when this evacuation goes on in a regular manner. Mr. A. Burns affirms the same thing. On the contrary, according to Prosser, this change in the constitution hardly ever affects the tumour.

TREATMENT OF BRONCHOCELE.

That certain localities, perhaps not yet correctly understood, contribute to the origin of this disease, is well proved by a fact stated by Alibert, viz. that change of air has more effect on the complaint than medicines, as he has known many Swiss ladies who came to Paris with bronchoceles, in whom the tumour subsided after they had resided some time in that city.—(*Nosol. Nat. t.* 1, *p.* 473.)

A blister, kept open, has put a stop to the growth of the tumour; but this method is not much followed at present, as better plans of treatment have been discovered. A few years ago the favourite mode of curing bronchocele consisted in giving internally burnt sponge, and occasionally a calomel purge, at the same time that frictions were made upon the tumour itself. The utility of burnt sponge in the treatment of bronchocele, as Dr. Coindet and others have now fully proved, depends upon the iodine in its composition.

The efficacy of burnt sponge was thought to be greatest, when exhibited in the form of a lozenge composed of ten grains of this substance, ten of burnt cork, and the same quantity of pumice-stone. These powders were made into the proper form with a little syrup, and the lozenge was then put under the tongue and allowed to dissolve. To the latter circumstance much importance was attached. Some practitioners gave a scruple of burnt sponge alone, thrice every day, while others added a grain of calomel to each dose. A purge of calomel was ordered about once a week or fortnight, at long as the patient persevered in the use of the calcined sponge; but when mercury was combined with

ach dose of this medicine, no occasional purgative was deemed requisite.

External means may very materially assist the above internal remedies. Frequently rubbing the swelling with a dry towel; bathing the part with cold water; rubbing the tumour two or three times a day with the liq. ammon. acet. or the camphor liniment; are the best steps of this kind which the surgeon can take.

"In the treatment of bronchocele," says Mr. A. Burns, "repeated topical detraction of blood from the tumour is highly beneficial. Electricity also has sometimes a marked effect; but there is no remedy which I would more strongly advise, than regular and long-continued friction over the tumour. By perseverance in this plan, a bronchocele, treated in London, was materially reduced in the course of six weeks. Its good effects I have likewise witnessed myself; and it is a remedy highly recommended by Girard in his '*Traité des Loupes.*' It has also been much used in scrofulous tumours by Mr. Grosvenor of Oxford, and by Mr. Russell of Edinburgh.—(*Surgical Anatomy of the Head and Neck, p.* 204.)

Mr. A. Burns recommends the friction to be made with flannel covered with hair-powder, and the part to be rubbed at least three times a day, for twenty minutes.

In two cases of bronchocele related by Dr. Clarke, the patients were cured by "the steady use of the compound plaster of ammoniac and mercury, conjoined with the internal exhibition of burnt sponge and occasional purgatives."—(See *Edin. Med. and Surgical Journal, vol.* 4, *p.* 280.)

We learn from Professor Odier, that, in Geneva, bronchocele used to be cured by burnt sponge exhibited in powder or infused in wine, and combined with purgatives to prevent the cramps of the stomach, which sometimes accompany the disappearance of the swelling. Muriate of barytes has likewise been recommended.—(See *Manuel de Médecine Pratique.*)

Mr. Wilmer, credulously imputing great influence to the changes of the moon, used to begin with an emetic the day after the full moon, and to give a purge the ensuing day. The night following and seven nights successively he directed the above-mentioned lozenge to be put under the tongue at bedtime, and administered every noon a bitter stomachic powder. On the eighth day the purge was repeated, and in the wane of the succeeding moon, the whole process, except the emetic, was renewed.—(*Cases in Surgery, Appendix.*) This, which is often called the Coventry plan of treatment, is said to be greatly assisted by rubbing the tumour with an ointment containing tartar emetic.

Prosser succeeded with his medicines, though the patient was nearly twenty-five years old, and the swelling had existed more than twelve years. It is said, that no instance of cure has been known after the patient was twenty-five. Prosser orders one of the following powders to be taken early in the morning, an hour or two after breakfast and at five or six o'clock in the evening, every day, for a fortnight or three weeks. The powder may be taken in a little syrup or sugar and water: ℞. Cinnab. ant. op. levigat. milleped. ppt. et pulv. ää gr. xv. Spong. calcin. ʒj. M.

These powders should be taken for two or three weeks, and then left for a week or nine days before a repetition. At bedtime every night, during the second course of the powders, some purgative pills composed of mercury, the extractum colocynthid. comp. and rhubarb, are to be administered; and in general it will be proper to purge the patient with manna or salts, before beginning with the powders. Prosser put no faith in external applications.

Some have recommended giving two scruples of calcined egg-shells every morning, in a glass of red wine; half a drachm of the sulphuret of potash every day, dissolved in water; or ten or fifteen drops of the *tinct. digit.* twice a day, the dose being gradually increased. Muriated barytes, cicuta, and belladonna have also been exhibited. Postiglione commends the muriate of lime as a medicine possessing great efficacy. The remedy is made in a bolus with honey, to which is sometimes added burnt sponge, with cinnamon in powder. He employs also frictions with flannel, liniments, and sometimes purges with calomel. The bolus is placed under the tongue, and allowed to dissolve there.—(*P.* 59, *&c.*)

Sir J. Wylie, physician to the emperor of Russia, prescribes three grains of the submuriate of mercury, three of the ammoniacal muriate of iron, four of burnt sponge, and ten of the bark of laurus cassia, divided into twelve doses, one of which is given twice a week with a gentle anodyne at night. He also directs twenty-four lozenges to be made, by triturating an ounce of burnt sponge with an equal quantity of the powder of gum arabic, and fifteen grains of cinnamon, first blended with a sufficient quantity of the syrup of orange-peel. One of these lozenges is put under the tongue daily and allowed to dissolve there. Lastly, to the tumour itself he applies a plaster composed of half an ounce of litharge, a drachm of the submuriate of mercury, and 10 grains of antim. tartariz.—(*Alibert, Nosol. Nat. t.* 1, *p.* 474.)

The virtues of burnt sponge in the cure of certain forms of bronchocele are now ascertained to be owing to the iodine which it contains. Iodine was discovered in 1813 by Courtois, manufacturer of saltpetre at Paris; but six years elapsed before it was tried as a medicine. From the first memoir of Dr. Coindet, addressed in 1820 to the Helvetian Society of Natural Sciences, it appears, that as he was searching for a formula in the work of Cadet de Gassicourt, he found that Russel had recommended the ashes of the *fucus vesiculosus*, or bladder wrack, under the name of æthiops vegetabilis, for the cure of bronchocele; and he was led from analogy between this substance and burnt sponge, so long celebrated for its efficacy in the treatment of bronchocele, to suspect that iodine was the active principle of both. "The great and unequalled success which resulted from its use in the treatment of bronchocele, at once indicated the power of iodine as a therapeutic agent, and encouraged Dr. Coindet to pursue his researches in rendering it an efficient article of the materia medica; and about the close of the same year, when Dr. Coindet had employed iodine in treating goitre for six months at least, his conjecture was confirmed by the discovery which Dr. Fyfe of Edinburgh made, that this substance was actually contained in the ashes of the burnt sponge," &c.

"It has been generally understood among the profession, that the happy conjecture which introduced iodine into medical treatment, originated with Dr. Coindet, of Geneva; yet we find that his claim to this honour is disputed by one of his countrymen, Dr. J. C. Straub, of Hofwyl, in the canton of Berne.

Dr. Straub, whose communication is found in Professor Meisner's Physical Intelligence of the General Helvetian Society for 1820, states, that before the discovery of iodine, attempts had been made to compound a substitute for burnt sponge, but without success; and that this failure and his observation of the similarity of smell between iodine, burnt sponge, and other marine productions, led him to suspect the existence of iodine or its salts in these substances, and that its absence in the artificial compounds was the cause of failure in these experiments. This conjecture, which appears to have been made previously to 1819, led Dr. Straub to examine the real burnt sponge, and he informs us, that though his time did not permit him to ascertain exact quantities, yet he obtained from 1½ oz. of burnt sponge as much iodine as to render his conjecture probable, and to be astonished that the ingredient should have escaped notice. He was therefore at once induced to think of its use in medicine; and in the same paper from which we obtain these facts, impressed with the poisonous quality ascribed by Orfila to iodine, he recommended first the trial of its salts, especially the hydriodates of soda and lime, and then that of the substance itself.

The communication of Dr. Straub is dated Dec. 1819, and was actually published in Professor Meisner's periodical work in February, 1820, five months at least before the first memoir of Dr. Coindet was communicated to the Helvetian Society of Natural Sciences at Geneva. It is unnecessary to have recourse to any supposition of injustice done to Dr. Straub; much less would it be right to deprive Dr. Coindet of the merit of originality in substituting the direct and certain action of iodine, for the irregular and sometimes inert qualities of burnt sponge in the treatment of goitre. Coincidence of this kind is not uncommon in science; in the present instance, the ingenuity of Dr. Straub does not diminish the merit of Dr. Coindet."—(See *Edin. Med. and Surg. Journal, No.* 80, *p.* 210, *&c.*)

That iodine is a medicine of considerable efficacy in

bronchocele, not a doubt can be entertained, after the many cases now recorded in proof of the fact; and that it will be found useful in some other chronic tumours, especially those of a scrofulous nature, seems highly probable, if such probability be no already converted into certainty. In bronchocele, friction with the ointment on the swelling may often be advantageously conjoined with the use of one of the preparations for internal exhibition.

In the *Archives Générales de Médecine* for July, 1823, Dr. Coster mentions the opportunity which he had had of remaining eight months at Geneva with Dr. Coindet, and of observing correctly the good effects of iodine in enlargements of the thyroid gland and in scrofulous tumours. Dr. Coindet first of all employed this medicine under the form of alcoholic tincture, and obtained very surprising effects from its administration in goître. He next tried friction on the tumour itself with an ointment composed of the hydryodate of potass and lard; and the success of this practice was so great, that of nearly one hundred individuals affected with goître, whose cases Dr. Coster collected, more than two-thirds were completely cured by it. Soon after these successful results, iodine was employed sometimes internally and sometimes in the form of friction in scrofula. "I shall not affirm (says Dr. Coster) that success was as uniform in the latter as in the former disease, but it is certain, that scrofulous tumours yield sooner to the action of iodine than to that of any other remedy at present known: when the tumours, whether of the thyroid gland, or of the lymphatic glands, are hard and renitent, experience proves, that the effects of iodine are much more prompt when the frictions are preceded by the application of leeches and a low regimen. Notwithstanding these precautions, however, the tumour sometimes continues stationary." In such a case, Dr. Coster put the tumour twice a day, for ten or twelve minutes, under the influence of the positive pole of the voltaic pile, taking care to change sides each time of using it; so that, in the morning, he made use of friction with iodine on the right side and the action of the pile on the left, and in the evening applied the friction to the left side and the galvanism to the right. In twenty days not the least trace of the bronchocele was left. It is stated, that in this instance, the voltaic pile, unassisted with the frictions of iodine, was as ineffectual as the friction by itself had been. By the internal and external use of iodine, I lately dispersed a bronchocele which had formed in the neck of a young lady, aged about 12, who was brought to my house by my neighbour Mr. Blair. The disease began to diminish in less than a week from the commencement of the treatment, and in six weeks the cure was complete. An interesting case, in which a similar plan was attended with success, is recorded by Dr. Roots.—(See *Med. Chir. Trans. vol.* 12, *p.* 310.) Another instance of its decided efficacy is reported by Dr. Barlow, of Bath (see *Edin. Med. Journ. No.* 79, *p.* 337); but whoever wishes to have a large and convincing body of evidence on this point, should consult the cases and observations published by Dr. Manson, of Nottingham, where bronchocele is said to be endemic. He gives the results of one hundred and twenty cases of bronchocele in which he administered iodine. Fifteen were in males, and one hundred and five in females. When the disease was complicated with diseased lymphatic glands, the thyroid gland first yielded and then the others. In the fourth case a scrofulous swelling of the foot yielded during the use of iodine. Of the hundred and twenty cases referred to, eighty-seven were cured, ten much relieved, and only two or three discharged without relief.—(See *Manson's Medical Researches on the Effects of Iodine in Bronchocele, Paralysis, Chorea, Scrofula, Fistula Lachrymalis, Deafness, Dysphagia, White Swellings, and Distortions of the Spine. Lond.* 1825.) Some farther notice of this gentleman's practice, as well as the results of Mr. Buchanan's experience will be taken in the articles *Ear, Iodine, Joints, Scrofula, Vertebræ, &c.* For the preparation and doses of *Iodine, see this word.*

In South America, a remedy for bronchocele called *aceyte de sal*, was found, by M. Roulin, to contain a proportion of iodine.—(See *Magendie, Journ. de Physiologie, t.* 5, *p.* 273.) The same gentleman has also proposed the trial of chlorine, or the free hydro-chloric acid.

Petit, Heister, and Schmucker make mention of inveterate bronchoceles which gradually subsided in consequence of suppuration. Volpi states, that such ulcerations are not unfrequent. He has published two facts of this kind which occurred after a nervous fever; and he records a third case, where the swelling inflamed in consequence of a blow, suppurated, and sloughed so as entirely to disappear.—(See *Léveillé, Nouvelle Doctrine Chir. t.* 4, *p.* 128.) A similar fact is recorded by Zipp.—(*Siebold, Samml. Chir. Beob. b* 2, *p.* 229.)

The disease in its inveterate form has also been sometimes removed by the application of caustic (*Mesny in Journ. de Médecine, t.* 24, *p.* 75; *Timæus, Cas. p.* 283); the establishment of issues (*Jeitteles, Obs. Med.*); the making of an incision into the swelling, or the introduction of a seton through it.—(*Foderé, Essai sur le Goître et le Crétinage, p.* 75; *Klein, in v. Siebold, Sammlung Chir. Beobacht, b.* 2, *p.* 11; *Flajani, Collezione d'Osservazioni di Chirurgia, t.* 3, *p.* 283.)

Bronchoceles have sometimes been removed by the part having been accidentally or purposely burnt to a considerable depth (*Motte, in Blegny, Zodiac. ann.* 2 *Febr. Obs.* 11; *Severinus de Efficaci Medicina, p.* 220.) The disappearance of bronchoceles has also been known to follow a wound.—(*Schmidmüller über die Ausführungsgänge der Schilddruse, p.* 37, *Landshut*, 1805.) A. Burns sometimes employed blisters, and found them useful.—(*Surgical Anatomy of the Head and Neck, p.* 204.) With respect to caustic, which is spoken of by Celsus (*lib.* 7, *cap.* 13), Flajani states, that its operation is tedious and painful, and attended with danger; and what he says about the practice of an incision is not more encouraging. When the disease contains a cyst, he prefers making an opening with a trocar, though he confesses that this plan is apt to be followed by a relapse, when the cyst is very thick and hard; in which circumstance, it will be necessary to have recourse either to an incision or the seton, for the purpose of exciting suppuration. Should the disease, however, be merely composed of one cyst of moderate size, Flajani recommends its entire removal. "Of all these methods (says he) proposed for the extirpation of bronchoceles, the seton is the least dangerous, and by means of it a radical cure may be generally effected without any severe symptoms, as I have found by experience in many cases. On the contrary I have been an eye-witness of the fatal consequences induced by the other plans. I was called to assist a gentleman, about forty years of age, brought to death's door by a bleeding, which arose from the application of caustic to the forepart of the neck. As tourniquets, bandages, &c. proved quite ineffectual, it was indispensable to make pressure on the part with the finger of an assistant, for twenty-four hours, ere the hemorrhage could be stopped; a copious suppuration ensued; and it was three months before the parts were healed. I was likewise present (says he) at the opening of a similar, but larger swelling in the same situation, the disease having afflicted an elderly respectable patient for several years. The incision caused the evacuation of a small quantity of serum, contained in the cellular membrane; but the following day the tumour inflamed, the difficulty of respiration increased, and for some days the patient was in great danger. At length suppuration was established, followed by a destruction of a great deal of the cellular membrane and several sinuses, and in five months the patient lost his life. On examination of the body, the lungs were found tuberculated, an effect of the impediment to the circulation of the blood through the smaller vessels of those organs."—(*Flajani, Collezione d'Osserv. t.* 3, *p.* 283, 8*vo. Roma*, 1802.)

The first proposer of the employment of setons for the cure of diseases of the thyroid gland, is perhaps not exactly known; but it is certain that the method has been known, and occasionally practised, ever since the middle of the last century. "Dr. Monro, senior, (as a well informed writer has observed) mentions in his lectures that he has seen a dropsy in the centre of the gland, complicated with bronchocele, cured by a seton, although the glandular swelling still continued."—(*A. Burns on the Surgical Anatomy of the Head and Neck, p.* 191.) This statement is given on the authority of some MS. notes taken by Dr. Brown, from Dr. Monro's lectures. According to Girard, many cases in his time had been communicated to the Royal

Academy of Surgery at Paris, in which the disease had been got rid of either by means of a seton, drawn through the swelling, or the application of an issue.—(*Lupiologie, &c. 8vo. Paris*, 1775. The occasional success of setons was also adverted to by Richter in the year 1788.—(*Bibliothek, b. 9, p. 478.*) And the plan is spoken of in another work, published in 1790, as being eligible where the disease is conjoined with a cyst.—(*Encyclopédie Méthod. partie Chir. t. 1, p. 231.*) The practice was particularly noticed by Foderé in his valuable treatise on bronchocele; and Alibert mentions the seton as being used at the Hospital St. Louis.—(*Nosol. Nat. t. 1, p. 466, fol. Paris*, 1817.)

In November, 1817, Dr. Quadri, of Naples, tried this practice, which he erroneously supposed to be quite new. "By means of a trocar-pointed needle, six and a half inches long, I passed (says he) a seton from above downwards through the gland, at the depth of about four lines from its surface. Suppuration took place in forty-eight hours. On the 18th of November the seton escaped, when the matter was squeezed out; and the irritation occasioned by replacing it, produced an abscess on the right side of the neck, which was opened on the 23d, when it was found that the suppuration had effected the destruction of nearly the whole gland." The woman, who was thirty-six years of age, was seen by Dr. Somerville, in April, 1818, with the circumference of her neck lessened, from sixteen to thirteen inches, French measure. In another case referred to, a seton was passed through each side of the thyroid gland, and the result was a removal of the tumour on the side where the seton was maintained long enough; but on the opposite side the seton being withdrawn too early, the matter collected in a sac; and at the end of four months a sinus and discharge still continued, the patient refusing to have a counter opening practised. When the seton does not prove stimulating enough, Dr. Quadri sometimes enlarges it, or attaches to it escharotic or irritating substances. He also frequently uses two setons. In one example, in endeavouring to perforate the gland rather deeply, Dr. Quadri appears to have injured the larger branches of the thyroid arteries, as more than an ounce of blood was discharged, and the tumour swelled as if injected with blood. The bleeding, however, ceased spontaneously. He states that the seton has been passed through the tumour not less than sixteen times, the direction being varied in every instance, without untoward accident; and he is confident, that unless the needle be pushed deep enough almost to touch the thyroid cartilage, the trunks of the thyroid arteries will not be exposed to injury, while the branches in the track of the needle will not cause any danger. He insists also upon the propriety of retaining the seton in the tumour a considerable time; and observes, that it remains to be ascertained whether this practice will answer in every description of bronchocele? For these and several other cases and particulars, the profession is indebted to Dr. Somerville.—(See *Med. Chir. Trans. vol. 10, p. 16, &c.*)

Mr. Gunning applied a seton in a case of bronchocele in St. George's Hospital; but in this instance the irritation brought on sloughing, and the patient after a time died. The particulars of this case, and of three successful examples of the practice in England, have been lately recorded. One of the successful cases was treated by my friend Mr. James, of Exeter, another by Mr. A. C. Hutchison, who has taken the trouble to collect the history of them, and the third by Dr. A. T. Thomson.—(See *Med. Chir. Trans. vol. 11, p. 235.*) Percy and Dupuytren have also employed setons in bronchocele with success. The plan, however, is sometimes inefficient, as is proved by two cases under Dr. Kennedy, of Glasgow.—(See *London Med. Repository, No. 99, Feb.* 1822.) The exact nature of cases relieved by this practice, and their difference from other examples, which are benefited by treatment of a different kind, are still desiderata in surgery.

The diseased thyroid gland has been successfully extirpated; but the operation is one of so much danger, that it ought never to be attempted except under the most pressing circumstances. The many large arteries naturally distributed to the gland itself; their still greater size in bronchocele; and the vicinity of the carotid arteries, and important nerves, render the undertaking a thing of no common difficulty.

Mr. Gooch relates two cases, which do not encourage practitioners to have recourse to the excision of enlarged thyroid glands. In one, so copious an hemorrhage took place, that the surgeon, though equally bold and experienced, was obliged to stop in the middle of the operation. No means availed in entirely suppressing the bleeding, and the patient died in a few days. In the other, the same event nearly took place, the patient's life being saved only by compressing the wounded vessels with the hand, day and night, for a whole week, by persons who relieved each other in turn. This was found the only way of stopping the hemorrhage, after many fruitless attempts to tie the vessels.

Hemorrhage is not the only risk: Dupuytren removed a large bronchocele that caused dangerous pressure upon the trachea: the whole gland was taken away, and the four thyroid arteries and many veins secured. Only a few spoonfuls of blood were lost. The woman, however, died soon after the operation, with pale face, hurried respiration, cold skin, sickness, &c., denoting injury of some important nerves.

I do not mention these facts to deter surgeons from the operation altogether, because it is proved by modern experience, and especially by six cases in which Dr. Hedenus, of Dresden, has successfully removed the thyroid gland, that not only it is occasionally a necessary proceeding, but one that may be well accomplished by a skilful operator, as will be particularly explained in a future article.—(See *Thyroid Gland.*) When bronchoceles by their pressure dangerously obstruct respiration, deglutition, and the return of blood from the head; and when the disease resists the efficacy of iodine, a seton, blisters, and every other plan of treatment found deserving of trial; what can be done with the view of saving the patient, but the bold operation of cutting away the swelling, or that of exposing and tying one or both of the upper thyroid arteries?

When the quantity of blood flowing into a tumour is suddenly and greatly lessened, the size of the swelling commonly soon undergoes a considerable diminution. The experiment was once made by Sir W. Blizard: he tied the arteries of an enlarged thyroid gland, and, in a week, the tumour was reduced one-third in its size. The ligatures then sloughed off, repeated bleeding took place from the arteries, and by the extension of hospital gangrene, the carotid itself was exposed. The patient died; yet, as Mr. A. Burns observes, this does not militate against a repetition of the experiment; as the same thing might have happened from merely opening a vein, and, in the confined air of a hospital, has actually happened.—(*Surgical Anatomy of the Head and Neck, p. 202.*)

In fact, the rationality of the experiment prevented surgeons from being intimidated by the failure in question; and, with that laudable spirit for the improvement of operative surgery every where diffusing itself through the profession, other gentlemen were soon found who had judgment enough to make farther trials of the practice. In a young man, twenty-four years of age, whose breathing was much impeded by a bronchocele, and whose upper thyroid arteries were very large, and affected with strong pulsations, Walther, of Landshut, tied the left of these vessels, the left side of the gland being the largest. The operation was done on the 3d of June, 1814. An incision, an inch and a half in length, was made in the direction of the inner edge of the sterno-cleido-mastoid muscle, where the throbbing of the artery was quite distinct. By a second stroke of the knife, the platysma-myoides was divided in the same direction, and to an equal extent. The vessel was then exposed by a cautious dissection, and separated from the surrounding parts, and one arterial branch which was divided was immediately secured. A ligature composed of three silk threads, was then conveyed with an aneurism-needle under the left thyroid artery, and tied with two simple knots. The wound was then closed with adhesive plaster, and the ends of the ligatures brought out at the angles. The ligature on the large artery came away on the 12th day; and, without any febrile symptoms, or other bad consequences, the wound was perfectly healed on the 23d day. As early as the third day after the application of the ligature, the left part of the tumour began to be less tense, and the throbbing feel in it soon ceased. By degrees it dwindled away, becoming as it lessened harder, and, as it were, cartilaginous. In a

fortnight, the left half of the swelling was one-third smaller than before the operation; and, at length, only one-third of it remained, while the right side also was somewhat smaller. On the 17th of June, Walther took up the right superior thyroideal artery, which was more difficult to get at, as it lay more deeply, and was much concealed under the enlarged gland, which had pushed it out of its natural situation. The operation lasted three-quarters of an hour, and several large and small arteries which were cut were tied. With respect to the thyroid artery itself, it could not be tied without including a part of the gland in the ligature. No unfavourable symptoms followed this second operation; the ligatures were detached in good time, and the wound healed up very well. The right portion of the bronchocele also now diminished; but though it was originally smaller than the left, it did not dwindle away so completely as the latter. The remains of the tumour, however, two years afterward, produced no inconvenience, and respiration was quite easy.—(See *Neue Heilart der Kropfes, &c. von Ph. Fr. von Walther*, p. 25, *&c.* 8vo. *Sulzbach*, 1817.) On the 29th of December, 1818, Mr. H. Coates, of Salisbury, took up the superior thyroideal artery for the cure of a bronchocele, which, in a young woman aged seventeen, made pressure on the trachea and œsophagus, attended with a great noise in breathing. The superior thyroideal arteries were in this instance large, and pulsated strongly. Mr. Coates cut down upon the left of these vessels, separated it from its accompanying nerve, and passed under it a small round ligature, which was drawn moderately tight and tied. The next day there was headache, and some swelling of the neck and side of the head, with increased difficulty of swallowing and febrile symptoms. These complaints, however, were relieved by bleeding and antimonial medicines. The ligature came away on the 9th day; and on the 14th, the wound was completely healed. On the 14th of February, the breathing being much improved, and the tumour reduced nearly to one-half of its former size, the patient was well enough to be discharged from the infirmary.—(See *Med. Chir. Trans. vol.* 10, *p.* 312.) My friend, Mr. Rose, once mentioned to me a case, in which a similar operation done by Mr. Brodie, did not produce any material diminution of the tumour.

Dr. Parry has remarked a frequent coincidence, either as cause or effect, between enlargement of the thyroid gland and cardiac diseases.—(*Elements of Pathology, &c. p.* 181.) And another modern writer mentions, that he has lately seen three cases of this complication.—(*Medico-Chir. Journ. vol.* 1, *p.* 181.) A case is detailed by Flajani, where the disease was accompanied with extraordinary palpitations of the heart.—(See *Collezione d'Osservazioni, &c. di Chirurgia, t.* 3, *p.* 270.) In the instance here referred to, there was great irregularity of the pulse, and the oppression of the breathing was such, that the patient was obliged to submit to venesection at least every month, whereby he was rendered quite emaciated.

[The prevalence of goitre in different parts of the U. States is stated by our author, and several American writers have described the disease as existing in various parts of our country, whose geological features very widely differ in many respects. In Vermont, in New-York, in Pennsylvania and Ohio, the disease is by no means unfrequent. Professors Barton and Gibson, of Philadelphia, have communicated many valuable observations on this disease. More recently, Professor Francis, of New-York, has made a series of observations on goitre as it appears in the western part of the state of New-York. From the communication with which he has politely favoured me, the following abstract is prepared. I may add, that agreeably to the facts deduced from the changes which our country undergoes in the progress of improvement, we have the strongest reasons to infer that as the climate and cultivation are meliorated, the instances of the existence of this disease will doubtless become less frequent.

However frequent cases of goitre may have formerly been in the state of New-York, the fact is certain, that they are much more rare at present. Even the representations of the late Dr. Dwight, relative to the great prevalence of the disease, though among the most recent with which we have been favoured, are to be received with allowance. That in particular portions of our western country repeated examples are to be found, may be known by any accurate observer. But "in the village of Utica, (says Dr. Francis) which contains between 4 and 5000 inhabitants, no case of bronchocele could be pointed out, and this village occupies the site of old Fort Schuyler, on the Mohawk, the vicinity of which has been referred to as the spot where goitre was peculiarly prevalent. I am strengthened in the accuracy of this statement relative to the almost total disappearance of goitre in this neighbourhood, by the testimony of Dr. Coventry. A similar remark may be made with regard to the former frequency of the disease throughout the extensive region from Utica to Buffalo. The late Uriah Tracy, in his excursion through this country some years since, was led to believe that bronchocele prevailed in the old settlements as well as the new, and thought it incidental to the country at large. In my late visit I made special inquiry as to the present condition of the health of the inhabitants, and am persuaded that the instances of goitre are much more rare than at the period of Mr. Tracy's observations. The number of cases which came under my notice during the tour were twenty-three. These were at Herkimer, Manlius, Syracuse, Onondaga, Batavia, Williamsville, and Buffalo; and I saw more cases in the neighbourhood of Buffalo than at any other place. In other parts of the state the disease may be seen, particularly in the county of Alleghany."

To assign a satisfactory cause for this disease is difficult, perhaps impossible. Dr. Barton has endeavoured to show that goitre and intermittent and remittent fevers have one common origin, and argues this opinion from the simultaneous prevalence of these diseases, from the frequency of glandular affections where intermittents abound, and from the opinion that persons afflicted with goitre are exempt from intermittents, though in the midst of these diseases. Dr. Coventry inclines to ascribe it to drinking water impregnated with alum. Dr. Dwight advocates the more current opinion that these affections originate from the lime contained in the water drank in those regions. Dr. Francis ascribes the production of the disease chiefly to humidity, and hence it prevails most in the vicinity of lakes and rivers where vegetation abounds. He says, it increases with the rainy seasons, and is diminished when the weather becomes cold and dry, and hence argues the reason of its disappearance as the country becomes cleared. He however does not altogether reject the agency of certain waters in aggravating if not producing the disease.

Of the 23 cases examined by Dr. Francis, two only were in male subjects, and one of them an adult Indian, in Niagara county. He saw it in an infant but a few months old, and he subscribes to the opinion that it often depends on constitutional causes, and is sometimes hereditary.

In Oneida county, Dr. Francis learned that goitre prevailed among sheep, and Foderé gives us a similar fact of its occurrence among dogs. The doctrines of Hunter and others, in considering the sexual functions connected with this disease, are sustained by its greater prevalence among women, and also according to Dr. F. by some well-known facts connected with parturition.

Dr. Coventry has removed several cases of goitre by the simple expedient of the patient wearing the muriate of soda about the neck. The recent plan of Mr. Holbrook, of employing steady pressure, has been tried in this country with some success. The efficacy of burnt sponge has often been seen, but instances of its failure are not unfrequent. The iodine has been used of late years with the best effects, and Dr. Congdon, of Buffalo, has reported its entire success in a number of cases.

Dr. Francis informs me, that in a subsequent journey through this state, he found a number of interesting cases, and that the disorder in every instance afflicted the female sex, and in eight or ten cases it was obviously associated with the function of menstruation and parturition. The left portion of the gland was most frequently the seat of the disease, but in no instance was it connected with idiocy. He reports one instance of the entire cure of a formidable case which occurred in a young married female, who, upon leaving the neighbourhood of Catskill and removing to the southern states, after a residence of three years, was entirely relieved of her goitre.

I can add my own testimony to the value of the iodine, having witnessed its success in a number of cases which had resisted the other remedies ordinarily employed.

The operation of removing the gland by the knife has been performed in this country with success, but is seldom advised, and will not be often repeated.—*Reese.*]

BRONCHOTOMY. (From βρόγχος, the windpipe, and τέμνω, to cut.) This is an operation by which an opening is made into the larynx or trachea, either for the purpose of making a passage for the air into and out of the lungs, when any disease prevents the patient from breathing through the mouth and nostrils; or of extracting foreign bodies, which have accidentally fallen into the trachea; or, lastly, in order to be able to inflate the lungs in cases of suspended animation. The operation is also named *tracheotomy*. Its practicable nature and little danger are founded on the facility with which certain wounds of the windpipe, even of the most complicated kind, have been healed, and on the nature of the parts cut, which are not furnished with any vessel of consequence.

When the incision is made in the larynx, the operation is termed *laryngotomy*. With respect to bronchotomy, its performance cannot be regarded as either difficult or dangerous: "*Dummodo* (says Fabricius ab Aquapendente), *qui secat sit anatomes peritus, quia sub hoc medico et artifice omnia tutissimè et felicissimè peraguntur.*"

Bronchotomy is occasionally practised in order to enable the patient to breathe, when respiration through the mouth and nostrils is impeded by disease.

Cynanche laryngea sometimes creates a necessity for the operation, and this is particularly the case when the disease is situated in the edges of the rima glottidis, which opening becomes so contracted, as scarcely to leave the smallest space. For this reason, and on account of the tension of the ligaments of the glottis, the voice is rendered excessively acute and hissing, as it were. The suffocation is imminent; the lungs not being expanded, the blood accumulates in them, and the return of the blood from the head is more or less impeded. There can be little doubt, that many patients who have perished under these circumstances, might have been saved by a timely incision in the trachea. The majority of writers who have treated of bronchotomy as a means of preventing suffocation in inflammatory diseases of the larnyx, have regarded this operation as the ultimate resource. Both the Greeks and Arabians were of this sentiment; and Avicenna only recommends bronchotomy in violent cases of cynanche, when medicines fail, and the patient must evidently die from the unrelieved state of the affection. Rhazes also advised the operation only when the patient was threatened with death. Thus, in former times, though practitioners were aware of the principle on which bronchotomy became necessary, they generally found the operation fail, because it was delayed too long, and rarely done ere effusion had commenced in the lungs.

Bronchotomy, says Louis, will always be done too late, when only practised as an extreme measure. In cases of inflammation about the throat, the danger of perishing by suffocation, as this author remarks, has been known from the very dawn of medicine. The advice of Hippocrates to remedy this urgent symptom, is a proof of it; and he observes, that the danger is evinced when the eyes are affected and prominent, as in persons who have been strangled, and when there is great heat about the face, the throat, and neck, without the appearance of any external defect. He recommends *fistula in fauces ad maxillas intrudenda, quâ spiritus in pulmones trahatur.* No doubt he would have advised more, had it not been for the doctrine of his time, that wounds of cartilages were incurable.

This method, defective as it was, continued till the time of Asclepiades, who, according to Galen, was the first proposer of bronchotomy. Since Asclepiades, this operation has always been recommended and practised in case of quinsy threatening suffocation, notwithstanding the inculcation of Cælius Aurelianus, who treated it as fabulous. The mode of doing it, however, has not been well detailed by any body who put it in practice, except Paulus Ægineta, who is precise and clear. "We must (says he) make the incision in the trachea, under the larynx, about the third or fourth ring. This situation is the most eligible, because it is not covered by any muscle, and no vessels are near it. The patient's head must be kept back, in order that the trachea may project more forwards. A transverse cut is to be made between two of the rings, so as not to wound the cartilage, only the membrane." The knowledge of this method, and its advantages in cases of the *angina strangulans*, when practised in time, ought, according to Louis, to have rendered its performance a general practice.

The convulsive angina of Boerhaave, which particu-

larly affects those who can only breathe well in an upright posture, has also been adduced as a case demanding the prompt performance of bronchotomy. Mead, in his *Precepta et Monita Medica*, mentions a case, in which the patient had been bled very copiously twice in the space of six hours, but he died notwithstanding this large evacuation. The same author noticed in Wales, especially on the seacoast, an epidemic catarrhal quinsy, which carried the patients off in two or three days. In these instances, bleeding was not of much use, and bronchotomy, which was not performed, was the only means by which the patients might have been saved.

In angina and croup, some modern practitioners are less sanguine in their expectation of benefit from bronchotomy than Louis was. From the observations of Dr. Cheyne, it would appear that in croup, the operation cannot be necessary for the purpose of admitting air into the trachea; for in those who have died of the disease, he has found a pervious canal of two-eighths of an inch in diameter, and through a tube of such diameter, even an adult can support respiration for a considerable time. According to the same writer, bronchotomy is equally unfitted for the removal of the membrane formed by the effusion of lymph; for, from its extent, variable tenacity, and adhesions, this is, in almost every case, totally impracticable; and even could the whole membrane be removed, still the function of respiration would be but little improved, the ramifications of the trachea and bronchial cells remaining obstructed.—(See *Cheyne's Pathology of the Larynx and Bronchia.*)

No doubt, Dr. Cheyne's statement of what is found in the dead subject is correct; and yet the operation may be necessary to prevent suffocation, which might otherwise be induced, partly by the diminution of the natural passage for the air by disease, and partly by the action of the muscles of the glottis; a circumstance to which Dr. Cheyne has not assigned sufficient importance. On this point, the sentiments of Mr. C. Bell are more correct; speaking of the membrane of croup, formed by the effusion of coagulable lymph, and of the cause of death in these cases, he says, "It has not appeared to me that it was the violence of the inflammation which destroyed the patient, nor the irritation directly from the inflamed membrane; but that the presence of this secreted membrane, acting like a foreign bo y, at the same time occasions spasms in the glottis, obstructs the passage, and confines the mucus. But I am bound to state in the strongest terms, that death is ultimately a consequence of effusion in the lungs, occasioned by the continued struggle and difficulty; for on opening the chest I have uniformly found, that the lungs did not collapse, and that the bronchiæ were full of mucus. This corresponds with the symptoms; for, before death, the violence of the cough and struggle has given place to coldness and insensibility, with a pale swelling of the face and neck, and *when the child has fallen into this state, giving freedom to the trachea will be of no avail.*"—(*Surg. Obs. p.* 16.)

In the cases of croup which Mr. Chevalier examined after death, he found the trachea obstructed with mucus, and he believed, that it is more by this secretion than by that of coagulable lymph that suffocation is finally produced. At all events, he succeeded in saving a boy on the point of suffocation, by making an incision in the trachea, and letting out an ounce, or an ounce and a half, of reddish brown, frothy mucus. And a case, of a very similar description, in which the same practice answered, I attended, a few years ago, with Mr. Lawrence and Dr. Blicke. This case, however, was different from Mr. Chevalier's, in the circumstance of a tube being required for a couple of days after the operation, when the removal of the instrument was followed by no inconvenience.

Pelletan joins several modern writers in representing bronchotomy as generally useless in cases of croup; the only example in which he thinks the operation might be serviceable being that in whicht he disease is confined to the larynx; a case which he sets down as uncommon, and difficult to be distinguished. "*En supposant enfin l'angine avec concrétion bien caractérisée, on se trouvera encore entre la crainte de pratiquer une opération inutile, si les concrétions se prolongent jusque dans les bronches, et l'impossibilité de juger si ces concrétions sont bornées au larynx. C'est en effet dans ce seul cas que l'operation peut être fructueuse; elle facilitera la respiration pendant que la nature, aidée de l'art, travaillera à dissoudre, détacher, et faire expectorer les fausses membranes qui oblitèrent la glotte et le larynx.*"—(*Clinique Chir. t.* 1, *p.* 28.)

Of course, the degree of success which will attend the practice of bronchotomy, in cases of this nature, must always mainly depend upon the operation being done early enough, and in cases where the lungs are not too seriously affected; for if the effects of pneumonia are far advanced, the patient's chance of recovery will be hopeless, whether the trachea be opened or not. In order, also, to have a reasonable chance of success, in cases threatening suffocation from inflammation of the parts about the fauces, as sometimes happens, the operation must not be deferred too long. We see this fact exemplified in two cases recorded by Flajani; in one, where the operation had not been allowed till a late period of the disease, the patient died; in the other, where the practice was adopted earlier, life was preserved.—(*Collezione d'Osservazioni, &c. t.* 3, *p.* 230—233.)

A few years ago, Dr. Baillie published three cases, in which death was produced in the adult subject, and in a very few days, by a violent inflammation of the larynx and trachea. The disease had a strong resemblance to croup; yet was different from it. There was not the same kind of ringing sound of the voice as in croup, and no layer of coagulable lymph was formed upon the surface of the inner membrane of the larynx and trachea, which, according to Dr. Baillie, uniformly attends the latter disease. In one of these cases, the cavity of the glottis was found to be almost obliterated, by the thickening of the inner membrane of the larynx at that part. The inner membrane of the trachea was likewise inflamed; but in a less degree. The lungs were sound. If, in thirty hours, no relief should be derived from bleeding ad deliquium, and the exhibition of opiates, Dr. Baillie conceives, that, in this sort of case, it might be advisable to perform the operation of bronchotomy at the upper part of the trachea, just under the thyroid gland. This operation, he thinks, would probably enable the patient to breathe till the inflammation in the larynx, more especially at the aperture of the glottis, had time to subside.—(See *Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 3, *p.* 275. 289.)

An acute affection of the membrane of the glottis, proceeding rapidly to a fatal termination by suffocation, has also been particularly described by Drs. Farre and Percival.—(See *Med. Chir. Trans. vols.* 3 *and* 4.) In some bodies, which Mr. Lawrence examined after death, he found appearances analogous to those mentioned by the above physicians. "The patients died of suffocation: but the progress of the complaint was much slower than in those cases; the symptoms were not acute, nor did the inspection of the parts disclose any evidences of active inflammation. The membrane covering the chordæ vocales was thickened, so as to close the glottis, and a similar thickening extended to a small distance from these parts, accompanied with an œdematous effusion into the cellular substance under the membrane. The epiglottis did not partake of the disorder. In one or two instances, this thickened state of the membrane was the only change of structure observed; but in others it was attended either with ulceration of the surface near the glottis, appearing as if it had been formed by an abscess, which had burst, or with a partial death of one or more of the cartilages of the larynx, viz. the arytenoid, thyroid, or crycoid. The rest of the air-passages and the lungs were healthy."—(*Med. Chir. Trans. vol.* 6, *p.* 222.)

In such examples, this gentleman is a zealous advocate for the early performance of bronchotomy, and he has cited several instances in which this operation was successfully performed, both for the relief of quinsy and the extraction of foreign bodies from the trachea.

What Bayle called *l'œdeme de la glotte*, no doubt, was the same kind of disease as that noticed by Mr. Lawrence: one case of it, in which tracheotomy was performed with success, and another in which the patient died suddenly, suffocated in consequence of the operation not being done, have been published by Liston.—(See *Edin. Med. and Surg. Journ. vol.* 19, *p.* 568.)

The affections of the larynx, requiring bronchotomy, would seem, indeed, to be more numerous and diversified than is usually supposed: thus, Mr. C. Bell mentions the case of a medical student, who was attacked with shivering, fever, and sore throat, and in three days

died of suffocation. On dissection, no obstruction in the larynx was observed, but only an inflammation of its membrane, and a spot like a small-pox *pustule* upon the margin of the glottis.—(*Surgical Obs. part* 1, *p.* 14.)

Children sometimes inadvertently drink boiling water from the spout of a tea-kettle. "The effects of this accident (says Dr. Hall) are not, as might be supposed, *à priori*, the symptoms of inflammation of the œsophagus and stomach, but of inflammation of the glottis and larynx, resembling those of *croup;* and the case constitutes another instance, in which the operation of laryngotomy, or of tracheotomy, may be performed with the effect of preventing impending suffocation, and perhaps of saving life."—(*Med. Chir. Trans. vol.* 12, *p.* 2.) The cases and remarks collected by Dr. Hall, Mr Gilman, and Mr. Stanley, on this new subject, cannot fail to be highly interesting to practitioners. In a case of the foregoing description, Mr. Wallace, of Dublin, performed tracheotomy with success.—(See *Lond. Med. and Phys. Journ. for July*, 1822.) Mr. Burgess, who has seen five cases, in which boiling water was taken into the throat, thinks that death, when it follows, is almost always produced by, obstructed respiration. In one of the examples which he has recorded, bronchotomy was the means of saving the child.—(See *Dublin Hospital Reports, vol.* 3.)

Great mechanical injury of the larynx, caused by a blow or fall, may create the necessity for bronchotomy, as is proved by a case lately reported by Mr. Liston.—(See *Ed. Med. and Surgical Journ. vol.* 19, *p.* 570.)

[There is no inconsiderable diversity of opinion among eminent surgeons as to the propriety of performing bronchotomy in cases of croup; and those who oppose the operation, very plausibly allege, that in the membranous stage of croup no advantage can result from the operation, however favourable the condition of the sufferer may be in other respects. The views of the celebrated Cheyne would seem to put beyond doubt the inutility of the operation as already noticed by our author, because it is inadequate to the removal of the artificial membrane which is effused in the advanced stage of cynanche trachealis. I am not prepared, from my own experience, wholly to decide the difficulty. We have evidence sufficient, I think, to justify an occasional recourse to this exercise of surgical skill; but there is still another means of relief, not stated by our author, that may fitly be introduced here, which will often render this operation unnecessary, even in those cases in which it is confidently recommended by some, and certainly ought to be fully tested before we avail ourselves of so doubtful a remedy.

In that stage of croup which has been aptly termed the fatal stage, from its so generally proving such, and which is characterized by the existence of the membrane, the vitriolic emetics have been introduced with decided success.

This practice was first introduced by Professor Francis, of New-York, in 1813; and since the report of his success, has become very generally adopted in this country, and with singular success. I have now in my possession a specimen of an entire membrane lining the trachea, detached and thrown up under the powerful emetic action of the blue vitriol, after venesection, blisters, calomel, polygala senega, and all the approved remedies had been tried ineffectually.

I regret that the limits assigned me preclude my inserting the interesting detail of the cases reported by Dr. Francis, in his valuable paper published on this subject, and have to content myself with referring to the *N. Y. Med. and Phys. Journ. vol.* 3, *p.* 58, *et seq.*, only remarking, that in the almost hopeless state in which the sequela of inflammation are so threatening, *calomel*, in large doses, is among the most efficient auxiliaries to which we can have recourse. "After the existence of the membrane," observes Dr. F., "and when the powers of life are on the wane, it is a judicious and sometimes an available resource;" and he admits, that in the cases in which he found the vitriolic emetics successful, their agency was probably favoured by that potent mercurial.

I find a similar practice has been adopted by Dr. Hoffman, of Vienna, who first used the vitriolic emetics in 1820; and so highly does he estimate them, that he declares their action to be a *specific* in this stage of croup. This is unquestionably saying too much in their behalf; yet certainly they are entitled to high consideration, and ought never to be omitted in these almost hopeless cases.—*Reese.*]

2. The compression of the trachea by foreign bodies, lodged in the pharynx, or by tumours, formed outwardly, and of sufficient size to compress the windpipe, but not admitting of immediate removal, is an equal reason for operating more or less expeditiously, according to the symptoms. Mr. B. Bell mentions two instances of suffocation from bodies falling into the pharynx. Respiration was only stopped for a few minutes; but the cases were equally fatal, notwithstanding the employment of all the usual means. This author thinks, that bronchotomy would have been attended with complete success, if it had been performed in time. The operation should also be done, when the trachea is dangerously compressed by tumours. The author of the article *Bronchotomie*, in *l'Encyclopédie Méthodique*, says, that about twenty years ago he opened a man, who had died of an emphysema, which came on instantaneously. He had had, for a long while, a bronchocele, which was of an enormous magnitude towards the end of his life. The cavity of the trachea was so obliterated, that there was scarcely room enough to admit the thickness of a small piece of money. Doubtless, bronchotomy, performed before the emphysema made its appearance, might have prolonged this man's days.

In cases of this last description, Desault would have advised the introduction of an elastic gum catheter into the trachea from the nose, in order to facilitate respiration. This practice, I believe, has not hitherto been attempted by English surgeons.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 236, &c.)

Habicot successfully performed this operation on a lad fourteen years old, who, having heard that gold, when swallowed, did no harm, attempted to swallow nine pistoles, wrapped up in a piece of cloth, in order to hide them from thieves. The packet, which was very large, could not pass the narrow part of the pharynx; and here it lodged, so that it could neither be extracted nor forced down into the stomach. The boy was on the point of being suffocated by the pressure which the foreign body made on the trachea; and his neck and face were so swollen and black, that he could not have been known. Habicot, to whose house the patient was brought, attempted in vain, by different means, to dislodge the foreign body. At length, perceiving the patient in evident danger of being suffocated, he resolved to perform bronchotomy. This operation was no sooner done, than the swelling and lividity of the face and neck disappeared. Habicot pushed the pieces of gold down into the stomach with a leaden probe, and the pistoles were, at different times, discharged from the anus, eight or ten days afterward. The wound of the trachea soon healed.—(See *Mem. de l'Acad. de Chirurgie, tome* 12, *p.* 243, *edit. in* 12*mo.*)

In such a case Desault would have introduced an elastic gum catheter into the larynx, instead of performing bronchotomy, which could not answer, were the foreign body low down.—(See *Œuvres Chirurg. de Desault, t.* 2, *p.* 247.)

3. Foreign bodies in the trachea may render it necessary to practise bronchotomy. Here I ought rather to say, perhaps, laryngotomy, which by several modern surgeons is deemed most applicable.—(*Desault; C. Bell, Surg. Obs. part* 1, *p.* 47, &c.)

Louis, in an excellent memoir on extraneous substances in the trachea, has proved, more convincingly than all other preceding writers, the necessity of the operation in circumstances of this kind. The following case fell under his observation.

On Monday, the 19th of March, 1759, a little girl, seven years of age, playing with some dried kidney-beans, threw one into her mouth and thought she had swallowed it. She was immediately attacked with a difficulty of breathing and a severe convulsive cough. The little girl said she had swallowed a bean, and such assistance as was thought proper was given her. Want of success was the cause of several surgeons being successively sent for, who vainly employed the different means prescribed by art for extracting foreign bodies from the œsophagus, or forcing them into the stomach. A fine sponge cautiously fastened to the end of a whalebone probang, was repeatedly introduced through the whole extent of the œsophagus. The little girl, who made a sign with her finger, that the foreign body was situated in the middle of the neck, thought that she felt some relief when the sponge was conveyed below the place which she pointed out. She had every now and then a violent cough, the efforts attending which produced convulsions in all her limbs. Degluti-

tion was unobstructed; and warm water and oil of sweet almonds had been swallowed without difficulty. Two whole days had been passed in sufferings, when the relations called in Louis. The little girl, with all possible fortitude and sense, was several times held in her friends' arms ready to die of suffocation. Louis, well aware of what had happened, came into the room where the patient was. She was sitting up in her bed, suffering no other symptom than a very great difficulty of breathing. Louis inquired where she felt pain, and she made such a sign in reply, as left no doubt concerning the nature of the accident. She put the index finger of her left hand on the trachea, between the larynx and sternum. The fruitless attempts which had been made in the œsophagus with a view of dislodging the foreign body; the nature and the smallness of this body, which was not such as would be stopped in the passage for the food; and the facility of swallowing, were negative proofs that the bean was not in the œsophagus. Respiration was the only function disturbed; it was attended with difficulty and a rattling in the throat. The little girl expectorated a frothy fluid, and she pointed out so accurately the painful point where the object producing all her sufferings was situated, that Louis did not hesitate to declare to the relations, from this single inspection, that the bean was in the windpipe, and that there was only one way of saving the child's life, which was to make an incision, for the purpose of extracting the foreign body. He apprized them, that the operation was neither difficult nor dangerous, that it had succeeded as often as it had been practised, and that the very pressing danger of the case only just allowed time to take the opinion of some other well-informed surgeons, respecting the indispensable necessity for such an operation. Louis thought this precaution necessary in order to acquire the confidence of the parents, and to shelter himself from all reproach in case the event of the case should not correspond with his hopes. Louis went home to prepare all the requisites for bronchotomy, and in two hours he was informed the surgeons who were consulted waited for him. After Louis went away, the child had become quiet, and was now lying on its side asleep. The opinion he had delivered had been ill explained by the friends and attendants, and had been discussed before his return. They who had been rendering their assistance, on the supposition that the foreign body was in the œsophagus, evinced surprise at the proposal of extracting by an operation a substance, the presence of which in any part of this tube was not obvious. Louis explained his advice in regard to bronchotomy, and did not expect a doubt to be set up against so positive a fact. It was objected, that a substance as large as a bean could not insinuate itself into the trachea. He brought every one into his sentiment by a short explanation of cases of this sort with which he himself was acquainted. The little girl was examined; she was better than when Louis saw her before, and a very palpable emphysema was seen above the clavicle on each side of the neck, a symptom which did not exist two hours previously. This swelling made Louis conclude, that the urgency for the operation was still greater. The friends, whose confidence had been shaken by the opposition he had experienced in bringing about unanimity, were in the greatest embarrassment when they were told, that the child might die of an operation which he had represented as only a simple incision free from all danger. Louis was repeatedly asked, if he would be responsible for the child's life during the operation, and he in vain replied, that if there were any thing to fear during the operation, it would be from the accident itself and not from the assistance rendered. This distinction was not perceived, and Louis withdrew, at the same time refusing his consent to the exhibition of two grains of emetic tartar, the effect of which would be useless and might be dangerous. The medicine was given in the night: the child was fatigued with its operation and quite unbenefited. On Tuesday morning, Louis found the little girl very quiet, and they who had paid their visits earlier, found her wonderfully well. The respiration, however, continued to be still attended with a rattling noise, which Louis had observed in the evening when the breathing was much more laborious. The child was nearly suffocated several times in the course of the day, and died in the evening, three days after the accident.

Bordenave, who had seen the patient, informed Louis of the child's death on Friday. The body was opened before a numerous assembly of persons. After making a longitudinal incision through the skin and fat along the trachea, between the sterno-hyoidei muscles, Bordenave slit open the trachea, cutting three of its cartilages. At this instant every one could see the bean, and Louis took it out with a small pair of forceps. It was manifest, from the ease with which this foreign body was extracted, that the operation would have had on the living subject the most salutary effect. The relations had to regret having sacrificed a child which was dear to them to an irresolution and a timidity which the most persuasive arguments could not remove.—(*Mém. de l'Acad. Royale de Chirurgie, t.* 12, *p.* 293, *&c. édit. in* 12*mo.*)

This case strikingly illustrates the symptoms which result from the presence of foreign bodies in the trachea, and shows the only surgical proceeding which can be of use. But among the phenomena apparently difficult of explanation, is the calm which at intervals followed the afflicting cough.—(See *Dr. Hunt's Case in Med. Chir. Trans. vol.* 12, *p.* 27.) Anatomy, however, has dispelled much of the doubt of this matter. It is known, that the whole canal of the trachea is much less sensible than the rima glottidis. A foreign body, like a bean, may remain a certain time in that canal without much inconvenience, the passage being only somewhat obstructed, according to the position of the substance. It may even remain several days, months, or years, without producing any symptom of its presence, except a trivial sensation of obstruction, and this is what happens when the body lodges in one of the ventricles of the larynx. Facts of this kind are to be found in Tulpius, Bartholine, and many other observers. But when the extraneous substance quits its situation and is carried into the trachea, the irritation which it produces there, and particularly about the larynx, occasions coughing; and if, in the fits, the foreign body should become fixed between the lips of the glottis, it may cause instantaneous death, as probably has happened in many of the cases of suffocation from extraneous substances.

Another remarkable circumstance which deserves more attention, as it confirms the presence of a foreign body in the trachea, is the emphysema which appeared about the clavicle towards the termination of the case. Louis did not believe that any of the persons who saw the patient could entertain a just idea of the origin of this symptom. The supposition that the obstruction which the foreign body caused, for two days, to the free passage of the air, might have occasioned a forcible distention of the trachea, and a rupture of the membrane which connects together the cartilaginous rings of this tube, was dispelled by the examination after death. The windy tumour had not originated in the circumference of the trachea; here its limits were only seen. The very substance of the lungs and the mediastinum were emphysematous. The air confined by the foreign body had ruptured the air-cells during the violent fits of coughing, and thus insinuated itself into the interlobular cellular substance of the lungs. Thence it had passed into the cellular substance of the lungs; and afterward into that connecting the pleura pulmonalis with the outer surface of these organs; and by the communication of these cells with each other, it had produced a prodigious swelling of the cellular substance between the two layers of the mediastinum. The emphysema, in its progress, at length made its appearance above the clavicles. The swelling of the lungs and the circumjacent parts, in consequence of the insinuation of air into the cellular substance, is a manifest cause of suffocation. The tumefaction appears to be so natural an effect of the presence of a foreign body in the trachea, that one can hardly believe it is not an essential symptom, though before Louis no author had made mention of it.

Foreign bodies in the trachea, however, do not always cause death so suddenly, which may be owing to their smallness, their smoothness, or the situation in which they are fixed. An example is related in the *Ephemer. Cur. Naturæ, Decad.* 2. *Ann.* 13. As a monk was swallowing a cherry, the stone of the fruit passed into the trachea. A violent cough and excessive efforts, as it were, to vomit, were the first symptoms of the accident, and of these the patient thought he should have died. A sleep of some hours followed this terrible

agitation, and the patient afterward did not feel the least inconvenience during a whole year. At the end of this time he was attacked by a cough attended with fever. These symptoms became worse and worse every day. At length the patient evacuated a stone as large as a nutmeg. It was externally composed of tartareous matter, to which the cherry-stone had served as a nucleus. A copious purulent expectoration followed the discharge of the foreign body, and the patient died consumptive some time afterward. No mention is made of the body being opened; but from the symptoms, there is every reason to believe, that an abscess must have arisen in the substance of the lungs from the presence of the foreign body. That foreign bodies in the trachea, even when they do not induce pressing symptoms of suffocation, may ultimately kill the patient by inducing disease of the lungs, is proved by several cases on record, and particularly by one which occurred to Desault: a cherry-stone was lodged in one of the ventricles of the larynx; the patient would not consent to an operation, and died in two years *d'une phthisie laryngé*.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 258.)

Some valuable observations confirming the necessity of an early recourse to bronchotomy, in cases where foreign bodies are lodged in the trachea, have been published by Pelletan. In one case, in which a bean had fallen into a child's trachea, and in which the most urgent symptoms of suffocation had prevailed for four days, and convulsions during the last thirty-six hours of this space of time, Pelletan performed the operation, which a timid practitioner, under whose management the patient was first placed, had neglected to do at an earlier period. Upon the incision being made into the trachea, the bean was immediately thrown out to the distance of two feet, and the child for a time was relieved. The little boy was so extremely weak, that it was at one time supposed he was dead. However, with some assistance, he gradually revived, even regained his senses, called his parents, and asked for such things as he wanted.

This hopeful state lasted eight or ten hours, after which convulsions came on again, and the child died fourteen hours after the operation.

Notwithstanding the turgid appearance of all the blood-vessels of the brain, as detected after death, the little boy had yet received a degree of relief at the instant of the foreign body being extracted. Pelletan deems it unnecessary to insist on the great possibility of success that would have attended the operation had it been performed at an earlier period.

Of such success, Pelletan gives us the following example.

In the month of May, 1798, a child about three years old, was brought to the Hôtel-Dieu, who, in playing with some French beans, and putting them into its mouth, let one of them slip into the trachea. For three days the child was afflicted with a continued cough, and sometimes the symptoms of suffocation were most pressing. The time had been spent in administering emetics, introducing instruments into the œsophagus with the design of forcing the foreign body into the stomach, and in inspiring the relations with a pernicious confidence, arising from the very long intervals of repose which the child experienced, during which, however, a rattling in the throat continued, a characteristic mark of the accident. Pelletan immediately decided to perform the operation. The child was very fat, and this circumstance, together with the small diameter of the trachea at this age, rendered the exposure of the anterior portion of the tube difficult. Pelletan was at this moment struck with the reflection, that bronchotomy should never be attempted except by men of science, coolness, and experience in operations. The rings of the trachea, however, were at length cut, and there was no sensible interval between the incision and the expulsion of the foreign body. The bean had swelled considerably with the moisture. The child seemed restored to life; it spoke freely; it was only troubled with coughing, the effect of a small quantity of blood insinuating itself into the trachea, which fluid was instantly rejected again. This event has the appearance of convulsions, and may alarm those who do not understand it; but according to Pelletan, it is the guarantee of the patient's life, by expelling incessantly and without difficulty, whatever happens to get into the trachea. The wound was healed in twenty days, and the child's voice was not perceptibly altered.

In another interesting case recorded by the same writer, a pebble was lodged in the windpipe, and the case, not being understood, was treated for about three weeks as a simple inflammation of the lungs. At last bronchotomy was performed, and by placing the child in a horizontal position the stone was soon discharged through the incision. The patient was immediately relieved; but the effects of the inflammation of the lungs, and injury which these organs had sustained, could never be cured, and the child died phthisical eight months afterward.

Pelletan details other cases in which the foreign body, being fixed in the trachea, could not be forced out by the breath as soon as the incision had been made, but required farther means to disengage it. In one instance Pelletan made a long cut in the windpipe of a child; but nothing made its appearance. A probe, wrapped round with some oiled linen, was then introduced several times up and down the larynx without creating a great deal of uneasiness, and the child continued to respire very well through the opening in the trachea. The foreign substance was presently brought to the wound and extracted: it proved to be part of the jaw of a mackerel, with many sharp teeth in it. This child soon experienced a perfect recovery.

In another instance, a young man came to the Hôtel-Dieu, in consequence of being afflicted for six weeks with a severe cough, frequently accompanied with a sense of suffocation. These complaints, on inquiry, were ascertained to arise from a button-mould having fallen into the trachea. An opening was therefore made in this tube; but though the button could be felt, it could not be extracted with the finger. The cricoid cartilage was now divided, and the foreign body taken out of the left ventricle of the larynx. The man recovered.

In one case related by Pelletan, a piece of tendon of veal got down the glottis, and gave rise to most dangerous symptoms. The foreign body was described as being so large that this surgeon could not but suppose that the complaints were owing to its lodgement in the œsophagus, as it seemed to be incapable of entering the glottis. The introduction of instruments down the pharynx, however, produced do relief; but, on dividing the thyroid cartilage, Pelletan passed his finger within the larynx, and, without knowing it, pushed the piece of tendon towards the glottis, when, with the aid of a probang, it was forced into the pharynx and swallowed. The patient experienced immediate relief, and got quite well.—(*Clinique Chir. t.* 1.)

With respect to bronchotomy or laryngotomy, for cases in which extraneous substances are supposed to be lodged in the trachea, one important caution seems necessary, viz. whenever the foreign body is above a certain size, a probang should be passed down the œsophagus before the windpipe is opened, for very similar symptoms to those which proceed from extraneous substances in the trachea may be caused by the lodgement of foreign bodies in the œsophagus. In fact, bronchotomy has actually been performed, while the extraneous substance was in the œsophagus, from which last situation no attempt was made to displace it, and the patient lost his life.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 261.) Examples in which various extraneous bodies have been successfully extracted by means of bronchotomy, are recorded by Engel.—(*Sendschreiben an Schmid, &c. Augsp.* 1750; *Guincourt, Journ. de Méd. vol.* 12, *p.* 44; *Heister, Wahrnehmungen, b.* 1, *p.* 1026; *Wendt, Hist. Tracheotomiæ, &c., Urastisl.* 1774. *Dr. Hunt, in Med. Chir. Trans. vol.* 12, *&c.*)

4. Bronchotomy has been proposed in cases in which the tongue is so enlarged as totally to shut up the passage through the fauces. Richter mentions an inflammation of the tongue, in which it became four times larger than in the natural state. Valescus had made the same observation: "*Ego aliquando vidi ità magnificatam linguam propter humores, ad ejus substantiam venientes, et ipsam imbibentes, quod quasi totum os replebat, et aliquando ex ore exibat.*"—(*Lib.* 2, *cap.* 66.) Such prodigious swellings of the tongue are said sometimes to occur in malignant fevers and the small-pox. They are also sometimes quite accidental, as, for instance, the cases which happen from the stings of insects, or the unskilful employment of mercury. Mr

B. Bell gives an example of the latter sort. He says, that the patient had taken in a very short time so large a quantity of mercury, that the part became alarmingly swollen in a few hours, and, though all the usual remedies were tried, none had the least effect. Bronchotomy was delayed till the patient was nearly suffocated; but he was restored as soon as an opening was made in the trachea. Some have objected to this practice, alleging that scarifying the tongue will bring relief in time.—(*Encyclopédie Méthodique: partie Chirurgicale, art. Bronchotomie.*) Malle's observations on the swelling of the tongue, and the most effectual means of relieving it, seem to confirm the latter sentiment.—(*Mém. de l'Acad. de Chirurgie, t.* 14, *p.* 408, *&c. édit. in* 12*mo.*)

In cases of the preceding description, Desault would have advised the introduction of an elastic gum catheter from the nose into the trachea, in order to enable the patient to breathe, until the swelling of the tongue had subsided.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 246.)

5. Bronchotomy has been recommended when both the tonsils are so enlarged as very dangerously to impede respiration. Here the inflammatory swelling is not meant; this commonly soon suppurates, and the spontaneous bursting of the tumour, or the opening of it with a pharyngotomus, generally removes all necessity for so extreme a measure. But even in acute inflammation and great enlargement of the palate, tonsils, &c. attended with imminent danger of suffocation, the practice has been sometimes deemed necessary, as the cases cited from Flajani in the preceding columns are sufficient to prove. The disease, however, which I here wish particularly to specify, as sometimes rendering bronchotomy indispensable, is a chronic enlargement of the tonsils, the case mentioned in the article *Tonsils*. From the remarks on the disease, however, it will be seen that more is to be expected from the excision of the tonsils than from the operation now in question. Besides, before the glands are so large as to threaten suffocation, they should be cut away in preference to performing bronchotomy, which might relieve the urgency, but could not remove the cause of the difficulty of breathing. In general, there is no urgent danger of suffocation till the swelling is such as not only to shut up the posterior aperture of the mouth, but also the posterior openings of the nostrils, which is exceedingly rare. In cases of obstructed respiration from enlargement of the tonsils, Desault preferred the introduction of the elastic catheter from the nose into the larynx, to the operation of bronchotomy. It is not common for a polypus to make this operation necessary. Boerhaave, however, mentions a case, in which the patient was suffocated as the surgeon was going to extirpate a tumour of this kind: no doubt this patient might have been saved if bronchotomy had been previously performed. Polypi growing in the larynx itself are very rare, but examples are recorded; and if such tumours happen to obstruct the glottis the patients are instantly suffocated. Some instances of this kind are related by Bichat. The only mode of getting at such swellings so as to extirpate them, is by performing bronchotomy.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 254, 255.)

6. Lastly, bronchotomy has been recommended to be done on persons recently suffocated or drowned. Detharding is the first author who has treated of the necessity of this operation in the latter case, in a letter addressed to Schroeck, entitled *De Methodo subveniendi Submersis per Laryngotomiam.* Haller approves of the practice, provided the mucous secretion with which the lungs are loaded should require to be discharged in this manner. Detharding maintains that drowned persons have no water in their chests or air-vessels of the lungs, and that they perish suffocated for want of air and respiration, and that while the person is under water the epiglottis applies itself so closely over the glottis, that not one drop of water can pass. But these assertions are quite contrary to numerous experiments made by Louis, who drowned animals in coloured fluids, and proved that such as are drowned inspire water, with which the air-vessels and cells are quite filled. Louis also opened men who had perished under water, but in them he never found the epiglottis applied to the glottis in the manner described by Detharding; indeed, anatomy proves the impossibility of its being so. Dotharding's theories were wrong, and, as he did not use any power to distend the lungs with air, his mere practice of bronchotomy must have been useless. When there is a free communication between the cells of the lungs and the atmosphere, the air will not expand these organs if the inspiratory muscles can no longer act. Hence, after opening the trachea, and letting as much water run out of this tube as possible, the pipe of a pair of bellows should be introduced, and the air blown into the lungs.

Detharding was right in his opinion, that drowning is a species of suffocation, and that the privation of oxygen gas is the cause of death. Hence the propriety of introducing air into the lungs as speedily as possible, whenever animation has not been so long suspended that every hope of restoration is over. Indeed, it is proper to distend the lungs with air in all cases in which animation has been recently suspended by suffocation, immersion under water, or by noxious vapours and gases. This measure is highly proper, in conjunction with electricity or galvanism; the communication of warmth to the body; the application of strong volatiles to the nostrils; rubbing the body with warm flannels; and the injection of warm wine or brandy and water into the stomach through a hollow bougie. However, tobacco clysters, which have had the sanction of the Royal Humane Society, should be reprobated, as the qualities of this plant are peculiarly destructive of the vital principle, and not simply stimulating. I am sorry to find this last means commended by so respectable a surgeon as Baron Larrey, who joins the rest of the French surgeons in condemning electricity and bronchotomy. He speaks in favour of opening the jugular vein, exposing the body to the fire, friction, &c. On dissecting the bodies of some drowned persons, Larrey found, as Louis had done long since, that the air-tubes of the lungs were filled with water instead of air, and that the epiglottis was raised and applied to the os hyoides.—(See *Mémoires de Chir. Militaire, t.* 1, *p.* 83—85.

There are many modern practitioners who consider bronchotomy needless in cases of suspended animation, because it is contended, that, as the patient is always destitute of sensation, a tube may easily be passed into the trachea from the nose or mouth, for the purpose of inflating the lungs. Either the curved pipe of a pair of bellows may be introduced into the glottis through the mouth, or an elastic gum catheter may be passed into the trachea from the nose. "*On peut mettre ce moyen à exécution* (says Pelletan) *chez les asphixiés, ou les enfans nouveaux nés, qui ne respirent pas; parceque, dans ces différens cas non seulement il n'y a pas d'inflammation, mais même toute sensibilité est suspendue, et la canule est commode pour souffler de l'air dans les poumons, en même temps qu'elle peut causer une irritation salutaire. M. Baudeloque, mon célèbre confrère, m'a temoigné se servir habituellement, et avec succès de ce moyen pour appeler à la vie les nouveaux nés dont la respiration ne s'établit pas.*"—(*Clinique Chir. t.* 1, *p.* 29.) Desault likewise conceived, that the lungs might be easily inflated without performing bronchotomy.—(*Œuvres Chir. t.* 2, *p.* 339.) Mr. A. Burns adopts the same sentiment.—(*Surgical Anatomy of the Head and Neck, p.* 384.) My own individual opinion upon this subject is, that if a surgeon knows that he can inflate the lungs as completely and expeditiously without performing bronchotomy, as he can by making an incision in the trachea, he is right in dispensing with the latter operation. But in the generality of cases of suspended animation (that of new-born infants excepted, where bronchotomy would be an objectionable undertaking), I much doubt whether in actual practice bronchotomy will not be found the best and most speedy means of enabling the surgeon to distend the lungs with air. If you follow Desault's suggestion, I contend that you are likely to be some minutes longer in getting the elastic catheter from the right nostril into the larynx, than you would be in cutting into the trachea and introducing into the incision the muzzle of a pair of bellows. Supposing the elastic catheter introduced, will you now be able to distend the lungs with air in an adequate degree, an object of the highest moment? A pair of bellows seems to me almost essential to this purpose. I shall say nothing on the probability of many practitioners coming to the patient unprovided with the requisite sort of tube.

If a pair of bellows with a curved pipe be employed, many surgeons would be a considerable time in getting

the nozzle into the glottis; and, in the mean while, every spark of life might be extinguished. On the other hand, bronchotomy (performed by a man of ordinary care and skill) is an operation free from danger. It may be executed with a penknife if no better instrument be at hand; and when the incision has been made, a pair of common bellows will suffice for the inflation of the lungs. Did I conceive that bronchotomy were a perilous operation; that the lungs could be effectually distended without the employment of bellows; that the object could generally be accomplished as expeditiously without cutting into the trachea; I should be as ready to join in the condemnation of this last proceeding as any contemporary writer. Greatly, however, as I respect most of the authors who differ from me on this point, the reasons I have assigned prevent me from subscribing to their sentiment. Desault, who may be regarded as the founder of the doctrine, concerning the inutility of bronchotomy, it is also to be observed, spoke only from theory, and not actual practice, in these cases.

With respect to the performance of the operation, no preparation is necessary, as delay only increases the danger. The patient being seated in an arm-chair, or, what is better, laid on a bed, with his head hanging backwards, an incision is to be made, which is to begin below the cricoid cartilage, and to be continued downwards about two inches, along the space between the sterno-thyroidei muscles. Care should be taken not to cut the lobes of the thyroid gland, lest a troublesome and dangerous bleeding be occasioned; and, as the left subclavian vein lies a little below the upper part of the first bone of the sternum, the incision should never extend so low as this point. The knife must not be carried either to the right or left, in order to avoid all risk of injuring the large blood-vessels situated at the sides of the trachea. The incision in the integuments having been made, the sterno-thyroidei muscles are to be pushed a little towards the sides of the neck, so as to bring the trachea fairly into view. Many authors recommend the point of the knife to be then introduced between the third and fourth cartilage of the trachea, and the opening to be enlarged transversely. It is true that in this way an opening may be safely made, large enough to allow a small cannula to be introduced. It is safer, however, in all cases, to enlarge the opening in the perpendicular direction, by cutting from within outwards. There is no advantage in avoiding a wound of the cartilages of the trachea, the only reason assigned for cutting the membrane between them, in a transverse direction; while a sufficiently large opening cannot thus be safely obtained, in cases in which it is necessary to introduce the nozzle of a pair of bellows, in order to inflate the lungs. In short, it is safer and better in every instance, to make the wound in the trachea in a perpendicular manner.

I have stated, that bronchotomy may be performed by a man of ordinary skill without hazard. It is far otherwise with a careless practitioner. We read in Desault's work, that in one instance the carotid artery was wounded. The following cautions, given by Mr. A. Burns, seem entitled to notice. "The arteria innominata is in risk in some subjects. I have seen it mounting so high on the forepart of the trachea, as to reach the lower border of the thyroid gland. Even the right carotid artery is not always safe. I am in possession of a cast, taken from a boy of twelve years of age, which shows the right carotid artery crossing the trachea in an oblique direction. In this subject, that vessel did not reach the lateral part of the trachea till it had ascended two inches and a quarter above the top of the sternum.

Where both carotid arteries originate from the arteria innominata, there is considerable danger in performing the operation of tracheotomy; for in such cases, the left carotid crosses the trachea pretty high in the neck. Professor Scarpa has seen a specimen of this distribution in a male subject, and I have met with five.

These varieties in the course of the arteries are worthy of being known and remembered; they will teach the operator to be on his guard, since he can never, *à priori*, ascertain the arrangement of the vessels with any degree of certainty. It will impress on his mind the impropriety of using the knife farther than merely to divide the integuments and fasciæ. If he then clear the trachea with the fingers, he will never injure any of the large arteries. When with the finger he has fairly brought the trachea into view, he ought to examine carefully, whether any of the large arteries lie in front of it; and if he find one, he ought to depress it towards the chest, before he penetrates into the windpipe.

In cutting into the trachea, the preferable plan is to cut the rings from below upwards, avoiding injury of the thyroid gland."—(See *A. Burns on the Surgical Anatomy of the Head and Neck*, *p.* 393, 394.)

As Mr. Francis White, of Dublin, was performing tracheotomy in a case of cynanche laryngea, "on separating the edges of the sterno-thyroid muscles, the two thyroid veins were exposed, *together with a considerable arterial branch*, the pulsation of which was quite perceptible, directing its course upwards towards the cross-slip of the thyroid gland." Mr. White states, that the artery here spoken of was the branch which Mr. Harrison in his work on the Surgical Anatomy of the Arteries, describes under the appropriate name of middle thyroid artery; and though looked upon as an irregular distribution, it is sufficiently frequent to make it necessary for the surgeon to be upon his guard.—(See *Dublin Hospital Reports*, *vol.* 4, *p.* 563.)

When bronchotomy is performed for the purpose of inflating the lungs, the cut in the windpipe must be made somewhat larger than when an opening is required merely to enable the patient to breathe through a small cannula. The larger size of the pipe of the bellows is the reason of this circumstance.

When a cannula is introduced, care must be taken not to pass it too far into the wound, lest it injure the opposite side of the trachea. This is a caution on which Fabricius ab Aquapendente dwells very strongly, and with good reason.

When tracheotomy has been performed in a case where mucus is secreted in such abundance, that the patient is threatened with suffocation from its accumulation, and his inability to cough it up, owing to the wound in the windpipe, Dr. Cullen is an advocate for the use of a large cannula for the sake of permitting free expiration, the only substitute for coughing, which the patient can no longer effect.—(See *Edin. Med. Journ. No.* 94, *p.* 82.)

Small as the vessels may be which are divided in bronchotomy, they occasionally bleed so much as to create apprehension, and even prevent the continuance of the operation. There is a case in Van Swieten's Commentaries confirming this remark. A Spanish soldier, aged twenty-three, was in the most urgent danger from an inflammation of his throat. It was thought nothing could save him except bronchotomy. After the longitudinal cut in the skin, and the separation of the muscles, the trachea was opened between two of the cartilages; but the blood insinuated itself into this canal, and excited so violent a cough, that the cannula could not be kept in by any means, though it was replaced several times. Louis remarks, that in this instance the patient's head should have been turned downwards, in order to keep the blood from flowing backwards into the trachea. It is asserted, that the opening of this tube was not always opposite the external wound, in consequence of the convulsive action of the muscles, and that the patient on this account could hardly breathe. Hence, Vigili was induced to slit open the trachea, down to the sixth cartilaginous ring; and it was only then that he inclined the patient's head forwards. The bleeding now ceased, the patient breathed with ease, and on the second day the inflammation was so much better, that respiration went on without the aid of the opening in the trachea.

The most simple and natural mode of obviating all trouble from the entrance of blood into the trachea, is to tie any bleeding branch of the thyroid artery or vein before the windpipe is opened.

Sometimes the cannula becomes obstructed with mucus or clots of blood. Such an accident nearly suffocated a patient at Edinburgh. An ingenious person happening to be at hand, suggested the introduction of a second cannula into the first; the second one being taken out and cleaned as often as necessary, and then replaced.

The use of the cannula must be continued as long as the causes obstructing respiration remain. Thus, in one very interesting case of cynanche, detailed in a

modern publication, the patient, thirteen months after the operation, had not been able to discontinue the tube.—(See *Med. Chir. Journ. vol.* 5, *p.* 7.) This example was attended in its progress with a singular circumstance, viz. the expulsion through the cannula of several portions of calcareous matter or bone. In the case operated upon by Mr. F. White, the tube had been worn two years; and in the well-known case of Mr. Price of Plymouth, the instrument had been worn ten years.—(See *Dublin Hospital Reports, vol.* 4, *p.* 565, 566.)

When respiration is suspended by the presence of a foreign body in the trachea, and the extraneous substance does not make its appearance at the opening, a trial may be made to discover its situation by means of a bent probe. When it lies downwards, which it hardly ever does, the wound in the trachea may be enlarged in this direction, and the body extracted with a pair of curved forceps. The extraneous substance is mostly forced out by the air, as soon as the incision in the trachea is opened. When it cannot be immediately found, some practitioners (Heister and Raw) have succeeded by keeping the lips of the wound asunder with a leaden cannula, by which means the force of the air in expiration has in a few hours expelled the foreign body.

Richter gave the preference to a curved cannula; and since his time many surgeons have chosen to use such an instrument, though if it be double the inner tube cannot be so easily introduced as that of a straight one; and no doubt the chief disadvantage of the latter has often proceeded from its having been made of too great length.

In some instances, like that referred to above, a cannula has been borne quietly in the trachea; while in others, it has produced so much irritation, cough, and sense of choking, as to render its immediate removal necessary. Mr. Lawrence, in speaking of the obstruction of the glottis from the disease already adverted to in this article, observes, that when the cannula causes inconvenience, he should advise a longitudinal incision, of about half an inch, in the middle of the trachea, and the removal of a thin slip of the tube, which would leave an artificial opening for respiration, equal in size to the natural one.—(See *Med. Chir. Trans. vol.* 6, *p.* 249.) The same plan was followed by Mr. F. White, and is also sanctioned by Mr. Carmichael.—(See *Dublin Hospital Reports, vol.* 4, *p.* 563, *&c.*, and *Trans. of Assoc. Physicians, vol.* 3, *p.* 174.) When this practice is not adopted, Mr. Carmichael recommends the use of as large a cannula as can be introduced.

On the continent the operation of laryngotomy, which was first advised by Vicq d'Azyr, and recommended by Desault, is frequently preferred to tracheotomy. The surgeon makes an incision over the anterior part of the thyroid cartilage, punctures the crico-thyroid membrane, and, if it be necessary, introduces a director and slits the thyroid cartilage upwards. A single opening in the crico-thyroid membrane would suffice for the introduction of a cannula for the purpose of enabling the patient to breathe; but for the extraction of foreign bodies it would be necessary also to cut the thyroid cartilage. The fact that extraneous substances, when they are loose, are almost always lodged at the upper part of the larynx, proves that laryngotomy, in such cases, must commonly be most advantageous; and according to Desault, even when the foreign bodies are lower down in the trachea, they may in general be most easily extracted with the aid of a pair of curved forceps. In this country laryngotomy has been less commonly practised, though commended a few years since by Mr. Coleman, and more recently by Mr. C. Bell.

"Of the three situations (says Mr. Lawrence), in which it has been proposed to make the opening, viz. in the thyroid cartilage, between that and the cricoid, or in the trachea, I consider the first as the least eligible. Besides the objection from the ossification of the cartilage, and the danger of wounding or otherwise injuring the chordæ vocales, there is the inconvenience in the case of angyna laryngea, arising from the swollen and thickened state of the membrane, which may actually impede the passage of the air. I am not aware of any objection to a transverse opening between the thyroid and cricoid cartilages. The prominence of the former in the neck serves as a guide to the part which should be opened. Whether bronchotomy or laryngotomy ought to be selected, must of course depend upon the nature of the case: in cases of cynanche, the proximity of the inflamed parts would be an objection to laryngotomy; while in examples of foreign bodies within the glottis this operation may generally be most advisable for reasons already explained. It is absurd to think of confining one mode of operating to different cases."—(See *Medico-Chir. Trans. vol.* 6, *p.* 248.)

Of the operation performed in the membranous space Mr. C. Bell entertains a favourable opinion. He directs us to slit up the membrane and open the incision with the handle of the knife, when the patient will immediately breathe with ease. Here, says he, there is nothing to alarm the most timid operator. No great turgid veins are opened; the cut is made above the thyroid gland, and above the anastomosing branch of the thyroid arteries. The part is strongly marked by the prominence of the thyroid cartilage above, and the ring of the cricoid cartilage below. "If the occasion be temporary, a simple slit of the membrane will be found sufficient. If necessary, a transverse cut will afford any degree of opening. If a round hole be desired, the four corners left by the incisions may be snipped off," or the edges of the opening may be kept asunder by means of the double wire of a catheter, the middle part of which lies on the wound, while the ends are bent round the neck and tied by a ligature behind. In Mr. C. Bell's cases, less annoyance was caused by this contrivance than by a tube

[Bronchotomy is frequently performed in this country for the removal of foreign bodies from the trachea, but seldom with any other intention. The situation most generally selected is between the thyroid and cricoid cartilages. Sometimes the foreign body escapes through the wound, or may be extracted by the forceps; at other times, so soon as the air is admitted into the lungs, the force of the respiration expels it through the mouth. I have known several cases in which, although the operation afforded immediate relief to the respiration, yet the escape of the foreign body did not take place for several hours; and in one instance days had elapsed, when it was coughed up with great violence.—*Reese.*]

BUBO. (Βουβών, the groin.) Modern surgeons mean by this term a swelling of the lymphatic glands, particularly of those in the groin and axilla.

The disease may arise from the mere irritation of a local disorder; from the absorption of some irritating matter, such as the venereal poison; or from constitutional causes.

Of the first kind of bubo, that which is named the *sympathetic* is an instance. Of the second, the venereal bubo is a remarkable specimen.—(See *Venereal Disease.*)

The *pestilential bubo*, which is a symptom of the plague, and *scrofulous* swellings of the inguinal and axillary glands, may be regarded as examples of buboes from constitutional causes.—(See *Scrofula.*)

The inguinal glands often become affected with simple phlegmonous inflammation, in consequence of irritation in parts from which the absorbent vessels passing to such glands proceed. These swellings ought to be carefully discriminated from others which arise from the absorption of venereal matter. The first cases are simple inflammations, and only demand the application of leeches, the cold saturnine lotion, and the exhibition of a few saline purges; but the latter diseases render the administration of mercury advisable.

Sympathetic is the epithet usually given to inflammation of glands from mere irritation; and we shall adopt it without entering into the question of its propriety.

The sympathetic bubo is mostly occasioned by the irritation of a virulent gonorrhœa. The pain which such a swelling gives is trifling compared with that of a true venereal bubo, arising from the absorption of matter, and it seldom suppurates. However, it has been contended that the glands in the groin do sometimes swell and inflame from the actual absorption of venereal matter from the urethra, in cases of gonorrhœa, and if this were true the swellings would be venereal; but this doctrine is now nearly exploded. —(*Hunter on the Venereal, p.* 57.)

The manner in which buboes form from mere irritation will be better understood by referring to the occasional consequences of venesection, in the article *Bleeding.* The distinguishing characters of the venereal bubo are noticed in the article *Venereal Disease.*

BUBONOCELE. (From *βουβών*, the groin, and *κήλη*, a tumour.) A species of hernia, in which the bowels protrude at the abdominal ring. The case is often called an *inguinal hernia*, because the tumour takes place in the groin.—(See *Hernia.*)

BUNYON. An inflammation of the bursa mucosa, at the inside of the ball of the great toe.—(See *Brodie's Pathological and Surgical Obs. on the Joints, p.* 356, *ed.* 2.)

BURNS are usually divided into three kinds. 1st. Into such as produce an inflammation of the cutaneous texture, but an inflammation which, if it be not improperly treated, almost always manifests a tendency to resolution. 2dly. Into those which occasion the separation of the cuticle, and produce suppuration on the surface of the cutaneous texture. 3dly. Into others in which the vitality and organization of a greater or less portion of the cutis are either immediately or subsequently destroyed, and a soft slough or hard eschar produced.—(See *Thomson on Inflammation, p.* 585, 586.)

Suppuration is not always an unavoidable consequence of the vesications in burns; but it is a common and a troublesome one. "In severe cases it may take place by the second or third day; often not till a later period. It often occurs without any appearance of ulceration; continues for a longer or shorter time; and is at last stopped by the formation of a new cuticle. In other instances, small ulcerations appear on the surface or edges of the burn. These spreading form extensive sores, which are in general long in healing, even where the granulations which form upon them have a healthy appearance."—(*Op. cit. p.* 595.)

Burns present different appearances, according to the degree of violence with which the causes producing them have operated, and according to the kind of cause of which they are the effect. Burns which only irritate the surface of the skin are essentially different from those which destroy it; and these latter have a very different aspect from what others present which have attacked parts more deeply situated, such as the muscles, tendons, ligaments, &c. Scalds, which are the effect of heated fluids, do not exactly resemble burns occasioned by the direct contact of very hot metallic bodies, or some combustible substance on fire. As fluids are not capable of acquiring so high a temperature as many solids, scalds are generally less violent than burns in the injury which they produce; but in consequence of liquids often flowing about with great rapidity, and being suddenly thrown in large quantities over the patient, scalds are frequently dangerous on account of their extent. It is worthy of remark, that the danger of the effects of fire is not less proportioned to the size than the degree and depth of the injury. A burn that is so violent as to kill parts at once, may not be in the least dangerous, if not extensive; while a scald, which perhaps only raises the cuticle, may prove fatal if very large. The degree of danger, however, is to be rated from a consideration both of the size and violence of the injury. The worst burns which occur in practice arise from explosions of gunpowder or inflammable gases, from ladies' dresses catching fire, and from the boiling over of hot fluids in laboratories, manufactories, &c.

Burns, which only destroy the cuticle and irritate the skin, are very similar to the effects produced by cantharides and rubefacients. The irritation, which such injuries excite, increases the action of the arteries of the part affected, and they effuse a fluid under the cuticle, which becomes elevated and detached. Hence, the skin becomes covered with vesicles or bladders, which are more or less numerous and large, according to the manner in which the cause has operated. But when the skin or subjacent parts are destroyed, no vesicles make their appearance. In this circumstance a black eschar is seen; and when the dead parts are detached, there remains a sore more or less deep, according to the depth to which the destructive effects of the fire have extended.

The parts may either be killed at the moment of the injury by the immediate effect of the fire, or they may first inflame, and then mortify.

In all cases of burns, the quantity of injury depends on the degree of heat in the burning substance; on the duration and extent of its application; and on the sensibility of the burnt part.

When a large surface is burnt, mortification sometimes makes its appearance with great violence, and very quickly after the accident; but in general, the symptom the most to be dreaded in such cases is inflammation. The pain and irritation often run to such a pitch, that, notwithstanding every means, there is frequently immense trouble in keeping down the

inflammation. When the burnt surface is very large, the effects of the inflammation are not confined to the part which was first injured; but even cause a great deal of fever; and in certain cases, a comatose state, which may end in death.

It has been observed, that persons who die of severe burns seem to experience a remarkable difficulty of breathing and oppression of the lungs. These organs and the skin, are both concerned in separating a large quantity of water from the circulation, and their participating in this function may perhaps afford a reason for respiration being often much affected, when a large surface of skin is burnt. However, the kidneys perform the same office, and they are not particularly affected in burnt patients; so that the asthmatic symptoms frequently noticed in cases of burns, are probably owing to a sympathy between the lungs and skin, or else to causes not at present understood.

According to Dupuytren, extensive and deep burns always bring on inflammation of the mucous membrane of the alimentary canal: a circumstance said to explain those curious instances of death which so often occur when the ulcers are on the point of healing.—(See *Medecine Operatoire par Sabatier, edit. de MM. Sanson et Beguin.*)

Two general methods of treating burns have at all times been followed. One consists in the application of substances which produce a cooling or refrigerant effect; the other in the employment of calefacient or stimulating substances. Dr. Thomson is satisfied, that each of these different modes may have its advantages in particular cases.—(*Lect. on Inflammation, p.* 588.)

The practice mostly resorted to in this country some years since, is explained by Mr. B. Bell. When the skin is not destroyed, but seems to suffer merely from irritation, relief may be obtained by dipping the part affected in very cold water, and keeping it for some time immersed. This author states, that plunging the injured part suddenly into boiling water would also procure ease; an assertion, however, much to be doubted, and a practice not likely to be followed. In some cases, emollients afford immediate relief; but in general, astringent applications are best. Strong brandy or alcohol is particularly praised. At first the pain is increased by this remedy; but an agreeable soothing sensation soon follows. The parts should be immersed in the spirit, and when this cannot be done, soft old linen soaked in the application should be kept constantly on the burn. The liquor plumbi superacetatis dilutus is recommended. It is said to prove useful, however, only by being astringent, as equal benefit may be derived from a strong solution of alum, &c. Such applications were frequently made with the view of preventing the formation of vesicles; but Mr. B. Bell always remarked, that there was less pain when the blisters had already appeared, than when prevented from rising, by remedies applied immediately after the occurrence of the injury.

The applications should be continued as long as the pain remains; and in extensive burns creating great irritation, opium should be prescribed. The stupor with which patients so situated are often attacked, receives more relief from opium than any thing else.

Some recommend opening the vesications immediately; others assert, that they should not be meddled with. Mr. B. Bell thinks that they should not be opened till the pain arising from the burn is entirely gone. At this period, he says, they should always be punctured; for when the serum is allowed to rest long upon the skin beneath it has a bad effect, and even induces some degree of ulceration. Small punctures, not large incisions, should be made. All the fluid having been discharged, a liniment of wax and oil, with a small proportion of the superacetate of lead, is to be applied.

On the subject of opening the vesications in burns, Dr. Thomson believes, that the diversity of opinion arises from the different effects resulting from the particular manner in which the opening is made. "If a portion of the cuticle be removed so as to permit the air to come into contact with the inflamed surface of the cutis, pain and a considerable degree of general irritation will necessarily be induced; but if the vesications be opened cautiously with the point of a needle, so as to allow the serum to drain off slowly, without at the same time allowing the air to enter between the cuticle and cutis, the early opening of the vesications will not only not occasion pain, but will give considerable relief, by diminishing the state of tension with which the vesications are almost always, in a greater or less degree, accompanied. When opened in this manner, the vesications often fill again with serum; but the punctures may be repeated as often as is necessary, without any hazard of aggravating the inflammation. Great care should be taken in every instance, to preserve the raised portion of cuticle as entire as possible," &c.—(See *Lectures on Inflammation, p.* 595.)

When there is much irritation and fever, blood-letting, and such remedies as the particular symptoms demand, must be advised. On account of the pulse being frequently small, quick, and vibratory, bleeding is at present not often employed. As Dr. Thomson remarks, however, it may become necessary in patients of a strong, robust constitution, in whom the symptomatic fever assumes an inflammatory type. He has often seen a single bleeding procure great relief in these cases; and he does not remember a case where bleeding was followed by injurious effects.—(*P.* 594.) When the skin ulcerates, the treatment does not differ from what will be described, in speaking of *Ulcers*.

When burns are produced by gunpowder, and the skin more or less destroyed, cooling emollient applications were formerly thought most effectual, and a liniment composed of equal proportions of lime-water and linseed-oil gained the greatest celebrity. Even at this day, the application is very often employed. Mr. B. Bell advises it to be put on the parts by means of a soft hair-pencil, as the application and removal of the softest covering are often productive of much pain. The same author admits, however, that there are some cases in which Goulard's cerate, and a weak solution of the superacetate of lead, more quickly procure ease than the above liniment.

The sloughs having come away, the sores are to be dressed according to common principles.—(See *Ulcers.*)

When burns are produced by gunpowder, some of the grains may be forced into the skin: these should be picked out with the point of a needle, and an emollient poultice applied, which will dissolve and bring away any particles of gunpowder yet remaining.

Burnt parts which are contiguous, frequently grow together in the progress of the cure. The fingers, toes, sides of the nostrils, and the eyelids, are particularly liable to this occurrence; which is to be prevented by keeping dressings always interposed between the parts likely to become adherent, until they are perfectly healed.

The sores resulting from burns are perhaps more disposed than any other ulcers to form large granulations, which rise considerably above the level of the surrounding skin. No poultices should now be used. The sores should be dressed with any moderately stimulating, astringent ointment: the ceratum calaminæ or the unguentum resinæ with the pulv. hydrarg. nitrat. rub. is now generally preferred: and if the part will allow of the application of a roller, the pressure of it will be of immense service in keeping down the granulations, and rendering them more healthy. When these methods fail, the sores should be gently rubbed with the argentum nitratum.

In the dry and hot state of the skin Dr. Thomson is an advocate for diaphoretics. "Laxatives (says he) are often necessary; but it is in general best to employ only the gentler sort, on account of the trouble and pain which moving always gives the patient. Anodynes are often required, not only to procure sleep, but even a temporary alleviation of the pungency of the pain which the burn occasions. A mild vegetable and farinaceous diet should be used during the period of the symptomatic fever. Animal food, wine, and other cordials may be required in the progress of a suppurating burn; but they are not necessary at first, and when given in this stage, are almost always injurious."—(See *Lectures on Inflammation, p.* 594.)

With respect to the topical applications recommended by this gentleman, he generally prefers, in cases of superficial burns, cooling and refrigerant remedies. When there are vesications, and suppuration takes place without ulceration, he advises us, after refrigerants have ceased to produce beneficial effects, to use the linimentum aquæ calcis. However, where the progress of cicatrization is slow, he recommends, instead

of this liniment, ointments containing lead or zinc, particularly the ceratum calaminæ.

In the ulcerating state of suppurating burns, he prefers emollient cataplasms. But when the discharge continues, or becomes more profuse under the use of poultices, they are to be left off, and astringent washes employed, such as lime-water, the compound decoction of oak-bark, a weak solution of sulphate of copper, &c.

Where the parts are destroyed and converted into sloughs, Dr. Thomson does not think it matters much whether vinegar, oily liniments, turpentine, spirits of wine, or emollient poultices be at first employed. He acknowledges, however, that the poultice is the remedy under the application of which the separation of the dead parts is most easily and agreeably accomplished. "The question (says he) at present most deserving the attention of medical practitioners with regard to the use of the warm emollient poultices in burns is, whether we should apply it immediately after the burn has been received, or interpose for some hours, as has been so strongly recommended, dressings with vinegar, spirits of wine, or oil of turpentine. My own experience has not been sufficient to enable me to determine this point to my entire satisfaction. Yet I think it right to state to you, that in a number of trials made at different times, I have had occasion to see burns to which common emollient poultices had been from the first applied, slough and granulate faster, and in a more kindly manner, than similar burns in the same persons, to which in some instances the Carron oil (lin. aq. calcis), and in others again oil of turpentine, were applied at the same time with the poultices."—(See *Lectures on Inflammation*, p. 609.)

MR. CLEGHORN'S PLAN.

This gentleman, who was a brewer at Edinburgh, was induced to pay great attention to the effects of various modes of treating burns, on account of the frequency of these accidents among his own workmen. His observations led him to prefer the immediate application of vinegar, which was to be continued for some hours, by any of the most convenient means, until the pain abated; and when this returned, the vinegar was repeated. If the burn had been so severe as to have produced a destruction of parts, these, as soon as the pain had ceased, were covered with a poultice, the application of which was continued about six or, at most, eight hours; and after its removal, the parts were entirely covered with very finely powdered chalk, so to as take away every appearance of moisture on the surface of the sore. This being done, the whole burnt surface was again covered with the poultice. The same mode was pursued every night and morning until the cure was complete. If the use of poultices relaxed the ulcers too much, a plaster or ointment, containing the acetate of lead, was applied; but the chalk was still sprinkled upon the sore.

With respect to general remedies, Mr. Cleghorn allowed his patients to eat boiled or roasted fowl, or in short any plainly dressed meat which they liked. He did not object to their taking moderate quantities of wine, spirits and water, ale, or porter. He never had occasion to order bark, or any internal medicines whatever, and he only once thought it necessary to let blood. When the patient was costive, Mr. Cleghorn ordered boiled pot-barley and prunes, or some other laxative nourishing food, and sometimes an injection, *but never any purgative*, as he remarked that the disturbance of frequently going to stool was distressing to a patient with bad sores. Besides, he thought that a hurtful weakness and languor were always (more or less) brought on by purgatives. From the effects too which he felt them have upon himself, and observed them to have upon others, they did not seem to have so much tendency to remove heat and feverish symptoms as is generally supposed, and he believed that they more frequently carried off *useful* humours than *hurtful* ones.

Diluted sulphuric acid was not found to answer so well as vinegar, and the latter produced most benefit when it was fresh and lively to the taste.

In cold weather Mr. Cleghorn sometimes warmed the vinegar a little, placed the patients near the fire, gave them something warm internally, and kept them in every respect in a comfortable situation. His object in so doing was to prevent the occurrence of tremblings and chilliness, which in two instances, after employing cold vinegar, took place in an alarming degree.

The account of Mr. Cleghorn's plan was published by Mr. Hunter.—(See *Med. Facts and Observations, vol.* 2.)

SIR JAMES EARLE'S PLAN.

This gentleman was an advocate for the use of cold water or rather ice; and published several cases of extensive burns, in which this method was employed with the best effect. Cold water was enumerated by Mr. B. Bell among the applications to burns, and it was not uncommonly used long before Sir James Earle communicated the result of his experience to the public. The method indeed is very ancient. "Cold is a remedy (says Dr. J. Thomson) which has long been employed to diminish the inflammation of superficial burns. Rhazes directs, that in recent burns cloths dipped in cold water, or in rose-water cooled with snow, be applied as soon as possible to the parts which have been injured, and that these cloths be renewed from time to time; and Avicenna says that this practice often prevents the formation of blisters."—(*Lectures on Inflammation, p.* 589.) Sir James Earle's publication, however, had the good effect of drawing considerable attention to the subject, and of leading surgeons to try the method in a great number of instances in which other more hurtful modes of treatment might otherwise have been employed. The burnt parts may either be plunged in cold water, or they may be covered with linen dipped in the same, and renewed as often as it acquires warmth from the part. The application should be continued as long as the heat and pain remain, which they will often do for a great many hours. —(See *Essay on the means of lessening the Effects of Fire on the Human Body*, 8vo. *Lond.* 1803.)

Some caution, however, in the application of cold becomes necessary when a scald is of very large size, or situated upon the trunk of the body. In extensive burns, superficial as they may be, the patient is liable to be affected with cold shiverings; and these shiverings may be greatly aggravated by exposure and by the application of cold. Perhaps, therefore, in these examples warm applications ought to be preferred.—(*Dr. J. Thomson's Lectures on Inflammation, p.* 591.)

BARON LARREY'S PLAN.

It seems to me, that on the subject of burns there is, even at the present day, as much contrariety of sentiment as in any part of surgery whatsoever. After all the praises which of late years have been heard of vinegar, cold applications, oil of turpentine, &c., a French surgeon, whose talents and opportunities of observation entitle his opinion to the highest attention, has recently censured the employment of all such remedies. Larrey, though a military surgeon, has had occasion to see numerous burns, in consequence of explosions. He declares, that he has been long struck with the bad effects of repellents, such as fresh water with the muriate of ammonia, oxycrate, the liquor plumbi subacetatis, and the solution of opium in ice-water. He recommends dressing all deep burns with fine old linen spread with saffron ointment, which, he says, has the quality of diminishing the pain and preventing irritation, by keeping the nervous papillæ from coming into contact with the air, or being pressed by the linen and clothes. This ointment is to be continued till suppuration takes place, after which Larrey employs the ointment of styrax for promoting the detachment of the eschars, and checking the extension of the sloughing. As soon as the dead parts have separated, he again has recourse to the saffron ointment, for which he gradually substitutes dry lint, with strips of linen spread with cerate. When the vessels exceed the level of the edge of the sore, he touches them with the argentum nitratum, and he occasionally applies a weak solution of the oxymuriate of mercury, or of the sulphate of copper.

Larrey prescribes emollient and antispasmodic beverages, which are to be taken warm, such as milk of almonds, containing nitre, and properly sweetened; hydromel, rice ptisan, &c. His patients are never deprived of light nourishment, such as broths, jellies, eggs, soups, &c. He has found this simple treatment, which he calls soothing and gently tonic, almost always successful.—(See *Mém. de Chir. Militaire, t.* 1, *p.* 93.)

DR. KENTISH'S PLAN.

From what has been stated, it appears, that in cases of burns, cold and hot, irritating and soothing, astringent and emollient applications have all been outwardly

employed without much discrimination. But the internal treatment has always been of one kind, and both the ancients and moderns agree in advising blood-letting, cooling purges, and, in short, the whole of the antiphlogistic plan. If we except Mr. Cleghorn, who condemned purges, and allowed stimulants internally, Dr. Kentish has been almost the only advocate for the latter means.

The fanciful theories advanced by Dr. Kentish, lead him to believe, that as burns are injuries attended with increased action, there are two indications for restoring what he terms *the unity of action:* viz. the excitement or action of the part is first to be gradually diminished; secondly, the action of the system is to be increased to meet the increased action of the part, holding this law as the system in view: *That any part of the system, having its action increased to a very high degree, must continue to be excited, though in a less degree, either by the stimulus which caused the increased action, or some other having the nearest similarity to it, until by degrees the extraordinary action subsides into the healthy action of the part.*

With this view, holding the part to the fire seems, to Dr. Kentish, the best mode of relief; but as parts of the body are injured to which this cannot be done, the most stimulant applications must be used; for in this class there is little fear of any of them being greater than that which originally caused the accident. The strongest rectified spirits, made still stronger by essential oils, are proper, and may also be heated as much as the sound parts can bear. These and many other applications of the same class, says Dr. Kentish, will give the most speedy relief. They are to be continued only for a certain time, lest they cause the very ill which they are given to cure. They are then to be succeeded by less stimulant applications, until the parts act by common natural stimuli.

The internal mode of relief is to give those substances which most speedily excite the system to great action, such as ether, ardent spirits, opium, wine, &c., by which means the solution of continuity of action is allowed to last the shortest time possible, and the unity of action is restored, which constitutes the cure.

Suppose, for instance, as a local application, we at first apply the strongest alcohol, heated to the degree which the sound part would bear without injury; it should afterward be gradually diluted until it becomes proof spirit, and the heat should be diminished, although gradually, as cold is always pernicious, bringing on that tendency to shiver which should ever be continually guarded against, as being a most hurtful symptom, and the forerunner of a violent sympathetic fever. To prevent this, the external heat should be kept at a high temperature, and the action of the whole system raised in as great a degree as may be safe. By this means the action of the whole is made to meet the increased action of the part, by which the lessening of the increased action of the part to join the action of the whole is rendered more easy. Thus there is, says Dr. Kentish, a unity of intention by both the external and internal means, leading to the restoration of the unity of action, and the cure is performed.

It may be said, these circumstances can only take place when there is an increased action; and when the parts are destroyed, other means should be used, emollients, &c. In replying to this remark, Dr. Kentish distinguishes burns into two kinds; one, in which the action of the part is only increased; and another, in which some parts have increased action, while other parts are destroyed. It is of little consequence, says Dr. Kentish, what is applied to the dead part, as the detachment of an eschar depends upon the action of parts which remain alive, and not upon what is applied to those which are dead. However, he never saw an instance of a burn in which, though some parts were totally destroyed, there were not always other parts in which there was only increased action. Now as our duty is always to save living parts, our mode of cure in the first instance will always be the same; viz. to cure the parts which have only an increased action, in the doing of which the dead parts will not be the worse, as their separation is a process of the system which requires time, and, if the injury is to any extent, draws forth the joint efforts of the system, and even, says Dr. Kentish, calls up the energy of its powers to violent fever. This state should be supported by every artificial aid, in order to bring the parts to suppuration, otherwise the subject falls in the contest; for if the living parts have not the power to throw off the dead, the dead will assimilate the living to themselves, and a mortification ensue.

When the living parts have been preserved (continues Dr. Kentish), which, according to this treatment, will be in the course of two or three days, the dead parts will be more plainly observed, and the beginning of the process to throw them off will be commencing. This process must be assisted by keeping up the powers of the system by stimulant medicines and a generous diet. The separation of the eschars will be greatly promoted by the application of the stimulus of heat by means of cataplasms frequently renewed. These may be made of milk and bread, and some camphorated spirit or any essential oil sprinkled upon the surface. Such means need only be continued until the suppuration is established.

After Dr. Kentish had supported the system to suppuration, he then found that gradually desisting from his stimulant plan diminished the secretion of pus, and wonderfully quickened the healing process.

When some parts are destroyed, there must be others with increased action; and in this case, according to Dr. Kentish, the foregoing mode will be the best for restoring the living parts, and promoting the separation of the dead ones. Suppuration having taken place, the exciting of the system by any thing stimulant, either by food or medicine, should be cautiously avoided. Should the secretion of pus continue too great, gentle laxatives and a spare diet are indicated. If any part, as the eyes for instance, remain weak, with a tendency to inflammation, topical bleedings, or small quantities of blood taken from the arm, are useful. For the purpose of defending the new skin, camphorated oil, or camphorated oil and lime-water in equal parts, are good applications. Wounds of this kind heal very fast, when the diminution of pus is prevented by attention to diet; if the patient's strength require support, small doses of bark taken two or three times a day in some milk will answer that purpose, without quickening the circulation as wine, ale, or spirits are apt to do. By attention to these principles (continues Dr. Kentish), I can truly assert that I have cured very many extensive and dangerous burns and scalds in one, two, three, and four weeks, which in the former method would have taken as many months; and some which I believe to have been incurable by the former method.

After explaining his principles, Dr. Kentish takes notice of the various substances which have commonly been employed. Of these he would chiefly rely on alcohol, liquor ammoniæ subcarbonatis, ether (so applied as to avoid the cooling process of evaporation), and spirit of turpentine.

In applying these, we are directed to proceed as follows: the injured parts are to be bathed, two, or three times over, with spirits of wine, spirits of wine with camphor, or spirit of turpentine, heated by standing in hot water. After this a liniment, composed of the ceratum resinæ softened with spirit of turpentine, is to be spread on soft cloth, and applied. This liniment is to be renewed only once in twenty-four hours, and, at the second dressing, the parts are to be washed with proof spirit, or laudanum, made warm. When the secretion of pus takes place, milder applications must be made, till the cure is effected.

The yellow ointment stops the pores of the cloth, impedes evaporation, and thus confines the effect of the alcohol to the burnt surface. The first dressings are to remain on four-and-twenty hours. Dr. Kentish thinks it of importance, that the injured surface should be left uncovered as little as possible. It is therefore recommended to let the plasters be quite ready, before the old ones are removed, and then only to take off one piece at a time.

It will seldom be necessary to repeat the application of alcohol, or that of oleum terebinthinæ. The inflammatory action will be found diminished, and, according to Dr. Kentish's principles, the exciting means should therefore be diminished. Warm proof spirits, or laudanum, may be substituted for the alcohol, and the unguentum resinæ flavæ is to be mixed with oleum camph. instead of turpentine. If this should be found too irritating, Dr. Kentish recommends ceratum plumbi acetatis, or cer. calaminæ. Powdered chalk is to be used to repress the growth of exuberant granulations, and to absorb the pus. In the cavities of separated eschars,

and in the furrows between sloughs and living parts, he introduced powdered chalk. Then a plaster is applied, and, in tedious cases, a poultice over the plaster.

With respect to the internal treatment, the author observes, that great derangement of the system arises in certain persons from causes which in others produce no effect; and that this depends on a difference in the degree of strength. Hence, he concludes that as strength resists the sympathetic irritative actions of parts, and weakness induces them, we should, in all cases, make the system as strong as we can, immediately upon the receipt of the injury. In considerable burns, he supposes a disproportion of action to take place between the injured parts and the system at large, or what he styles a solution of the continuity of action; and that, by a law of the system, a considerable commotion arises, for the purpose of restoring the equilibrium, or enabling the constitution to take on the action of the part. Hence, Dr. Kentish is of opinion, that the indication is *to restore the unity of action of the whole system, as soon as possible*, by throwing it into such a state as to *absorb the diseased action*, and then gradually bring down the whole to the natural standard of action by nicely diminishing the exciting powers. Ether and alcohol, or other stimulants, are to be immediately given in proportion to the degree of injury; and repeated once or twice within the first twelve hours, and afterward wine or ale is to be ordered, till suppuration takes place, when it will be no longer necessary to excite the system.

In a second essay, Dr. Kentish remarks, that, in the first species of burns, *in which the action of the part is only increased*, he has not found any thing better for the first application than the heated oleum terebinthinæ and ceratum resinæ, thinned with the same. In superficial burns, when the pain has ceased, he considers it advisable to desist from this application in about four-and-twenty hours, and use at the second dressing a digestive, sufficiently thinned with common oil, beginning, on the third day, with the ceratum lap. calaminaris. This author has frequently seen secondary inflammation excited by the remedy. The most certain remedy for this unpleasant symptom is a digestive ointment thinned with oil, or a plaster of cerate, and over that a large warm poultice. The cerate will finish the cure. Should there be much uneasiness of the system, an anodyne, proportioned to the age of the patient, should be given.

The growth of fungus, and the profuse discharge of matter, are to be repressed, as already mentioned, by sprinkling powdered chalk on the surface, and by the use of purgatives, in the latter stages. The chalk must be very finely levigated.

Dr. Kentish's theories are, as far as I can judge, visionary: they may amuse the fancy, but can never improve the judgment. They are nearly unintelligible; they are unsupported by any sort of rational evidence; and, as being only the dreams of a credulous, sportive imagination, they must soon decline into neglect, if not oblivion. However, in making these remarks, it is far from my intention to extend the same animadversion to the mode of treatment insisted upon by Dr. Kentish, which forms a question which cannot be determined by reason, but by experience.

OF DRESSING BURNS WITH RAW COTTON.

In America, it is asserted that the best application for superficial burns is *raw cotton*, thinly spread out, or carded, and put directly on the injured part.—(See *Dallam on the Use of Cotton in Burns, in Potter's Medical Lyceum, p. 22; and Gibson's Institutes and Practice of Surgery, p. 62, vol. 1, 8vo. Philadelphia*, 1824.) According to Professor Gibson, it is only in superficial burns that this practice answers; but Dr. Anderson, of Glasgow, who has tried it on a large scale, represents it as applicable to injuries, whether occasioned by scalding or actual fire, whether superficial or deep, recent or old, vesicated or sphacelated. He states, that it has been long adopted by the inhabitants of the Greek islands. One of its advantages, he says, is, that, except in cases of deep injury, the cure is always accomplished without any appearance of cicatrization.—(See *Glasgow Med. Journ. vol. 1, p. 209.*) Another is the avoidance of the pain always attending the frequent renewal of other kinds of dressings; for this is left unchanged a considerable time. Some care, says Dr. Anderson, is necessary, both in preparing and applying the cotton. For this purpose, it should be finely carded, and disposed in narrow fleeces, so thin as to be translucent; by which means it can be applied in successive layers, and is thus made to fill up and protect the most irregular surfaces. The burnt parts, if vesicated, are to be washed with tepid water, and the fluid evacuated by small punctures. Or, if more deeply scorched, they may be bathed with a spirituous or turpentine lotion. The cotton is then applied, layer after layer, until the whole surface is not only covered, but protected at every point, so that pressure and motion may give no uneasiness. On some parts, it will adhere without a bandage, especially when there is much discharge; but, in general, a support of this kind is useful. Where the vesications have been broken, and the skin is abraded, or where there is sphacelus, more or less suppuration always ensues; and, in such cases, Dr. Anderson admits, the discharge may be so great as soon to soak through the cotton, and become offensive, particularly in summer, so that it may be necessary to remove the soiled portions. This, however, he advises to be done as sparingly as possible, care being taken to avoid uncovering or disturbing the tender surface.—(*Op. cit. p.* 213.) According to Dr. Anderson, there appears to be a twofold effect from this kind of treatment. The primary effect arises from the *exclusion of the air*, and the slowly conducting power of cotton, by which the heat of the part is retained, while a soft and uniformly elastic protection from pressure is afforded. The secondary effect, he says, depends entirely on the sheath, or case, formed by the cotton, absorbing the effused serum or pus, and giving the best possible substitute for the lost cuticle. "But in order that the full benefit may be derived from this substitute, and to ensure an equable and continued support to the tender parts, until the new skin is formed, it is absolutely necessary that the cotton should not be removed, except under particular circumstances, until the real cuticle is sufficiently formed to bear exposure."—(*P.* 217.) As Dr. Anderson admits, the theory is of little consequence; and we shall not, therefore, criticise it. The merit of the practice can be determined only by experience. We have noticed, that Gibson restricts the plan to superficial burns; and when it is recollected, that in other cases the discharge would soon convert the unchanged cotton into a most fetid mass of scabs, putridity, and even maggots, one can hardly doubt that his statement is correct. It is true, the fetor may be counteracted by wetting the cotton in a solution of chloride of lime; but directly this is done, the soft elastic property of that substance is lost, and the method is not essentially different from that in which linen and lint are applied, after being wet with the linimentum calcis, or other fluid applications; and would equally require frequent change. If much constitutional irritation be evinced after the cotton has been for some time applied, Dr. Anderson confesses, that it may be necessary to let out the discharge, or even remove the cotton altogether. "We are then to be guided by the symptoms and appearances, whether to reapply the same dressings, or first restore a more healthy action in the constitution."—(*Op. cit. p.* 218.)

[The "*exclusion of the air*" is the true indication in the treatment of *burns*; but it is imperfectly fulfilled by the carded cotton. In superficial burns, salt has long been a domestic application, and can only act in this way; yet when the part is completely covered with a layer of salt, the relief is immediate, and in superficial burns is permanent.

Some surgeons, in this country, treat all kinds of burns on the refrigerant plan; among whom Professor Davidge, of Maryland, was among the most prominent. He uniformly directed a saturnine solution to be applied to all recent burns, and persevered in until the acute inflammation was subdued, when he used Turner's cerate as the subsequent dressing. Dr. Kentish's plan is, however, most popular in this country, and alcohol, spirits of turpentine, and the mixture of linseed oil and lime-water are in almost universal use.

As, however, the relief afforded in burns is generally the result of the exclusion of the air from the raw surface, the modern practice introduced on the continent of covering burns with *wheat flour*, or other farinaceous material, will be found by far the most immediate in its action, and the most successful in its results; and this application is adapted to every species of burns, "whether occasioned by scalding or actual fire, whether superficial or deep, recent or old, vesicated or sphace-

tated." In the most desperate burns, where the injury is extensive and the destruction of the cutis almost universal, the patient is unable to sustain either the refrigerant treatment, or any modification of Dr. Kentish's plan. In these shocking cases, if the flour be applied all over the injured surface until the air is entirely excluded, the pain is almost annihilated; and from the most excruciating torture, the patient is instantly placed under circumstances of comparative comfort. The flour should be repeatedly applied, and persevered in, until the acute inflammation is removed, or, in common parlance, "the fire is out." No other application or dressing will be necessary until the acute stage is past; and then the plan of Dr. Kentish, modified according to the circumstances of the case, will be found adequate to the restoration of the injured surface, however extensive. I can confidently recommend this practice, having witnessed its success in the most hopeless cases.—*Reese.*]

The cicatrix of a burn is often of great extent, and, on this account, the subsequent absorption of the granulations on which the new skin is formed (a process by which the magnitude of the scar is afterward lessened) is so considerable, as to draw the neighbouring parts out of their natural position, and occasion the most unpleasant kinds of deformity. Thus, burns on the neck are apt to cause a distortion of the head, or even draw down the chin to the breast-bone; and in the limbs, such contractions as fix the joints in one immoveable position. Simply dividing these contractions again mostly fails altogether, or only produces very partial and temporary relief, as, after the cicatrization is completed, the newly formed parts are absorbed, and the contraction recurs. A few years ago, a proposal was made, by my friend Mr. Earle, to cut away the whole of the cicatrix, and then bring the edges of the skin as much towards each other as possible, in the transverse direction, with strips of adhesive plaster. In one case, in which, from the fore part of the upper arm, to within about two inches of the wrist, a firm tense cicatrix of an almost horny consistence extended, which kept the elbow immoveably bent to a right angle, this gentleman performed such an operation. After removing the cicatrix, the flexor muscles at first made some resistance to the extension of the limb; but by degrees they yielded, and the arm was brought nearly to a right line. The whole limb was kept in this position by means of a splint and bandage. In the end, the contraction was cured, and the use of the limb restored."—(See *Med. Chir. Trans. vol.* 5, *p.* 96, *&c.*)

Probably, as this patient was a young growing subject, only six years of age, the operation would have proved equally successful, if a simple division of the contracted skin had been made, and the arm kept extended for a length of time by the use of a splint. It is hardly necessary to observe, that cutting a large cicatrix entirely away, must always be a severe, and sometimes a dangerous operation; therefore, the avoidance of it, if possible, cannot but be desirable.—(See *B. BURSÆ MUCOSÆ. These are small membranous sacs, situated about the joints, particularly the large ones of the upper and lower extremities. For the most part, they lie under tendons. Mr. Brodie comprehends also under the same head, the membranes forming the sheaths of tendons, as they have the same structure, and perform a similar office. The celebrated Dr. A. Monro, of Edinburgh, published a very full account of the bursæ mucosæ and their diseases. These parts are naturally filled with an oily kind of fluid, the use of which is to lubricate surfaces, upon which the tendons play in their passage over joints. In the healthy state, this fluid is so small in quantity, that it cannot be seen without opening the membrane containing it; but occasionally such an accumulation takes place, that very considerable swellings are the consequence. Tumours of this sort are often produced by bruises and sprains; and now and then by rheumatic affections. They are not often attended with much pain, though in some cases it is very acute, when pressure is made with the fingers. The tumours yield, in a certain degree, to pressure; but they rise again, with an appearance of elasticity not remarked in other sorts of swellings. At first they appear to be circumscribed, and confined to a small extent of the joint; but sometimes the fluid forming them is so abundant that they extend over a great part of the circumference of the limb. The skin when not inflamed retains its usual colour.

In this morbid state of the bursæ mucosæ, they contain different kinds of fluids, according to the cause of the disease. When the tumour depends on a rheumatic affection the contents are ordinarily very fluid. They are thicker when the cause is of a scrofulous nature. When the disease is the consequence of a bruise or sprain, the effused fluid often contains hard concretions, and as it were cartilaginous ones, which are sometimes quite loose, and more or less numerous. Mr. Brodie states, that they have the appearance of small melon-seeds, and are not unusual when the inflammation is of long standing. Such substances may frequently be felt with the fingers.

In the greater number of instances, inflammation of the bursæ mucosæ occasions an increased secretion of synovia. In other cases the bursa is distended with a somewhat turbid serum, containing floating portions of coagulable lymph. The inflammation sometimes leads to the formation of an abscess; and occasionally the membrane of the bursa becomes thickened, and converted into a grisly substance. Mr. Brodie has seen it at least half an inch in thickness, with a small cellular cavity in the centre containing synovia. In other instances, however, though the inflammation has lasted a considerable time, the membrane of the bursa retains nearly its original structure.—(*Pathological and Surgical Obs. on the Joints, p.* 351, *ed.* 2.)

According to the same authority, the disease may be the consequence of pressure, or other local injury; the abuse of mercury; rheumatism, or other constitutional affection; and, in such cases, the complaint is frequently joined with inflammation of the synovial membrane of the joints.—(See *Joints.*) Sometimes it has the form of an acute, but more commonly that of a chronic inflammation.

While the swellings are not very painful, an attempt may be made to disperse them, by warm applications, friction (particularly with camphorated mercurial ointment), or blisters, kept open with the savin cerate. But if these tumours should become very painful, and not yield to the above methods, Dr. Monro recommends opening them. This author was continually alarmed at the idea of the bad effects of air admitted into cavities of the body; and hence, in the operation, even in opening the bursæ mucosæ, he is very particular in directing the incision in the skin, not to be made immediately opposite that made in the sac.

In the beginning, Mr. Brodie recommends the use of leeches and cold lotions; and afterward, that of blisters or stimulating liniments. In particular cases, he says, these means should be combined with such constitutional remedies as circumstances indicate. When the disease is of long standing, the preternatural secretion of the fluid will often continue after the inflammation has entirely subsided. If blisters now fail in procuring its absorption, Mr. Brodie recommends friction; and if this be unavailing, he considers it advisable to discharge the fluid by a puncture. The presence of loose substances in the bursa, he thinks, may of themselves keep up a collection of fluid.

Dr. Monro met with cases in which amputation became indispensable, in consequence of the terrible symptoms brought on by opening a bursa mucosa.

On account of such evil consequences, which are imputed to the air, though they would as often arise

were the same practice pursued in a situation in which no air could have access at all, it has been recommended to pass a seton through the swelling, and to remove the silk, after it has remained just long enough to excite inflammation of the cyst, when an attempt is to be made to unite the opposite sides of the cavity by pressure.

This practice is sometimes approved of by Mr. Brodie on other grounds: he has noticed, that after the whole cavity of the bursa has been converted into an abscess, and this has been cured, no fluid generally collects there again. Hence, he has sometimes been induced to pass into the puncture a seton or tent, or (what he deems better) the blunt end of a probe, for the irritation of the inner surface of the bursa. This practice I tried very successfully on a young woman who was under my care last year. I punctured the bursa below the patella, and discharged about an ounce of fluid, resembling white of egg. The disease had existed several months, and the bursa was much thickened. I kept the puncture open about ten days, during which time there was a discharge from it of the same kind of fluid without any tendency to suppuration. I therefore introduced a tent into the opening, by which means the necessary degree of inflammation was excited, the bursa suppurated, and the disease was soon permanently cured, without any severe symptoms. At the same time, I believe Mr. Brodie to be perfectly right in cautioning surgeons against the indiscriminate adoption of this practice. Inflammation and suppuration of a large bursa (he says) sometimes disturb the constitution so much, that it might be prudent merely to make a puncture, and keep the patient afterward perfectly quiet. He mentions a diseased bursa mucosa, which he had seen between the lower angle of the scapula and the latissimus dorsi, and which was not much less than a man's head. In this case, death followed the constitutional disturbance excited by a puncture and the seton. In another example, seen by this judicious surgeon, where the patient was in bad health, and the due observance of quietude was neglected, puncturing a diseased bursa mucosa was soon followed by death.—(*Op. cit. p.* 360.)

One or two similar cases, which happened in St. Bartholomew's Hospital, have also been communicated to me. In some instances, the making of too free an incision into the bursa mucosa has been followed by extensive phlegmonous erysipelas of the whole limb, ending in death.

When the coats of a bursa mucosa are much thickened, and cannot be restored to their natural condition, Mr. Brodie says, that the bursa, if superficially situated, may be removed with as much facility as an encysted tumour. This practice, however, he has only as yet applied to the bursa between the patella and the skin, though he entertains no doubt of there being other superficial bursæ which would also safely admit of removal.

C. Brodie's Pathological and Surgical Observations on the Joints, chap.* 9, *ed.* 2, 8*vo. Lond.* 1822.

C

CÆSAREAN OPERATION. Called also *Hysterotomia*, from ὑστέρα, *uterus*, and τομὴ, *sectio*. Pliny, book 7, chap. 9, of his Natural History, gives us the etymology of this operation. "*Auspicatius* (says he) *enectâ parente gignuntur, sicut Scipio Africanus prior natus, primusque Cæsar à cæso matris utero dictus; quâ de causâ cæsones appellati. Simili modo natus est Manlius qui Carthaginem cum exercitu intravit.*"

From this passage we are to infer that the Cæsarean operation is extremely ancient, though no description of it is to be found in the works of Hippocrates, Celsus, Paulus Ægineta, or Albucasis. The earliest account of it in any medical work, is that in the Chirurgia Guidonis de Cauliaco, published about the middle of the fourteenth century. Here, however, the practice is only spoken of as proper after the death of the mother, and is alleged to have been adopted only at such a conjuncture in the case of Julius Cæsar.—(See *Cap. de Extractione Fœtus.*) Vigo, who was born towards the close of the fifteenth century, takes no notice of the Cæsarean operation; and Paré, who greatly improved the practice of midwifery, thinks this measure only allowable on women who die undelivered.—(*De Hominus Generatione, cap.* 31.) Rousset, who was contemporary with Paré, collected the histories of several cases, in which the operation is said to have been successfully performed; and, after the publication of these, the subject excited more general interest.

By the *Cæsarean operation* is commonly understood that in which the fœtus is taken out of the uterus, by an incision made through the parietes of the abdomen and womb. The term, however, in its most comprehensive sense, is applied to three different proceedings. It is sometimes employed to denote the incision which is occasionally practised in the cervix uteri, in order to facilitate delivery; but this particular method is named the *vaginal Cæsarean operation*, for the purpose of distinguishing it from the former, which is frequently called, by way of contrast, the *abdominal Cæsarean operation*. With these cases we have also to class the incision which is made in the parietes of the abdomen for the extraction of the fœtus, when, instead of being situated in the uterus, it lies in the cavity of the peritoneum, in consequence of the rupture of the womb, or in the ovary, or Fallopian tube, in consequence of an extra-uterine conception.

VAGINAL CÆSAREAN OPERATION.

Disease, malformation, or a preternatural position of the cervix uteri, may render this practice indispensable. A scirrhous hardness of the neck of the uterus is the most frequent. When the induration is such that the cervix cannot be dilated, and the patient is exhausting herself with unavailing efforts, the parts should be divided in several directions. This has been successfully done under various circumstances. Cases have been met with, in which the cervix uteri presented no opening at all; and yet the preceding operation proved quite effectual. Such is the example which Dr. Simson has inserted in the third volume of the Edinburgh Essays. A woman, forty years of age, became pregnant, after recovering from a difficult labour, in which the child had remained several days in the passage. She had been in labour sixty hours; but the neck of the womb had no tendency to dilate. Dr. Simson, perceiving that its edges were adherent, and left no opening between them, determined to practise an incision, with the aid of a speculum uteri. The bistoury penetrated to the depth of half an inch, before it got quite through the substance which it had to divide, and which seemed as hard as cartilage. As the opening did not dilate, in the efforts which the woman made, it became necessary to introduce a narrow bistoury on the finger, in order to cut this kind of ring in various directions. There was no hemorrhage; and the only additional suffering which the patient encountered, arose from the distention of the vagina. As the child was dead, Dr. Simson perforated the head, in order to render the delivery more easy.

Strong convulsions at the moment of parturition, may create a necessity for the vaginal Cæsarean operation. These sometimes subside as soon as the membranes are ruptured and the waters discharged, so as to lessen the distention of the womb. However, if the convulsions were to continue, and the cervix uteri were sufficiently dilated, the child should be extracted with the forceps or by the feet, according to the kind of presentation. On this subject Baudeloque has recorded a fact, which was communicated to the Academy of Surgery by Dubocq, professor of surgery at Toulouse. The woman was forty years of age, and had been in convulsions two days. She was so alarmingly pale, that she could scarcely be known. Her pulse was feeble and almost extinct, and her extremities were cold and covered with a clammy perspiration. The edges of the opening, which was about as large as a crown piece, felt, as it were, callous; and hardly had this aperture been dilated, when delivery took place spontaneously. The child was dead. The symp-

toms were appeased, and the woman experienced a perfect recovery. Another case, in which the indurated cervix uteri was successfully divided, is recorded by Lambron, a surgeon at Orleans.—(See *Dict. des Sciences Méd. t.* 23, *p.* 297.)

A considerable obliquity of the neck of the womb, combined with a pelvis of small dimensions, may also be a reason for the performance of the vaginal Cæsarean operation. Not that such obliquity always occasions that of the rest of the uterus; nor is the neck of this viscus invariably directed towards that side of the pelvis which is opposite to its fundus, although this is sometimes the case. In the latter circumstance, as the contractions of the uterus do not produce a dilatation of its cervix, which rests upon the bones of the pelvis, the adjacent part of that organ is dilated and pushed from above downwards, so as to present itself in the form of a round smooth tumour, without any appearance of an aperture. Such a case may have fatal consequences. Baudeloque furnishes us with an instance. A woman in her first pregnancy, not being able to have the attendance of the accoucheur, whom she wished, put herself under the care of a midwife, who let her continue in labour-pains during three days. When the accoucheur came, on being sent for again, the child's head presented itself in the vagina covered with the womb. The portion of the uterus which included the fœtus, was in a state of inflammation. The os tincæ was situated backwards towards the sacrum, hardly dilated to the breadth of a penny-piece, and the waters had been discharged a long time. The patient was bled, and emollient clysters were administered. All sorts of fomentations were employed. She was laid upon her back with the pelvis considerably raised. The accoucheur had much difficulty in supporting the head of the child, and keeping it from protruding at the vulva, enveloped as it was in the uterus. Notwithstanding such assistance, the patient died.

So fatal an event, says Sabatier, might have been prevented, by making the woman lie upon the side opposite the deviation of the uterus, and employing pressure from above. If these proceedings had failed in bringing the os tincæ towards the centre of the pelvis, this opening might have been brought into such position by means of the finger, in the interval of the pains, and kept so until it were sufficiently dilated for the membranes to protrude.

This is what was done by Baudeloque in one case, where the womb inclined forwards and to the right. The os tincæ was situated backwards. The waters escaped and the head advanced towards the bottom of the pelvis, included in a portion of uterus The whole of the spherical tumour which presented itself could be felt with the finger; but no opening was distinguishable; and the swelling might also be seen on separating the labia from each other and opening the entrance of the vagina. It became necessary to keep the patient continually in bed, and to have the finger incessantly introduced; but she was not sufficiently docile to submit to such treatment. Fortunately, the unexpected appearance of two officers of justice, forty-eight hours after the commencement of the labour, had the effect of making her more manageable. It was time for her to become so; for the uterus had now become tense, red, and painful. The abdomen was also so tender, that it could scarcely bear the contact of the clothes. Febrile symptoms had begun, and the ideas were beginning to be confused. Baudeloque made her lie down; and he pressed with one hand on the abdomen, for the purpose of raising the uterus, while with the other he pushed the head a little way back, in order that he might reach the os tincæ, which he now brought with his finger towards the centre of the pelvis, and kept there for some time. The efforts of the patient being thus encouraged, she was delivered in about a quarter of an hour. The infant was of a thriving description, and the case had a most favourable termination.

When the obliquity of the uterus is such, that the os tincæ cannot be found, and the mother and fœtus are both in danger of perishing, it is the duty of the practitioner to open the portion of the womb that projects towards the vulva. Lauverjat met with a case of this description in his practice. A woman, pregnant with her first child, suffered such extreme pain in her labour, that Lauverjat was solicited to ascertain the real state of things. He was surprised to find the vulva completely occupied by a body which even protruded externally and yielded to the pressure of the fingers, except during the labour-pains. In examining this tumour he could only find at its circumference a cul-de-sac, half an inch deep, without any aperture through which the child could pass. Other practitioners, who were consulted about this extraordinary case, were also anxious to learn what had happened. They found in the tumour a laceration, which only affected a part of the thickness of its parietes. This laceration was deemed the proper place for making an incision. The operation having been done, the finger was passed into the cavity in which the child was contained. A large quantity of turbid fluid was discharged. The child presented and passed through the opening, with a trivial laceration on the right side. Lauverjat, having passed his hand into the utherus, was unable to find either the os tincæ or the cervix. No particular indisposition ensued, and the lochia were discharged through the wound, which gradually closed. In the course of two months the os tincæ and neck of the uterus were in their natural position again.—(*Lauverjat, Nouvelle Méthode de pratiquer l'Operation Césarienne. Paris,* 1788.)

When the case is a scirrhous induration of the cervix uteri, or a laceration of the parietes of this viscus at the place where it projects into the vagina, the vaginal Cæsarean operation is attended with no difficulty. It is performed with a blunt-pointed bistoury, the blade of which is wrapped round with lint to within an inch of the point. The instrument is to be introduced, under the guidance of the index finger, into the opening presented by the uterus, and the aperture is to be properly enlarged from within outwards, in various directions. But when the scirrhous hardness of the cervix presents no opening at all, or when the part of the uterus projecting in the vagina is entire, the incision should be made from without inwards, with the same kind of knife. Too much caution cannot be used in introducing the instrument, in order that no injury may be done to the child, which lies directly beyond the substance which is to be divided. No general direction can here be offered, except that of proceeding slowly, and of keeping the index finger extended along the back of the knife, so that it may be immediately known when the substance of the womb is cut through, into the cavity of which the finger ought to pass as soon as the knife. If it should be necessary to extend or multiply the incisions, the cutting instrument should be regulated in a similar manner with the same finger. The cervix uteri having been divided, the expulsion of the child is either to be left to nature, or to be promoted by the ordinary means. The operation that has been described requires no dressings. If the bleeding should prove troublesome, we are recommended to apply to the incision a dossil of lint wet with vinegar or spirit of wine.—(See *Sabatier, Médecine Opératoire, t.* 1.) The chief object would here be to prevent adhesions between the cervix of the uterus and the upper part of the vagina.—(*Dict. des Sciences Méd. t.* 23, *p.* 298.)

ABDOMINAL CÆSAREAN OPERATION.

This is a far more serious operation than that which has just now been treated of, and is the proceeding to which the term Cæsarean operation is more particularly applied.

There are three cases in which this operation may be necessary. 1. When the fœtus is alive and the mother dead, either in labour, or the last two months of pregnancy. 2. When the fœtus is dead, but cannot be delivered in the usual way, on account of the deformity of the mother, or the disproportionate size of the child. 3. When both the mother and child are living, but delivery cannot take place from the same causes, as in the second example.

In many instances, both mother and child have lived after the Cæsarean operation, and the mother even borne children afterward.—(See *Heister's Institutes of Surgery, chap.* 113. *Mém. de l'Acad. de Chirurgie, t.* 1, *p.* 623, *t.* 2, *p.* 308, *in* 4*to. Edin. Med. Essays, vol.* 5, *art.* 37, 38. *Edin. Med. and Surgical Journal, vol.* 4, *p.* 179. *Med. Chir. Trans. vol.* 9 *and* 11, *&c.*) Very recently an example has been recorded, in which Dr. Müller, of Lowenburg, in Silesia, performed the Cæsarean section, and saved both the mother and the child.—(*Magazin fur die gesammte Heilkunde,* 1828; *b.* 28, *p.* 146.)

An instance of similar success is reported by C. H. Graefe.—(*Journ. fur Chirurgie, &c. b. 9, s. 1.*) Two successful cases, in which both women and children were operated on at the hospital of Maestricht, by M. Bosch.—(*Bibl. Med.* 1823.) And in a valuable periodical work, one example is reported from Hufeland's Journal, where the mother and twins were all saved by the operation.—(See *Quarterly Journ. of Foreign Medicine, &c. vol. 4, p. 625.*)

The most extraordinary case of Cæsarean operation on record, is one performed by a negro girl on herself, who recovered.—(See *New-York Med. and Physical Journ. March*, 1823.) Dr. Mosely mentions the case of a negro woman at Jamaica, who opened her side with a butcher's knife, and extracted a child, which died of locked-jaw. The woman recovered.—(See *Ryan's Manual of Midwifery, p. 280.*)

In England, the operation has been attended with remarkably ill success; and perhaps there is not one unequivocal example, in which the mother has here survived the true Cæsarean operation. In the third edition of this work, indeed, I referred to the case recorded by Mr. James Barlow, of Chorley, Lancashire, who made an incision into the abdomen, extracted a dead child, and saved the mother's life.—(See *Medical Records and Researches, p. 154, 1798; also, J. Barlow's Essays on Surgery and Midwifery.*) My friend Dr. Gooch, however, having obligingly communicated to me his doubts, and those of Dr. Hull, respecting the reality of an incision having been made in this instance into the uterus, I am glad to have the opportunity of expressing my perfect conviction of the more correct view of the case taken by these physicians. "I suspected from the first (says Dr. Hull), that Mr. Barlow was deceived in this case, from the account he gave of the *remarkable thinness of the uterus.* And I had formed an opinion, that the *child had escaped through a laceration of the uterus into the abdomen*, enveloped in the secundines, and that he had merely divided the membranes, when he fancied he had divided the uterus." Dr. Hull then proceeds to explain the confirmation of his own sentiments by those of Mr. Howarden, a very intelligent practitioner at Blackrod, who assisted at the operation. In fact, the particulars stated by this gentleman leave no doubt, that the fœtus had escaped through a laceration of the uterus into the cavity of the abdomen.—(See *Hull's Defence of the Cæsarean Operation, &c. p. 72.*) The case also referred to by Mr. D. Stewart (see *Edin. Med. Essays, vol. 5*), where the labour had endured twelve days, and the life of the mother was saved, after the dead fœtus had been extracted by a midwife, was also probably of the same nature: at all events, the want of authentic particulars, and the circumstance of the operation having been done by a woman, leave the true nature of the case questionable.

If, therefore, when we speak of the Cæsarean operation, we mean that in which the parietes of the abdomen and those of the uterus are divided by the surgeon, and the fœtus extracted, I believe, that as far as the history of the practice extends in this country, it cannot be said, that the mother has ever recovered after such a proceeding; though, some years ago, a calculation was made, that the operation had been done not less than eighteen times in Great Britain; and since then it has been repeated in several instances with the same ill success.—(See *Henderson's Case, in Ed. Med. and Surg. Journ. vol. 17.*) It is said now, indeed, to have been performed about thirty times in the British dominions.—(See *Ryan's Manual of Midwifery, p. 270.*) Several of the children, however, are stated to have been saved. And in the case operated upon in April, 1826, by Mr. Crichton, of Dundee, the infant was preserved, though the mother sunk eight hours after the operation.—(See *Edin. Med. and Surgical Journ. No. 96, p. 54.*) On the continent, the practice has proved infinitely more successful; for of 231 cases of this operation to be found in the records of medicine, 139 are said to have terminated successfully.—(*Kellie in Edin. Med. and Surgical Journ. vol. 8, p. 17.*) No doubt, the ill success of the Cæsarean operation in England was correctly explained by Dr. Hull: "In France, and some other nations upon the European continent, the Cæsarean operation has been, and continues to be, performed where British practitioners do not think it indicated; it is also had recourse to early, before the strength of the mother has been exhausted by the long continuance and frequent repetition of tormenting, though unavailing pains, and before her life is endangered by the accession of inflammation of the abdominal cavity. From this view of the matter, we may reasonably expect, that recoveries will be more frequent in France than in England and Scotland, where the reverse practice obtains. And it is from such cases as these, in which it is employed in France, that the value of the operation ought to be appreciated. Who would be sanguine in his expectation of a recovery under such circumstances, as it has generally been resorted to in this country, namely, where the female has laboured for years under *malacostion* (*mollities ossium*), a disease hitherto in itself incurable; where she has been brought into imminent danger by previous inflammation of the intestines, or other contents of the abdominal cavity; or been exhausted by a labour of a week's continuance, or even longer?" Dr. Hull thus refutes the opinion of Mr. W. Simmons, that our ill success was owing to climate, or some peculiarity in the constitutions of the females of this island.—(See *Hull's Defence of the Cæsarean Operation, p. 10.*)

The general readiness of continental practitioners to have recourse to the Cæsarean section has been sometimes censured, because they have even operated in cases in which the patients had previously borne children in the natural way. According to Dr. Ryan, however, there are but four such cases on record: "One by Nagele in his *Erfahrungen und Abhandl. aus dem Gebiete des Krankheiten des Weiblichen Geschlechts;* another by Henderson, in the *Edin. Med. and Surg. Journ. No. 66*; a third by Meier, in *Siebold's Journ.*; and a fourth in the same Journ. by Berger."—(See *Ryan's Manual of Midwifery, p. 279.*) Certainly, if a woman had already borne children in the natural way, the fact should be received as a strong argument against the necessity of the operation, but perhaps not as an absolute prohibition, since every thing must depend on the actual dimensions of the lower aperture of the pelvis in relation to the size of the existing fœtus.

When the fœtus is contained in the womb, and cannot be expelled, by reason of the invincible obstacles to which I have already referred, and embryotomy, or the practice of sacrificing the fœtus and extracting it it piecemeal by the vagina, be deemed improper, the Cæsarean operation should be practised, before the mother and fœtus both perish from the violence of the pains, hemorrhage, convulsions, &c.

For this purpose it is necessary to make an extensive incision in the integuments of the abdomen, and in the uterus. Some have thought that cutting the parietes of the belly would be mortal; while others have believed a wound of the uterus equally dangerous. Hence such persons have condemned the operation on the principle that religious reasons do not authorize taking one life to save another. All the opponents of the Cæsarean operation fear the hemorrhage which they say must follow. Indeed, if the uterus were not to contract sufficiently when the fœtus and after-birth had come away, the bleeding would really be perilous. But when, by means of the Cæsarean operation, the fœtus is extracted, together with the placenta and membranes, the uterus contracts just as it does after a natural labour. Besides, even when the mother is alive, the operation is not commonly done till the uterus evinces a propensity to deliver itself, and begins to contract. The womb being delivered of its contents, the incision becomes closed, the vessels obliterated, and there is no fear of hemorrhage. The wound must also make so irritable an organ more disposed to contract; but whatever arguments may be adduced, it is enough to say in this case, *Artem experientia fecit, exemplo monstrante viam.* Rousset, in 1581, published a work in French, entitled *Hystérotomie, ou l'Accouchement Césarean.* This book, in 1601, was translated into Latin, and enlarged with an appendix by the celebrated Bauhin. Even then the practice of the Cæsarean operation on the living mother had its defenders. Bauhin relates, that in the year 1500 a sow-gelder performed the Cæsarean operation on his wife, *tam feliciter, ut ea postea gemellos et quatuor adhuc infantes enixa fuerit.* This is said to be the first instance in which the operation was ever done on the living mother with success. Many other cases were afterward collected and published.

The possibility of operating successfully on the

living mother was proved with great perspicuity and accuracy by Simon, in the *Mémoires de l'Acad. de Chirurgie, t.* 1, 4*to.* Here we are presented with a collection of sixty-four Cæsarean operations, more than a half of which had been done on thirteen women. Some of these had undergone the operation once or twice; others five or six times. There was one woman in particular who had undergone it seven times, and always with success. This seems to prove, notwithstanding all assertions to the contrary, that the operation for the most part succeeds. But if the life of the mother should not invariably be preserved, the Cæsarean operation ought not to be rejected on this account; it ought always to be done when relief cannot be obtained by other means; just as amputation and lithotomy are practised, though they are not constantly followed by success. Would any thing be more cruel than to abandon a mother and her child, and leave them to perish while there is any hope of saving them both? It is true, that when a pregnant woman dies of any inward disorder, and not from the pains and efforts of labour, the fœtus is sometimes still alive in the uterus; but in cases of death after difficult labours, and the great efforts made by the uterus to overcome the obstacles to parturition, the fœtus is generally dead; and the operation therefere is less likely to be availing.—(See *Bertrandi, Traité des Opérations de Chirurgie, chap.* 5.)

It is the opinion of the best writers upon this subject, that whenever a woman dies at all advanced in pregnancy the performance of the Cæsarean operation is highly proper. The propriety of this practice in such circumstances was known to the ancient Romans; for by a decree of Numa Pompilius, no woman who died pregnant was suffered to be buried, ere her body had been opened, with the view of preserving the infant for the use of the state.—(*Sprengel, Geschichte der Chir. th.* 1, *p.* 371.) Experience has proved, that when the fœtus has not attained the period at which parturition commonly happens, it will sometimes survive the operation a considerable time, and that when it is full grown its life may be most happily preserved. Although instances are cited, in which the fœtus in utero has been found alive upwards of four-and-twenty hours after the death of the mother, little stress should be laid on such prodigies. The operation ought to be done without any delay. Even then we are not certain of saving the infant's life. In the greater number of instances the fœtus perishes at the same time with the mother, and from the same causes. The cases which are recorded of the fœtus being extracted alive after the death of the mother, are numerous: I shall here only refer to three, two of which rest on the unimpeachable authority of Flajani, who was himself the operator.—(*Collezione di Osservazioni, &c. di Chirurgia, t.* 3, *p.* 144—146.) In one of these instances, the operation was done on a woman killed by violence in the ninth month of pregnancy; the child lived six hours; in the other, a fœtus was extracted from a woman who had died of typhus fever in the seventh month, and though the operation was not done till she had been dead about an hour, the child was taken out alive, and continued to live full ten minutes. A living child was also taken out of its mother by Vesling, after her death by typhus.—(*Welsch. Obs. Med. Episagm. No.* 74, *p.* 47; *Sprengel, Geschichte der Chir. th.* 1, *p.* 374.) On the 15th of April, 1820, Mr. Green, of St. Thomas's Hospital, extracted by the Cæsarean operation, from a woman suddenly killed in the ninth month of pregnancy by the passage of a stage coach over her, a fœtus that lived 34 hours after its removal from the uterus.—(See *Med. Chir. Trans. vol.* 12, *p.* 46.) With respect to the statements of Cangiamila, a Sicilian practitioner, I join Sprengel in considering them as incredible exaggerations: five instances are given, in which the fœtus was taken out of the mother from fifteen to twenty-four hours after her death, and yet it continued to live. Cangiamila says, that at Syracuse, in the course of eighteen years, the operation had been practised twenty times under the same circumstances; that at Girgenti, thirteen children were saved out of twenty-two women who had died pregnant; and that in twenty-four years, at Montereali, twenty-one children were preserved in the same manner.—(*Embryologia Sacro. Venet.* 1763, *fol.*) As Sprengel remarks, one might almost suppose from this account, that in Sicily pregnancy was generally fatal.

If the mother should happen to die in labour, and the neck of the uterus were sufficiently dilated, or disposed to be so, an attempt should be made to accomplish delivery in the ordinary way; for examples have occurred in which women, supposed to be dead in this circumstance, were in reality alive. Hence we find that the Senate of Venice, in 1608, enacted a law, by which practitioners were liable to punishment in case they neglected to operate with as much caution on a pregnant woman supposed to be dead, as on a living subject; and rules to be observed were again issued by the same government in 1720.—(*Seb. Melli, La Commare levatrice, p.* 108, 4*to. Venez.* 1721; *Personé, Diss. sopra l'Operaz. Cesar. p.* 15, 8*vo. Venez.* 1778.) A law to the same effect was likewise made in 1749, by the king of Sicily, who decreed the punishment of death to those medical men who omitted to perform the Cæsarean operation on such women as died in the advanced stages of pregnancy. In the Journal des Sçavans de Janvier, 1749, the following case, confirming the propriety of such caution, was inserted by Rigaudeaux, surgeon to the military hospital at Douay. This practitioner having been sent for to a woman, to whose residence he was unable to proceed till two hours after her apparent death, he had the sheet with which she was covered removed, and perceiving that the body retained its suppleness and warmth, he tried whether the fœtus could not be extracted in the ordinary way, which was easily effected as soon as the feet were got hold of. The first endeavours to save the child were very unpromising; but after a few hours they had the desired effect. As the woman continued in the same state five hours afterward, Rigaudeaux recommended that she might not be buried before her limbs were quite cold and stiff. He afterward had the satisfaction to learn that she was also restored to life. This remarkable case happened on the 8th of June, 1745, and both the mother and child were living at the period when Rigaudeaux published the observation.

Supposing, however, delivery in the ordinary manner to be impracticable, at all events the Cæsarean operation ought to be performed with the same cautions as if the mother were alive, only one incision being made for the purpose of opening the uterus.

Almost all the insurmountable obstacles to delivery originate from the bad conformation of the pelvis, depending upon rachitis; though they are not an invariable consequence of it, since there are women extremely deformed, in whom no imperfection of the pelvis exists, while it prevails in others whose shape is but trivially disfigured. An examination of the dimensions of the pelvis is the right mode of ascertaining whether there is really such an impediment to parturition. In order that the dimensions may not be an obstacle to delivery, the distance between the upper edge of the sacrum and the os pubis ought to be three inches and a half; and the distances between the tuberosities of the ischium and between each of these protuberances and the point of the os coccygis, three inches. Women have indeed been known to be delivered without assistance, although the first of the above distances was only two inches and a half; but then the heads of the children were so elongated, that the great diameter was nearly eight inches, while that which extends from one parietal protuberance to the other was reduced to two inches five or six lines, and the infants were lifeless. If they are to be born alive, they must be taken out of the womb by the Cæsarean operation; but the latter proceeding should never be adopted without a certainty that they are actually living; for when dead they may be extracted in a way that is attended with much less risk to the mother.

It is not always an easy matter to ascertain with certainty whether a fœtus in utero be living or dead. If it has entirely ceased to move, after being affected with a violent motion, the probability is that it is no longer alive. But to be certain, manual examination is necessary, which may be practised in two ways. One consists in pressing upon the uterus, through the parietes of the abdomen. If the child lives, such pressure makes it move, and the motion can be plainly felt and distinguished. In the other method, one hand is employed in pressing upon the uterus externally, while with the fingers of the other hand passed up the vagina, corresponding pressure is also to be made. The uterus is likewise to be allowed to descend as far as possible, in order to induce the

fœtus to move. When no decisive indications can be thus obtained, it becomes necessary to rupture the membranes, if they have not already given way, introduce the hand into the uterus, and put a finger into the child's mouth, for the purpose of making it move its tongue. The finger may also be applied to the region of the heart, so as to examine whether this organ is beating; and the umbilical cord may be touched, in order to ascertain whether there is still a pulsation in it. When none of these proceedings furnish unequivocal information, the conclusion is that the child is dead, and its extraction is indicated, unless the narrowness of the parts be such that the hand cannot be passed into the uterus, in which case, the Cæsarean operation is indispensable.

But how are we to form a judgment respecting the dimensions of the pelvis? And how can we know whether that diameter which extends from the upper edge of the sacrum to the os pubis, is long enough to allow the passage of the child? The proper conformation of this part is known by the roundness and equality of the hips, both in the transverse and perpendicular direction; by the projection of the pubes; by the moderate depression of the sacrum; by an extent of four or five inches from the middle of this depression to the bottom of the os coccygis; by an extent of seven or eight inches from the spinous process of the last lumbar vertebra to the highest part of the mons veneris, in a woman moderately fat; and by there being an interspace of eight or nine inches between the two anterior superior spinous processes of the ossa ileum.

These general calculations, however, are insufficient. In order to acquire more correct opinions, double compasses have been employed. The branches of the first being applied to the top of the sacrum and middle of the mons veneris, three inches are to be deducted from the dimensions indicated by the instrument, viz. two inches and a half for the thickness of the upper part of the sacrum (which is said to be constant in subjects of every size), and half an inch for that of the os pubis. In women who are exceedingly fat, some lines must also be deducted on this account. Hence, when the total thickness of the pelvis measured in this direction is seven inches, there will remain four for the distance from the upper part of the sacrum to the os pubis, or for the extent of the lesser diameter of the upper aperture of the pelvis.

For taking the measurement internally, a kind of sector was invented by Coutouly. It bears a considerable resemblance to the instruments employed by shoemakers for measuring the feet. It is passed into the vagina, with its two branches approximated, until one arrives opposite the anterior and upper part of the sacrum, when the other is to be drawn outwards, so as to be applied to the pubes. The distance between the branches is judged of by the graduations on the instrument. This was named by its inventor a pelvimeter. According to Sabatier, it is not always easy to place it with accuracy; its employment is attended with some pain; and there are particular cases in which it cannot be used.

Instead of this contrivance, the celebrated Baudeloque recommended a means which seems to be very safe and simple. The index finger of one hand is to be introduced into the vagina to the upper part of the projection of the sacrum. The finger, having the radial edge turned forwards, is then to be inclined anteriorly till it touches the arch of the pubes. The point of contact being then marked with the opposite hand, the length from the point in question to the end of the finger is to be measured. This length, which indicates the distance between the sacrum and the bottom of the symphysis pubis, usually exceeds that of the lesser diameter of the pelvis by about six lines. Baudeloque acknowledges that this measurement is not exactly accurate; but he believes it will do very well, because, unless the narrowness of the pelvis be extreme, two or three lines hardly make any difference in the facility of parturition.

The following is the description of the pelvis of the woman twice operated upon by Dr. Locher: the ossa pubis, which should be on the same level with the promontory of the sacrum, were found perpendicularly under it; so that the child necessarily extended the abdominal integuments by its own weight, into a pendulous bag overhanging the thighs. For the same reason, nothing could be felt of the child by examination per vaginam. The sacrum, instead of closing the pelvis behind by a semicircular curve, which forms a kind of conductor for the child in parturition, stretched nearly horizontally backwards. A representation of this pelvis, with a few other particulars, may be seen in a modern publication.—(*Med. Chir. Trans. vol.* 11, *p.* 199.)

The pelvis may be every where well formed, and yet present an insurmountable obstacle to delivery, in case an exostosis, lessening its dimensions, should exist on one of the bones which compose this part of the skeleton. Pineau met with a case of this description in a woman who died undelivered. The tumour originated from one of the ossa pubis. A steatomatous swelling, situated with the head of the child in the upper aperture of the pelvis, might produce the same effect unless it were detected, and could be pushed out of the way, so as to make room for the fœtus to pass. Baudeloque mentions a swelling of this kind. It was six or seven inches long, and an inch and a half in width. The extremity of it, which was as large as half a hen's egg, had a bony feel, and contained nine well-formed teeth, the rest of the mass being steatomatous. It had descended into the lesser pelvis, below the projection of the sacrum, and a little to one side. It might have been taken for an exostosis of this last bone. The labour-pains continued sixty hours, and the propriety of performing the Cæsarean operation was under consideration. Baudeloque was averse to this proceeding. He recommended turning the child and extracting it by the feet, because he thought that the pelvis was sufficiently capacious to admit of delivery. The event proved that it was three inches nine lines from before backwards, and four inches nine lines transversely. The fœtus was soon easily extracted. The assistance of the forceps was necessary to get out the head. The child was still-born. The mother, exhausted with numerous unavailing efforts, only survived between fifty and sixty hours. Baudeloque was of opinion that a defective regimen also tended to occasion her death.

Among the insurmountable obstacles to delivery may be reckoned such a displacement of the uterus that this viscus protrudes from the abdomen and forms a hernia. The records of surgery have preserved some examples of this extraordinary occurrence. Twice has the Cæsarean operation been performed, and in one of the two cases, the woman survived so long that hopes were entertained of her recovery. Indeed, as Sabatier observes, why should not the operation succeed in such a case, where the uterus is only covered by the integuments, and there is no occasion to cut into the abdomen, just as well as other instances in which it is indispensable to divide the muscles, and open the cavity of the belly? In the other case on record, delivery was effected in the ordinary way, either by raising the abdomen and keeping it in this position with towels skilfully placed, or by making pressure on the uterus, which had the beneficial effect of making this organ resume its proper situation.

Having shown the absolute necessity for the Cæsarean operation under certain circumstances, it remains to consider the proper time for performing it, the requisite preparatory means, and the method of operating.

With regard to the time of operating, practitioners do not agree upon this point: some advising the operation to be done before the membranes have burst and the waters been discharged; others not till afterward. The arguments in favour of the first plan are, the facility with which the uterus may be opened without any risk of injuring the fœtus, and the hope that the viscus will contract with sufficient force to prevent hemorrhage. The advocates for the second mode believe, that in operating after the discharge of the waters, there is less danger of the uterus falling into a state of relaxation, in consequence of becoming suddenly empty after being fully distended, and that this method does not demand so extensive an incision. Hence they recommend, as a preliminary step, to open the membranes. Whatever conduct be adopted, it is essential that the labour should be urgent and unequivocal, that the cervix uteri should be effaced, and that the os tincæ should be sufficiently dilated to allow the lochia to be discharged; but at the same time, says Sabatier, if the operation is not to be done till after the escape of the waters, there ought not to be too much delay, lest the patient's strength should be exhausted,

and the violent efforts of labour should bring on an inflammatory state of the parietes of the uterus.

The propriety of emptying the rectum and bladder is so evident, that it is unnecessary to insist upon it. This precaution is more particularly requisite in regard to the latter of these viscera, which has been known to rise so much over the uterus as to conceal the greater part of it. Baudeloque had occasion to remark this circumstance, in a woman upon whom he was operating. The bladder ascended above the navel, and presented itself through the whole extent of the opening made in the parietes of the abdomen.

The instruments, dressings, &c. which may be wanted, are two bistouries, one with a convex edge, the other with a probe-point; sponges, basins of cold water acidulated with a little vinegar; long strips of adhesive plaster; needles and ligatures; lint; long and square compresses; a bandage to be applied round the body, with a scapulary, &c.

For the purpose of undergoing the operation, the patient should be placed at the edge of her bed, well supported; her chest and head should be moderately raised; her knees should be somewhat bent, and held by assistants, one of whom ought to be expressly appointed to fix the uterus by making pressure laterally, and from above downwards, so as to circumscribe, in some degree, the swelling of the uterus, and prevent the protrusion of the bowels. These things being attended to, the integuments are to be divided with the convex-edged bistoury to the extent of at least six inches. The place and direction of this incision differ with different operators.

In the most ancient method, it was customary to make the incision between the outer edge of the rectus muscle, and a line drawn from the anterior superior spinous process of the ileum, to the junction of the bone of the first rib with its cartilage. This cut was begun a little below the umbilicus, and was continued downwards as far as an inch above the pubes. After the integuments had been divided, the muscles, aponeuroses, and peritoneum were cut, and the uterus cautiously opened. The left index finger was then introduced into this viscus, the wound of which was dilated by means of the probe-pointed bistoury.

This manner of operating is subject to great inconveniences. The place where the incision is made is the situation of muscles, the fibres of which have a different direction, and, on contracting, separate the edges of the wound, and make it gape. The considerable blood-vessels which ramify there, may be the source of perilous bleeding. The bowels can protrude in that situation more readily than any where else. When the position of the uterus is oblique, and when, consequently, the edges of this viscus are turned forwards and backwards, and its surfaces to the right and left, the incision will be made in one of the lateral portions of the uterus, where the trunks of its blood-vessels are known to be situated, and sometimes even the Fallopian tube and ovary may be cut. The fibres of the uterus are cut transversely, so that the edges of the incision are apt to gape, instead of being in contact. This last circumstance may the more readily permit the lochia to escape into the abdomen, inasmuch as the uterus is cut nearly through its whole length, and there is no cavity in which they can accumulate in order to be discharged through the cervix of that organ.

The linea alba has been frequently considered the most eligible place for making the incision. As Sabatier informs us, it was the method adopted by Soleyrès and Deleurye, and it has the recommendation of Baudeloque, because there are fewer parts to be cut, and when the uterus is exposed, an incision parallel to its principal fibres may be made in its middle part. Soleyrès thought that this plan of operating originated with Platner and Guérin, a surgeon at Crepi en Valois Platner says: *Incidentar juxta lineam albam, plagâ majore quæ ab umbilico ad ossa pubis ferè descendit, tum abdominis musculi, tum peritonæum, ubi tandem vitandum ne violetur arteria epigastrica.* Guérin, in his case, made an incision six inches long, which began a little above the umbilicus and extended to within an inch and a half of the pubes. He afterward divided the fat, muscles, and peritoneum, in order to get at the uterus, the anterior part of which was opened, the wound being made rather in the body than the fundus of that viscus. Deleurye will not admit that these writers actually divided the linea alba, because they speak of having cut muscles which in reality do not exist in that situation; and he attributes the honour of the invention to Varoquier, a surgeon of Lisle, in Flanders; but the method was known to Mauriceau, as we may be convinced of by the following passage, extracted from the chapter in which he treats of the Cæsarean operation: "*La plupart veulent qu'on incise au côté gauche du ventre; mais l'ouverture sera mieux au milieu entre les muscles droits, car il n'y a en ce lieu, que les tégumens et les muscles à couper.*" Lauverjat, who has made this remark, and cited the Latin edition of Mauriceau, page 247, also observes, that the incision in the linea alba was practised by a contemporary of La Motte, a circumstance which Sabatier has not been able to ascertain.—(*Médecine Opératoire, tom.* 1.) The following would be the proper manner of operating in the linea alba. The operator should first divide the integuments perpendicularly, so as to expose the linea alba, making the wound about six inches long. An opening should then be carefully made through the aponeurosis, into the abdomen, either at the upper or lower part of the linea alba in view. A curved bistoury is then to be introduced into the opening, and the tendon and peritoneum cut from within outwards, as far as the extent of the wound in the integuments. The latter cut should be cautiously made with the crooked bistoury, guided by the fore-finger of the left hand, lest any of the intestines be accidentally injured. The uterus must next be carefully opened, making an incision in it of the same length as the preceding wound. The fœtus is to be taken out through the wound, and then the placenta and membranes. In this way, M. Artiste lately operated so as to save both mother and child.—(See *Edin. Med. and Surg. Journ. vol.* 4, *p.* 178.)

This mode of operating, as Sabatier observes, gives more hopes of success than the plan first described: but he argues, that such hopes have not been realized by experience. Though the operation may have been more easy, he contends that the edges of the wound in the skin, and those of the incision in the uterus, have had no tendency to remain in a state of proximity to each other, because the linea alba is the point on which all the large muscles of the abdomen principally act, and because the contraction of the uterus invariably takes place from above downwards. Sabatier alleges that the wound in this viscus has been found to incline to one of its sides, for the same reasons as occur in operating at one of the sides of the abdomen. He also states, that the incision has been concealed under the integuments of the upper part of the pubes, and that the presence of the bladder hinders the wound from being carried sufficiently far down. Perhaps, says he, a part of these inconveniences which depend upon the contraction of the uterus, and the return of this organ to its natural state, might be avoided by extending the incision to its highest part. Baudeloque has advised this plan with the view of preventing the fatal extravasations in the abdomen, which frequently follow this operation. Sabatier, however, has doubts whether in operating in the linea alba, the wound can be carried high enough. Besides, he maintains, that this precaution would not prevent the wound from gaping, nor the greater tendency of the lochia to be extravasated in the abdomen than to accumulate in the uterus, and be discharged through the os tincæ.—(*Médecine Opératoire, tom.* 1, *p.* 274, 275.)

In this country (where, indeed, the Cæsarean operation has proved most unsuccessful) the linea alba is preferred, I believe, by the majority of practitioners. That the method is not always attended with the formidable objections urged against it by Sabatier, is quite certain: the case lately published by Dr. Chisholm is a decisive proof of this assertion.—(See *Edin. Med. and Surgical Journ. vol.* 4, *p.* 178, 179.)

There is a third method of performing the abdominal Cæsarean operation. It consists in making a transverse incision five inches in length, through the parietes of the abdomen, between the rectus muscle and the spine, and in a situation more or less high, according to the more or less elevated position of the uterus. This plan was recommended by Lauverjat, in a publication entitled, *Nouvelle Méthode de pratiquer l'Opération Césarienne. Paris,* 8*vo.* 1788. Lauverjat acknowledges that the method had been suc-

cessfully practised by different persons before himself; and especially in one instance, which was particularly remarkable, as, in consequence of the first incision having been made too high up, it became necessary to make a second one, which extended obliquely from the other. However, according to Sabatier, Lauverjat has as much merit as if he had invented the plan, since he has given a better explanation of its advantages than any of his predecessors.

The side on which the operation is to be done is in itself a matter of indifference. But if the liver or spleen were to project, one ought to avoid it. Also, if the uterus were to incline more towards one side than the other, it would be proper to operate on the side where this viscus could be most conveniently exposed. The patient being put in a proper position and held by assistants, and her abdomen kept steady by an attendant, who must apply the palms of his hands to the sides of the uterus, the integuments, muscles, and peritoneum are to be divided with the usual precautions. The uterus is then to be opened, and the wound in it enlarged in the requisite degree, by means of a probe-pointed bistoury. Should the placenta present itself, care must be taken not to injure it, for fear of opening one of the arteries of this mass which communicate with the umbilical arteries of the child, or of leaving a portion of it in the uterus; but it should be separated, in order to facilitate breaking the membranes at its circumference. The child is next to be extracted. This part of the operation is subject to no general rule. Delivery being accomplished, we are recommended to introduce through the vagina anodyne injections, in order to lessen spasm, and wash out the coagula. This method is preferable to that of clearing out the uterus with the hand. Sabatier most properly condemns the plan formerly advised by Rousset and Ruleau, of passing up the neck of this viscus a catheter for the purpose of washing out the lochia, as well as the absurd proposal of employing a seton to promote their escape. Should the lochia not pass readily outwards, we are recommended to introduce the finger occasionally into the cervix uteri, so as to free it from the coagula which may obstruct it.

Sabatier observes, that nearly all authors who have spoken of the Cæsarean operation, whether performed at the sides of the abdomen, or in the linea alba, have advised keeping the edges of the wound in the skin, muscles, and peritoneum together, by means of the interrupted or twisted suture, care being taken to place at the lower part of the incision a tent, in order to prevent adhesion, and leave a free issue for whatever discharge may take place from the abdomen. Others have been content with recommending the use of adhesive plasters and the uniting bandage.

Sabatier condemns sutures as painful and irritating, and he states that the other means only act upon the skin, without fulfilling the object in view, because the integuments have no fixed point, and the divided muscles tend to contract. He assures us, that in the last mode of operating, the edges of the wound may be brought into contact by merely laying the patient upon her side. Besides, he remarks, that there are not many muscular fibres cut, those of the transversalis being only separated from each other. He affirms, that this manner of operating also favours the approximation of the edges of the wound in the uterus, in consequence of this organ contracting most extensively in the perpendicular direction. It is likewise asserted, that as the uterus has only been opened at its upper part, it affords in its middle and lower portions a large cavity, which does not communicate with the abdomen, and in which the lochia may easily accumulate, and afterward be discharged by the natural way. The only dressings advised by Sabatier are, a large pledget, compresses, and a moderately tight bandage round the body. These are to be changed when soiled with the matter or discharge. In this country practitioners would not neglect to bring the edges of the wound as much as possible together, by means of strips of adhesive plaster; for though they may not act with so much effect in this situation as many others, they undoubtedly assist in promoting the main aim of the surgeon, which is to heal at least all the upper part of the incision, if possible, by the first intention. I have no doubt there are many who would be advocates for sutures. In this country, the last method of operating has also been tried.

Mr. Wood, of Manchester, performed the Cæsarean operation, in a case in which parturition was prevented by deformity of the pelvis. The incision was made nearly in a transverse direction, on the left side of the abdomen, about five inches in length, beginning at the umbilicus. This part was fixed upon because the nates of the child could be felt there, and it was evident that no intestine was interposed between the abdominal parietes and the uterus. There was scarcely any effusion of blood, either from the external wound or from that of the uterus, though the latter was made directly upon the placenta. Instead of dividing the placenta, Mr. Wood introduced his hand between it and the uterus, and laying hold of one of the child's knees, extracted the fœtus with ease. His hand readily passed between the placenta and uterus; this produced a hemorrhage, but not in any considerable degree, for the whole quantity of blood lost did not exceed seven or eight ounces. After the uterus was emptied, the intestines and omentum protruded at the wound. These having been reduced, the integuments were brought into contact with sutures and adhesive plaster. This operation, however, did not save the woman's life; she died on the fourth day after its performance.—(See *Med. and Physical Journ. vol.* 6.) As I have already explained, the ill success of the Cæsarean operation in England has been such, that not a single case has yet happened in which the life of the mother has been preserved after the child was truly extracted from the womb by incision. The probable reason of this circumstance I have also noticed. Abroad, however, the success of the practice forms quite a contrast to what has occurred in this country, the operation having been often done so as to save the lives both of the mother and child, of which an interesting example was recently published by Dr. Locher, of Zurich.—(See *Med. Chir. Trans. vol.* 9, *p.* 11.) And in vol. 11 of the same work, may be read a case in which Dr. Meyer, of Minden, lately saved a woman by the operation, but the fœtus was dead. Likewise an example in which Dr. Spitzbarth, in 1819, preserved the lives both of the infant and mother, and another interesting relation of two Cæsarean operations performed by Lorinser, on a woman still living at Nimes, in Bohemia.—(See also *Siebold's Journ. für Geburtshulfe, &c. vol.* 3, *part* 1, *Frankf.* 1819.) In 1801, Dr. Schlegel, of Merseburg, likewise operated on a woman who recovered, notwithstanding the bowels became strangulated, and she is still living, with a hernia in the situation of the wound.—(*Schweighäuser, Archiv. des Accouchemens, p.* 135, 8*vo. Paris*, 1797.) The Cæsarean section has been successfully performed by Graefe, at Berlin, the woman and child both having been saved.—(*Journ. b.* 9.) And besides this and various other instances of success already referred to, another was afforded in April, 1823, in the practice of Vanderfurh.—(See *Revue Méd.*)

[In the *Western Journal of Medical and Physical Sciences* for April, 1830, Dr. Richmond, of Newton, Ohio, reports a successful case of Cæsarean operation, performed in 1827. He was under the necessity of performing the operation at midnight, on the spur of the moment, without a consultation, and under most unfavourable circumstances. After he had divided the uterus and the placenta, which was attached directly under his incision, he found it impossible to remove the fœtus, until he had divided the muscles of the back, near the upper lumbar vertebræ, when it was extracted with facility. The mother recovered entirely in four weeks.

The necessity for the operation arose from malconformation of the os tincæ and vagina. On examining the patient per vaginam, since her recovery, Dr. Richmond found the whole depth of the vagina only two-thirds of a finger's length, its anterior coat being a kind of septum passing obliquely upwards, from before backwards, leaving about one and a half inches between it and the fourchette, and the abnormal os tincæ would not be discovered by the most minute examiner. He inclines to the opinion, that it is an unnatural hymen, and he describes a kind of tube extending from the os uteri to within three-fourths of an inch of the meatus urinarius; impervious below, but probably entering obscurely into the vagina. He offers no theory on the manner in which conception had taken place. The woman was unmarried at the time, but has since lived with a husband two years, but no conception has

taken place. This is the first and only instance of the successful performance of the Cæsarean section in the United States.—*Reese.*]

OF OPERATING WHEN THE FŒTUS IS EXTRA-UTERINE.

Delivery cannot possibly happen in the ordinary way, when the fœtus is situated in the ovaries, or Fallopian tube, or in the cavity of the peritoneum. However, there are many instances recorded of ventral pregnancies, which the mothers survived, the dead fœtus having been discharged by fragments out of an abscess in the parietes of the abdomen. A remarkable case under Mr. Gunning, in St. George's Hospital, I had an opportunity of seeing a few years ago, in which the child was discharged piecemeal from an abscess on the fore part of the abdomen; and I have lately seen another case under Dr. Blicke, of Walthamstowe, in which portions of bone and a great deal of matter have been voided through the vagina, though the swelling is altogether on the right side of the abdomen.

Practitioners are occasionally called upon to do a very similar operation to the Cæsarean, when the child has passed into the cavity of the peritoneum, in consequence of the rupture of the uterus. Unfortunately, such an accident is not uncommon, and though the causes of it may not be obvious, nothing is more certain than that the fœtus itself is entirely passive, and has no share in producing the misfortune. The symptoms, by which the event can be known, are not always easy of comprehension. When, however, the pains have been violent; when the last, after being excessively severe, has been followed by a kind of calm; when the countenance loses its colour, the pulse grows weak, and the extremities become cold and covered with a cold sweat; when the abdomen is generally flat and only partially affected with a swelling, occasioned by the fœtus, which either continues to move, or is dead and motionless; when the patient complains of a moderate degree of heat about the belly; and lastly, when the child shrinks from the touch of the accoucheur; it is manifest that the uterus is lacerated. If the child has passed completely into the abdomen, gastrotomy is the only resource. Should a part of it, however, yet remain in the uterus, it may be extracted with the aid of the forceps, if the head presents, or by the feet, provided only the upper part of the body be in the abdomen.

Baudeloque quotes three instances of gastrotomy, performed on account of the rupture of the uterus. The first is that inserted by Thibaud Dubois, in the *Journal de Médecine*, for May, 1760. Every preparation was made for a natural labour, when, after excessively violent pains about the upper and left part of the uterus, the child disappeared. Thibaud opened the abdomen, though not till some hours after the accident. The infant was dead; but the mother experienced no ill effects after the operation, except such as are usual after ordinary labours.

The second and third cases were communicated to the French Academy of Surgery in 1775, by Lambron, a surgeon of Orleans. He practised the operation twice on the same woman with success. In the first instance, he operated eighteen hours after the rupture of the uterus. The child was dead. An ill-conditioned abscess formed near the wound; but the patient got quite well in the course of six weeks. She was pregnant again the following year, and the uterus was once more ruptured. Lambron now had recourse to the operation without delay. The child betrayed some signs of life, but soon died. The mother not only survived; but afterward became pregnant again, and had a favourable delivery.

In a foregoing column, I have adverted to the case in which Dr. Locher, of Zurich, saved both the mother and child by the Cæsarean operation, performed in the linea alba. After her recovery, a small point of the wound, not exceeding two or three lines in length and breadth, required a long time to be quite healed, though no particular inconvenience was experienced from it. Some time afterward the cicatrix gave way again, and a portion of omentum protruded, which was reduced, when a piece of bowel came out, and was also returned. The edges of the wound were then brought together; but a small superficial ulcer continued open in spite of every effort to close it. In 1818, the year following that in which the Cæsarean operation had been performed on her, she became pregnant again, and the chief particularity which happened during gestation, was an increase in the size of the preceding ulcer, which became three inches in width. The sore, however, was covered with charpie, and the integuments well supported with adhesive plaster. On the 23d of May, she was seized with labour-pains; and about seven in the evening, she complained all at once of a very acute pain, and at the same moment voided a considerable quantity of blood from the vagina. On examining by this passage, nothing was discovered; but, when the hand was applied below the navel, in the line of the old wound and under the ulcer, a circumscribed firm swelling was felt, caused by the child's head, of which the sutures were plainly discernible. Dr. Locher naturally concluded, that the uterus had burst, so as to allow the child to escape, and the hemorrhage was thus easily explained. A repetition of the Cæsarean operation was deemed indispensable. The place of the incision was determined by the round swelling, caused by the child's head. An incision, six inches in length, was made into the abdomen, where a quantity of coagulated blood was found. When this had been removed, the membranes presented themselves, exhibiting a bluish hue, and after they had been opened, the head of the child immediately appeared. The navel-string passed round the neck, which was also compressed in the opening of the uterus. The child evinced no signs of life. The placenta came away during the attempts to reanimate the child. The uterus contracted, and there was little bleeding. This patient, after a good deal of indisposition, and occasional approaches to a perfect recovery, was at length attacked with inflammation of the stomach and bowels, and died on the 9th of July. The uterus was found contracted to a small size, with an opening of about the size of an almond, on its anterior surface, with a rounded callous edge. This aperture, Dr. Locher thinks, had remained ever since the first operation, and had allowed the escape of the child in the second labour; a circumstance which may be doubted, as the hemorrhage indicated the period when the uterus had been lacerated, as this gentleman indeed has in one place particularly noticed himself.—(See *Med. Chir. Trans. vol.* 11, *p.* 182, *&c.*) An almost incredible case is related of what may be called a Cæsarean birth, effected solely by the powers of nature, and, as would appear, by a sudden rupture of the uterus and parietes of the abdomen, after the patient had been in labour three days.—(See *Essays and Obs. Physical and Literary, vol.* 2.)

A laceration in the uterus, or the wound made in this viscus in the Cæsarean operation, may give rise to dangerous and even fatal symptoms of strangulation if any of the intestines insinuate themselves into the preternatural opening. When such an occurrence happens in the performance of the preceding operation, the intestine must be directly withdrawn and replaced. If the accident were to happen, when the child is extracted in the natural way, the bowel is to be pushed back into the abdomen from the uterus. Were the occurrence to take place several days after the operation, Sabatier inquires, what ought to be done? A surgeon is said to have pushed back the intestine from the uterus as late as the third day. Sabatier thinks, that later it could not be done. In this circumstance, Baudeloque advises the operation suggested by Pigrai, namely, that of opening the abdomen and withdrawing the bowel from the place in which it is incarcerated. But there are serious objections to this proceeding. There is no certainty that the intestine is strangulated, and if it were so, the adhesions which are soon formed, would frustrate the design of the operator.

Gastrotomy has not only been recommended for cases where the child has passed into the abdomen through a rupture of the uterus; it has likewise been advised for instances, in which the fœtus has grown in the Fallopian tube, ovary, or cavity of the abdomen. Here, indeed, the operation deserves to be called Cæsarean; for, in addition to the incision in the skin and muscles of the abdomen, it is necessary to open the pouch in which the child is contained. The instances of conception in the Fallopian tube are not uncommon. Those in the ovary and cavity of the peritoneum are more rare. Sabatier conjectures, that most of the cases reported to be of the latter kind, if attentively examined, would have been found to be in reality conceptions in the Fallopian tube.

Extra-uterine conceptions hardly ever arrive at maturity. However, the fœtus formed in the Fallopian tube has sometimes been known to attain the term of nine months, and then die, either from the impossibility of its expulsion, or from the insufficiency of the nourishment afforded it. The pouch in which it was contained, and the neighbouring parts, have then inflamed, and after becoming connected together by numerous adhesions, have suppurated. The abscess has burst, partly at some point of the circumference of the belly, and partly into the rectum; and the dead fœtus has been discharged piecemeal with the matter.

In other examples, the fœtus, instead of giving rise to the abscesses, has become ossified with the enveloping membranes, and continued in this state many years, without any other inconvenience to the patient than what depended on the size and weight of the tumour within the abdomen.

Most frequently, however, the pouch containing the fœtus bursts about the middle of the ordinary period of gestation, and the child passes into the cavity of the peritoneum. At the same moment, the blood-vessels ramifying on the parietes of the containing parts usually pour forth into the abdomen so much blood, that the patients generally die in the space of a few hours.—(See *a case by Dr. Clarke in Trans. of a Society for the Improvement of Medical and Chirurgical Knowledge. Also another, adverted to by Mr. C. Bell, in Med. Chir. Trans. vol. 4, p. 340.*)

Two facts of this kind fell under Sabatier's observation. The women were in the end of the fourth month of pregnancy. Excepting a swelling, which affected only one side of the abdomen, and frequent dragging pains in this cavity, there was no indication of any thing extraordinary. In other respects the patients were well. They were both, all on a sudden, attacked with extremely acute pains which lasted two or three hours. A more violent suffering than the rest was followed by entire ease. The abdomen subsided, and became, as it were, flat. An equal moderate warmth diffused itself over this part of the body. The skin lost its colour. Almost continual syncopes occurred. The pulse was feeble and concentrated. The whole body was covered with a cold sweat, and the women died. The rapid course of these symptoms rendered it impossible for Sabatier to be of any service. The patients were actually dying when he was called to them. The examination of their bodies evinced, that the abdomen contained a large quantity of blood; that the fœtuses lay on the intestines, connected with the lacerated Fallopian tube by means of the umbilical cord; and that the tube itself, which was strongly contracted, presented no other tumour, except that which depended on the after-birth.

There is nothing that announces an extra-uterine pregnancy with sufficient certainty to justify any positive conclusion respecting the nature of the case, before the ordinary time of parturition. In many women the gravid uterus inclines to one side, and numerous pregnant females have dragging pains, which may depend upon other causes. Things, however, are different when the fœtus has lived to the ordinary period of parturition, and the woman is attacked with labour-pains; because, besides the unequivocal signs of the presence of a child in the abdomen, the womb is empty, and is little changed from its common state. Should we now, asks Sabatier, have recourse to the Cæsarian operation, just as if the fœtus were in the womb? Can we be sure, that the pouch which contains the child, will contract itself like the uterus, and that the incision which is in contemplation, will not give rise to a fatal hemorrhage? Would it be easy to separate and remove the whole of the placenta? How could the discharge, analogous to the lochia, find an outlet, and would not its extravasation in the abdomen be likely to prove fatal? Sabatier thinks, that the risk which is to be encountered, is much less when things are left to nature. The child, indeed, must inevitably perish. It will either give rise to abscesses, with which it will be discharged in fragments, or it will remain for a length of time in the abdomen, without any urgent symptoms. Sabatier also calls our attention to the great precariousness of an infant's life, and expresses his opinion, that there can be no difficulty in deciding what conduct ought to be adopted. Happily, practitioners are not often placed in circumstances so delicate, and extra-uterine conceptions mostly perish before the end of the common period of gestation. We have then only to second the efforts of nature; either by promoting suppuration, if it should seem likely to occur, by making a suitable opening, or enlarging one that may have formed spontaneously; by extracting such fragments of the fœtus as present themselves; by breaking the bones when their large size confines them in the abscess, as Littre did in an instance where the abscess burst into the rectum; and lastly, by employing suitable injections.—(*Sabatier, Médecine Opératoire, t.* 1.)

An extremely uncommon case of extra-uterine conception was related a few years ago by Josephi; the fœtus having at length passed into the bladder by ulceration, and caused such affliction as rendered an incision into that receptacle indispensable, with the view of extracting the parts of the fœtus lodged in it. The operation was done above the pubes; but the internal mischief already existing was so great, that the patient did not recover.—(*Ueber die Schwangerschaft ausserhalb der Gebärmutter; Rostock*, 1803, 8vo.)

Govei, p. 401, relates a case of ventral conception, in which instance the Cæsarean operation was done, and the child preserved. A lady, aged twenty-one, had a tumour in the groin, which was at first supposed to be an epiplocele, but an arterial pulsation was perceptible in it. In about ten weeks the swelling had become as large as a pound of bread. Govei, solicited by the lady, opened the tumour. He first discovered a sort of membranous sac, whence issued a gallon of a limpid fluid. The sac was dilated, and a male fœtus found, about half a foot long, and large in proportion. It was perfectly alive, and was baptized. After tying the umbilical cord, the placenta was found to be attached to the parts just behind, and near, the abdominal ring; but it was easily separated. Govei does not mention whether the mother survived; but the thing would not be very astonishing, considering the situation of the fœtus. Bertrandi says, he was unacquainted with any other example of the Cæsarean operation being done, in cases of extra-uterine fœtuses, so as to save both the mother and infant. This eminent man condemned operating, in ventral cases, on the ground that the placenta could not be separated from the viscera, to which it might adhere, or, if left behind, it could not be detached, without such inflammation and suppuration as would be mortal. But if, in addition to such objections, says Bertrandi, the operation has been proposed by many, and practised by none, we may conclude, that this depends on the difficulty of judging of such pregnancies, and of the time when the operation should be attempted. He puts out of the question the dilatations which have been indicated for extracting dead portions of the fœtus, and also Govei's case, who operated without expecting to meet with a fœtus at all.—(*Bertrandi, Traité des Opérations de Chirurgie, chap.* 5.)

Whenever the Cæsarean operation, or gastrotomy, has been performed, the practitioner is not merely to endeavour to prevent inflammation, heal the wound, and appease any untoward symptoms which may arise; he should also prevail upon the mother to suckle the child, in order that the lochia may not be too copious; and, after the wound is healed, she should be advised to wear a bandage, for the purpose of hindering the formation of a ventral hernia, of which, according to surgical writers, there is a considerable risk.

[The following case of extra-uterine conception is here inserted as being perfectly unique in its kind. No such case is to be found referred to in *Ploucquet's Lit. Med. Digest*, nor in any of the numerous periodicals which enrich the profession. It occurred in the practice of Drs. Cotton and Harlow, of Georgia, and was communicated to Prof. Francis, of New-York. The subject was a negro woman, aged 30 years. On the night of the 23d of Jan. 1819, she was taken in labour. There appeared no doubt that she had arrived at the full time of labour. Her labour-pains ceasing, she was attended to for a few days for dropsical symptoms, under which she suffered greatly. On the 4th of February, she was again taken in labour. The pains, however, shortly after entirely ceased; and after five weeks she expired. On examination after death, the following facts presented themselves. In the first place, Drs. Harlow and Cotton drew off from the abdomen three and a half gallons of an extremely turbid and offensive fluid. On opening the abdomen, the first thing that

presented itself was the child, extending itself across the abdomen; its head in the right, its feet in the left, hypochondriac regions; its back immediately to the umbilicus of the mother. It was as large a child as either of them had ever seen at birth, and perfectly formed. *The funis was of the usual size, about six inches in length, and inserted into the fundus uteri without the intervention of a placenta.* The uterus was about the size of an orange; its coats very much thickened and indurated, with a small quantity of a thin glassy fluid within its cavity. The abdominal viscera were all diseased, save the bladder. The liver retained its original shape and position, but looked more like a mass of glue than organized animal matter. The spleen had gone into a state of complete decomposition. As to the omentum, there was not the slightest vestige left. The bladder appeared to be the only viscus that had escaped uninjured from this digression in nature. The bowels had firmly adhered in one uniform mass from the stomach to the rectum, and to the posterior and lateral parietes of the abdomen.—(See *New-York Med. and Phys. Journal, vol.* 1.)

The case of extra-uterine fœtus in which Dr. MacKnight of New-York operated with success, is often referred to.—(See *Lond. Med. Society's Trans. vol.* 4.) This interesting case confirms the views of those who believe in the entire production and perfection of the human fœtus *extra-uterum.*—(*Thacher's Med. Biography.*) But even this operation is not entitled to the epithet Cæsarean, and therefore does not detract from the claims of Dr. Richmond, who opened the uterus itself.—(See *the preceding note, p.* 221.)

Gastrotomy has been performed for the removal of extra-uterine fœti several times in America, with complete success.

Mr. Wm. Baynham, of Virginia, member of the Royal College of Surgeons, London, succeeded, as early as 1791, in removing an extra-uterine fœtus from the abdomen, after it had lain there ten years. He thus preserved the life of a valuable woman, who was otherwise sinking into the grave, with hectic fever and the most dangerous symptoms.

In 1799, he repeated the operation with the like success on a servant woman of Mrs. Washington's, Fairfax Co., Virginia. In the publication of these cases in the *N. Y. Med. and Phys. Journal, vol.* 1, Mr. B. has performed a valuable service to the profession, in the judicious remarks with which he accompanies the report.

In the same work, Dr. J. Augustine Smith, now Professor of Anatomy in the University of New-York, has published a case in which he performed this same operation in 1808, in the city of New-York, with the most satisfactory result. I have not been able to find any other cases of success in this operation in this country, except those of Dr. MacKnight, Mr. Baynham, and Professor Smith, and must refer to the journals I have named for their interesting details.

The following cases of Cæsarean operation are extracted from the *N. Y. Med. and Phys. Journal, vol.* 2, *for* 1823; and as two of them were self-performed, and the other accomplished by an illiterate female accoucheur, they will be found interesting in a high degree. The recovery of these women should be regarded as extraordinary escapes, rather than as affording encouragement rashly to attempt this great and dangerous achievement.

"In the afternoon of Jan. 29th, 1822, (says Dr. S. M'Clellen), I was called upon by Mr. Kipp, of Nassau, to consult with Dr. Bassett on the case of his servant girl, who, he said, was in a deplorable situation. I immediately repaired to his house, and found the patient to be a girl fourteen years of age, one-fourth black. She had a firm pulse, and complained of little or no pain. Dr. B. informed me, that she had a wound in her abdomen, near the centre of the epigastric region, from which he had extracted a full-grown fœtus, that was in part protruded, together with a considerable portion of her intestines. The placenta having two umbilical cords attached to it, he had removed from the same orifice, and had also introduced his hand into the uterus per vaginam, &c.

On examination I found an irregular incision of about four inches in length, extending in a diagonal direction, as respects the abdomen, about two inches above the umbilicus, and an incision of about two inches in length at nearly a right angle with the former, extending towards the sternum. The lower part of the abdomen was considerably distended with blood.

Our attempts were in the first place directed to the evacuation of the blood contained in the abdomen, which was partly effected by a change of posture and slight compression. We then brought the lips of the wound in contact by the interrupted suture, dressed it with lint spread with emollient unguent, and secured the whole with a broad bandage. After administering an anodyne, we left her for the night. I did not see her again, but was informed by Dr. B. that she never had any very *violent* symptoms.

The second day he bled her, gave her a cathartic, and pursued the antiphlogistic regimen a few days, when the febrile excitement subsided. An ordinary use of tonics was then resorted to, and in a few weeks the patient was perfectly recovered.

The circumstances attendant on the infliction of the wound were these. While the family was at dinner, she went a distance of perhaps fifty rods from the house, and placed herself on a snow-drift, near a fence, where she was first discovered by her master in the act of covering something with snow, which afterward proved to be a naked child. As soon as she perceived that she was observed, she immediately ran to the house, with the second child hanging out at the wound, together with a considerable portion of her intestines; laid by her razor and large needle, which were the instruments she had previously prepared for the operation, and shortly began to complain.

I should judge from the appearance of the blood upon the snow, there being three several places where she evidently stopped, that the incision was made *immediately* preceding the rupture of the membranes, and that the first child was delivered *per vias naturales*, the third pain after the rupture.

As some of the greatest discoveries in every department of science are made by accident, or without any particular previous design, may not the conduct of this desperate girl give a useful hint for an improvement in the Cæsarean operation, consisting in a division of the uterus diagonally, near the fundus, instead of the ordinary method?"

The following is the case of Alice O'Neal, inserted in the Medical Essays and Observations published by a society in Edinburgh, by Mr. Duncan Stewart, surgeon in Dungannon, in the county of Tyrone, Ireland.

Alice O'Neal, aged about thirty-three years, wife to a poor farmer near Charlemont, and mother of several children, in January, 1739, took her labour-pains; but could not be delivered of her child by several women who attempted it. She remained in this condition twelve days: the child was judged to be dead after the third day. Mary Donally, an illiterate woman, but eminent among the common people for extracting dead births, being then called, tried also to deliver her in the common way: and her attempts not succeeding, performed the Cæsarean operation, by cutting with a razor, first the containing parts of the abdomen, and then the uterus; at the aperture of which she took out the child and secundines. The upper part of the incision was an inch higher, and to a side of the navel, and was continued about six inches downwards in the middle between the right *os ileum* and the *linea alba*. She held the lips of the wound together with her hand, till one went a mile and returned with silk and the common needles which tailors use. With these she joined the lips in the manner of the stitch employed ordinarily for the hare-lip, and dressed the wound with whites of eggs, as she told me some days after, when, led by curiosity, I visited the poor woman who had undergone the operation. The cure was completed with salves of the midwife's own compounding.

In about twenty-seven days, the patient was able to walk a mile on foot, and came to me in a farmer's house, where she showed me the wound covered with a cicatrix; but she complained of her belly hanging outwards on the right side, where I observed a tumour as large as a child's head; and she was distressed with the *fluor albus*, for which I gave her some medicines, and advised her to drink the decoctions of the vulnerary plants, and to support the side of her belly with a bandage. The patient has enjoyed very good health ever since, manages her family affairs, and has frequently walked to market in this town, which is six miles' distance from her own house.—(*Essays, vol.* 5.)

In the year 1769, a negro woman (belonging to Mrs

Bland, a midwife) at Mr. Campbell's grass plantation at the Ferry, between Kingston and Spanish Town, in Jamaica, being in labour, she performed the *Cæsarean operation* on herself, and took her child out of the left side of her abdomen, by cutting boldly through into the uterus.

She performed this operation with a butcher's broken knife, about two inches and a half long—the part which joined to the handle. The position of the child was natural; she cut through near the *linea alba*, on her left side, and cut into the child's right thigh, which presented at the part, about three lines deep, and two inches and a half long. The child came out by the action of its own struggling. A negro midwife was sent for to her, who cut the navel cord and freed the child; and returned the part of the navel cord adhering to the placenta, and a considerable portion of the intestines also, into the abdomen, which had come out of the wound with the child.

The surgeon who attended the plantation was sent for, a few hours after the accident happened; and judging, from the situation in which he found her, that some dirt had been put into the wound, by the old midwife, with the intestines, he cut open the stitches that had been made, and carefully washed the parts clean, extracted the placenta at the wound, and then stitched it up again.

On the third day, after she had recovered from her low state from the loss of blood, which was considerable, a fever came on, which was removed by cooling medicines; she then took bark for ten days. The wound was fomented and dressed properly, and was soon cured; and the woman was well in six weeks' time from the accident, and able to go to her work.

The child died on the sixth day, with the *Jaw-falling*, as it is called; but came into the world healthy and strong.

The woman continued perfectly well, menstruated regularly, and was with child again a year or two afterward. She attempted the same operation again; but was watched and prevented, and had a regular and proper labour. She had borne three children before this affair, all with natural and easy births. She was an impatient and turbulent woman, whose violence of temper was the only cause assigned for her conduct.—(*Mosely on Tropical Diseases.*)—*Reese.*]

CALCULUS. Calculi form in the ducts of the salivary glands; in the kidneys, bladder, urethra, gall-bladder, &c. A paper on calculi formed in the lachrymal sac is contained in Graefe's new Journal.—(*Journ. fur die Chir. No. 1, Berlin*, 1820.) For an account of stones in the bladder, refer to *Urinary Calculi.*

[CALCULOUS DEGENERATION OF THE SCROTUM. The following singular case is communicated by Professor Mott. It was first published in the *Philadelphia Journal* for 1827.

"In the practice of surgery we frequently observe very singular morbid alterations of texture, which are worthy of being recorded notwithstanding our inability to account for their production. None of the works that we have examined contain a description of such a degeneration as that we are about to describe, nor have we ever met with another instance of a similar kind. It may, therefore, be useful to state the fact, as a contribution towards a more complete history of the morbid anatomy of the scrotum.

In the summer of 1824, I was requested to visit J. R. aged about seventy-three, a wealthy farmer, residing upon Long Island. His health had been declining for two or three years from an affection of his stomach, accompanied, as he stated, with an uncommon disease of the scrotum. The latter complaint had so far increased within the last year, as materially to injure his health, in consequence of an ulceration and very fetid discharge therefrom.

The constant and severe burning which he experienced in the region of the pylorus, with an ejection of the contents of the stomach shortly after eating, together with frequent acrid eructations and costiveness, led to the fear that there was some organic derangement of the lower orifice of the stomach.

As the disease of the scrotum was the particular object of my visit, I requested permission to examine it. It exhibited a monstrous, and to me a very unique appearance, reaching fully two-thirds the length of his thighs, being from twelve to fifteen times its ordinary bulk, and studded, particulary on each edge (it being flattened anteriorly and posteriorly) with several dozen tumours, of a stony hardness, covered with the integuments, from the size of nutmegs to that of a large pea. It resembled an enormous bunch of grapes, or more closely some morbid conditions of the pancreas and spleen which we have occasionally met with. The tumours had all a very white appearance, and the integuments of two or three of the largest, having been ulcerated for upwards of a year, poured forth a constant and very fetid discharge. At these openings white bodies were seen, which, when touched with a probe, felt of a stony hardness. A white substance resembling mortar was discharging from these openings, which resulted from the crumbling away of the calculi,

and the combination of this subetance with the fluid from the ulcers.

This state of the scrotum was of upwards of twenty years' duration, and had been gradually increasing, the tumours multiplying as the scrotum augmented in size. The patient knew of no cause to which it could be ascribed.

From its size and weight, as well as the loathsome nature of the discharge, he becam desirous to have it removed if practicable and proper. His health being sufficiently good, and the testes appearing to move freely in the diseased mass, led me to recommend that the operation should be performed.

An incision was made around the root or base of the scrotum, beginning on each side of the under part of the penis, at a point a little above the scrotum, so that some integument of this part of the penis in a diseased state was also removed, and carried down to the perinæum, leaving an angular portion of the scrotum below of about an inch in length. Cautiously cutting through the diseased integuments and the subcutaneous cellular structure, the vaginal coat of each testis was readily discovered and avoided. The whole of the morbid mass was removed by cautious dissection, leaving the tunica vaginalis on each side sound and unopened. Numerous arteries were secured during the dissection in the integuments, as well as several large ones in the septum scroti.

The perinæal portion of the scrotum was susceptible of very considerable elongation, but it was altogether insufficient to cover the testes. A new covering for them, therefore, could only be looked for from the granulatory process. Light dressings of lint, compress, and a T bandage were applied for the first two days, followed by emollient poultices to favour the second mode of healing.

Suppuration and granulation being well established, the new scrotum was increased and fashioned by the use of adhesive straps.

His complete recovery from the operation, and the reproduction of a scrotum, was not interrupted by any circumstance. Three years have now elapsed, and he enjoys excellent health, being occasionally obliged to take for a week or two a few grains of the subnitrate of bismuth, to remove the affection of his stomach, which, before the operation was performed, threatened to become an organic disease."—*Reese.*]

CALCULUS IN THE INTERIOR OF THE EYE. See *Eye, &c.*

CALLUS, *new bone*, or the substance which serves to join together the ends of a fracture, and for the restoration of destroyed portions of bone.

1. The old surgeons believed callus to be a mere inorganic concrete, a fluid poured out from the extremities of the ruptured vessels, which was soon hardened into bone. They always described it as an "exudation of the bony juice," and imagined that it oozed from the ends of broken bones, as gum from trees, sometimes too profusely, sometimes too sparingly. The reunion of broken bones, and the hardening of callus, they compared with the glueing together of two pieces of wood, or the soldering of a broken pot.—(*A. Paré.*) They also conceived, that callus sometimes flowed into the joints, so as to form a clumsy, prominent protuberance. They imagined that callus was a juice which congealed at a determinate period of time, and they therefore had fixed days for undoing the bandages of each particular fracture. They supposed, that its exuberance might be suppressed by a firm and well-rolled bandage, and its knobby deformities corrected by pillows and compresses; that it might be softened by frictions and oils, so as to allow the bone to be set anew. All their notions were mechanical; and their absurd doctrines have been the apology for all the contrivers of machines, from Hildanus down to Dr. Aiken and Mr. Gooch.

2. By Galen and Duhamel, however, a second doctrine was entertained, which imputed the formation of callus altogether to the periosteum and medullary texture, which were supposed to produce two solid rings round the fracture, the interspace between them being afterward effaced.

3. A third opinion, maintained by Bordenave, and the best modern observers, is, that the process of nature, in the production of callus, bears a great resemblance to the changes which take place in the reunion of the soft parts.

A bone is a well-organized part of the living body; that matter, which keeps its earthy parts together, is of a gelatinous nature. The phosphate of lime, to which a bone owes its firmness, is deposited in the interstices of the gluten, undergoing a continual change and renovation. It is incessantly taken up by the absorbents, and secreted again by the arteries. It is this continual absorption and deposition of earthy matter which forms the bone at first, and enables it to grow with the growth of the body. It is this unceasing activity of the vessels of a bone which enables it to renew itself when it is broken or diseased. In short, it is by various forms of one secreting process, that bone is formed at first, is supported during health, and is renewed on all necessary occasions. Bone is a secretion, originally deposited by the arteries of the bone, which arteries are continually employed in renewing it. Callus is not a concrete juice, deposited merely for filling up the interstices between fractured bones, but it is a regeneration of new and perfect bone, furnished with arteries, veins, and absorbents, by which its earthy matter is continually changed, like that of the contiguous bone. Indeed, there could be no connexion between the original bone and callus, were the latter only the inorganic concrete, as it was formerly supposed to be.

Notwithstanding the more accurate opinions now entertained concerning callus, the supposition is still very common, that the slightest motion will destroy callus, while it is being formed. But, says Mr. John Bell, it is an ignorant fear, proceeding merely from the state of the parts not having been observed; for, when callus forms, the perfect constitution of the bone is restored; the arteries pour out from each end of a broken bone a gelatinous matter; the vessels by which that gluten is secreted expand and multiply in it, till they form between the broken ends a well-organized and animated mass, ready to begin anew the secretion of bone. Thus, the ends of the bone, when the bony secretion commences, are nearly in the same condition, as soft parts which have recently adhered; and it is only when there is a want of continuity in the vessels, or when a want of energetic action incapacitates them from renewing their secretion, that callus is imperfectly formed. This is the reason why, in scorbutic constitutions, in patients infected with syphilis, in pregnancy, in fever, or in any great disorder of the system, or while the wound of a compound fracture is open, no callus is generated.—(*John Bell's Principles of Surgery, vol.* 1, *p.* 500, 501.) How far some of the latter statement is correct, or not, will be seen in the article *Fractures.*

For some time the secretion of earthy matter is imperfect; the young bone is soft, flexible, and of an organization suited for all the purposes of bone; but hitherto delicate and unconfirmed; not a mere concrete, like the crystallization of a salt, which, if interrupted in the moment of forming, will never form; not liable to be discomposed by a slight accident, nor to be entirely destroyed by being even roughly moved or shaken. Incipient callus is soft and yielding; it is ligamentous in its consistence, so that it is not very easily injured; and in its organization it is so perfect, that when it is hurt, or the bony secretion interrupted, the breach soon heals, just as soft parts adhere, and thus the callus becomes again entire, and the process is immediately renewed.

In consequence of the above circumstances, if a limb be broken a second time when the first fracture is nearly cured, the bone unites more easily than after the first accident; and Mr. J. Bell even asserts, that when it is broken a third and a fourth time, the union is still quicker. In these cases the limb yields, it bends under the weight of the body which it cannot support; but without any snapping or splintering of the bone, and generally without any over-shooting of the ends of the part, and without any crepitation.

Callus is found to be more vascular than old bone. Mr. J. Bell mentions an instance of a bone, which had been broken twelve years before he injected it, yet the callus was rendered singularly red. When a recently formed callus is broken, many of its vessels are ruptured, but some are only elongated, and it rarely happens that its whole substance is torn. It is easy to conceive how readily the continuity of the vessels will be renewed in a broken callus, when we reflect on its great vascularity and the vigorous circulation excited by the accident in vessels already accustomed to the secretion of bone. These reasons show why a broken or bent callus is more speedily united than a fractured bone.

While the ends of a broken bone are connected together by a flexible substance of cartilaginous consistence, Dupuytren calls this bond of union the *provi-*

sional callus, which generally lasts until the thirtieth or fortieth day. In a later stage the intervening cartilaginous matter ossifies; the swelling of the soft parts subsides; and in from six to twelve months the callus or new bony matter filling the medullary canal is absorbed, whereby the latter is restored. The callus remaining after the completion of this process, Dupuytren terms *definitive*.

When bones granulate, says Mr. Wilson, the granulations at first appear exactly similar to those of the soft parts, and, as in the soft parts, take place to restore any loss which the bones may have suffered. This process is very similar to that of the first formation of bone. In the skull membrane was first formed; and here, also, in the process of restoration the granulations change into membrane, and then into bone. In cylindrical bones, the granulations first produce a species of cartilage, and this is afterward converted into bone. Thus, in the restoration of bone, nature is guided by the same laws which prevail in its first formation. If the granulations thrown out on the surface of a bone be viewed in a microscope, they appear to form a number of small points like villi, the bases of which first become similar to cartilage, and then to bone. "The preparations from the surface of granulating stumps show the extreme delicacy of the first bony threads, and also their mode of uniting laterally with each other."—(*On the Structure, Physiology, and Diseases of the Bones, &c. p.* 197, 8*vo. Lond.* 1820.)

And in another place he repeats, "I have examined several skulls on the death of the persons, at different periods, from days to years after pieces of bone had been removed, and before vacancies had been completely filled up; but I never could in any of them discover the least appearance of cartilage." A membrane here always precedes the formation of bone.—(*P.* 210.) For additional observations on callus see *Fracture. N. M. Muller, De Callo Ossium; 4to. Norimb.* 1707; *Duhamel in Mém. de l'Acad. CALOMEL. (Submuriate of mercury; hydrargyri submurias, L. P.) Its extensive utility in numerous surgical diseases will be conspicuous in a large proportion of the articles in this work. When prescribed as an alterative the common dose is a grain once or twice a day; when ordered as a purgative, from three to eight grains may be given; and when directed with the view of exciting salivation, one or two grains, conjoined with opium, are usually administered night and morning.

CAMPHOR is used externally, chiefly as a means of exciting the action of the absorbents, and thus dispersing many kinds of swellings, extravasations, indurations, &c. Hence it is a common ingredient in liniments. It has also the property of rousing the action of the nerves and quickening the circulation in parts on which it is rubbed. For this reason, in paralytic affections it is sometimes employed. Perhaps there is no composition that has greater power in exciting the absorption of any tumour or hardness than camphorated mercurial ointment.

In cases of delirium, depending on the irritation of local surgical diseases, and in some descriptions of mortification, camphor is occasionally prescribed. It has also been recommended as singularly useful for the relief of stranguries, even those depending on the opetion of cantharides. But although it may occasionally have succeeded, when given with this view, it not only does not always do so, but it has been known to cause an opposite effect, sometimes producing great scalding in voiding the urine, and sometimes pains like those of labour.—(*Medical Trans. vol.* 1, *p.* 470.) In chordee its utility is generally acknowledged. Persons who cannot procure rest unless they take very large doses of opium, sometimes find smaller ones answer, if combined with camphor.—(See *Brande's Manual of Pharmacy, p.* 46.)

CANCER. (Derived from *cancer*, a crab, to which a part affected with cancer and surrounded with varicose veins was anciently thought to have some resemblance.) *Carcinoma.*

The disease has two principal forms, one named *scirrhus* or *occult cancer*; the other, *ulcerated* or *open cancer*. According to the usual definition, as Mr. Pearson observes, an indolent scirrhus is a hard and almost insensible tumour, commonly situated in a glandular part and accompanied with little or no discoloration of the surface of the skin. But when the disease has proceeded from the indolent to the *malignant* state, the tumour is unequal in its figure, it becomes painful, the skin acquires a purple or livid hue, and the cutaneous veins are often varicose.—(*Principles of Surgery*, § 331. 343.) The pain is remarked to be acute and lancinating, and its attacks recur with more or less frequency. At length the tumour breaks, and is converted into cancer, strictly so called, or the disease in the state of ulceration.

The female breast and the uterus are particularly subject to the disease. The breasts of men are but rarely affected. The testes, lips (especially the lower one of male subjects), the penis, the lachrymal gland and eye, the tongue, the skin (particularly that of the face), the tonsils, the pylorus, the bladder, rectum, prostate, and a variety of other parts, are recorded by surgical writers as having frequently been the seat of scirrhus and cancer. They seem, however, to have comprehended an immense number of different malignant diseases under one common name, and in many of the cases called cancerous there are no vestiges of the true scirrhous structure.

OF SCIRRHUS, OR CANCER NOT IN THE ULCERATED STATE.

Mr. Abernethy has given a matchless history of this affection as it appears in the female breast, where it most frequently occurs, and can be best investigated. Sometimes, as he has remarked, it condenses the surrounding substance so as to acquire a capsule; and then it appears, like many sarcomatous tumours, to be a part of new formation. In other cases the mammary gland seems to be the nidus for the diseased action. In the latter case the boundaries of the disease cannot be accurately ascertained, as the carcinomatous structure, having no distinguishable investment, is confused with the rest of the gland. Sir Everard Home also remarks, that when the disease originates by a small portion of the glandular structure of the breast becoming hard, which is very commonly the case, it is readily distinguished by the hard part never having been perfectly circumscribed, and giving more the feel of a knot in the gland itself than of a substance distinct from it. In each of these instances carcinoma begins at a small spot, and extends from it in all directions, like rays from a centre. This is one feature distinguishing this disease from many others, which at their first attack involve a considerable portion, if not the whole, of the part in which they occur. The progress of carcinoma is more or less quick in different instances. When slow, it is in general unremitting. Mr. Abernethy thinks, that though the disease may be checked, it cannot be made to recede by the treatment which lessens other swellings. On this point, however, he is not positive; for surgeons have informed him, that diseases which eventually proved to be carcinomatous, have been considerably diminished by local treatment. With great deference to Mr. Abernethy, I may be allowed to remark in this place, that every tumour which ends in cancer is not from the first of this nature, though it has in the end become so; consequently, it may at first yield to local applications, but will not do so after the cancerous action has commenced. Hence Mr. Abernethy's opinion, that a true carcinomatous tumour cannot be partially dispersed, at least remains unweakened by the fact that some tumours have at first been lessened by remedies, though they at last ended in cancer. Sir E. Home's observations tend to prove that any sort of tumour may ultimately become cancerous.

Without risk of inaccuracy we may set down the backwardness of a scirrhous swelling to be dispersed or diminished, as one of its most confirmed features,

This obdurate and destructive disease excites the contiguous parts, whatever their nature may be, to enter into the same diseased action. The skin, the cellular substance, the muscles, and the periosteum, all become affected if they are in the vicinity of cancer. This very striking circumstance distinguishes carcinoma, says Mr. Abernethy, from several other diseases. In what this author calls *medullary sarcoma*, the disease is propagated along the absorbing system; but the parts immediately in contact with the enlarged glands do not assume the same diseased action. Neither in the *tuberculated* species does the ulceration spread along the skin, but destroys that part only which covers the diseased glands. According to Mr. Abernethy, a disposition to cancer existing in the surrounding parts, before the actual occurrence of the diseased action, was a circumstance noticed by Mr. Hunter. Hence arose the following rule in practice: *That a surgeon ought not to be contented with removing merely the indurated or actually diseased part, but that he should also take away some portion of the surrounding substance in which a diseased disposition may probably have been excited.* In consequence of this communication of disease to the contiguous parts, the skin soon becomes indurated, and attached to a carcinomatous tumour, which in like manner is fixed to the muscles or other part over which it is formed.

As a carcinomatous tumour increases, it generally, though not constantly, becomes unequal upon its surface, so that this inequality has been considered as characteristic of the disease. A lancinating pain is common; but it is not experienced in every case without exception. It is also a symptom attending other tumours, which are unlike carcinoma in structure, and it cannot, therefore, be deemed an infallible criterion of the nature of the disease.—(*Abernethy's Surgical Works, vol.* 2, *p.* 69, *&c.*)

A hard and painful glandular swelling, having a disposition to become cancer, says Richter, is the common, but inadequate and erroneous definition of scirrhus. The disease is not regularly attended with swelling; sometimes scirrhous parts diminish in size and shrink. Hardness is not a characteristic property; for many tumours which are not scirrhous, are exceedingly indurated. The disease is not always situated in a gland; it frequently attacks structures which cannot be called glandular; and hard glandular swellings are often seen which do not partake of scirrhus. The disposition to cancer cannot be enumerated among the marks of scirrhus, since it is not discoverable till carcinoma has actually commenced. Its termination in open cancer is not an invariable occurrence; and other tumours become cancerous to which no one would apply the term scirrhi.—(*Anfangsgr. der Wundarzn. b.* 1.)

With regard to the observation that *tumour* is not an essential character of carcinoma, Mr. C. Bell admits its correctness only in a certain sense: "It is true (says he) that there is not always an increase of the dimensions of the whole breast; on the contrary, true carcinoma is often accompanied with a contraction and diminution of the general bulk. But what is true of the breast or mamma is not true of the tumour; for the proper structure of the gland either shrinks or is compressed; and sometimes the surrounding fat is diminished by absorption, so that the whole mass is less than the natural breast, or than what the breast was before the commencement of the disease. But still the diseased part is properly a tumour: there we see an increased mass, a preternatural growth, or new matter, corresponding to the old definition, *morbosum augmentum*. But farther, and in respect to the adipose membrane, the fat is not always diminished in carcinoma mammæ, but sometimes quite the contrary; and this difference in it will sometimes produce a variety in the external character, when there is none in the disease actually or in the internal structure. Sometimes, from the diminution of fat, the irregular tuberculated structure of this disease will be apparent to the eye and to the touch: while in another patient the breast will be large, full, and smooth, only marked more than naturally with large blue veins, and having an ulcer like a hole dug in the centre of the breast."—(*C. Bell, in Med. Chir. Trans. vol.* 12, *p.* 220.) These observations fully agree with those which some attention to the appearances of cancer have enabled me to make.

Scientific surgeons ought undoubtedly to have a definite meaning when they employ the term scirrhus; the word is generally used most vaguely; and, perhaps, influenced by its etymology, surgeons call an immense number of various morbid indurations scirrhi, which are not at all of a malignant or dangerous character.

I have always considered scirrhus as a diseased hardness, in which there is a propensity to cancerous ulceration, and a greater backwardness to recede than exists in any other kind of diseased hardness, although the skin may occasionally not break during life, and a few scirrhous indurations may have been lessened.

Though Richter states that this disposition cannot be discovered till carcinoma has actually taken place; though Mr. J. Burns and Sir E. Home affirm that other indurations and tumours may terminate in cancer; though Mr. Abernethy shows that sarcomatous and encysted tumours may end in most malignant diseases, and such as equal cancer in severity (*Chir. Works, p.* 83); yet it is now well ascertained, that in all these instances, the changes which precede cancerous ulceration bear no resemblance to those of a true malignant scirrhus.

The puckering of the skin, the dull, leaden colour of the integuments, the knotted and uneven feel of the disease, the occasional darting pains in the part, its fixed attachment to the skin above, and muscles beneath and in the breast, the retraction of the nipple, form so striking an assemblage of symptoms, that when they are all present, there cannot be the smallest doubt that the tumour is a scirrhus, and that the disease is about to acquire, if it have not already acquired, the power of contaminating the surrounding parts and the lymphatic glands to which the absorbents of the diseased part tend.

As Sir Everard Home has observed, the truly scirrhous tumour, which is known to be capable of changing into the true open cancer, when allowed to increase in size, is known to be hard, heavy, and connected with the gland of the breast; and, when moved, the whole gland moves along with it. The structure of a scirrhous tumour in the breast is different in the various stages of the disease; and a description of the appearances exhibited in the three principal ones, may give a tolerable idea of what the changes are which it goes through previous to its breaking, or becoming what is termed an open cancer.

When a section is made of such a tumour in an early stage, provided the structure can be seen to advantage, it puts on the following appearance: the centre is more compact, harder to the feel, and has a more uniform texture than the rest of the tumour; and is nearly of the consistence of cartilage. This middle part does not exceed the size of a silver penny; and from this, in every direction, like rays, are seen ligamentous bands of a white colour and very narrow, looking, in the section, like so many extremely irregular lines passing to the circumference of the tumour, which is blended with the substance of the surrounding gland. In the interstices between these bands the substance is different, and becomes less compact towards the outer edge. On a more minute examination, transverse ligamentous bands, of a fainter appearance, form a kind of net-work, in the meshes of which the new-formed substance is enclosed. This structure accords with what Dr. Baillie describes as presenting itself in cancerous diseases of the stomach and uterus.

In a more advanced stage of the tumour, the whole of the diseased part has a more uniform structure; no central point can be distinguished; the external edge is more defined and distinct from the surrounding gland; and the ligamentous bands in different directions are very apparent, but do not follow any course that can be traced.

According to Mr. C. Bell, it is the ligamentous bands which produce the retraction of the nipple, by extending between its ducts and destroying its spongy texture. —(*Med. Chir. Trans. vol.* 12, *p.* 233.)

On dissection, Sir Astley Cooper observes, that the breast is one solid mass like cartilage, with very little vascularity except at its edges, and internally fibrous. When the breast has acquired any magnitude, he says, there is generally an opening in it, in which case it has the appearance internally of being worm-eaten and spongy. In the situation of the ulceration it is very vascular, and bloody serum is met with. The absorb-

ent glands put on the same character as the scirrhous breast. The cellular membrane, skin, and muscles are also affected. Sometimes the diseased glands above the clavicle press upon the thoracic duct, and thus interrupt the transmission of chyle into the blood. Hence the appetite is sometimes voracious, though the patient is rapidly wasting. In the chest, on the same side as the disease, hydrothorax prevails, and the absorbents on the pleura are in a morbid state, and small white spots, like pins' heads, are visible. Traces of scirrhous disorder Sir Astley Cooper likewise represents as occasionally existing in the liver, uterus, &c. —(See *Lancet, vol.* 2, *p.* 373.)

When the tumour has advanced to what may be called cancerous suppuration (which, however, does not always happen in the centre before it has approached the skin and formed an external sore), it exhibits an appearance totally different from what has been described. In the centre is a small irregular cavity filled with a bloody fluid, the edges of which are ulcerated, jagged, and spongy. Beyond these there is a radiated appearance of ligamentous bands, diverging towards the circumference; but the tumour near the circumference is more compact, and is made up of distinct portions, each of which has a centre, surrounded by ligamentous bands, in concentric circles.

It is remarked by Sir Everard Home, that in some instances scirrhus has no appearance of suppuration or ulceration in the centre, but consists of a cyst filled with a transparent fluid and a fungous excrescence, projecting into this cavity, the lining of which is smooth and polished. When a large hydatid of this kind occurs, a number of very small ones have been found in different parts of the same tumour; and in other cases there are many very small ones, of the size of pins' heads, without a large one. These hydatids are by no means sufficiently frequent in their occurrence to admit of their forming any part of the character of a cancerous tumour.—(*Obs. on Cancer, p.* 156, *&c.* 8*vo. Lond.* 1805.)

In the fourth chapter of this work the author relates two cases of hydatids found in the breast. In the first, the contents of the cyst were bloody serum; in the second, a clear fluid. These two cases of simple hydatids in the breast, unconnected with any other diseased alteration of structure, led Sir E. Home to consider more particularly the nature of such hydatids as are sometimes found in cancerous breasts: he believes that they form no real part of the disease, but are accidental complaints superadded to it; and that, as they occur in the natural state of the gland, they are much more likely to do so in disease.—(*Op. cit. p.* 108. 159.) These *hydatid* or *encysted* swellings of the breast are not always regarded as true scirrhi, and in particular Sir Astley Cooper and Mr. C. Bell describe them, according to my judgment very correctly, as a different form of disease.

Sir E. Home defines what he means by cancer as follows:—"As cancer is a term too indiscriminately applied to many local diseases for which we have no remedy, though they differ very much among themselves, it becomes necessary to state what the complaints are which I include under this denomination. The present observations respecting cancer apply only to those diseased appearances which are capable of contaminating other parts, either by direct communication or through the medium of the absorbents; and when they approach the skin, produce in it small tumours of their own nature, by a mode of contamination with which we are at present unacquainted.

There is a disease, by which parts of a glandular structure are very frequently attacked, particularly the os tincæ, the alæ of the nose, the lips, and the glans penis. This has been called cancer, but differs from the species of which we are now treating, in not contaminating the neighbouring parts with which it is in contact; and neither affecting the absorbent glands nor the skin at a distance from it. It is, properly speaking, an eating sore, which is uniformly progressive; whereas, in cancer, after the sore has made some progress, a ridge is formed upon the margin, and the ulceration no longer takes that direction. It also differs from a cancer in admitting of a cure in many instances and under different modes of treatment.

From the facts which have been stated (*see the cases detailed in this gentleman's work*), it appears that *cancer is a disease which is local in its origin.* In this respect the cases (alluded to) only confirm an opinion very generally received among medical practitioners; but in favour of which no series of facts had been laid before the public of sufficient force entirely to establish the opinion."—(*P.* 145, *&c.*)

Sir E. Home endeavours to establish a second point, that *cancer is not a disease which immediately takes place in a healthy part of the body; but one for the production of which it is necessary that the part should have undergone some previous change connected with the disease.* In proof of this, the first two cases in his work are brought forward, and the innumerable instances in which a pimple, small tumour, or wart upon the nose, cheek, or prepuce may remain for ten, fifteen, or thirty years, without producing the smallest inconvenience; but at the age of sixty or seventy, upon being cut in shaving, bruised by any accidental violence, or otherwise injured, assumes a cancerous disposition.

All the cases of induration of the gland of the breast, or of indolent tumours in it, which have continued for years without producing any symptom, and after being irritated by accidental violence have assumed a new disposition and become cancerous, admit of the same explanation; and are adduced as so many proofs of the truth of this latter position.—(*P.* 147, *&c.*)

With regard to the common opinion, that the production of scirrhus of the breast is connected with the cessation of the menses, Sir Astley Cooper also expresses his belief, that if a person has a tumour, not originally of a malignant nature, in the breast, an undue action may afterward be excited in it when the change of life takes place; and the disease then assumes the character of scirrhus.—(*Lancet, vol.* 2, *p.* 376.)
