The patient should pay particular regard to cleanliness of his person; he should use freely the ablution of cold water, sometimes to the whole, sometimes to parts of the body; he should sponge the body every morning for a considerable part of the year with cold vinegar and water, or salt and water, much used by the ancient physicians under the name of *ὑδρολουσία*—*frigidi consuetudo lavacri*—and should afterwards rub the body well with a coarse towel; at another period he may use the shower-bath, the cold sea plunging-bath, or the cold fresh-water bath, or exercise himself in swimming; and when none of these means can be used, he should not omit dry friction of the body with the flesh-brush or a flannel glove, a salutary exercise for the indolent, and a useful substitute for it in the convalescent, or those who have not the benefit of locomotive exercise. The patient should pass much time in the open air; he should change his air from the town to the country, from the plain to the mountain, from the sea-side to the inland parts; (*Adhibitâ mutatione longâ, terrenâ et maritimâ*,—*Celsus*); or he may find a continued change by a well-planned, not hurried, tour, the most effectual. Of exercise as an alterative we have already spoken; as a tonic it is not less to be regarded; and to both these means—air and exercise—respiration and perspiration—we agree with Aretæus in granting a peptic power greater than medicine. (*Ἐχὲν γὰρ τὴν ἡ διαπνοὴ καὶ ἡ ἀναπνοὴ τοιοῦτος φάρμακον πεπτηριον*. De Cur. Mor. Diut. lib. i. cap. 7.)

We must bring our method of curing this form

* *Habitare vero ædificio lucido perflatum æstivum, hibernium solem habente, cavere meridianum solem, matutinum et vespertinum frigus itemque aurum flammium atque stagnorum—ne modo frigus, modo calor noceat.*—*Celsus*.—See also Dr. Clark's *Treatise on Climate*.

of dyspepsia to a conclusion with observing that though complete success is only to be expected from a steady perseverance, it will not be so readily obtained by strict and undeviating monotony. No regimen of the body is perfect which does not leave room for variety. It is the nature of the body as well as of the mind to desire and require novelty. The same diet long continued becomes loathsome, the same exercise irksome, the same occupation uninteresting, the same medicine inert and powerless. The very disease we are endeavouring to cure may in our opinion be induced by too strict an adherence to one regimen long-continued. "*Quod enim consuetudinem est, nocet, seu molle, seu durum est.*" It is, therefore, the duty of the physician to be well stored with a diversity of means equivalent, but not identical, all capable of effecting the same object, by whose changes, substitutions, and modifications, he may keep alive the languishing resources of the body, drawing a lesson from the wisdom of nature, which has provided us with such an ample variety, that every year hath its own peculiar character, every season its food, every day its weather, every hour its temperature, and yet all are uniform, consonant, consistent, but subservient. And so our methods should be diversified in their details and particulars, but uniform in their general plan and spirit. In this principle of variety, this law of our constitution, are explained the astonishing effects of change of air and climate in the disease of which we have been treating, in which is comprehended the change of all our habits, of diet, exercise, and occupation.

But our advocacy of variety in means and method, is not opposed to perseverance in a plan of regimen, but in support of it, the most efficient way of giving it the permanency of habit and success; and even after success, neither may the regimen be relinquished. "*Illud quoque in omnibus stomachi vitiis præcipiendum est, ut quo modo se quisque refecerit, eodem sanus utatur; nam redit huic imbecillitas sua, nisi iisdem defenditur bona valetudo, quibus reddita est.*" (*Celsus*.)

II. INFLAMMATORY GASTRIC DYSPEPSIA.

Synonyms.—*Stomachi æstus et inflammatio, Cels.*; *passio stomachica stricturæ, et cyananche stomatica, Cæl. Aurel. et Method.*; *stomachi adstrictio, Ætius*; *Cardialgia inflammatoria, et à veneno, gastrodynia adstringens, pyrosis à phlogosi, et Suecica, et anorexia canicularis, hypochondriasis sanguinea et algida, Sauvag.*; *Gastritis erythematica, Cullen*; *Gastrite chronique, Broussais*.

General Character.—Painful digestion, sense of heat, tenderness, or pain at the epigastrium, increased upon taking food, or pressure; thirst; tongue more or less of a bright red colour, sometimes of a brownish red, sometimes dry, glossy, and adhesive; taste saltish or alkaline, occasionally like that of blood; bowels generally confined; urine high-coloured; skin dry, occasionally profuse, partial sweats, chiefly in the direction of the extensor muscles; temperature of the trunk increased, of the extremities diminished, except occasionally in the palms of the hands and soles of the feet, which, especially at night, are frequently dry, hot, and burning; aggravation of the symp-

toms under the use of stimulants or irritating ingesta.

Forms of the Disease.—As this disease may present itself in different degrees of intensity, the symptoms are liable to a corresponding variation.

In its lowest degree it is not manifested by loss of appetite, but by increase of thirst, particularly during the night, by increased heat of the skin, flushing of the face, and redness of the conjunctiva, particularly after meals, by disturbed sleep, unpleasant dreams, and by the patient awaking wearied and unrefreshed. The tongue on its anterior half is of a red colour, brighter than natural, often by superficial observers mistaken for a clean tongue; it is seldom dry except during sleep, but soon dries on exposure, and is generally found in this state on awaking; sometimes there is an increased flow of saliva, particularly during sleep, sufficient to leave large stains upon the pillow. When the stomach is loaded with crudities, the tongue is covered with a brownish yellow fur towards its base. The lips are generally dry, and of a glossy red colour, the fauces dry, flushed, or erythematous. The bowels are confined, only dry scanty stools being voided; the urine is scanty, but clear and high-coloured; if any sediment be deposited, it is small in quantity, forming a thin lateritious coating on the bottom of the vessel. The pulse is somewhat harder, more contracted, but seldom much accelerated except during digestion. Contemporaneous with these may exist various secondary symptoms, such as a painful sensation of tension in the head, increased on motion and after eating, or a painful pulsating tension, sometimes a sense of fulness; pain between the scapulæ,* pain of the left side, left shoulder, or left arm, and sometimes local pains in various parts of the body, often felt most acutely on awaking; eruptions of the skin, chiefly lichen, erythema, urticaria, psoriasis, and pityriasis.

In a more advanced stage of the complaint the patient begins to refer his sufferings to the seat of his disorder. He complains of a burning pain at the pit of the stomach, which is much increased upon pressure, and after taking food; or of a sensation of oppression at the stomach, with great uneasiness and discomfort during the digestion of his food, which is generally also accompanied with flushing of the face, acceleration of the pulse, and frequently a tense pulsating headach. If the appetite is not impaired, it is sooner satisfied, and taking food sometimes causes nausea. There is considerable thirst; the face is red and swollen, the eyes are red, the lips red and parched, sometimes blistered and swollen; the tongue is either of a bright glossy red, sometimes smooth, having the papillæ obliterated, disposed to be dry and adhesive when touched, or of a brownish red colour, or presenting a red ground covered with a thin film of the colour of coffee; small vesications or ulcerations are common upon the tongue, upon the inside of the lips and cheeks, and the mouth generally, which is also redder than natural. The fauces are also red, presenting an erythematous blush; they are generally dry, and frequently the seat of ulcerations. The taste is saltish or alka-

line, frequently corresponding precisely to that produced by nitrate of potass; there is also very often a sensation of heat or of scalding at the point of the tongue, such as follows the taking very hot soup. The bowels are constipated, the urine is scanty and of a high colour; the skin dry and harsh, except during sleep, when the patient is sometimes bathed in a heavy transient sweat; the pulse is now permanently quicker than natural, small and contracted, but always quicker and stronger during the progress of digestion; the temperature of the body is increased, and the patient complains of burning of the palms of the hands and soles of the feet at night; the sleep is disturbed by painful or unpleasant dreams.

The preceding symptoms, the constant signs of the disease, may be obscured or thrown into the shade by some of the more prominent secondary affections, often the chief subject of the patient's suffering and complaint, and of the physician's attention. The principal of these are headach, a tense splitting headach, increased by motion, by stooping or eating, sometimes deep pains plunging through the head; these are accompanied with a morbidly increased sensibility to light, sound, and all impressions; pain in the left side, in the left hypochondrium extending to the shoulder and arm, pain of the back between the scapulæ, particularly severe on awaking; strong and painful pulsation of the heart, increased in impulse, bearing all the appearance of hypertrophy of the ventricles; inflammation of the eyes or eyelids; soreness, redness, and ulceration of the membrane of the nose; eruptions of the skin, chiefly scaly and exanthematous; suppression of the menstrual function for a time, not unfrequently followed by increased menstruation. With these are conjoined more or less peevishness of temper, irritability of feeling, sullen oppression of spirits, anxiety or restlessness of disposition, all strongly though not elegantly expressed in the words of Cælius Aurelianus; "*animi angustia, jactatio, anxietas, sive concatenatio mentis et desponsio.*"

In a more acute degree of the complaint there is a total loss of appetite, or disgust for food, which on being swallowed causes nausea or is instantly vomited. There is an indistinct dull pain across the pit of the stomach, or a sensation of constriction as if something were tied tightly across it. The pain is increased on pressure, and sometimes a strong palpitation is felt at the same time. Frequently the pain is felt more in the chest, or the patient complains more of darting pains under the breast, which, being accompanied by a hard dry cough, bears all the appearance of, and is not unfrequently mistaken for, a pulmonary affection, but which may be easily distinguished from it by the cough being always excited by stimulating ingesta, by its returning in paroxysms, by the accompanying state of the tongue, and by the general complexion of the disease. The features are drawn and dejected, the face flushed, and the forehead moist and clammy; the lips are red, the conjunctiva injected, and the eyes prominent. There is considerable thirst; the tongue is dry and parched, sometimes hard and scabrous; it is generally of a brick-red colour, or it is covered with a thin brownish mucous crust; sometimes it presents the appearance of raw flesh, and has

* Dolor inter pares tenens.—Cæl. Aur.

been not inaptly compared to a beefsteak or cleanly dissected muscle. If crudities be present in the stomach, which is, however, seldom the case, or if a saburral be added to an inflammatory state of the mucous membranes, the root of the tongue is loaded with a yellowish white fur, whilst its point and edges are of a bright red colour, or the papillæ are prominent, projecting through the fur; the breath is fetid and the taste bitter. In this state only are there ever acid, nidorous, or fetid eructations. The throat is sore, the fauces are erythematous, and, together with the inside of the mouth, frequently become aphthous. Sometimes the tongue is of a dark red colour, resembling the lees of wine, occasionally as dark as logwood. This colour indicates the co-existence of congestion and plethora of the abdominal circulation. The bowels are constipated, but to this state diarrhoea is apt to succeed as the disease continues. The urine is high-coloured; the skin dry, harsh, and flaccid, except during sleep, or while digestion is in progress, when there are frequently heavy, partial, unsatisfactory sweats. The pulse is quick, hard, and small. In the evening and during sleep there is generally an exacerbation of all the symptoms, marked by agitation and restlessness.

There is also a more chronic form of this complaint, which either arises more gradually, or into which the states we have just been describing may have subsided. It is marked by great uncertainty of appetite, sometimes impaired, sometimes morbidly increased, a sensation of heat at the pit of the stomach, sometimes likened to the feeling of a burning coal placed there, or there is a distressing sensation of craving, sinking, or indescribable anxiety. The patient is generally much tormented with flatulence, and the symptoms to which it gives rise, a sensation of choking, anxiety, restlessness, and hiccup; and he sometimes suffers much from pulsation at the præcordia, from spasmodic pains in the epigastric and left hypochondriac regions, or there may be a violent pain at the epigastrium extending through the left hypochondrium and left shoulder; frequently there is a sense of heat internally when the surface is cold, not inaptly termed by the common people an *inward fever*. All the symptoms are much increased by taking food, even the mildest, so much so that patients are afraid of taking food on account of the uneasiness produced by it, from a feeling as if the stomach were incapable of holding anything beyond the smallest quantity. When the stomach is empty, some patients are entirely free from complaint. The bowels are costive, the urine scanty and high-coloured; the tongue is moist and clean, but redder than natural, generally broken by sulci and studded with large developed papillæ; sometimes it is covered with a thin, milky, white fur, through which the papillæ project; the gums are often red, swollen, and spongy, and there is often a taste of salt, of alkali, or of blood in the mouth; sometimes the tongue presents a dry and glazed appearance, with insatiable thirst, and a dry parched state of the mouth; sometimes there is a raw and tender state of the mouth and throat, with uneasiness in swallowing; or there is a sense of burning in the mouth and throat, with hysterical constriction, pain and soreness in the course of the œsophagus. The pulse

is small and feeble, and quicker than natural; the skin is dry, rough, shrivelled, flaccid, and sometimes at length almost scaly; the nails become dry and brittle, and often curved; the hair is parched, and inclined to stand on end, and the whole surface is cold. The patient is constantly hanging over the fire, and frequently experiences fits of chilliness, approaching to shivering. The feet and hands are either preternaturally hot or cold; there is coldness or a cold torpor of the extremities, with a general sensation of chilliness; extreme morbid sensibility of any change of temperature, so that when the patient gets warm in bed he soon becomes hot and oppressed, the soles of his feet and palms of his hands burn, and he tosses about restless until he breaks out into a strong and heavy sweat. His sleep is interrupted and unrefreshing, and he awakes hot, thirsty, and weary, in a state of confusion of mind.

The ordinary accompaniments of this chronic affection of the mucous membrane of the stomach are great languor and depression, sometimes insupportable, the patient sinking into a state of extreme debility on the least exertion. The body is wan and emaciated, frequently sallow, the temper fretful, anxious, impatient, or dejected; sometimes there is a troublesome cough, dry, or with scanty mucous sputa; or there is dyspnoea, and pain of the chest like pleurisy; and in either case the symptomatic febrile affection approaches so near to hectic, that it is not rarely mistaken for consumption; sometimes there is palpitation and other irregular actions of the heart; sometimes headach, a tense binding pain across the head, vertigo, or tinnitus aurium; sometimes neuralgic pains of the limbs, sometimes osteocopic or painful affections of the periosteum; and frequently some affection of the skin, chiefly *erysipelas*, *erythema*, *lichen*, *urticaria*, *pityriasis*, *psoriasis*, *alopecia areata*, the head becoming bald in round patches. But whatever be the most prominent secondary affections, the chief subject of the patient's complaint, there is a characteristic colouring common to every one of them,—they entirely engross his thoughts and occupy his attention, unless, which is not rarely the case, his bodily suffering be transformed into, and represented by, some mental hallucination. The patient's mind never turns from his sufferings, or if it does for an instant, it is only to revert to them with increased earnestness; and as the external senses constantly exercised acquire a fine and acute delicacy of sensation, so that they can take cognizance of minute and subtle objects which escape the ordinary sense, so the internal sense, painfully exercised in suffering which occupies his exclusive attention, acquires a keen microscopic power, and a fineness and subtilty of perception, which, surpassing common experience, is classed as partly nervous, partly imaginary, under the term of *hypochondriasis*,—a disease which M. Broussais satisfies himself with explaining as consisting in an excess of gastric susceptibility.

The change which takes place in the process of digestion is also a remarkable feature, which ought not to be omitted in the history of inflammatory dyspepsia. The food seldom runs into fermentation, acid or rancid eructations are rarely observed, and heartburn becomes comparatively

rare: so that if the patient have previously suffered from atonic dyspepsia, he will observe that his heartburn has entirely left him. Certain kinds of food also are observed to be more easy of digestion, as farinaceous food, preparations of the fecula of vegetables, vegetable jellies, and mucilages, vegetable acids, and sweet diluents; the fat of meat, even the fat of bacon in moderate quantities, is more easily digested than lean, than animal jellies, than fibrous or albuminous substances, than eggs or milk.

The symptoms of inflammatory dyspepsia are invariably aggravated in spring, the period during which they are most severely felt being from the spring equinox to the summer solstice. They are also exasperated under the use of medicines of a stimulating quality, which can seldom be borne for more than a few days; and the same is observed of any strong purgative, which invariably gives rise to griping, irritation, and general exhaustion.

Causes.—Inflammatory dyspepsia is much influenced by age, sex, temperament, climate, and season. It is frequently met with in youth and early adolescence, but prevails most from the age of twenty to forty. It affects much more the male than the female sex, and chiefly the sanguine and bilious temperaments, people of a bright florid or of a dark complexion, but of a dry hard fibre. It is met with most frequently in hot and in dry climates, but more especially in those subject to an excessive range of temperature. It is frequent in windy situations, in places exposed to dry winds, whether they be hot or cold. European Turkey, Greece, Italy, Spain, and the south-eastern parts of France, are places which unite all the foregoing conditions, for which reason this disease is also endemic in these countries. The Venetian Friuli was the country in which this disease seems first to have arrested the attention of M. Broussais, a country placed pre-eminently in the foregoing predicament. The late Dr. Parry, of Bath, has taken notice of the prevalence on the sea-coast of the morbid condition of the mucous membranes on which this disease depends, an observation which we have had frequent occasion of confirming at Nice, Genoa, Marseilles, and at Brighton, which may account for the indispositions, in common language, the *bilious attacks*, which many persons experience on coming to the sea-side; but we are disposed to think that the sea-air is not the only condition, for we do not recollect to have met with it much on the coast of Devonshire, where we have had equal opportunities of observing it. We must, therefore, limit the observation to the sea-coast in dry climates. Spring, as has been already observed, has great influence in calling forth and in aggravating the complaint: it returns also with the approach of cold in October. It occurs, however, at all seasons, in extremely hot or extremely cold weather, during sharp or long-continued frosts, during the prevalence of dry winds, whether hot or cold; hence we find it to prevail in England during the north-east wind, in Provence during the *mistrale*, in Switzerland during the *bise*, and in Italy when the *tramontana* blows. It is met with in every rank of life, in the country as well as the city, in the outdoor peasant as well as in the artisan.

Certain states of body predispose to this disease,—as a state of general vascular plethora, a state of congestion of the abdominal circulation, suppression of the hemorrhoidal flux, suppression of the menstrual discharge, for which reason it is not uncommon in women at the critical term of life, to which we may add protracted atonic dyspepsia, the stomach becoming irritated by the habitual remora of crudities.*

But certain habits of life have the chief influence in inducing this complaint, such as living on dry, heating, and high-seasoned food, the habitual use of ardent spirits, of liqueurs, of punch, and of opium; hence it is the dyspepsia of the dram-drinker and opium-eater, and belongs altogether more to the drunkard than the glutton.

[Dr. Beaumont (*Experiments and Observations on the Gastric Juice*, &c. p. 240: Plattsburg, 1833,) found, in the case of the Canadian with the fistulous aperture into the stomach, that the free use of ardent spirits, wine, beer, or any intoxicating liquor, when continued for some days, invariably produced erythematic and aphthous patches in the villous lining of the stomach. He found, also, that eating voraciously, or to excess, swallowing food coarsely masticated, or too fast, almost invariably produced similar effects, if repeated a number of times in close succession. These morbid effects were seldom indicated by any ordinary symptoms or special sensations, and could not, in most cases, be anticipated; their existence was only ascertained by actual ocular observation.]

It may, however, independently of all predisposing circumstances, be at any time excited by certain accidental causes; as, for instance, by drinking cold liquids after violent exercise or fatigue, when the body has been cooled by perspiration, as frequently occurs in summer; by any unusual excess in diet or drink, more especially if the body is in a state of exhaustion; by any accidental indigestion, as from eating mushrooms, cucumbers, some kinds of shell-fish, nuts, and such-like; by change of diet, from a succulent refreshing to a dry heating diet,† as our French and German friends frequently experience on first coming to dwell amongst us; by a change of water from a soft to a hard calcareous water; by fatiguing and forced journeys; by night-watching; and hence it occurs frequently in nurses, or those fatigued by long attention upon sick friends or relatives; by grief, anxiety, sad or depressing passions, or by sudden bursts of passion; by change of air from a heavy dull atmosphere to a clear dry sky, and hence it is, in connection with the influence of sea-air, observed in a slight degree amongst our citizens during the first days of their visit to Brighton; by strong and stimulating medicines,‡ thus we have known it to follow the use of cubebs and copaiba given for gonorrhœa, of Fowler's arsenical solution given for affections of the skin, of strong and irritating purgatives, stomachic medicines, tonic tinctures and elixirs, and irritating vomits, as mustard. It occurs frequently under a course of mercury, when the

* *Magis istam jugis indigestio parat.*—*Cal. Aur.*

† *Ariditate et erethismo ventriculi a defectu potus aquei.*—*Sauvages.*

‡ *Medicamentis insueti potatio.*—*Cal. Aur.*

constitutional action takes place quickly or runs high. It may also accompany catarrh, or be itself an effect of exposure to cold; it succeeds to the imperfect convalescence of gastric fevers, and supervenes on suppressed perspirations, and the repulsion of cutaneous eruptions.

Pathology.—That the form of dyspepsia we have just described proceeds immediately from vascular excitement of the mucous membrane of the stomach, it would be idle to set about proving. It would be superfluous to observe that no other hypothesis will account for the symptoms, or explain the operation of the causes of the disease, when the fact has been directly proved by innumerable dissections.

Whilst many of our predecessors have recognised and distinguished this particular form of disease, some of them have pointed out the morbid condition on which it depends. Thus, though Hippocrates has described it under a false name, he has yet set it apart as a particular form of repletion; whilst Celsus in its name has explained its nature—*stomachi ingens calor—ubi stomachus exæstuat*. The Methodists knew the disease under the term of *passio stomachica strictura*, and by their method of cure we may see that they also understood its nature. It was afterwards accurately described by Ætius under the term of *stomachi adstrictio*,* and may, indeed, be traced downwards under various appellations in the writings of every succeeding physician. In Italy the knowledge of the disease, its nature and its cure, have been handed down by traditional experience, and are now safely deposited in the hands of the vulgar, within the reach of every *baglia*. Not to cite unnecessary examples from modern physicians, Sauvages has, under several of his diseases of symptoms, described its form and indicated its nature, for his *anorexia biliosa vel canicularis*, his *cardialgia inflammatoria a veneno et sputatoria*, his *pyrosis a phlogosi et Suecica*, and his *gastrodynia adstringens*, not to mention several others, are only so many symptoms of this disease. Under the term *gastritis erythematica*, Cullen has recognised this disease, but the false principle of his nosology separated it from dyspepsia; and we can hardly recollect any instance in which false classification has been so detrimental to sound practice, or in which the influence of good and bad classification upon practice is more strikingly illustrated. From the time of Cullen to the time of Broussais, the symptoms of indigestion were considered purely a nervous disease, an adynamic affection, one of deficient vital power. For though Prost (*Sur la Sensibilité*) in France, and Parry in England, had, the one by dissections, the other inferentially, arrived at the conclusion that dyspepsia or disordered digestion might arise from an increased vascularity, a morbid fulness of the vessels of the villous coat of the stomach, it was unquestionably the author of the *Histoire des Phlegmasies Chroniques* who led us back to the right point of observation, and who afforded us the means of recognising and distinguishing these affections. His view of the

matter has been amply confirmed by succeeding physicians, even by those who have arrived at his conclusions by a different path, by W. Philip, Andral, Louis, Abercrombie, Cooke, not to mention many more. It is probable, that, had Parry not fallen into the error which obscures the merit of Broussais—that of considering this morbid condition as exclusively the proximate cause of every form of dyspepsia—he might have had more influence on the sober minds of his countrymen.

The vascular excitement of the mucous membrane of the stomach occurs in various degrees of intensity, from a state of mere dryness or defective secretion of the membrane, of injection, congestion, or morbid fulness of the vessels, from a state of erethism or increased action, to actual inflammation. And dissection reveals to us that the inflammation of the mucous membrane of the stomach, and so probably the erethism of vascular excitement, which is not aggravated to inflammation, may present itself under three varieties; for it may affect the general substance of the mucous membrane, or it may be confined to the villousities which project from its surface, or the follicles which are embedded in it,—in all probability giving rise to diversities and modifications of the disease hereafter to be ascertained by closer and finer observation.

In the dyspepsia of the dram-drinker, marked by loss of appetite, by nausea and vomiting when the stomach is empty, and pain at the pit of the stomach, the stomach itself has often been found with a smooth glass-like surface internally, the extremities of the vessels in the villous membrane having been abraded or absorbed.

Inflammation of the mucous membrane of the stomach appears in many cases to commence in a very small and circumscribed portion; its progress seems to be very slow, and it is probable it may continue for a considerable time, and then subside, and again occur after various intervals, until at last it produces some permanent and extensive disease by thickening of the parietes of the stomach, by adhesion to the neighbouring parts, or by ulcerations.

Dr. Cullen observes, “Erythematic inflammations of the stomach are more frequent than those of the phlegmonic kind. It appears at least from dissections, that the stomach has often been affected with inflammation, when neither pain nor pyrexia had before given any notice of it; and such inflammation I apprehend to have been chiefly of the erythematic kind.” “This affection of the stomach, viz., inflammation of the mucous membrane, sometimes spreads into the œsophagus, and appears in the pharynx, as well as on the whole internal surface of the mouth.” “When, therefore,” he continues, “an erythematic inflammation affects the mouth and fauces, and when at the same time there shall be in the stomach an unusual sensibility to acrids, with a frequent vomiting, there can be little doubt of the stomach being affected with the same inflammation that has appeared in the fauces. Even when no inflammation appears in the fauces, yet if some degree of pain be left in the stomach, if there be a want of appetite, an anxiety, frequent vomiting, or an unusual sensibility with regard to acrids, some thirst and frequency of pulse, there will be

* *Molestia inter digerendum, cum alvo constipata, æstu generali maxime vero manuum ac pedum, faciei rubore, pulsu frequenti, aut juxta quosdam febricula; accidit temperamentis aridam et densam carnem habentibus.*—Lib. iii. Ser. 1. cap. 13.

then more room to suspect an erythematic inflammation of the stomach; and we have known such symptoms discover their cause more clearly by the appearance of the inflammation of the fauces or mouth." "The erythematic inflammation," he also observes, "is often disposed to spread from one place to another upon the same surface, and, in doing so, to leave the place it had first occupied. Thus such an inflammation has been known to spread superficially along the whole course of the alimentary canal, occasioning in the intestines diarrhoea, and in the stomach vomiting; the diarrhoea ceasing when the vomitings come on, or the vomitings upon the coming on of the diarrhoea." In the following passage Parry has made a corresponding observation. "In that state of tongue so common in the West Indies, in which the mucous membrane of that and the adjacent parts is affected with chronic inflammation, tending to aphthæ and suppuration, the stomach, apparently by mere extension of disease, suffers all the symptoms of flatus, acidity, &c. which are common to dyspepsia." Broussais has remarked that a contracted state of the stomach and alimentary canal always co-exists with an inflamed state of their mucous surfaces.

Inflammatory dyspepsia occurs frequently as a secondary as well as an idiopathic disease. Hence it appears as a symptom of some essential fevers, (In febribus circa ventriculum et fortis æstus et cordis morsus, malum—*Hipp.*) of variola and rubella, (dyspepsia febrilis); it occurs in the last stage of phthisis pulmonalis, and in many organic diseases; it is frequently symptomatic of inflammation of the mucous membrane of the uterus, particularly that which follows retention of a part of the placenta; it is observed in plethora of the uterine system, and in plethora of the abdominal circulation (*dyspepsia hemorrhoidalis*); and is met with consecutive to extensive burns; and contemporary and reciprocally with erysipelas, erythema (*dyspepsia metastica*), and several cutaneous diseases; and we have several times found it co-existing with ichthyosis, and that dry impervious state which might be distinguished by the term of *constipation of the skin*.

Method of Cure.—I. Instead of exercise, as in the former species, we must here seek for repose of every description, (Omnifaria requies—*Cæl. Aur.*) of mind as well as of body; but as some exercise is desirable for the general health, it must be of the easiest kind, such as gentle sauntering, walking, or the passive exercises of gestation in a carriage, sailing, swinging, rocking, and gentle friction. Instead of a dry diet, consisting chiefly of animal food, we shall find that a liquid diet, bland and farinaceous, small in quantity at a time, from which animal food and all indigestible substances are excluded, is the most to be recommended. The different articles of food comprehended under the saccharine, acidulous, mucilaginous, farinaceous, and feculent, are most easily digested in this morbid condition of the stomach, and therefore their opposite kinds, milk, eggs, cheese, fish, animal food, animal gelatine, the substantial, solid, or fibrous parts of vegetables, and fruits, are to be abstained from. After repose, or rather diminution of labour and exercise, and a refrigerant diet, suited in degree and kind to the

particular state of the digestive organs, the warm bath may form part of the regimen. It should be used at a temperature from 92° to 96°, from a quarter to half an hour. If the symptoms require, it may be used every day; and it is of more benefit if used continuously, in a course of ten or twelve daily baths, than if taken interruptedly. Under this mode of administration, the tepid bath forms a direct remedy of great efficacy. But the general cure of this morbid condition of the stomach consists in a judicious use of the antiphlogistic regimen, graduated to the degree of the disease and the strength of the patient.

In the lowest degree of this complaint a change of diet, avoiding stimulating and heating food and drink, abstaining from active exercise, the use of a tepid bath, of some cooling acidulated drink, as lemonade, orangeade, imperial, orgeat, preserving the bowels open by a simple warm-water clyster, and, if necessary, any mild cooling aperient, for which purpose none answers better than manna dissolved in infusion of tamarinds, to which a small dose of some neutral salt may be added, afford all that is requisite for the cure.

In a higher degree of this complaint it may be necessary to have recourse to a regimen more rigidly abstemious, consisting of gruel, arrow-root, whey, sago, blanc-manges of rice, jelly of bread, of Iceland or Irish moss, solution of gum tragacanth, acidulated with lemon-juice, taken in small quantities at a time, in order to avoid distension; to prescribe largely acidulated saccharine drinks, as lemonade, cool, cold, or iced, or such bland drinks as orgeat, emulsions, decoction of liquorice, linseed-tea, &c.; to apply leeches or cupping-glasses freely to the epigastrium; (*Cucurbita adjuncta scarificatione, sive hirudinum appositio—Cæl. Aur.*) or, which is probably to be preferred, a moderate bleeding from the arm, proportionate to the degree of the disease: if there be signs of plethora or congestion of the abdominal circulation, leeches to the anus; to relieve the bowels by clysters or the mildest aperients, and to solicit the hepatic secretion by small doses of the pil. hydrarg. or pulv. hyd. cum cretâ given at bed-time, followed in the morning by small doses of castor-oil. The effects of mercurials must be assiduously watched; for in this disease they are apt to act locally on the mucous membrane, and thus affect the mouth, without, however, affecting the system at large. When mercurials are not used, the nitrate of potass may be given in repeated small doses; for this medicine, antimonials, castor-oil, hydrocyanic acid, the vegetable acids and saline medicines, are the means we are acquainted with which possess most eminently the direct power of lowering the vascular excitement of the stomach; and we do not hesitate sometimes to rely upon them in cases where venesection might otherwise be necessary. These means will be assisted, and their operation promoted by the use of fomentations, or emollient cataplasms to the abdomen, and by the daily use of the tepid bath. As the excitement subsides, the patient may gradually return to a better diet, beginning with light broths of veal or chicken, and at last, but more cautiously, solid food.

We are not unaware that the vascular excitement of the mucous membrane of one portion of the alimentary canal may be diminished by caus-

ing a determination to and a secretion from another part of it, and that thus the vascular excitement of the stomach may be reduced by a course of purging; but though this method may be frequently successful, it is not rarely prejudicial, sometimes dangerous.

In the chronic form of the complaint great nicety is required in adjusting the cooling treatment to the strength of the patient and the degree of the disease; for if the disease has been of long continuance, the nervous system is generally affected, and tolerates with difficulty the means suited to the relief of the local complaint; and if the depressing means be disproportionate to the degree of the disease, the stomach sinks into the opposite state, atonic dyspepsia supervenes, and the method of treatment is disparaged. This last consequence is more especially apt to occur if the inflammatory have succeeded to the atonic form of dyspepsia. It is on this account necessary to be cautious in the change of diet, and in the gradual withdrawal of stimulus. It may be advisable to continue in moderate quantities, the use of such animal food as is easy of digestion, as light beef-tea or veal-broth, in small quantities at a time, so as to avoid distention, and, by the bye, solid animal food; if not followed by thirst, increased heat, or headach, they are always useful. If the patient have been accustomed to stimulants, they must not be all at once, but gradually withdrawn; for it is an unquestionable fact that a highly morbidly sensitive state of the stomach may be developed, and even a certain degree of inflammation of its mucous membrane may be exasperated, by leaving off an habitual stimulus. The exhibition of medicines and of other directly depressing means must be modified by the same caution. Leeches will be less seldom necessary. Seltzer water, whey, two-milk whey, and goat's whey, may be used as substitutes for the acidulated drinks. The nitrate of potass may be made to be more easily tolerated by the stomach by mixing it with infusion of hop, chamomile, or quassia, to which, if no heat be present, a little tinct. cort. aurant. or tinct. card. comp. or spirit. æth. nitric. may be added. Dr. W. Philip observes that its alterative effect is not impaired by this addition. Or the hydrocyanic acid may be combined with these instead of the nitrate of potass, if there be any painful affection of the stomach. The vinum seminum colchici in very small doses has also to a certain degree the same effect. We have also observed that a water-ice eaten very slowly in the evening, instead of tea, is attended with very good effects; and in summer we have known great benefit derived from swallowing slowly and at intervals small pieces of solid ice when the stomach is empty, which, if the stomach can bear it, proves both a tonic and refrigerant.

With this plan of medical treatment much advantage may be derived from a diet well-timed and tempered, always varying it a little: as, for instance, animal food at first only on alternate days, afterwards on two succeeding days, and so on, but now and then interposing a day of abstinence. The same observation is also applicable to medicines: a certain change and variation of several is preferable to a long continuance of any one.

The bowels must be preserved open by the

mildest and least irritating remedies. For this purpose clysters are to be preferred; they should consist of simple tepid water, from a pint to a quart, barley-water, gruel, linseed-tea, or such-like, or in smaller quantities with the addition of a little salt, honey, or electuary of senna; sometimes cold spring water is found to answer best. When aperients must be had recourse to, they should be bland and unirritating,—castor-oil, manna, soda with citric acid in effervescence, tartarised soda in infusion of tamarinds, confection of cassia or of senna. Ripe fruits eaten in the morning in considerable quantities have been found to have the effect of mild aperients, and to be at the same time refreshing to the stomach, such as ripe grapes, strawberries, and figs, which we believe to be the full meaning of the *cure des raisins* so much spoken of in Switzerland; but this method requires considerable caution, for if the fruit be not digested, the object is more than frustrated.

In the chronic state of the disease it is generally necessary to promote the secretions of the liver and alimentary canal by very small alterative doses of mild mercurial medicines. They afford valuable assistance to the general principle of treatment; but we must not forget the readiness with which they are apt to affect the mouth. Neither should the morbid condition of the skin which obtains in the chronic form of this disease be allowed to escape the attention of the physician in combining his method of treatment. He should seek not only to relieve its dry, impervious, constipated state by tepid bathing, particularly the tepid sea bath, but he will find it a means of relieving the vascular excitement of the stomach to produce a derivation to the surface by small doses of antimonials, either combined with a little liquor. acet. ammoniæ, or with the nitrate of potass, or by giving alone a grain of James's powder every night at bed-time, or the tenth of a grain of tartar emetic three times a day. If much irritability be present, the hyoscyamus is usefully combined with the antimonial. The following formula is well adapted to this intention:—*R Tr. hyoscyam mxii. tr. opii m ii. vel iii. vini ipecac. m xx. potassæ nitratis gr. v. aq. flor. aurant. ʒi. fiat haustus h. s. sumendus.* The determination to the skin may also in some cases be usefully promoted by the vapour-bath, and by moistening the skin every morning with a lotion of nitro-muriatic acid. The ancients appear to have had this object in view when they recommended the patient to be enveloped in woollen cloths impregnated with sulphur, and in directing friction to be made with nitre and oil.

But we must confess that in the protracted form of this complaint we have observed every object of this method of treatment fulfilled, and all medicinal means far surpassed in efficacy, by a course of mineral waters, such as those of Harrogate at home, and those of Ems, Vichy, Plombières, and Caunterets abroad. To any of these, however, we should prefer the Kreutzbrunnen of Marienbad. Under its use we have often seen the tongue get cool, clean, smooth, and moist; the irritated papillæ subside; the uneasy sensations at the stomach give way; the skin become soft, smooth, and permeable; the bowels regular; and the healthy function of digestion entirely restored.

It should be taken gradually and in small quantities, in repeated doses of three ounces each. It may be taken warm or cold, as most agreeable to the stomach; if it produce distension, the gas should be allowed to escape; if spasm or diarrhoea, it may be diluted with the Kesselbrunnen of Ems.

The same effect is sometimes obtained from a course of goat's whey, taken in considerable quantities in the morning after the manner of a mineral water, a practice which is followed in Wales, and in the highlands of Scotland, but more particularly at Geiss in Switzerland, with the greatest success.

Neither in the acute nor the chronic form of this complaint does our experience lead us to place much confidence in counter-irritants, and we think we have not rarely seen the complaint exasperated under their use. But many physicians, whose opinions deserve the highest consideration, place considerable reliance upon them. They consist of blisters, the tartar emetic ointment, and issues. In the chronic form of the complaint we have certainly known great relief to attend the wearing a large warm plaster over the surface of the stomach, and in very protracted cases we consider it a good preservative from a relapse, from spasmodic pains, &c.

M. Broussais, having observed the frequency of this complaint in the south of Europe, has mentioned a change to a colder climate amongst his means of cure; but our own experience is in favour of a soft climate, if not too cold. In this complaint we have known one season in Devonshire of considerable benefit; on the continent, the climates of Pau in the south-west of France, Rome, and Pisa, are chiefly to be preferred. In the harsh, dry, impervious state of the skin, which takes place in the protracted state of this complaint, it is of great service to have an atmosphere and temperature soft, mild, and equable; and this consideration should also suggest the propriety of warm clothing, of rooms of equal temperature, and the occasional use of the tepid bath.

We think it unnecessary to enter into particular directions for mitigating or relieving the painful and distressing symptoms which are occasionally present in this disease, such as vomiting, pyrosis, gastrodynia, flatulence, and the various uneasy sensations felt in the region of the stomach. Their specific treatment is comprehended in the general method of cure; and for the secondary affections which originate in this morbid condition of the stomach, we can safely refer to the separate articles under which each of them will be considered as symptomatic diseases.

II. For the means of preventing the returning of this complaint, and correcting the predisposition of body on which it depends, we beg to refer to our plan of prevention in atonic gastric dyspepsia. With some modifications in the degree of the means suitable to the particular nature of this complaint, it will be found also to be of useful application here, after the morbid condition of the mucous membrane of the stomach has completely subsided.

III. IRRITABLE GASTRIC DYSPEPSIA.

Synonyms.—Ἡ στομαχικὴ, *Aretæus*; καρδίακη δαδύσις, *Auct. Græc*; cardialgia sputatoria; pyrosis vulgaris et a conceptione; gastrodynia atte-

rens, hysterica, periodynia, et a frigore; vomitus nephriticus et hystericus; anorexia melancholica; flatulentia hypochondrica, *Sauvag.*; anorexia ex desuetudine veneris, *Galen*; gastralgia, *French*; pain of stomach, most felt when it is full, *Pemberton*.

General Character.—Pain, uneasiness, uncomfortable or unnatural sensations in the stomach, generally increased on taking food, and during the process of digestion, neither the frequency of the pulse, nor the heat of the surface being at the same time sensibly increased; the pain rather relieved than increased by moderate pressure; appetite variable, seldom much impaired; bowels constipated; stools little altered; urine clear and sufficiently copious; micturition frequent; tongue clean or thinly furred, never thickly coated; temper impatient, restless, and changeable; easily dejected, easily excited; the attention constantly and exclusively fixed upon the uneasy sensations; great variableness in the degree and duration of all the symptoms.

Form of Disease.—In the slighter degree or earlier stage of this complaint, when the stomach is empty the patient is comparatively free from uneasiness, but on taking food or in the course of digestion various uncomfortable sensations are wont to arise. The patient may feel a sense of choking or constriction in the stomach, as if the progress of the food had been arrested; the throat feels dry, so that it requires an unusual effort to swallow each succeeding mouthful, and after the food has passed down he is disposed frequently to repeat the act of swallowing, as if to relieve the uneasy sensation; without thirst, he continues to sip small quantities of liquid from the same instinctive feeling, or the same sensation leads him to be constantly hawking and spitting, as if he had some foreign substance in the throat. This is sometimes accompanied with dull, indistinct, but anxious pains in the back, between the scapulae, where the patient rubs or strikes himself, or requests some by-stander to hit the seat of the pain, hoping to be relieved thereby. In an aggravated degree the sensation in the stomach amounts to a severe constricting pain, and is attended with nausea, which, extending up the oesophagus, is met by a sensation of very painful constriction and stiffness of the lower jaw, chiefly in the situation of the parotid and submaxillary glands, followed by a copious discharge of a saltish saliva, which generally affords relief; or all these symptoms are relieved by vomiting, the food being returned very little changed in its appearance, though frequently an hour has expired from the time of taking it: these symptoms together constitute *pyrosis*. Or, instead of constriction, a sensation of heaving or nausea follows the taking of food, which is also occasionally terminated by vomiting. Sometimes it is a sensation of heat or burning, of coldness, sometimes of itching, tickling, or formication; sometimes there is pulsation at the epigastrium, in the hypochondria or abdomen, appearing suddenly, at first violent, and abating gradually, observed by Schmidtman (*Summa Observationum medicarum ex Praxi clinica triginta annorum depromptarum. Berlin, 1826.*) to be synchronous neither with the pulsation of the heart nor arteries, and occasionally changing place

suddenly, even sometimes transferring itself to the extremities. These symptoms are usually accompanied by various degrees of general irritation, by a state of fidgetiness, or restlessness, inquietude, or anxiety. Sometimes the uneasiness is not perceived in, or referred to, the stomach, but is felt sympathetically in some other part of the body. Thus, the patient may complain of a sense of tension, of painful anxiety in the head, or of an acute pungent pain limited to one spot; or the heart may be the seat of similar affections accompanied with palpitation or irregular action, seldom with stronger impulse, with flushing of the face, or quickness of the pulse; or the patient may be seized with fits of loud coughing, with convulsive asthma, or spasmodic affections of the muscles of respiration; with cramp of the limbs, spasmodic pain in the uterus, bladder, or urethra; or neuralgic pain in some part of the body, in the uterus, testicles, or rectum; frequently a fit of hysteria, sometimes even symptoms of hysteria in men. Or the patients may feel restless or unquiet, or be seized with a fit of depression, of ungovernable impatience or anxiety. These symptoms generally terminate with digestion, but may be renewed by taking the mildest food. They are usually accompanied with coldness of the extremities, and early in the attack a discharge of pale limpid urine takes place. The tongue is seldom furred, more usually clean, or it is covered with a thin mucous fur, interrupted by fine waving transverse lines; under actual irritation it is dry without being accompanied by thirst; more generally there is a deficiency of saliva, but the tongue and lips are covered with a white frothy secretion which the patient is ever endeavouring to get rid of by spitting; sometimes it is moist, and the mouth is filled by an unusual flow of saliva; frequently the tongue is thinly furred, as if a fine white gauze were thrown over it; sometimes it is covered with a thin milky white fur, as if the patient had just been drinking milk, and sometimes it is besmeared with a thin frothy mucus. The tongue is generally rather paler than natural, but even when clean is never of a brighter red colour than in health. It is generally of a dull red, sometimes darker than natural. But the surface of the tongue, whether furred or not, presents the appearance of plush or velvet, which arises from the papillæ being fine and elongated, never either large, tuberos, and developed, or smooth and obliterated. The bowels are usually costive. The pulse is generally small, feeble, and soft, or small and contracted; it is seldom accelerated, more frequently slower than natural, except under some temporary excitement or agitation, when it is momentarily hurried or irregular. The skin is generally soft, rather glossy, but never dry, harsh, and scaly, as in inflammatory dyspepsia; it is permeable but seldom moist, except sometimes from a sudden breaking out of perspiration on particular parts of the body; perspiration is rather suppressed than obstructed.

In the more protracted forms of this complaint the stomach is rarely free from uneasiness or discomfort of one kind or another; the patient is never unconscious of sensations in the stomach, and to whatever object his attention may be directed, the uneasy feelings of the stomach are

mingled in all his perceptions, tinge and darken all his thoughts, thus giving rise to another form of hypochondriasis. These sensations are sometimes that of burning heat, sometimes of icy cold, sometimes of gnawing, grinding, or dragging of the stomach, or of some foreign substance in the stomach, sometimes of emptiness or hollowness, of falling or sinking of the stomach, sometimes of nausea; or there is a constant sense of rising in the throat, sometimes of a round ball, sometimes of an insipid liquid. These uneasy feelings completely take away all power both of mind and body; the spirits become dejected, the body torpid, the limbs powerless,* the mind is prostrate, exclusively fixed upon the uneasy bodily sensation, or ever contemplating the gloomy association of the dark course of thoughts which they call forth;† and the sensibility of the stomach becomes consequently so highly exalted, that patients refer to it all their sensations, as is well expressed in a letter to Pinel from a lady, one of his patients: "*Le principe de tous mes maux est dans mon ventre; il est tellement sensible, que peine, douleur, plaisir, en un mot toute espèce d'affections morales, ont là leur principe. Un simple regard désobligeant me blesse cette partie si sensiblement, que toute la machine en est ébranlée. Je pense par le ventre, si je puis m'exprimer ainsi.*" Or there may be a feeling of anxiety, of restlessness, or impatience, which can neither be controlled nor overcome, with great nervous susceptibility; the mind is much impaired; the senses become delicate, the head giddy, the eye dazzled by the least effort of attention. Sometimes this morbid irritability is most apparent in the vascular system, the pulse being quickened, the heart made to palpitate, the face to flush with a sound of rushing or ringing in the ears. This peculiarity seems frequently to arise from excessive loss of blood. Urticaria, prurigo, stinging or itching of the skin, are not unusual attendants.

These symptoms are occasionally for a time relieved by taking food, and only return as the stomach becomes empty, which acquires a painfully irritable state as the period of taking food is delayed, but they are more commonly aggravated during the process of digestion; and sometimes, in a higher degree of gastric sensibility, severe pain is excited by swallowing the smallest morsel, which is on some occasions instantly rejected. In some cases liquids produce greater uneasiness than solids, and sometimes medicines are the greatest irritants. The symptoms are very much aggravated by purgatives; flatulence, violent palpitations, with a sensation of approaching syncope, and vertiginous feelings in the head, have been observed to arise upon the action of the mildest purgatives; sometimes violent diarrhoea follows the action of a moderate aperient. The pain and uneasy sensations at the stomach are frequently relieved, but sometimes inordinately increased by touch or pressure upon the epigastrium.

In this complaint there is great uncertainty or

* "Αση, ἀπορίη, ὀψιες ἀμυροί, ὄρων ἥχοι, βάρια κεφαλῆς, νάρκη μελῶν, καὶ τὰ γνῖα λένονται. παλμὸς ἐν τοῖσι ὑποχονδρίοις.—Aretæus.

† Ἰσχυροί, ἔξωχοι, ἀσθενεῖς, ἐκλυτοί, λιποδρανεῖς, ἀψυχοί, οὐλοί, ἡσυχιοί, ἐξαπίνης δ' ὀργίλοι, κάρτα μὲν λαγχολώδεες.—Aretæus.

variableness of appetite; sometimes inappetency, even disgust for food, in its most aggravated form; frequently capriciousness, not rarely craving for food; remarkable antipathies and likings for particular kinds of food are frequently observed, and sometimes sudden fits of voraciousness, for such persons generally eat their meals very quickly. There is seldom thirst, but frequently a feeling of dryness in the throat and fauces. The bowels are universally confined, but the fecal evacuation is little altered in quality. The urine is abundant and pale-coloured, and frequently occasions smarting in its passage, its specific gravity being considerable and the urea abundant. The sleep is variable, but seldom refreshing;* patients in this disease are easily put off their sleep; they either sleep heavily, or have difficulty in getting to sleep; if the mind be in the least degree excited or occupied, they pass a wakeful night, the mind being thrown into a state of erethism which they cannot quiet.

Complication of Irritable and Inflammatory Gastric Dyspepsia.—When irritable gastric dyspepsia has been of long continuance, when stimulating or irritating remedies have been used for its cure, either heating, stomachic, and anti-spasmodic medicines, or strong and irritating purgatives, or if the patient have been led by his uneasy sensations into the habit of taking small quantities of ardent spirits or opium, an inflammatory state of the mucous membranes is apt to be superadded to the morbid sensibility and irritability of the stomach, and thus is formed the most difficult and obstinate form of the disease with which a physician has to contend. The symptoms of both diseases are mixed up together, forming a combination very difficult to unravel, a difficulty much increased by the conflicting evidence which the *juvantia* and *ledentia* afford. The tongue affords the most distinct indication; it is red along its margin, frequently having round spots or points of a darker red interspersed; it is little furred, or has a brownish slimy fur; small ulcerations occur upon the tongue, as likewise upon the inside of the mouth. This appearance, united with symptoms of great nervous irritability, always indicates the combination of both morbid conditions.

Causes.—The circumstances capable of inducing irritable dyspepsia are, either such as act directly or locally upon the stomach, or such as influence the stomach indirectly by acting upon the general system; but the coincidence of causes belonging to both these classes, has the most powerful influence in determining irritable gastric dyspepsia.

To the first description belong the habitual remora of crudities in the stomach, and therefore, in certain temperaments and under the modifying influence of more general causes, irritable not rarely succeeds to atonic dyspepsia; living upon hard, poor, and indigestible kinds of food, not suited to the nature of the body. From this cause proceeds the dyspepsia which afflicts the Irish poor, a great portion of whom live entirely on the potato, without milk, butter, or any kind of condiment; and many of the peasants of Scotland, highland and lowland, too strictly confined to the

oaten bread; which accounts for the prevalence of pyrosis in these countries; and to a deficiency of quantity and an unnatural quality of food is no doubt owing much of the dyspepsia of the poor in large cities, where it has been known that families have subsisted for a time on the rind of potatoes, and every description of poor and loathsome food;† men in the centre of civilization experiencing all the uncertainty of subsistence which belongs to savage life, without the habits which give them strength to sustain it. Other causes are, change from a stimulating, nutritious diet, to one of a poor, cold nature; leaving off any accustomed stimulus, as opium; a certain tenderness (*teneritudo*), delicacy, or partial irritability of the stomach, sometimes inherited, but also the consequence of over care and restriction in the choice of food;‡ abstinence and prolonged fasts: hence dyspepsia is a frequent consequence of the strict observance of the Catholic fasts, and hence Pinel numbers among the causes of dyspepsia the abstinence of the Bramins, of the Fakirs, and the ancient anchorites of the Thebaid. Certain acrid and irritating ingesta, as the habitual use of mercurial preparations, sometimes irritating purgatives, very strong green tea, and such like.

The causes of the second description are a delicate, irritable, nervous temperament, hereditary or acquired; irritability of mind, usually the consequence of moral causes, as of anxiety, vexation, envy, jealousy, nostalgia, contrarieties, reverses of fortune, over-indulgence in tender feelings, nourishing a delicate sensibility, and avoiding too carefully the ordinary rubs of life. Baglivi says, "*Patres familiaris et rei familiaris curâ distenti aut in dignitate fuerint constituti, aut in aulâ vivant.*" He might also have added the mothers of families, for we are not acquainted with a more general cause of this disease than the anxieties of mothers watching over the health and education of their children, their own health at the same time being frequently undermined by diseases peculiar to their sex. We may add causes which disturb, extremely exhaust, or debilitate the body, as concussion of the brain, repeated venesections inopportunistically employed; protracted and exhausting hemorrhages, weakening discharges; all which causes are more powerfully felt if the stomach be irritated by indigestible food or exciting physic; climates and season of year, frequent and sudden variations of temperature, to which probably may be attributed the colic of Madrid, nearly related to this disease, and also the prevalence of this disease in the spring in our own country.

The morbid irritability of the stomach may be also sympathetically induced from its consent with other organs. This affords a common source of the disease in the female sex, in whom it is often induced by an irritable or painful state of the womb, as occurs in dysmenorrhœa, in some forms of menorrhagia, in leucorrhœa, pregnancy, lactation, and hysteria. But the same effects may follow an irritable or painful performance of the

† Συνήθεις δὲ καὶ τοῖς ὑπὸ τε ἀνάγκαις ἐκδεσχημένοις λεπτῇ καὶ σκληροτέρῃ διαίτῃ.—*Areteaus.*

‡ Multi ceteroquin sani et robusti parcè atque timide cibum sumunt ob metum ne in cruditatem et exinde morbos delabunt cum ob illum ipsum timorem et vanam imaginationem non solum exiguum illum cibum male digerant sed ob hoc in morbos incidunt.—*Baglivi.*

* Οὐχ ὕπνῳ ἀρεσκῶν.—*Areteaus.*

function of other organs, as is exemplified in a painful state of the kidneys and ureters, in stricture of the urethra, in an irritable state of the testicles, and in other painful local complaints.

Pathology.—Though the ancients did not generalize the phenomena of this disease under any specific term, they have most accurately described them. Hippocrates has detailed the symptoms in his account of that state of body in which the fatigue exceeds the support,—*οἱ πόνοι κρατεῖοντι τῶν σπέρων*, and we doubt much whether a more faithful portrait of it is to be found than that left us by Aretæus of his disease—*στρομαχική*. The Methodists would seem to have known it under the term *durities stomachi*, a sub-species of their *passio stomachica strictura*. It was very fully described and treated of by Cheyne, was noticed by Tissot, Pommé, and other writers, but most especially by Whytt, who was himself a sufferer from it. The nature of it was very clearly pointed out by Pemberton under the term of "*pain of the stomach increased upon taking food*," as will appear from his own explanation. "The pain of the stomach, which is most felt when it is full, would appear to arise from irritability of the muscular coat of that organ, and not to be at all connected with the glandular secretions of it; for unless the pain be called forth by taking food, it will rest perfectly at ease. This disease seems particularly to attack chlorotic women and hypochondriacal men; I am, therefore, inclined to believe that it owes its origin to the muscular fibres of the stomach partaking of the general irritability of all muscular parts in an irritable habit; and I think that the advantage derived from the method of treatment hereafter mentioned will add considerable strength to this opinion." In Germany it was very accurately treated of by Schmidtman under the name of one of its symptoms, *cardialgia*, (op. cit.) by which is understood any pain or uneasiness of the stomach, not heartburn, as it is usually translated; in France by Loyer Villermay under that of hypochondriasis, which he considers to depend upon some modification of the organic sensibility of the abdominal viscera, especially of the stomach; and was, lastly, more fully developed by Barras, (*Traité sur les gastralgies de Paris, 1827*.) he himself having experienced the disease to a deplorable degree. We are indebted to Dr. James Johnson for having recalled the attention of the profession in England to this disease in his able work on the morbid sensibility of the stomach.

They who are practically conversant with the sufferings of the human body, are too well aware that it does, under certain circumstances, assume a morbid condition which supports with difficulty the impressions of all external agents, even the most ordinary, whether their property be to excite, to depress, or otherwise modify the vital powers. This state of body perceives impressions, in kind and degree, not cognizable in the healthy state of sensation, and is excited to action by slight causes, which in the ordinary state of health would have no effect. Persons labouring under this affection are disturbed beyond all measure by the weakest stimulants, and are overwhelmed by a sedative of the lowest powers. In such persons we have known a few grains of nitre to cause fainting, or a severe fit of colic, the loss of a trifling quantity of blood

to induce a convulsion, a Plummer's pill to bring on deadly cold sweats, inexpressible agony, and all the threatening symptoms of instant death, a few drops of laudanum to induce convulsive fits and delirium. The phenomena of this morbid state of body have been generalized under the term *irritability*, consisting, as is evident, not only in a morbid sensibility, but also in a morbid susceptibility, or mobility, in some respects the reverse of that of atony, in which both the sensibility and mobility of the body are remarkably diminished, sometimes requiring the most powerful stimulus to call them into action; but both appear in some measure to be connected with a state of deficient vital power, from the manner in which they are aggravated, if not produced, by debility and debilitating causes. In this respect, perhaps, their common nature might be acknowledged, whilst their particular character was distinguished, and thus atony might be termed passive debility, debility in repose,—irritability, active debility, debility in action.

This constitution of body may be hereditary or it may be acquired, but the manner in which it is engendered, though well deserving of investigation, has not yet been satisfactorily explained. It seems, however, capable of being produced in the strongest bodies by painful suffering or long-continued strain of body or mind. A painfully sensitive state of any part of the body, permanent or frequently recurring, by which as it were the nervous system is sustained in a constant state of erethism or wakefulness, and by which a second or morbid sensorium becomes by degrees developed, where every sensation is felt or reflected, seems to have the power of inducing this condition of body. The tic douloureux, calculus of the kidneys or bladder, stricture of the urethra, painful menstruation, chronic rheumatism, prurigo, even such insignificant ailments as tooth-ach or painful corns, afford every-day examples of this power. Painful gestation, difficult parturition, afford similar examples, but sometimes rendered more remarkably striking when combined with debilitating causes, as they frequently are, particularly by excessive losses of blood, as in flooding after miscarriages or lying-in. But, debilitating causes without pain have much less power in inducing this state of body. The most complete anæmia may sometimes be observed without irritability, and we fancy it will be found that the debility has been in the one case induced with pain, and in the other without it. Pain, however, supervening upon a state of debility, affords the combination of circumstances the most powerful in inducing irritability.

In the same manner the affections of the mind most capable of inducing this state of body, are long-continued care and anxiety, expectations deferred, and repeated disappointments, all the feelings usually comprehended under the term vexation, the effects of which, if examined into, will be found to consist in a state of painful consciousness, exactly corresponding to the state of the body just described, both agreeing in exciting a constant and continued state of nervous erethism, and in developing a new seat of sensorial power, distinct from that of the common sensorium.

This view of the manner in which irritability is acquired, is amply borne out by the nature of the operation of the causes which are capable of ex-

citing it, whether general or local, to both of which we must refer.

According to the operation of these two kinds of causes, this morbid condition may be general, affecting every organ of the body, or it may be local, confining itself to some particular system or to some particular organ. It may commence in some particular organ, and thence propagate itself to the general system, or it may, emanating from the general system, diffuse its influence over the whole body, or, from certain local causes, be concentrated upon particular organs. Instances of the former are afforded by the eye, which sometimes acquires a morbid degree of irritability out of all proportion to the general state. The same may be observed of the womb in painful menstruation, or after frequent miscarriages; of the bladder, which sometimes, without any inflammation, acquires a degree of irritability, rendering it incapable of retaining the smallest quantity of urine; of the urethra, giving rise to painful and spasmodic stricture; and the testes and kidneys, equally susceptible of this state, afford similar examples. The heart and vascular system appear also, from the influence of particular causes, to be sometimes placed exclusively under the influence of this state, as is shown by the quick, irregular, and easily excitable pulse, the palpitation and disturbed action of the heart, the sudden flushing sometimes of the whole surface, sometimes confined to a small extent. It is not, therefore, to be doubted that the stomach and bowels may be affected in the same manner, and placed in the same morbid condition, consequently giving rise to a corresponding form of dyspepsia.

Nor is it difficult to understand either, how from local causes this state of morbid irritability should be engendered in the stomach, or how any disorder of the digestive function, when the constitution or any particular organ is under the influence of this state of irritability, should, by virtue of the law of consent, assume the form of disease.

When from any cause, as from habitual indigestion, the stomach is kept continually in a state of irritation or erethism by the remora of crudities, it becomes a seat of conscious sensation, to which the attention is continually directed. In consequence of which, as we have already explained, the stomach acquires an acute degree of sensibility like any other sense long exercised under the constant effort of the attention. To use the words of M. Barras, "la sensibilité de l'estomac s'exalte à un point étonnant; d'organique elle devient animale, pour me servir du langage de Bichat. Tout ce qui se passoit dans le principal organe de la digestion, je le sentois comme s'il se fut passé sur l'organe du tact, la présence des alimens y étoit perçue, comme elle auroit été sur la main." That such is the effect of the remora of crudities we have a strong proof in the parallel case where foreign bodies are lodged in the stomach, (*Gastrodynia à peregrinis*), or generated there, as in the case of bezoartic concretions, (*Gastrodynia Calculosa*, vomitus Bezoarticus, *Sauvages*), or parasitic animals. (*Dyspepsia verminosa*, *Cardialgia verminosa*, vomitus verminosus, nausea à tæniâ.—*Id.*) In all these cases the same morbid irritability is developed, giving rise to all the

peculiar symptoms which belong to irritable gastric dyspepsia. The following case affords a good illustration. "A man of sixty years of age had for a long time experienced, whenever he took a little nourishment, violent cramps of the stomach, accompanied with a sensation of heat in that organ, and with the eructation of liquid so acrid that it ulcerated the pharynx and corroded the enamel of the teeth; to these symptoms were added vomiting, which returned several times in the day, a continual sensation of pressure and of agony at the præcordial region, disgust for food, habitual constipation, almost entire loss of sleep, and at last gradual wasting. One day, in one of his usual efforts of vomiting, a calculus was ejected, which afforded the patient some relief, and the day after a return of the vomiting effected the expulsion of a second. The first of these calculi weighed a drachm, the second half a drachm. A short time after these were ejected, the patient was restored to health." (*Andral*, Anat. Path. p. 168.) Similar cases with corresponding results are also to be met with from organic causes, as, for instance, when tumours, fungous, vegetative productions have been found projecting into the stomach, they have been always preceded by the symptoms of irritable dyspepsia; ulcers of the mucous membrane of the stomach, and diminished capacity of this organ, have also been known to give rise to similar symptoms. And to this manner of operation may also be referred all the other local causes of irritable dyspepsia.

Of the secondary origin of irritable gastric dyspepsia, where the disorder of digestion emanates from, or is modified by the irritable state of the constitution, or of some other organ, we have examples of the former kind in concussion of the brain, in nostalgia, in the *cardialgia lactantium*, *anorexia*, *cachectorum*, and *anorexia melancholica* of Sauvages; in the *anorexia exhaustorum*, *dyspepsia cachectica* of Cullen; and of the latter, in the *nausea nephritica*, vomitus nephriticus, in the *gastrodynia hysterica* and *chlorotica*, the nausea and vomitus gravidarum, the *pyrosis à conceptione*, of Sauvages; and in the *dyspepsia nephritica*, *hysterica*, *catamenialis*, *dysmenorrhœica*, *gravidarum*, *chlorotica*, and *hypochondriaca*, of Cullen.

We must also notice in this place a form of secondary dyspepsia arising from spinal irritation, which has been particularly described by Mr. Teale, of Leeds, in his very able and practical work on neuralgia. There can be no doubt that every species of dyspepsia may originate in a morbid state of the spinal marrow; but according to this writer the spinal irritation will be always perceptible on pressing some of the middle or lower dorsal vertebræ, or by tenderness in the neighbourhood of the middle and lower thoracic ganglia. This affords the chief distinction of this variety of dyspepsia, which, with the other secondary forms of dyspepsia, only derives permanent relief by the treatment of the primary disease.

Treatment.—The method of cure which experience sanctions is in exact correspondence with the pathological explanation which we have given of the disease. It consists of the following indications—viz. 1, endeavouring to render the function of digestion easy of performance by a selec-

tion of food suited to the nature of the disease; 2, correcting the morbid condition of the stomach, either *directly*, by the use of medicines which have the power of modifying its innervation, of diminishing its morbid sensibility and irritability; or *indirectly*, by such means as soothe and assuage the irritability of the whole body; and 3, by restoring the tone of the stomach and of the whole system, by which the morbid condition is not only removed, but its return prevented.

1. The first indication will be fulfilled by a proper regulation of the diet, suited to the sensibility of the stomach, and apportioned to the wants of the body, adjusting it to the exercise of the body and the occupation of the mind.

It may be collected from what has been said, that the waste outruns the supply, that the wear and tear of the body and mind exceeds the ratio of supply; but it would be in vain to think of restoring the equilibrium by increasing the quality or quantity of the nourishment, for the stomach could neither bear it nor appropriate it. It is therefore to be adjusted by diminishing the fatigue of body or the wear of the mind, as either may be the offending habit.

The chief object to be held in view in selecting the diet, is, that it should be of such a nature and in such a quantity as may be digested with the least labour and the least irritation, and such as leaves no indigestible refuse to gall and fret the stomach, thus keeping its sensibility ever awake. What answers this purpose best is a mixed diet, what Cheyne was used to call a *trimming diet*. It consists partly of animal and partly of farinaceous food, neither entirely dry nor entirely fluid or pultaceous, avoiding all those kinds which have been already specified under the treatment of atonic gastric dyspepsia, as universally indigestible. The quantity is also of paramount importance. The meals, of whatever they consist, ought to be very small, but may in proportion be more frequently repeated, it being of the first importance to avoid distension of the stomach. Some of the most aggravated forms of this complaint appear to have been cured by carrying this principle to its full extent. The cases related by Dr. William Hunter (Medical Observations and Inquiries, vol. vi.) and by Mr. Hey of Leeds were cured by feeding the patients on skimmed milk, given in very minute quantities, one or two table-spoonfuls at a time; and another similar case (*Abercrombie*, Diseases of the Abdomen, p. 51,) was treated successfully by Dr. Barlow of Bath, by restricting his patient to a diet consisting wholly of fresh-made uncompressed curd, of which she took only one table-spoonful at a time, repeating it as often as she found it advisable. And we have known a similar case in which a preparation of the fecula of oats, known in Scotland by the name of *sowens*, in Ireland by that of *flummary*, given in repeated small quantities, proved equally efficacious: milk has been also used in the same way. Such a plan of diet refers, of course, to extreme cases. We have only mentioned these instances for the sake of impressing the importance of small meals. We have found the strictly dry diet invariably difficult of digestion, and would in general recommend to begin dinner by a few spoonfuls of light plain refreshing soup. A very small quantity of

properly dressed tender vegetables is admissible. One glass of sherry, or two of claret, Sauterne, hermitage, or hock, or a proportional quantity of brandy and water, may be permitted, or these may be taken alternately with a small quantity of home-brewed beer. The temperature of the diet has also been found of very great consequence. It has sometimes been found that the food eaten perfectly cold has digested easily, when the hot has been immediately rejected, though the reverse is generally the case. It is of the greatest importance in every form of dyspepsia, but most especially in this, to eat deliberately, and to masticate the food with scrupulous care.

Procuring easy and satisfactory relief of the bowels is another means of indirectly relieving the irritability of the stomach. This object ought to be attained by the mildest means, for purgatives frequently disagree, and the milder purgatives act better than the rough or violent ones. When the simple clyster will effect this purpose, it is to be preferred: if not, some mild aloetic pill, similar to the formula already given, or the decoct. aloes comp. are the most suitable. It is sometimes of service to combine the extract of hyoscyamus, sometimes a minute quantity of opium, sometimes the sulphate of quina, and sometimes bismuth or steel, with the aperient.

Fatigue of body is sedulously to be avoided, and when the condition of life imposes labour, it is to be lightened as much as possible. Even for those with whom labour is voluntary, much exercise in this disease is not found advantageous, though dwelling as much as possible in the open air is always to be desired. The exercise should be easy, sauntering, soothing, and amusing, as slow moderate walking upon plain ground, exercise on horseback, or an easy-paced pony, driving in an easy open carriage, boat-sailing, or a sea voyage, if the season permit. Some light amusing game may be added to the exercise, as golf.

2. Some medicines have the power of acting directly upon the nerves of the stomach, and in that way of diminishing their irritability. One of the most powerful of these is the hydrocyanic acid, either as it is prepared, or as it is found in the distilled laurel-water. The same power is also possessed by the extract of belladonna, and the nux vomica is used by the peasants of Lapland for their endemic pyrosis. The subnitrate of bismuth, the sulphate of iron, the arsenical solution, and the nitrate of silver, are also remedies of the same nature, and have been attended sometimes with surprising effects. Camphor, valerian, and the fetid gums, are similar remedies of weaker powers. Their preparations, however, afford useful media for the exhibition of the more powerful medicines. If these medicines do not soon afford some mitigation of the symptoms, they ought to be discontinued. Alkali or alkaline mineral waters have considerable power in soothing the irritation of the stomach, as the liquor potassæ or lime-water, but most especially the Kesselbrunnen of Ems, the Theresienbrunnen of Carlsbad, and the waters of Vichy.

Counter-irritants applied to the epigastrium in obstinate cases have seemed to afford relief, but more permanent benefit has appeared to us to follow the continued use of a warm emollient opiate

or Burgundy plaster. The warm douche upon the stomach, as used at the baths of Lucca and at other thermal springs, we have known to be of considerable use in this way.

Relaxation and repose of mind prove frequently of themselves a cure for this complaint, by which the disturbed functions recover themselves; and to a certain degree they are essential to the success of the general plan of treatment. Though we may not have the power of throwing off the burden as we will, much is to be effected by disposing the mind to it. By a gentle steady effort it may be subdued to a state, if not of ease, certainly of quietude. They who know how to appreciate health will not hesitate to make any sacrifice, and they who cannot or will not make the sacrifice, may still do much to correct their habits. If they cannot have entire relaxation, they may seek to change or interrupt their occupations: "*Levat quoque lassitudinem etiam laboris mutatio.*" And if they cannot conquer the habit which care and anxiety have established, they may obtain much by seducing the mind into other occupations.* "*It is upon this account,*" says Cheyne, "*that I would earnestly recommend to all those afflicted with nervous distempers, always to have some innocent entertaining amusement to employ themselves in for the rest of the day, after they have employed a sufficient time upon exercise, towards the evening, to prepare themselves for the night's rest. It seems to be absolutely impossible, without such help, to keep the mind easy and prevent its wearing out the body as the sword does the scabbard; it is no matter what it is, provided it be but a hobby-horse, and an amusement to stop the current of reflection and intense thinking, which persons of weak nerves are apt to run into. The common division of mankind into quick thinkers, slow thinkers, and no thinkers, is not without foundation in nature and philosophy. Intervals of no thinking or Swiss meditation are necessary for health.*" Under this impression it has often occurred to us that the innocent pastimes of life are very much undervalued, and we have not hesitated to recommend our patients their quiet rubber of whist, a party at piquet, a game at draughts or backgammon, even chess, or any thing by which the mind is amused without being excited; light occupations of the mind which divert the attention without occupying or fatiguing it; light reading, arithmetical calculations, any game where the stake excites no interest: music (*flute-playing*), drawing, embroidery, and every description of handywork. We have also known the greatest advantage derived from practising some of the mechanical arts; one of the most inveterate cases of irritable dyspepsia we have known was very much alleviated by the patient taking to the employment of turning.

But frequently all these objects are most completely attained by a tour, a sea voyage, a change of air, which, including change of food, of exercise, occupation, and habits, invigorates the body whilst it relaxes the mind.

The general irritability of the body is much diminished by an open dry air, and by dwelling in

it as much as possible; by a long sea voyage, in severe cases, by the use of the rocking-chair, the rocking-sofa, and by the swing. But the restoration of no function tends so effectually to calm the irritation and repress the jaded fibres of the body as sleep, and we are of opinion that this, which is left to return as an effect of the general improvement, might probably be advantageously solicited and sought for, as a means as well as a consequence of recovery, if possible, by the more natural means, by gentle exercise in the open air, by early hours, by tepid baths, proportioned in duration to the strength of the patient, the warm pediluvium; but if these are not successful, by anodynes, by the acetate or muriate of morphia, or the black drop, judiciously managed, so as not to derange the function of digestion. This object is so important that it is often desirable to give up an hour or two in the middle of the day to sleep. If the tepid bath does not produce headach or sleeplessness, it is always of service; but to the extreme cases of the disease, where the patient's strength is much exhausted, it is not applicable.

The temperature of the body is to be supported by warm clothing; a flannel roller is of great use; and medicines determining to the skin often afford relief, as ipecacuanha or James's powder in small doses, combined with extract of hyoseyamus. The tone of the body will be invigorated, and the morbid irritability directly diminished, by dwelling much in the open air in a dry temperate atmosphere. We are convinced that, besides the influence of change of habit, this is one of the most important effects of passing a winter in the south of Europe. This effect we have known many persons feel most sensibly, saying they felt as if their nerves were loosened and set free—as if they were out of fetters. When the patient's sensibility is not too delicate, the daily cold ablution is of great service; and in a higher degree of strength the shower-bath may be used with advantage.

3. Provided the bowels are properly regulated, and the function of the liver correctly performed, some tonic medicines may be had recourse to; but if the preceding plan be faithfully executed, their use will be found of secondary importance. Whatever quiets and strengthens is expedient in irritable dyspepsia, and tonics and stimulants often appear to possess a specific effect in subduing irritable action of the nervous system. They consist of the sulphate of quina, which some have administered endermically; steel in its various preparations. Pemberton was in the habit of giving Griffith's green draught. The ferrum ammoniacum is a convenient form, or the vinum ferri. The carbonated chalybeate waters are frequently successful when no officinal preparation of iron can be borne, chiefly those of Eger, Spa, and Pyrmont. The irritability is also sometimes diminished by a judicious use of stimulants, but it is a practice which demands much judgment and discretion.

The secondary forms of this disease must be treated by a proper consideration of the primary disorder in which they originate; and for the cure of the secondary affections which originate in irritable dyspepsia, we must refer to the separate articles to which they belong. In conclusion we cannot better explain our notion of the principle

* Vita namque tamdiu in perturbatione est, remedia nequicquam proficiunt, et licet ea recipiat, viribus tamen illorum non auscultat.—Baglivi.

which ought to preside over the treatment of this disease in all its forms than by quoting the words of Baglivi: "Blandè et leniter tractandi sunt; a nimia remedium copia et vehementia quam maxime abstinendum."

IV.—FOLLICULAR GASTRIC DYSPEPSIA.

Synonyms.—Stomachi pituita, *Cels.*; rheumatismus vel fluor stomachi, *Cæl. Aur.*; cardialgia, *Plateri*; anorexia pituitosa, vomitus pituitosus, cardialgia bradypeta, *Sauv.*; anorexia humoralis, *Cullen*; catarrhe de l'estomac, *Pinel*; estomac glaireuse,* *Fr.*; pain of the stomach, most felt when the stomach is empty, *Pemberton*.

General Character.—Pain, nausea, cramp, sensation of gnawing, of weight, or other uneasiness in the stomach, chiefly felt in the morning or when the stomach is empty, and frequently followed by vomiting of an insipid, viscid, sub-pelucid fluid.†

Form of Disease.—This species of dyspepsia is chiefly met with in crapulous old people, and in young persons of a cold phlegmatic temperament about the age of puberty. It prevails most in cold and damp climates, and in cold and damp seasons; it is the usual attendant of the winter cough of old age, and frequently supervenes in the course or upon the decline of a catarrh, and is usually relieved in summer and aggravated in winter. It is commonly manifested by pain, a sense of weight, of gnawing, sometimes by craving, or by obtuse spasmodic pain, or other uneasiness, when the stomach is empty; by loss of appetite, nausea, and sometimes by vomiting of a transparent ropy tasteless fluid, clear and glairy like the white of an egg, more generally in the morning, but sometimes towards night. The nausea and other uneasy sensations of the stomach are usually very much relieved by the rejection of this fluid, the quantity of which is in some cases very considerable. In a woman mentioned by Andral, this discharge amounted to about four pints in the twenty-four hours; and, what is remarkable, she never vomited either food or drink, showing this fluid to be highly offensive, and a source of irritation to the stomach. (*Clinique Medicale*.) The pain and uneasy feelings of the stomach sometimes assume the form of *pyrosis*, accompanied with a copious flow of saliva, or a continual watering of the mouth, corresponding with nausea, or a sensation of gnawing at the stomach.‡ Besides these more specific symptoms, this disease is attended by those which are common to the other forms of dyspepsia, by flatulence, by eructations of flatus or fluid, generally insipid, sometimes slightly acid; by oppression at the stomach after eating, although the pain and uneasiness are considerably diminished by taking food. There is a frequent desire to take food, attended with thirst, and as the disease continues, there is also considerable wasting of the flesh. The uneasiness produced by laborious digestion subsides as the process is finished, but be-

fore the time of taking food arrives, the stomach becomes irritated by its own secretion, which produces all the inconvenience of a foreign indigestible substance in that organ, such as a sense of sinking, of dragging or trembling of the stomach, of nausea, faintness, gnawing or erosion, which are again for a time relieved by the taking of food.§

The distension of the stomach by flatus sometimes gives rise to great oppression or anxiety at the stomach, to the same sensation in the breast, and to vertigo and other uneasy feeling in the head, to palpitation or irregular action of the heart, trembling of the knees, and coldness of the feet and legs. These symptoms are generally relieved as the flatus is expelled, which is, however, accomplished with more difficulty in the recumbent posture; if not accomplished, restlessness, agitation, requiring a constant change of posture, frightful dreams, or incubus, are common attendants.

In this form of dyspepsia there is generally some thirst; the tongue is covered with a viscid mucus; sometimes the papillæ only are tipped with a dull white fur, but frequently it presents a continuous white fur and a sodden appearance; under irritation the tongue becomes dry, presenting a shining or glossy appearance, but still continues paler than natural. The bowels are generally confined, and the evacuations scanty; sometimes large quantities of mucus, generally fluid, sometimes concrete, are mixed with them. The urine is usually high-coloured, seldom sedimentous. Unless there be great debility, the pulse is slow and soft, and the extremities are generally cold.

The sympathetic affections which characterize this form of dyspepsia are, a troublesome cough, with considerable mucous expectoration, which is much increased by taking food, dyspnoea, humoral asthma, and leucorrhœa. It has also appeared to us that *acne*, in some of its forms, is a disease of the skin very frequently connected with this particular derangement of the digestion; and we have had occasion to notice a form of rheumatism, accompanied by palsy of the parts affected, which frequently attends it,—that species which has from some physicians received the name of *paraplexia rheumatica*. Sympathetic headach is less common.

Causes.—The predisposing causes of this disease are a phlegmatic temperament, natural or acquired; the decline of life, that period after the forty-fifth year, the *senium crudum*, green old age, *l'âge de retour* of the French; the latter part of childhood, the period bordering upon puberty, before and after; damp climates, damp seasons, and damp weather; low marshy situations; indolence of body and mind, and sedentary habits. The ancients thought that particular kinds of food, also, favoured this predisposition. "Crassiores autem pituitam faciunt ova sorbilia, alica, oryza, amyllum, ptyzana, lac, bulbi, omniaque ferè glutinosa."—(*Celsus*.) Some physicians have also considered it to be more common in great ale drinkers and smokers.

The exciting causes are accidental indigestions from food of an improper quality, and catarrhal colds.

This disease may succeed to atonic as well as

§ Quæ sumpto cibo temporaliter depellitur. — *Cæl. Aurel.*

* Doussin—Dubreuil. Des Glaires, de leurs causes, et de leurs effets. Paris, 1831.

† Est ea quæ a viscosis adiposis, lentis humoribus in stomacho contentis excitatur; quod cognoscitur ex sensu gravitatis in ventriculo, ructibus insipidis, vomitione pituitæ insipide glutinosæ, ex assumtis oleosis, pingui-bus sensu expletionis. — *Sauvages*.

‡ Oris humectatio nauseabilis cum mordicatione interiorum. — *Cæl. Aurel.*

inflammatory dyspepsia, probably presenting in each case a corresponding variety, a circumstance which leads us to doubt whether we are perfectly correct in erecting this form of dyspepsia into a distinct species, and whether it might not have been more so, to have arranged each of their varieties as sub-species respectively of atonic and inflammatory dyspepsia. But not having been able to distinguish these varieties by their proper symptoms, we must leave the task to a better method and a more refining analysis.

Pathology.—This species of dyspepsia was noticed by Hippocrates as a form of repletion, was clearly distinguished by Celsus, (interdum stomacho pituita oritur,) and described by the sect of Methodists as a variety of their *stomachica passio solutionis* under the term *rheumatismus stomachi*, using that term in its etymological sense of fluxion, and not under its modern arbitrary limitation. Under *anorexia pituitosa* and *vomitus pituitosus*, corresponding with the French term *estomac glaireux*, Sauvages has correctly laid down this species of dyspepsia, and Cullen has included it in his local disease of *anorexia humoralis*. We may also find that this form of disease (or its appropriate symptoms) has not escaped the observation of most of our best writers; but it was more particularly singled out by Dr. Thomson in the Edinburgh Medical Essays, by the late Dr. Pemberton in his practical work on the diseases of the abdominal viscera; and we are of opinion that the disease to which Daubenton had his attention chiefly directed, was this particular form of dyspepsia. (Daubenton on Ipecacuanha, Lond. 1806.) We form our opinion on this point, however, as much from the nature of his remedy as the description of the disease, for he has indeed only described the symptoms common to slow and laborious digestion, the *concoctio tarda* or *bradypeptia* of some authors.

The older physicians attributed this disease to a cachochymy of the fluids by which the cold phlegm becomes predominant, and they thought to explain the disorder by describing it as a fluxion of the degenerated humour to the chylopoietic organs. But there can be little reason to doubt that, however it may be induced, the proximate cause of this disease chiefly consists in a disordered state of the mucous follicles of the stomach, the *glandulæ aggregatæ et solitariae* of anatomists. The nature of the symptoms will not acknowledge any other cause, and it would be difficult to find any other morbid condition to account for the peculiar matter so frequently vomited. That the disorder of the function of the mucous follicles may be frequently only a part of a more general derangement of the mucous surfaces of the stomach, is highly probable; but that the disorder also frequently predominates in the mucous follicles—nay, is sometimes exclusively confined to them,—we have ample proof in dissection, and it would certainly be highly unphilosophical not to admit it as a morbid condition of the stomach capable of giving rise to its own peculiar form of indigestion.

The disease of the follicles may be simply functional, or it may be organic, and both of these morbid conditions admit of great variety. Dissection shows us that a disordered state of the secretion of the mucous follicles may proceed from

very different states of these organs. It may be the consequence of an increased development of the follicles which sometimes succeeds to inflammation, but frequently arises without it. In persons who had formerly suffered from gastric irritation, an increased activity of the secretion, and a remarkable development of the follicles, have been observed. "In opening certain bodies," says Andral, "we are struck with the vast quantity of mucus which sometimes covers the inner surface of the stomach or intestines. This mucus often forms a thick coating extended over a considerable surface. At the first view we might mistake this coating for the mucous membrane itself, which presents a white healthy appearance. Under the covering of mucus, the surface of the mucous membrane may, however, present itself in two very opposite states. Either there may be found under the mucus a bright redness of the membrane by which it has been produced, the more common state, or it may be found pale and without any trace of redness or injection. For the augmentation of a secretion does not necessarily imply the notion of a sanguineous congestion of the secretory organ." (Patholog. Anat.) It is possible, as we have already remarked, that these two opposite pathological states may also afford a distinction of symptoms to be hereafter ascertained by a clearer and finer observation, which may divide this form of dyspepsia into two different varieties, each arranged under their respective species of atonic and inflammatory dyspepsia.

That the accumulated mucus is the proximate cause of much of the painful feelings in this form of dyspepsia may be inferred from the relief which is experienced on its being ejected, as well as from its sometimes being the only thing which is ejected, the food and medicine being constantly retained. "The increased secretion of the glands of the mucous membrane of the stomach," observes Pemberton, "irritates the nerves of the stomach, and thus causes pain. When it is secreted in small quantities, it may be so enveloped by any food that is taken as to render it inert; or when it is secreted in larger quantities, it may be thrown up by vomiting after causing violent pain." For being indigestible by the stomach, when it accumulates, as it most frequently does during the night, it becomes a kind of foreign substance, the source of much irritation, giving rise to a great variety of uneasy and painful sensations, and frequently to habitual daily vomiting, a complaint which M. René Prus considers the cause of a considerable number of cases of hypertrophy of the muscular coat of the stomach, frequently mistaken for cancerous degeneration of that organ.

Method of Cure.—As in every species of dyspepsia, so in this, the method of treatment must necessarily consist of the following indications:—1. to render the process of digestion as easy as possible by a selection of food proper in kind and quantity, and suited to correct the morbid condition of the stomach: 2. to excite the function of digestion by exercise adapted to the strength and habits of the patient, calling forth the stimulus of demand: 3. to promote the function of digestion by restoring the harmonious action of the different parts of the alimentary canal, chiefly by preserving an open state of the bowels; and 4. to correct

the particular morbid condition, the specific and proximate cause of this form of dyspepsia.

1. The patient should in his diet observe a cautious economy of liquids; his meals should consist chiefly of solid food, of the lean of animal food of such kinds as are easy of digestion, avoiding all that is fat, glutinous, and tough. His meat should be thoroughly dressed, never twice cooked, and his food should be taken hot. In general he should avoid fish, fruit, vegetables, cheese, milk, and eggs. Vegetables are at all times to be eaten sparingly; if prepared in the French fashion, they are certainly less unwholesome; but cabbages, all roots, and all bulbous vegetables, and all of a flatulent nature, are to be strictly forbidden. He should be careful not to drink before his meals; but plain light soup or broth, impregnated with the juice of vegetables, may be permitted in small quantities. Bread should be eaten stale, and the quantity should be limited. Malt liquors of every description are prejudicial, but a glass or two of dry wine, or sherry, sauterne, hock, or white hermitage, or a proportionate quantity of brandy and water may be allowed, and is frequently very useful. For breakfast, coffee is to be preferred to tea; and it is also in this case a good stomachic after dinner. Butter may also be permitted in moderate quantity; but whatever be the diet selected, the rule which is universal in dyspepsia, must not be forgotten—that a small meal of whatever kind is, *ceteris paribus*, more easy of digestion than a bulky one; and that by whatever plan of diet the patient has been restored, he must adhere to it for a considerable time after his recovery.

2. Horse exercise is the most suitable in this species of dyspepsia; but active walking, even to a certain degree of fatigue, sufficient to produce moderate perspiration, is frequently of great service. The exercise of the arms by the dumbbells or fencing, of the chest by singing, reading aloud, or declaiming, is of much importance, and ought to be sedulously persevered in. Great advantage has also been derived from boat-sailing and sea-voyages, whether from exciting vomiting we cannot say: but no description of exercise ought to supersede friction morning and evening, either with the flesh-brush or with a glove made of a piece of coarse blanket; and, for obvious reasons, it is more useful when performed by the patient himself than when administered by an assistant.

3. The best aperients in this disease are the decoct. aloes comp. which is sometimes advantageously combined with lime-water; or pills consisting of equal parts of aloes, rhubarb, calumba, and soap; or equal parts of the pil. rhei comp. and pil. galban. comp. or pil. scill. comp. We have also found the lac sulphuris an aperient well suited to this complaint. The object ought to be to obtain easy, satisfactory, and consistent evacuations, which the lavement alone is seldom able to accomplish; but it may be used to promote the operation of other means.

4. In the early stage of the disease the disordered state of the mucous follicles is sometimes quickly and readily corrected by an emetic, probably by exciting and evacuating their contents. For this purpose ipecacuanha is to be preferred;

and, when requisite, it may be rendered more active and efficient by combining it with the acetum scillæ. But though emetics, by stimulating and emulging the follicles, do afford considerable relief, their frequent repetition is not advisable; and in the more advanced state of the disorder, where vomiting becomes sometimes one of the most troublesome accidents of the disease, they cease to be serviceable. It has been found that, if ipecacuanha, instead of being taken in doses sufficient to excite vomiting, be administered in repeated small doses, it is of much more permanent use. With this view Dr. Thomson (*Op. cit.*) was accustomed to divide a full dose of ipecacuanha into several equal parts, which he directed to be taken in the course of twenty-four hours; and in the same way he was accustomed to divide a full dose of an aperient, (his favourite was the old-fashioned tinct. hieræ picræ, well replaced by our tr. aloes comp.) which he gave in the same way, in separate portions, alternating a course of aperients with a course of emetics. Daubenton used ipecacuanha apparently upon the same principle in much smaller quantities, restricting his dose from a quarter of a grain to two grains, just sufficient to occasion a slight vermiculatory motion in the stomach; but he only gave it once in the twenty-four hours, in the morning fasting. (*Op. cit.*) He recommends it to be given in water, wine, jelly, or in a lozenge. It is sometimes conveniently combined with the aperient. Where nausea is easily excited by it, we have been in the habit of uniting it with a little subcarbonate of ammonia, aromatic powder, cayenne pepper, or sulphate of quina; when flatulence is troublesome, with the pil. galb. comp. or the pil. scill. comp.; and when symptoms of acidity are present, we administer it in lime-water; we have often seen much advantage from modifying its action by such auxiliaries.

The sulphuret of potass in doses from a few grains to half a drachm alone, if the sensibility of the stomach does not forbid it, or combined with subcarbonate of ammonia, bitter extracts, aromatics, carminatives, with rhubarb, aloes, the pil. galb. or pil. scill. comp., as circumstances may indicate, is another remedy appearing to possess a specific action upon the mucous follicles. It is probable from a similar property that the sulphureous waters, as those of Harrowgate, Balaruc, Cauterets, and several others, have been found such efficient remedies in this disease.

Heidler of Marienbad also relates several speedy and perfect cures of this complaint by means of the Kreuzbrunnen mineral water. We have reason also to speak highly of tar water and lime water as valuable correctives of this morbid state of the mucous follicles.

Pemberton placed his chief reliance upon opium in union with astringents. In the incipient stages he was accustomed to give ten grains of kino and half a grain of purified opium, made into two pills, every fourth hour. He preferred kino to any other astringent, because, unless there was diarrhœa, it appeared to have no tendency to confine the bowels. This is not very different from the method of Prus, according to which Andral treated, at La Charité, a man who had for a long time vomited a certain quantity of transparent mucus resembling a strong solution of gum arabic

in water. He gave him for a month from one to six grains of the watery extract of opium daily. The vomiting disappeared, and under the influence of this medicine, the ordinary effect of which is to disorder the digestion, the function of the stomach was entirely restored.

The good effect of these remedies may be protracted or increased by a suitable use of tonics, either bitters or chalybeates. The vinum absinthii was once a favourite remedy in this complaint. The pil. ferri comp., vinum ferri, tr. muriatis ferri, and ferrum ammoniatum are suitable forms of chalybeates, care being taken that the bowels are at the same time preserved in a soluble state. But the chalybeate mineral waters of Eger, Spa, and Pyrmont are much to be preferred to any medicine of the same class.

The morbid condition of the mucous follicles may also be corrected by exciting the action of the skin, by increasing its tone and vigour by friction as already noticed; but also by cold ablution with vinegar and water, or salt and water; by the nitro-muriatic lotion, by cold affusion, or the shower-bath, remedies corresponding to the *ψυχρολουσία* of the ancient Methodists. And in addition to them, if circumstances permit the patient to choose his place of abode, he should seek above all things for a dry air, that of the mountains in summer, and of the sea-side in winter; and to fulfil the last intention, the best climates of which we have experience are Nice, Genoa, and Brighton. But wherever the patient may live, he should as much as possible select the driest situation, where the drainage, natural or artificial, is most perfect.

[Some of the cases of what have been termed *Alkaline Indigestion* and *Neutral Indigestion*, appear to have been gastrorrhœa. The fluids, brought up by some of those who have the power of vomiting at pleasure, instead of being acid, have been looked upon as alkaline. Whether this be the case or not, we can readily understand, that there may be a deficiency of acids secreted by the stomach, as we know there frequently is a redundancy. In these cases of alkaline indigestion, acids—as the muriatic—have been found very beneficial, along with appropriate general management. Of late years, lactic acid, which has been presumed to be one of the gastric acids, has been strongly advised by Magendie, (*Formulaire*, &c., 9ème édit. Paris, 1836,) given in the form of lemonade. The recent researches of Liebig, however, (*Animal Chemistry*, edited by Drs. Gregory and Webster, Cambridge, 1842,) would appear to show that this acid never exists in the healthy stomach; and he affirms that the property possessed by many substances such as starch, and the varieties of sugar, by contact with animal matters in a state of decomposition, of passing into lactic acid, has induced physiologists too hastily to assume the fact of the production of lactic acid during healthy digestion.]

II. DUODENAL DYSPEPSIA.

Disordered digestion proceeding chiefly from derangement of the functions of the duodenum, and the other small intestines.

To say precisely where duodenal dyspepsia begins, or where gastric dyspepsia ends, would not be an easy matter. Subordinate processes in the

performance of a complex function, conspiring for one general effect, the healthy actions of the stomach and duodenum, though different, are not easily to be distinguished; and though in disease their difference becomes more developed and more apparent by their discordance, it is more easy to describe than to mark the line which divides them. Nature indeed never separates things by strong or abrupt lines, though she stamps each with features sufficiently bold and clear to distinguish it from its neighbour. Her system is one continuous tissue of great variety and diversity, in which different parts are united together without sign of interruption or joining. In the coloured spectrum no one can say where one colour ends and where its neighbour begins, yet any one may distinguish its different colours, the violet from the blue, the blue from the green, each from its neighbour, and every one from the other. So in diseases having an affinity, where they approach each other they cannot easily be distinguished, whilst in their general character it would be difficult to mistake them. And, likewise, in the function of digestion, though such is the functional dependence of one part of the alimentary canal upon another, that one being affected speedily induces disorder in the remainder, yet attentive observation will discover the part primarily and chiefly deranged, the leading features, the permanency of some symptoms, indicating directly the part affected; whilst the more variable and less marked character of other symptoms excludes the derangement of other organs.

General Character.—Appetite generally little impaired, frequently keen, sometimes ravenous; the oppression, distension, pain, or other uneasy sensations, the signs of difficult digestion, not referred to the stomach, nor felt soon after taking food, but a considerable time, generally from two to four hours, after a meal; urine sedimentous; feces more or less unnatural in appearance.

Although Hippocrates had distinguished between gastric and enteric dyspepsia, it would be difficult to single out from amongst the diseases described by the ancient physicians, any precisely corresponding with those of which we are about to treat, though most of their symptoms might be found in the *ventriculosa passio* and *phagedæna* of Cælius Aurelianus, and in the *morbus atrabiliaris* and *morbus hepaticus* of the Greeks. Amongst modern writers it may be detected under the terms of *intemperies hepatis*, (*Sennertus*, lib. iii. p. 6,) *infarctus hepatis*, (*Junckeri* tabul. 39,) *dolor hypochondrii*, (*Boneti Sepulchret.* tom. ii.) *hepatalgia*.* But it was not until a knowledge of the anatomy and functions of the human body directed the researches of the physician, that the symptoms of these disorders began to be classed together, and the diseases to be traced to their seat. Hoffmann,† who dignified the duodenum with the name of the second stomach; and, because of the secretions poured into it, *ventriculus succentriatus*, commenced this important task, in which he was afterwards followed by Bonnazoli, (*Transactions of the Academy of Bologna.* 1745,) an academician

* *Sauvages*.—Morbus est cujus præcipuum symptoma est molesta sensatio, gravativa, tensiva, aut alia quævis in regione hepatis; differt ab hepatitide defectu pyrexiam acutæ.

† De Duodeno, multorum malorum causâ. Opera, tom. vi. 1740.

of Bologna, by the elder Monro, (Edinburgh Medical Essays, 1752,) at a later period by Dr. Classen, (Sandifort's Thesaur, tom. iii. 1778,) and more recently by Dr. Warren, (On Headach, Medical Transactions); but the subject remained incomplete until the very scientific and practical essay of Dr. G. D. Yeats (Medical Transactions, vol. vi.,) on the diseases of the duodenum, delivered as the Gulstonian lecture for 1817. Availing ourselves of the assistance of our predecessors, we accordingly propose following the same course in treating of *duodenal dyspepsia* as we have attempted with gastric, dividing it into species according to the morbid condition of the organ, the essence and proximate cause of the disease. We should therefore have to speak separately of *atonic*, *inflammatory*, *irritable*, and *follicular*, *duodenal dyspepsia*; but the irritable form of the disease we do not profess to have yet ascertained. To the second of these species we propose subjoining a variety commonly met with in scrofulous habits, which may with propriety be distinguished by the name of *strumous dyspepsia*.

I.—ATONIC DUODENAL DYSPESIA.

Synonyms.—Hepatalgia infarctus, intemperie frigidâ; aurigo frigidâ ab obstructione; gastrodynia biliosa, *Sauvages*; chylipoietic disorder, *Abernethy*; bilious dyspepsia, *W. Philip*.

General Character.—Sense of weight, fulness, or distension, or a heavy, dull, dragging pain in the right hypochondrium, felt generally some hours after eating; bowels confined; evacuations unnatural; urine dark-coloured and sedimentous; pulse slower than natural; skin rather sallow, and conjunctiva generally tinged with bile; no fever, but considerable languor and oppression.

Form of Disease.—When a person labouring under this disease comes to consult a physician for his complaints, it will seldom be found that he blames the state of the digestive organs, but, on the contrary, his physician will sometimes find him quite unconscious of their being in a disordered state; for his patient will tell him that his appetite never fails him, that he never finds any kind of food disagree with him, and therefore he is quite clear that his digestion has nothing to do with his ailments. He may complain of headach, affecting more particularly the back part of the head; of pain of the back, or under the right scapula, of lumbago, or pains in the joints; of pain or numbness of the right arm; of cough, dyspnoea, languor, loss of strength, or depression of spirits, or of many other similar sympathetic affections, but the disorder of the digestive organs has never drawn his attention. If, however, the physician enters into particulars, he will find that though the appetite be good, the digestion is laborious; that not immediately, but a considerable time after eating, the patient is oppressed, drowsy, and incapable of either mental or bodily exertion, and that he awakes from a nap uneasy, restless, fidgety, and irritable. This state of general discomfort is frequently attended with a sense of fulness, distension, or weight towards the right side, or with a heavy dull pain felt chiefly in some part of the right hypochondrium. This pain in the right hypochondrium extends sometimes to the back, frequently between the spine and the right scapula, or under the right scapula, or it corresponds with

a dull pain felt chiefly at the top of the shoulder, or with numbness or dull pain extending down the right arm to the elbow, wrist, and little finger, more rarely with pain of the right hip, extending down the right leg. Under certain circumstances these symptoms are very much exasperated, and the pain in the right hypochondrium becomes very acute, accompanied with great anxiety or with spasm in the situation of the duodenum, and a sensation of weight in the hypochondrium and loins, amounting to a complete attack of gastrodynia. If the right hypochondrium be examined, more especially if the examination be made when the patient is in the erect posture, a fulness will be perceptible through the whole hypochondrium, more sensibly apparent when compared with the left; sometimes a circumscribed puffiness is perceptible in the site of the duodenum, most particularly just before the cartilage of the eighth rib, in which situation it is observed that pressure is disagreeable, sometimes occasioning a sense of oppression or dyspnoea. This puffiness not unfrequently disappears in a day or two, particularly after free evacuations of the bowels, and then gradually returns, but is sometimes quite stationary, and occasionally so obvious as to be observed through the clothes, more especially in females. On some occasions it is so circumscribed and prominent as to give almost the appearance of a hernia. Such a case we have met in consultation with our amiable and lamented friend, the late Professor Andrea Vaccà, of Pisa, which appeared to derive considerable relief from the pressure of a bandage. Instead of pain or sense of weight in the right hypochondrium, there is occasionally a feeling which conveys the notion of torpor, of stoppage in or dryness of the bowels, as if their contents made no progress downwards, to which frequently corresponds a sensation of fulness in the lower bowels, leading to ineffectual efforts to relieve them, and not rarely spasmodic stricture of the rectum. Or there is soreness or a sense of fulness below the pit of the stomach in the situation of the arch of the colon, but deeper-seated. These affections are disposed to occur in paroxysms, seeming to be connected with the state of digestion, for the symptoms are more or less relieved as the process of digestion is completed, or they are relieved by satisfactory evacuations of the bowels, and relief is even experienced as soon as the upper portion of the bowels is put in motion, often long before an evacuation.

With the above symptoms, distinctly referable to the seat of the disease, or in place of them, the patient may complain of headach, which, generally unaccompanied with nausea, commences with a feeling of uneasiness of the head, with indistinctness of ideas, and disinclination or incapacity for mental exertions, chilliness of the body, coldness and dampness of the hands and feet. The headach itself consists in a pain or dull aching, sometimes of the forehead, but more commonly of the crown or posterior part of the head, which is attended with restlessness, with intolerance of noise, with dazzling or mistiness before the eyes, or with the appearance of various colours or luminous forms. The headach is invariably much aggravated during the period of digestion; sometimes it terminates with the process of digestion in a

few hours, but when it has become habitual, it may continue for one or two days. Instead of headach, there is sometimes a sense of fulness or of distension of the head without any fixed pain. Vertigo is occasionally the most troublesome symptom, and we have known it to persist uninterruptedly for weeks together; or the patient being seized with temporary loss of consciousness, and of muscular power of the limbs, falls down suddenly, without syncope or convulsion. Contractions of the countenance, rolling of the eyes, cramps or numbness of the limbs, are very common symptoms, and even hysteria, chorea, a fit of epilepsy or apoplexy, are not rarely connected with it. Rheumatic gout, aching pain in the knees and ankles, particularly of the right side, lumbago, pain of the back, especially in the direction of the right kidney, commonly aggravated by the recumbent posture, languor, lassitude, and weakness of the limbs, feeling as if the legs would give way, and sometimes actual paraplegia, are amongst the secondary affections of this disease. Fluttering, irregular action, and sense of distension of the heart, irritation of the larynx or trachea, causing a constant hawking or effort to expectorate, singultus, dyspnœa, and even asthma, are not unusual symptoms. A degree of spasm, sometimes stricture, with a sense of weight or load about the rectum, spasmodic stricture of the urethra, or difficult micturition, are not rarely observed in this complaint. The various forms of *epheles*, *pityriasis versicolor*, some species of *herpes*, particularly *herpes præputialis* and *circinnatus*, the *impetigo sparsa*, are the diseases of the skin which we have most frequently remarked as connected with this complaint, and their eruption is not rarely attended with relief of the internal disorder. Indolence, sluggishness, listlessness, or indifference of temper, want of the usual distinctness of ideas, a feeling of a cloud over the intellect, loss of memory, confusion of intellect, or oppression of spirits, are characteristic symptoms of this disease.

With more or less of the foregoing symptoms, either directly referable to a deranged state of the digestion, or secondary consequences of it, the appetite is observed to be seldom impaired, but on the contrary soon returns after eating, and even during the period of suffering is often preternaturally increased and voracious, sometimes unusually keen, particularly for food which disagrees, which last proves not seldom a premonitory symptom of an exacerbation of the complaint. The tongue is large, broad, soft, and flaccid, covered with a yellowish white mucous fur towards the root, but moist, slimy, and of a dull red colour towards the point and margin, presenting in general a flabby and sodden appearance. The bowels are costive, more rarely alternating with occasional diarrhœa, and the alvine evacuations when costive are hard, dry, and adust, of a dark brown or dull olive or greenish black colour; if more lax, generally of too light a colour, resembling that of whitish brown paper, of a dull clay or light brownish colour, and devoid of their natural smell; or sometimes yeasty, tape-like, sometimes of a faint yellow colour floating upon the water, giving out an odour like that of saliva, or frequently containing bits of undigested food, uncombined bile, or

occasionally consisting chiefly of bile. The urine is unhealthy, not remarkably deficient in quantity, but dark-coloured, of a deep colour like that of mahogany or stale beer, but always sedimentous, either lateritious, or yellow, or cream-coloured, but more generally white and furfuraceous, and so copious as to be thick throughout like gruel, its surface being generally covered with an oily iridescent film. The pulse is soft, slower than natural, sometimes preternaturally slow or labouring, frequently intermitting or irregular, faint, and fluttering. The skin is dry, dull, flaccid and inelastic, and sallow, and the eye dull and tinged with bile. The feet are habitually cold, the sleep is heavy and unrefreshing; the patient either awakes frequently in the night, or is troubled with disagreeable dreams, and, instead of being refreshed, is oppressed with fatigue in the morning. When the preceding signs of deranged function of the organic system present themselves in combination with some of the complaints or sympathetic affections above specified, there can remain little doubt that they are referable to a deranged state of the duodenum, of which distension or irritation of that intestine is the consequence; and if the preceding signs of derangement of the organic system be present without any complaint, the physician may be sure that a process of disease is in progress which will sooner or later declare itself.

Pathology and Causes.—The particular process of the function of digestion, which is more especially deranged by this disorder of the duodenum, is that which, consisting chiefly in the mutual actions and re-actions of the chyme, the bile, and the other intestinal juices, has hence received the name of *encholosis*, and of which the result in health is chylification; and the proximate cause of this derangement is no doubt a pathological condition of the duodenum, consisting partly in deficiency of tone, partly in deficiency of sensibility, from which arises discordant action in relation to the stomach on the one hand, and the intestines on the other. For the duodenum allowing of the accumulation of the chyme, an impediment is opposed to the function of the stomach; the secretion of the bile, depending on the healthy state of the duodenum, is imperfectly solicited, and the peristaltic motion of the intestine being impeded, its discharge into the intestine is obstructed; while the other intestines cease to receive, both in kind and quantity, their natural material of operation. This disordered state of the duodenum rarely, however, originates in itself; from its intermediate position, it is more generally a consequence of an imperfect performance of the function of the stomach or of the large intestines; sometimes, but more rarely, it originates in the liver. If the stomach have not sufficiently subdued the food to a healthy and natural chyme, the duodenum becomes the recipient of unnatural ingesta, unsuited to its particular function, from which disorder must ensue. This state of things appears to us to be more liable to occur to those who, fasting long, are apt to swallow their meals hurriedly, and therefore masticate their food imperfectly, or to those who, ever intent on the business of life, eat, as they think, quickly,—a habit very constantly induced in those who have contracted the pernicious practice of reading or trans-

acting business at their meals. The same effect which arises from the hurried, imperfect mastication of wholesome victuals, may also be induced by the ingestion of indigestible substances, and therefore the use of such things as the stomach has no power of digesting frequently leads to duodenal dyspepsia, as for instance, nuts or the kernels of fruits, hard indigestible fruits, crude vegetables, the seeds and skins of fruits and vegetables, cherry-stones and similar substances. The same consequence follows for the same reason in some great feeders, whose pylorus allows imperfectly digested food to pass; in this respect some persons, and particularly children, seem to have a great facility.

But a disproportionate quantity of the healthiest chyme poured into the duodenum quicker than the process of *encholosis* can be performed, or than its transmission can take place, must lead to precisely the same result as the passage of chyme imperfectly elaborated. This is the reason that children are proportionately more subject to duodenal dyspepsia than adults; for having in general a good appetite and a powerful gastric digestion, they are wont to eat at all hours and seasons, taking a second meal before the first is digested, so that the duodenum becoming distended with chyme which it cannot transmit, interrupts the discharge of the bile, and accumulation takes place. Of this we have a proof in the crampulous diarrhoea consisting of light-coloured stools, which so often ensues. "Children," says Dr. W. Philip, "are still more inclined to this accumulation than adults, most of their complaints being connected with this state of the digestive organs. Of children who are out of health, with the exception of those labouring under contagious diseases, not one in twenty will be found free from more or less of it; and their restoration to health is never permanent till the due action of the first intestine is restored." Precisely the same effect will, in the same manner, be produced by any cause impeding the transmission of the chyme from the duodenum onwards, though it be neither unnatural in quality nor disproportionate in quantity; thus leading to accumulation in the duodenum, to distension, and all the consequences of duodenal dyspepsia. Now this may arise simply from a confined state of the bowels, which, gradually propagated upwards, ends in inducing duodenal dyspepsia; thence we find that healthy people having vigorous powers of stomach, who, from sedentary habits or confining themselves to the passive exercise of a carriage, have their bowels confined, readily become subject to this form of dyspepsia.

The accumulation of feces in the colon, which in some constitutions, by sympathy, induces atonic gastric dyspepsia, also by its pressure upon the duodenum mechanically interrupts its free action, and prevents it from discharging its contents. And the same consequence results from the postures necessary in certain trades and professions, which have the effect of opposing the proper evacuation of the duodenum. This unhealthy posture is found in the highest degree in shoemakers, as they stoop to their last; and we have certainly met with more cases of this disease in persons of that trade than in any other. Tailors, engravers, and many others whose occupation re-

quires the same posture, suffer in the same manner; literary people and clerks, from bending to the desk or table, frequently suffer from the same affection of the stomach; the stooping of women in their sedentary occupations of needle-work, and still more the pressure of the stays or tight lacing, tend in no slight degree to the same result.

An accumulation of chyme in the duodenum, in whatever way induced, soon lays the foundation of its own increase and continuance, for its immediate effect is to impede or interrupt the proper supply of the bile, either mechanically, (the pressure of the contents of the bowel closing by compression the oblique valvular orifice of the common gall-duct,) or by preventing the proper peristaltic motion of the duodenum which promotes the flow of bile, or lastly by deranging the sympathy of the duodenum and liver, so that the mutual actions and re-actions of the bile and chyme—the process of *encholosis*—cannot have place, and the intestine is thus deprived of the natural stimulus for promoting the propulsion of its contents. In this way, therefore, a deficient supply of bile, without either an unhealthy state or an accumulation of chyme, may prove a primary cause of duodenal dyspepsia. Hence this form of dyspepsia is that which is induced by idiopathic icterus, and is reciprocally one of the most ordinary proximate causes of icterus. Or it may be that the sensibility of the duodenum being diminished or otherwise disordered, and the natural sympathetic relation between the liver and duodenum becoming deranged, the bile is not supplied in proper season, or a bile of a less active quality is secreted; for which reason the action of the duodenum begins to languish, and the disposition to accumulate is increased. Thus dyspepsia have for months, even years, a constant accumulation in this intestine; the duodenum never emptying itself thoroughly, a great portion of aliment is retained there beyond the due time, and is not evacuated before a fresh supply from the stomach has laid the foundations of other accumulations, until at last an enlargement evident to the eye as well as the touch often takes place.

This account of the manner in which atonic duodenal dyspepsia is induced, is in perfect accordance with the phenomena, explaining both the origin of the symptoms and the operation of the causes which more especially give rise to it. For we may thus see how the uncomfortable feelings in this form of dyspepsia are chiefly experienced a considerable time after taking food; how the stools present their unnatural appearances, how they are deficient of bile, resembling whitish brown paper, and sometimes as white as pipe-clay—an effect frequently observed to result from the action of opium upon the liver; how the chyme, being prevented from undergoing its proper changes, and accumulating, ferments and gives rise to diarrhoea of light-coloured sour-smelling stools; or how the bile, occasionally suppressed, occasionally accumulated, from time to time is copiously evacuated, and a bilious diarrhoea is the consequence; how, the secretion of bile being suppressed or impeded, the kidneys assume a vicarious function, and discharging what ought to pass by the liver, give rise to the unhealthy appearance of the urine; how the duodenum, from

derangement of its function becoming distended by gas or by the accumulation of chyme, or irritated by food imperfectly digested, or by substances indigestible, may by its extensive nervous connections be the source of all the various sympathetic affections above enumerated; and, finally, how inflammation of its mucous membrane or lesion of its structure may be the result.

The peculiar character of disorders of the duodenum are well illustrated by a case of organic disease of that intestine related by Dr. Irvine, in the Medical Journal of Philadelphia, for August, 1824; several others are also upon record.

Treatment.—The morbid condition which constitutes the proximate cause of this disease readily suggests the indications for accomplishing the cure. These are obviously:—1. to afford present relief by unloading the duodenum; 2. to render the function of the duodenum easy of performance, *a.* by a proper regulation of diet, *b.* by proper exercise, *c.* by promoting a healthy secretion of bile, and *d.* by preserving an open state of the bowels; and 3. by seeking to correct the morbid condition of the intestine upon which the disease depends.

1. Unless the accumulation in the duodenum be the consequence of pressure from a loaded state of the colon, it is best evacuated by some aperient; otherwise an active enema affords the most immediate relief. For emptying the duodenum, senna is the medicine which deserves the preference, being well fitted to promote the action of that intestine. Dr. Wilson Philip observes that it has appeared more effectually to remove the fulness of the right hypochondrium, when it depends on morbid distension of the duodenum, than any other medicine equally mild in its operation. It is best given in the form of infusion with an equal part of some carminative water or some light bitter infusion, and its action will be rendered more certain and more satisfactory by the addition of a small quantity of tartarized potass or tincture of rhubarb, which has also a tendency to prevent griping; but if this unpleasant effect be much felt, it may be avoided by the addition of a few drops of liquor potassæ, of spiritus ammoniæ aromat. or a small quantity of tr. cardamom. comp. to each dose of the medicine. When there is any disposition to fever, the infus. sennæ comp. of the Edinburgh Pharm. ought to be preferred. It may be combined with manna and tartarized potass. Where senna does not agree, rhubarb is the next best substitute. It may be given in substance in some carminative water combined with sulphate of potass or tartarized soda. For this purpose it is not necessary that the aperient should, according to the prevailing practice, be preceded by a mercurial purgative. Mercurials are more efficient and more necessary after the duodenum has been already evacuated. The extract of colocynth, combined with extract of hyoscyamus, affords also a purgative adapted to this form of disease:—

R Ext. colocynth. comp.

Ext. hyoscyam. aa. ʒi.

T. fiant pilulæ xii. una vel bina hor. som. sum.

There can be no doubt that the duodenum is also sometimes spontaneously evacuated upwards by vomiting, and under certain circumstances this method may be imitated by art; but in general,

emetics are found to be of little use, and, failing in the object, are liable to do harm.

2. *a.* In order to lighten the burden of the duodenum, and render its function easy of performance, a careful selection of such articles of food as are generally held to be easy of digestion, and a scrupulous adjustment of the quantity to the powers of digestion, are of all things the most essential. The reader may refer for ample regulations on this head to the regimen of atonic gastric dyspepsia. We shall content ourselves with observing in this place that the patient should eat his meals slowly, and that he should masticate his food with the greatest care. In order to avoid infringing these rules he should endeavour to avoid long fasting, which leads to full meals quickly devoured. It is in this sense only that we can understand the reason of that old man's practice recorded by Lord Bacon, in his Essays, who, when asked by what means he had preserved himself to so great an age, answered that he knew no other except that he never waited to eat until he was hungry or to drink until he was thirsty, by which he was able always to make a temperate repast; a rule of great value, provided we do not fall into the opposite extreme of eating too frequently. Small meals, then, eaten slowly and at moderate intervals, is the most comprehensive rule of regimen in this complaint. Patients should endeavour as much as possible to keep their minds disengaged at their meals; for they who are accustomed to read, or have their minds much occupied at table, are apt to eat fast and voraciously, and chew their food imperfectly. The food should be of that description which is entirely digested, and which leaves little excrementitious refuse. It should, therefore, consist chiefly of animal food, of stale bread, or moderate quantities of well-boiled rice. Light refreshing broths, which are entirely digested in the stomach, afford occasionally a good form of nourishment in this disease; but they should be taken in moderate quantities, and not every day. Wine in small quantities is useful, but malt liquors are to be renounced.

b. The activity of the function of digestion will be excited by proper exercise of the body carried to a certain degree of fatigue; active walking over uneven ground, coursing, leaping, cricket, fencing, the broad-sword, or dancing, each proportioned to the strength and habits of the patient, are the exercises most to be recommended; reading aloud, declaiming, and singing are also useful. Horse-exercise is also well adapted to this form of dyspepsia, particularly when the patient's strength is at all impaired.

c. In endeavouring to restore the healthy secretion of the bile, some form of mercurial cannot easily be dispensed with; but the employment of this mineral should be so managed as to produce the desired effect upon the liver with as little injury as possible to the other parts of the system. All that is here wanted is something that may speedily correct the disordered function of the liver; and it is therefore unnecessary to give it so as to be received into the circulating system. To effect this object its local effect on the alimentary canal is all that is necessary; for, whether it act upon the liver by sympathy during its passage through the alimentary canal, or whether, ab-

sorbed from the alimentary canal, by the radical branches of the vena portarum, and circulating through the liver, it stimulates that organ, its effect is so direct that it may be considered strictly local. It is best given in moderate doses repeated daily until the quality of the alvine evacuation or the state of the urine is decidedly improved. A few doses generally suffice; and its long-continued use is never necessary. It is more advisable to administer it in sufficiently active than in repeated small doses. The particular action sought for from the mercury is more certainly obtained by combining it with a small quantity of extract coloc. comp. or extract of aloes, to which a minute portion of the powder of ipecacuanha may be added. The pil. hydrargyr. is decidedly the best form of mercurial in this disorder. It may be given in doses of from two to four grains.

d. The impediment which is opposed to the healthy function of the duodenum by a torpid state of bowels, is to be corrected by yielding a ready obedience to the calls of nature, and by endeavouring to establish an habitual evacuation by visiting the water-closet every morning after breakfast; by the use of the tepid water lavement morning or evening; and, failing these, by the use of the mildest aperients. According to our experience, those of which aloes forms the chief ingredient are the best. It may be combined with rhubarb, guaiacum, soap, and a small quantity of ipecacuanha, or James's powder; and in case of flatulence, with the pil. galban. comp. according to the formula already given. The aperient pill appears sometimes to be more efficacious and less injurious when taken with dinner. A convenient formula, given by Dr. Yeats, is the following:—

R Infus. anthem. ℥i.
Vini aloes ℥i.
Liquor. potass. gr. xv.
Fiat haustus mane sumendus. But he prefers a combination of senna and quassia, viz.:
R Lign. quassiae ℥i.
Fol. sennae ℥i. ad ℥iii.
Aque ℥i.

Fiat infusum.

As soon as possible, attempts should be made to discontinue the use of these artificial means, for a constant recurrence to any aperient medicine is sure to establish ultimately a more permanent disease of the intestines.

3. Besides the means for fulfilling the last indications, all directly tending to correct the morbid condition of the duodenum, those which have the power of improving the tone of the alimentary canal in general, or the whole system, possess to a certain degree this power. Amongst the first we have seen the nitric acid in decoction of sarsaparilla or some light bitter infusion most advantageously used. Amongst the latter we may specify the cold ablution of the surface, the shower-bath, the nitro-muriatic acid lotion, and assiduous friction with the coarse flannel glove. But in obstinate cases we have found the most effectual remedy in a course of alterative aperient waters, as those of the Muhlbrunnen of Carlsbad, either

natural or artificial; more especially if (which is not rarely the case) this disordered function of the duodenum be engrafted upon, or be the result of, a general state of excrementitious plethora.

II.—INFLAMMATORY DUODENAL DYSPEPSIA.

Synonyms.—*Phagedæna*, Cæc. Aurel.; hepatitis obscura; hepatalgia infarctus, intemperie calida; aurigo ab obstructione calida; hypochondriasis melancholica, Sauvages; hepatitis chronica, Cullen; indigestion, second stage of, W. Philip; duodenite chronique, Cazimir Broussais.

General Character.—Heavy dull pain; sense of weight or uneasiness in the right hypochondrium, confined to one point, or more generally diffused, more or less constant, but varying in degree, being sensibly increased a certain time after taking food, and in some degree subsiding as the process of digestion is finished; skin dry; extremities cold; but increased heat of surface during sleep, particularly of the palms of the hands and soles of the feet; complexion sallow; countenance dejected; urine scanty, high-coloured, and depositing a lateritious sediment; tongue more or less furred behind, of a glossy red colour at the point and margin, the redness being either bright, equal, or continuous, or brighter red points are dispersed over the general redness, or the papillæ unusually red, large, and developed, sometimes tuberosæ.

The form of dyspepsia which we are anxious to specify by the foregoing character, has been merged in the description of the diseases of organs considered more important, and whose functions were better known. By Hippocrates it was comprehended under atrabiliary affections; by Celsus and Aretæus it was not distinguished from the diseases of the liver or the disorders of the stomach; by the Methodists its symptoms were distributed amongst several diseases. The moderns have been misled by the same errors. Sometimes confounded with other diseases, we may find it under chronic hepatitis or hepatalgia, or, undue importance being attached to some of its symptoms, it assumes the name of gastrodynia or icterus, but still more commonly we may detect it under the mask of hypochondriasis or melancholy. Of the pathological condition which constitutes the disease, Cullen had a proper conception, and evidently includes it under *enteritis erythematica*; but he does not seem to have ascertained the symptoms of the particular disease, for he has nowhere described them except under chronic hepatitis. The disease is well described by Dr. Ferriar, of Manchester, who had himself been the subject of it, and was by him distinguished from diseases of the liver. Dr. G. D. Yeats followed up the observation of Dr. Ferriar with a spirit of practical and scientific inquiry; but it is to Dr. Wilson Philip that we are indebted for the full development of the nature of this disease and the distinct knowledge we possess of it, though we can by no means subscribe to the limitations by which he has defined its origin, or to the latitude which he has allowed to its issue.

Form of Disease.—The derangement of the function of digestion which arises from an excited state, from increased vascularity, or from chronic inflammation of the mucous membrane of the

pylorus and duodenum, is by no means a rare species of dyspepsia, and although manifesting itself by a great variety of symptoms, is in no degree difficult of detection. Its symptoms are either direct, indicating the seat of the disorder, or indirect, showing the full and various play of sympathy by which the different parts of the body hold communication with each other. Of the former kind are the dull heavy pain, the sense of weight, of anxiety, or uneasiness, which, sometimes commencing in the epigastrium, is generally seated in the right hypochondrium. This uneasy feeling is either confined to one circumscribed point, or it is diffused over the whole hypochondrium; sometimes it extends from the epigastrium round the right side to the spine like half a zone, giving the feeling as if the side were begirt and compressed by a sickle; often the course of the pain traces with anatomical accuracy the course of the duodenum downwards, and backwards in the direction of the right kidney, and then again inwards towards the umbilicus; very frequently the pain extends directly backwards under the right scapula. The uneasy feeling of the right hypochondrium very often corresponds with pain of the right acromion, of the upper part of the right arm, elbow, or wrist, or with a feeling of weakness or numbness of the whole arm; occasionally it extends down to the thigh, to the knee, right leg, or ankle, giving rise to some topical pain in this extremity, or to a more general dull pain or sense of numbness, so that the whole right side of the body feels weaker than the left. When digestion is not in progress, the pain and uneasy feeling of the right hypochondrium is considerably less sensible, seldom amounting to more than a sense of heat, gnawing, or sinking towards the epigastric region, with a frequent desire to take food, which frequently corresponds with a sense of heat, smarting, or blistering of the tip of the tongue, and with watering of the mouth. By complying with this craving for food, relief is for a time afforded, but after a considerable interval, from two to four hours, the uneasy feelings are very much aggravated, in severe cases amounting to excruciating pain, bearing all the symptoms of a fit of gastrodynia, which continues for some hours, then gradually subsides; or which is at other times only relieved by vomiting, generally taking place three or four hours after taking food. The uneasy feeling does not usually amount to actual pain, but is described as a rawness and tenderness, and sometimes as a feeling of heat, as if hot water were passing through the intestine, or there is a painful feeling of distension, especially after meals, though no actual appearance of distension can be perceived. But often there is very sensible fulness in the same situation, extending downwards along the edge of the cartilages of the ribs and through the whole hypochondrium. The part of the right hypochondrium which is the seat of pain or uneasiness is also often very tender, the pain being sensibly increased by pressure, but generally it is not increased, on the contrary it is sometimes relieved by it. This tenderness is perceptible in the epigastrium, but most especially at the pyloric extremity of the stomach, and in the course of the duodenum, in the soft parts close to the edge of the cartilages of the false ribs on the right side;

the cartilages themselves often become very tender, not unfrequently more so than the soft parts. This tenderness on pressure, which becomes much more apparent if the effects of pressure of the right and left hypochondrium be compared, like the pain, is very often circumscribed, being generally situated midway between the point of the sternum and the lowest cartilage of the ribs: in the region of the pylorus it is generally more constant, in the region of the duodenum only occasional. The patient is in general quite unconscious of this tenderness until it is pointed out by the physician. But not unfrequently neither pain, uneasiness, nor tenderness is referred to the bowel; but when food has been taken a considerable time, the general uncomfortable feelings of the patient are very much aggravated, the process of digestion being attended with an insupportable languor, lassitude, oppression, dejection of spirits, headach, thirst, fever, or other sympathetic affections.

Amongst the sympathetic affections or indirect symptoms of this diseased state of the duodenum, the affections of the head are most frequent; they are either a general painful confused headach, increased by stooping or by holding the breath, or a dull pain in the back part of the head, which feels tightly bound, or painful pulsation of the head excited by the least effort of attention: vertigo is also a very common symptom. Not rarely the intellectual functions are very much weakened or disordered; there is a general confusion of mind, impaired memory, or deficient power of attention. The external senses become sometimes quite dull, the vision indistinct or veiled with dark motes; the hearing, smell, and taste much impaired. The entire function of the mind not unfrequently becomes disordered, and mania itself we have distinctly traced to local irritation of the duodenum.

Irritation of the larynx, producing a short dry cough, or causing frequent efforts to expectorate a grey transparent mucus, (which sometimes becomes very considerable,) hoarseness and loss of voice, a sensation of constriction of the chest with laborious breathing, and complete paroxysms of spasmodic asthma, are the sympathetic affections of the respiratory organs which frequently originate in this disease. In protracted cases of this disease, it is by no means uncommon for phthisis pulmonalis to supervene, and ultimately terminate the life of the patient. It most frequently assumes the form of laryngeal phthisis, but generally a tubercular affection of the lungs lurks behind. Nor does there seem any difficulty in understanding this issue of the disease; nothing is more comprehensible than that the irritation of the duodenum should be communicated sympathetically to the mucous membrane of the larynx, trachea, and bronchi, or that the cachectic state induced by the long-continued derangement of the digestive organs, should produce the tubercular disease. This conversion of dyspepsia to phthisis was noticed by Dr. Ferriar, but has been only fully explained and insisted upon by Dr. W. Philip (*Op. cit.*) and Dr. [Sir] James Clark. (*Influence of Climate, &c.*)

Painful affections of the heart are consequences not less common, simulating the character of hypertrophy of the ventricles, sometimes of angina pectoris.

The urinary and sexual organs frequently feel the effects of duodenal irritation: hence spasmodic stricture of the urethra, painful affections of the testicles, priapism, and venereal dreams; also painful menstruation. Lumbago, painful affection of the hip and knee joints, rheumatism, rheumatic gout, nodosity of the joints, severe and deep-seated neuralgic pains of the legs, we have observed connected with this disease.

Sometimes the skin is the seat of the secondary effects of this disease. We have noticed, in conjunction with it, *herpes zoster*, *acne induratum*, *urticaria*, *lichen*, *psoriasis*, *pityriasis*, and *alopecia areata*.

Inflammatory or spasmodic affections of either extremity of the alimentary canal are common attendants of irritation of the duodenum, such as erysipelatous affections of the fauces, generally with a sense of tickling, soreness, or rawness of the throat. The uvula sometimes becomes much elongated, and, losing much of its contractile power, gives the sensation of something resting on the back part of the tongue, and sometimes descending lower, creates a cough, a sense of choking, nausea, and even vomiting, frequently all comprehended under the common term of relaxation of the throat; not rarely the fauces and neighbouring parts are the seat of troublesome ulcerations, which, united with affections of the skin and osteocopic pains, make up the symptoms of pseudo-syphilis. On the other hand, *prurigo podicis*, sometimes accompanied with eruptions in various forms, spasmodic stricture of the anus or rectum, inflammation of the mucous membrane of the rectum, hemorrhoidal swellings, painful and irritable excrescences and fissures, are sympathetic consequences of this disease.

But whatever be the particular sympathetic affection which may result from the disorder of the duodenum, there is one general and constant which belongs and gives character to them all—hypochondriasis, despondency and dejection of spirits, the mind constantly intent upon and occupied with the bodily feelings.

The preceding complaints, whether direct or indirect, are always attended by symptoms sufficient to indicate that the natural functions of the body are in a state of disorder. Though the appetite may not be deficient, it is seldom natural; it is various and capricious, generally keen, craving, not rarely ravenous; there is a sense of sinking, of gnawing, or a constantly recurring desire for food, only temporarily relieved by taking it; or an uneasy sensation, or craving, mistaken for hunger—*mendax fames*, *cibi appetentia*, *corpore non indigente*. Bulimia is sometimes a symptom of duodenal irritation, corresponding to the *phagedæna* of Cælius Aurelianus, which we have accordingly not hesitated to place among the synonyms of this disease. There is no particular thirst. The bowels are habitually confined; under the use of animal food they are more costive; with a vegetable diet they are frequently disposed to be relaxed; a fit of bilious diarrhœa from time to time is not however a rare occurrence; and an habitually loose or irritable state of bowels is sometimes observed, a dejection following soon after a meal; purgatives also occasionally act in small doses, but frequently with aggravation, in-

stead of relief, of the symptoms. In this state laxative medicines are generally uncertain in their effects, and frequently apt to act too violently. The evacuations present great variety in their appearance; they are not always different from those of health; sometimes they are perfectly natural, but generally mixed with mucus in a concrete tenacious state; more frequently they are scanty, adust, and hard, in small knots of a dark blackish green, frequently of a dark olive green, sometimes of a blackish brown colour; they are frequently smeared with mucus and deficient in smell; occasionally two or three dark fetid stools are discharged, small in quantity without being figured; or there is a loose stool of a greenish brown colour, in smell resembling the grounds of sour beer, which is often preceded by great depression of spirits; not rarely they are like tar. Generally they are too dark, and occasionally almost black, but frequently they are of a white clay colour; sometimes there is frequent purging of a substance like the whitest pipemaker's clay, more or less diluted with water; which state has been known to occur when dissection proved the liver to be free from disease, and the gall-bladder containing healthy bile. The urine is scanty, high-coloured, sometimes of a dark copper colour, or even opaque, and as dark as mahogany or porter; it always reddens litmus paper, and generally deposits a lateritious sediment. The tongue is smooth, or covered with a thin loose mucous fur towards the root, of a clear red colour, neither a bright nor a pale red; but its anterior part is spotted with small red flat spots of a darker or brighter red colour, not rising above the level of the surface of the tongue, the papillæ being very small or very indistinct; or the whole surface of the tip of the tongue and anterior margin is unusually red, with some of the papillæ more or less enlarged; and in this situation there is frequently a sense of heat, smarting, or of blistering, frequently distinctly corresponding with the uneasy sensation in the right hypochondrium. The tongue is always more or less furred towards the root, either with a thin shining coat anteriorly, or clean and moist. The lips always correspond with the state of the tongue; they are of a glossy red colour, or their cuticle is dry and exfoliatory. In protracted cases the lips grow dry, and are divided by fissures; the tongue is covered with a rough yellowish crust, brown towards the root; in some cases there is a peculiar raw appearance of the tongue and throat; at other times the tongue presents a peculiar red, dry, and glazed appearance.

The skin is generally dry and scabrous, sometimes scaly almost to ichthyosis; the complexion is dull and sallow, and the conjunctiva has invariably a tinge more or less of yellow. The pulse is either quicker than natural, or easily accelerated, but seldom ranges habitually above eighty. In the quality of the pulse there is always perceptible a certain degree of hardness or rather tension, which, according to Dr. W. Philip, is in its slighter degree easily detected, in feeling the pulse, by gradually diminishing the pressure of the finger. On some occasions it is very quick and small, but always with a certain degree of tightness, the most certain measure of the general state of the

secretory surfaces. The temperature of the body is very variable and unequally distributed; sometimes there is considerable fever or feverish heat; sometimes chilliness independent of any change of temperature of the surrounding medium, at times interrupted by fits of oppressive heat; during the day the hands and feet are often obstinately cold, but after eating and during the night the palms of the hands and soles of the feet often become preternaturally dry and hot, and there is a tendency to partial heavy sweats, sometimes very profuse during sleep, more especially towards the morning. And not unfrequently there is a feeling of a slight but protracted feverishness when the pulse is not at all affected.

Pathology and Etiology.—That the symptoms we have just described are all referable to different degrees of increased vascularity, sometimes to inflammation of the mucous membrane which lines the pylorus and duodenum, there is little room to doubt. It has been directly proved by numerous dissections; it has been confirmed analogically by cases of organic disease of this part of the alimentary canal, where the pathological condition gave rise to increased sensibility of the mucous surfaces, as in ulceration; the nature of the remedies most usually giving relief afford strong confirmation of this opinion; and, were more direct proofs wanting, it is the only hypothesis capable of rendering a satisfactory explanation of the symptoms. For if we consider the nature of this pathological state of the mucous membranes, the various degrees in which it exists, the particular part of these organs in which it may be seated, whether above or below the termination of the common gall-duct, whether it may affect the whole mucous tissue, or confine itself to the follicles or to the villousities, and, lastly, the extensive sympathetic relation of these organs, by which the irritations of their morbid conditions may be felt and reflected, we shall be furnished with abundant elements from whose combinations it will be easy to explain all the variety of symptoms, direct and indirect, primary and secondary, constant and accidental, which the disease presents. We shall thus understand how the appetite, if there be no fever, instead of being impaired, is generally increased, sometimes keen and ravenous, though the bowels are habitually confined, knowing it to be the nature of the alimentary canal to have its peristaltic motion increased towards any point situated below, and diminished from any point of irritation situated above; how the erythematous state of the mucous membrane of the duodenum, disordering its peristaltic motion, may impede the flow of bile, and may in different ways derange the functions of the liver; how the secretions of bile, generally diminished, may be sometimes increased when inflammatory irritation exists about or below the orifices of the biliary ducts, thus leading to bilious diarrhoea, to imperfect *encholosis*, and all the variety of alvine evacuation; how an inflammatory action of the duodenum, even when existing only in a slight degree,—so slight as to elude the closest observation unless the mind be attentively directed to it,—may excite the liver to an unhealthy action, from which a state of erethism and irritability of the whole alimentary canal may ensue; and hence

how purgatives act so irregularly;—or, on the contrary, how the vascular injection of the mucous membrane of the duodenum, being the effect of a sanguineous congestion of the liver, by which its freedom of circulation and its secretion is suppressed, may be attended with a diarrhoea in which the alvine evacuations are of a light colour; and how a particular form of jaundice (*icterus à plethorâ*) may be produced. The well-known sympathies of the different parts of the alimentary canal with each other, supply the means of accounting for the appearances presented by the throat, the mouth, and the tongue, and for the uncomfortable and painful symptoms which sometimes take possession of the other extremity of the canal; and the universal consent of the state of the alimentary canal with the body in general, or with some organs in particular, explains the multifarious secondary affections which may supervene upon this disease. (For a full account of the sympathetic relations of the duodenum with other parts of the body, the reader may consult with advantage Dr. Yeats's excellent paper, *Med. Trans.* vol. vi.)

Nor does it seem more easy to explain the symptoms of this morbid condition of the mucous membrane of the duodenum than to account for its production, if we consider the operation of the causes in which it originates. Thus it is that atonic gastric dyspepsia long-continued, (by which as it were the stomach shifts its function upon the duodenum, the pylorus being irritated by the passage of substances imperfectly digested, and the duodenum, instead of receiving a substance of the bland nature of chyme, becomes the receptacle of the crude residuum of an imperfect digestion,) is observed to prepare the way for this form of dyspepsia, and frequently to terminate in it—more rarely to be relieved by it. In the same manner, though the function of the stomach may not be imperfectly performed, if persons indulge in the use of substances which no power of digestion can assimilate, (as unripe fruits, crude vegetables, the seeds and skins of fruit, the kernels of nuts and stone fruit,) the operation and the consequence will be the same. And in like manner, when sufficient time has not been allowed for the digestion of one meal before another is taken, the duodenum becomes unnaturally distended, from which irritation and an inflammatory state of the mucous membrane may arise,—a circumstance which, occurring frequently in children, inducing a saburral state of the mucous membranes amounting to inflammation, constitutes the preparatory process to the particular remittent fever which afflicts that period of life. But from whatever cause gastric or intestinal fever may arise, chronic inflammation of the mucous membrane is one of their most constant sequelæ; and we must confess that our experience knows no cause of this form of dyspepsia more common than improper diet in the convalescence of those fevers. In persons habitually subject to dyspepsia, which naturally predisposes to irritation of the mucous membranes, an inflammatory state of the duodenum may arise from suppressed perspiration, from exposure to cold, particularly in dry weather, either hot or cold, as is frequently observed in the spring; and in the same way it is a common sequel of catarrh, and a

frequent consequence of the retrocession of eruptions of the skin. But of all the causes capable of inducing this morbid condition of the duodenum, there is undoubtedly none more sure, and none more general, than the injudicious use of medicines in the treatment of other forms of dyspepsia, in which irritating drastics, heating tonics, and stimulants are lavishly and uninterruptedly applied to delicate and sensitive membranes, either already inflamed, or which they seldom fail to make so.

There is also another source of this disease which deserves notice, where it presents itself as a secondary affection, the consequence of a state of plethora or congestion of the vena portarum, from which results vascular injection of the mucous surfaces, giving rise, under irritation, to inflammation of a sub-acute or passive form, *dyspepsia hemorrhoidalis*, (Cullen); and also a corresponding form of disease which arises from plethora of the uterine system, where the menstrual relief has been insufficient, *dyspepsia dysmenorrhæa* and *amenorrhæa*. (Id.) Upon this state of disease it is not uncommon for menorrhagia from time to time to supervene. The irritation of teething in children, from some sympathy, direct or indirect, with the liver, the bile being suppressed and hepatic plethora induced, not rarely induces the morbid condition of the mucous membrane which constitutes this disease, *dyspepsia dysodontiasis*. Hence the light-coloured evacuations, and hence the discharges of blood, in short the dysentery of infants in dentition.

Treatment.—The method of cure of this species of dyspepsia naturally divides itself into the following indications: 1. to correct the morbid condition which constitutes the disease—to remove the vascular excitement or inflammatory state of the mucous membrane lining the pylorus and duodenum; and 2, to render the function of digestion easy of performance, by which the causes of the disease will be avoided.

1. The principle of this indication must necessarily be antiphlogistic; but its application requires nice and delicate modifications and adjustments to ensure its success, or the physician may plunge his patient into a state of depression which will frustrate his intentions. General bloodletting is seldom necessary; but if there be signs of general plethora, if the pulse be hard, tense, and resisting, if the pain of the right hypochondrium be severe, with much heat of surface, and much heat and dryness of the mouth and redness of the tongue, a small general bloodletting will be found to be the means which afford the most speedy and the most permanent relief. It spares the necessity of topical depletion, and renders a much smaller quantity of medicine necessary, facilitates its action, and ensures its success. When the symptoms indicate a state of plethora of the abdominal circulation, such as a full or varicose state of the veins of the lower extremities, swelling of the feet, pain in the loins, more especially in the sacrum, indicative of a hemorrhoidal disposition, dark-coloured or sedimentous urine, a large tongue, seemingly swollen with blood, and eruptions of the skin, the congestion is more speedily subdued, and with less expense to the constitution, by very small bloodlettings, repeated at intervals of a fortnight, than by any other method; and the result is easy of ex-

planation—it seems as if the quantity taken away from the general circulation were supplied from the circulation of the vena portarum, by which the congestion is diminished, and freedom given to the passage of the blood in the hepatic system. Where either of the above-mentioned states is present, the local detraction of blood from the tender part of the epigastrium or hypochondrium by leeches or by cupping, to the amount of from four to twelve ounces of blood, according to the circumstances, will be found to satisfy the object of this indication; but if after a few days the symptoms do not indicate improvement, it must be repeated. Except in nervous, irritable, and easily excitable persons, it is often of general service and sometimes very successful to endeavour to induce a derivation of blood upon the hemorrhoidal vessels by the application of leeches to the margin of the anus. The antiphlogistic effect of both general and topical bloodletting may be increased, and rendered more durable by the various methods of counter-irritation and derivation to the skin. For this purpose we think the tartar-emetic ointment or plaster is much to be preferred to blisters; but these also are occasionally useful. In old and protracted cases we have known the greatest comfort derived from the long-continued use of a warm plaster, gently stimulating, sufficiently large to cover the whole hypochondrium. In cases where the obstinacy of the complaint justifies it, either yielding with difficulty or frequently recurring, no method of counter-irritation is to be compared to a seton, from which the most permanent good results are frequently obtained: it should be introduced obliquely in the direction of the cartilages of the false ribs.

In aid of depletory means, or where the degree of the symptoms have not called for them, considerable benefit may be derived from certain medicines which have a direct antiphlogistic effect upon the mucous membranes of the intestines. These, according to our experience, are castor-oil, nitrate of potass, antimonials, and vegetable acids. The castor-oil should be given in doses of a drachm, repeated once in the twenty-four hours; it is best given at bed-time for its soothing and antiphlogistic effect upon the mucous membrane; but in the morning, if its aperient action is desired. In inflammatory irritation of the pylorus and duodenum it is a most valuable remedy, often by its soothing effect acting like an opiate, and has the most direct and the most remarkable power in allaying and relieving a heated state of the mucous membranes of the pylorus and duodenum. We must confess that we know no medicine more eminently endowed with this property. In obstinate chronic cases of this disease, we have known a small tea-spoonful of castor-oil taken every night at bed-time, as long as the stomach could easily bear it, a remedy attended with the most signal success. The effects of the castor-oil upon the stomach afford a very good test of the nature of the morbid condition of its mucous membranes. In atonic dyspepsia it is borne with the greatest difficulty, producing nausea and vomiting; in purely irritable dyspepsia a small dose of castor-oil acts severely and with much griping; but if there be any degree of vascular excitement of the mucous membranes, it soothes and quiets, and its effect is often most useful in this way when it

has no aperient action. Its good effects will not be frustrated by administering it in any mild carminative water, in emulsion, in coffee, or by combining it with a little liquor potassæ. The nitrate of potass given in repeated small doses is a useful medicine, and of considerable power in correcting the vascular excitement of the mucous membranes. It may be given in doses of from five to ten grains three times a day, in an ounce of water, to which a very small quantity of mucilage of gum arabic has been added. If there be much thirst, the nitrate of potass may be given in a saline draught; and if there be great irritability or restlessness, it may be combined with a small dose of the tincture of hyoscyamus, of lettuce, hop, or conium; if there be much dryness of the skin, it may be combined with a very small dose of vinum ipecacuanhæ, or Dover's powder. When the cold or atonic state of the stomach tolerates with difficulty the nitrate of potass, or as the symptoms subside, it may be exhibited in some bitters, as infusion of chamomile, quassia, or orange-peel, to which a very small quantity of spiritus ætheris nitrici, tincture of cardamom, or orange-peel, has been added: tartarised antimony in very small doses, as small as one-twelfth of a grain, may be given with the same intention as the nitrate of potass, and, by determining to the skin, sometimes more efficiently. It may be given in various vehicles, which, acting as modifying agents, adapt it to the particular circumstances of each case, as in saline draughts, orange-flower water, camphor julap, infusion of quassia, and such like.

In a highly irritable state of the alimentary canal, small doses of colchicum or hydrocyanic acid are frequently of signal service, and may be combined in the same way as the nitrate of potass and tartarised antimony.

The general effect of these antiphlogistic means will be very much promoted by the use of the fresh-water or sea-water tepid bath, daily, or every alternate day.

The intention of this indication will also be indirectly fulfilled by those means which, promoting the healthy secretion of bile, give freedom of circulation to the liver; and therefore, not before, but after depletion suitable to the case, and in aid of and combined with the means above specified, recourse must be had to hepatic alteratives, chiefly mercurial medicines, which require great care and discretion in their use. The pil. hydrargyri is in general the most suitable form of this medicine; if the bowels are irritable, or if there be a disposition to diarrhœa, the pulv. hydrargyri cum cretâ is to be preferred; if the bowels are extremely sluggish, calomel. In recent cases it is most advisable to give five grains of pil. hydrargyri, or three grains of calomel; in protracted cases, small and repeated doses are to be preferred, one grain, sometimes half a grain of blue pill two or three times a day, the object being to obtain the action of the mercury upon the liver without irritating the mucous membranes. We think it better to give the medicine continuously until the secretion of the bile is improved, than interruptedly, thus keeping the body longer under the irritation of the medicine. When the mercury appears to be exciting the mucous membranes without promoting the secretions, which will be known by the

increased redness and dryness of the lips and tongue, it may be prudent to interrupt the use of the medicine from time to time. The mercurial may be advantageously combined with other medicines, to modify and facilitate its action; as with small doses of the antimonium tartarizatum, or of the pulv. ipecacuanhæ, when it is desirable to influence the secretion of the skin; with nitrate of potass, pil. scillæ comp. to favour the action of the kidneys; with extract. aloes to promote the action of the bowels; with extract. hyoscyami, extract. conii, or extract. papav. if there be pain or restlessness; with pil. galban. comp. if there be flatulence or hysterical symptoms; and with any bitter extract or aromatic confection, if it oppresses the stomach. We have seen no advantage in this complaint from the inunction of mercury, and have found it less easy to regulate its action in this way; besides it thus affects the whole system unnecessarily; and the advantage of mercury in this complaint being chiefly derived from its local action upon the liver, any thing more is pernicious, and whenever the least sign of salivation appears its use ought to be discontinued.

The use of mercury will be very much assisted by taraxacum, a medicine which has also a very sensible effect in soothing the mucous membranes; and in mild cases this last will alone suffice. When given in an efficient formula, it is a most valuable remedy in this species of dyspepsia. The extract may be given in infusion of hop, chamomile, or orange-peel, in the compound decoction of sarsaparilla, and in nervous patients in camphor julap, to which may be added, according to the intention, a small quantity of nitrate of potass, of sulphate of potass, of compound decoction of aloes, or spiritus æth. nitrici.

Potassæ nitratis, ℥ss.

Spiritus æth. nitrici, ℥i.

Infus. cort. aurant. ℥vi. M.

Cochleare amplum bis terve die sumendum.

The nitric acid, nitro-muriatic acid, and the solution of chlorine, are also useful auxiliaries after mercury, in some cases substitutes for it. They may be used internally in decoction of liquorice, or compound decoction of sarsaparilla, to either of which a little spiritus æth. nitrici may be added; or they may be used externally either in the form of bath or lotion. In case of diarrhœa supervening, their use should be immediately suspended.

2. This indication will be fulfilled, *a.* by a proper regulation of diet, suited to the degree of the complaint; *b.* by preserving an open state of bowels; and *c.* by assisting the function of digestion by mild tonics, and by proper air and exercise.

a. In the slighter degrees of this complaint very low diet is seldom necessary; a little mutton or chicken may be taken daily, or every second day, and is preferable to a diet consisting exclusively of farinaceous food. In other respects it should be light, bland, and cooling, and in small quantities at a time: light refreshing broths or soups in moderate quantity, light puddings, arrow-root jelly, rice-gruel, blancmange of rice or semolina. In some forms of this disease it is sometimes necessary to restrict the patient wholly to a fluid diet, to jellies of amylaceous and farinaceous food, gruel, asses' milk, and jelly of Iceland moss. In

ordinary cases the stomach requires a certain quantity of animal food, and in this species of dyspepsia the fat of animal food, particularly the fat of bacon, is more easily digested than the lean; and it appears besides to have a useful effect in allaying the irritation of the mucous membranes, and in assisting the action of the bowels.

In severe cases, where there may be a disposition to feverishness, any increase of heat of surface, thirst, or night perspirations, it is advisable to abstain from wine. It must at all times be taken in very limited quantity, and its use from time to time interrupted, but it need not be wholly abstained from, and the digestion is very frequently promoted by it. Seltzer water is the best beverage in this complaint; but we have not found any inconvenience from light table-beer in small quantities.

b. The warm or cold water lavement is the best means of preserving an open state of the bowels. If this does not succeed or cannot be used, castor-oil may be given in small doses night or morning; its aperient action may be assisted by combining it with manna, or a pill formed of pulv. aloes comp. two parts, and soap one part, may be used instead.

c. The process of digestion may in some degree be facilitated and assisted by light bitters, as the infus. quassiae, calumbae, or cort. aurant. to which some neutral salt, as the nitrate or sulphate of potass, may be added in small doses; by the mineral acids, as the phosphoric, the aromatic sulphuric acid, or nitric acid in small doses; or by the cautious use of wholesome wine in small quantities. But the means which restore the tone and strength of the body in general are far preferable. These are proper exercise, neither heating nor fatiguing, as horse exercise, or a sea voyage; dwelling much in the open air, in a dry open air; change of air and place; cold ablution with vinegar and water; proper clothing, warm but not oppressive; and gentle occupation of the mind; all which remedial measures have been already sufficiently noticed.

We must not, however, omit to mention the use of mineral waters in the treatment of the chronic form of this disease, which combine the means of at once fulfilling all the foregoing indications, and render it difficult to know under which head to class them. The most efficient of these according to our experience are the Kreutzbrunnen of Marienbad, and the sulphureous waters of Harrowgate. They may be taken warm or cold, as best may suit the sensibility of the stomach, its power of digesting or absorbing them. Their action should as soon as possible be derived on the bowels, and they ought to be continued until the healthy function of the bowels has been restored, and until the tongue has lost its heated and red aspect, and assumed a healthy appearance. In order to render their good effects more permanent, their dose ought to be gradually diminished. A course of goats' milk or whey drunk every morning in considerable quantities, has been known to have a similar effect. In Scotland and in Switzerland it is frequently had recourse to; and we heartily join the late Dr. Ryal in his earnest wishes that an establishment for the supply of goats' whey were formed upon our Brighton

Downs, which afford every means of doing so, and where the adjacency of a large town promises a ready consumption. We are inclined to think that the disorders of the liver in which it has been found to be so useful, have been only forms of inflammatory duodenal dyspepsia.

Though the treatment of the primary disease has only occupied our attention, we do not think that the secondary or sympathetic affections which originate in it should be wholly left to depend upon it. We think, whenever symptoms can be relieved without interfering with the general plan of treatment, it is always useful, and ought always to be attempted. As has been correctly observed by Dr. W. Philip, the secondary affections undergo the same change and partake of the same nature with the disease from which they spring; therefore the secondary affections in this disease are apt to assume an inflammatory character, to become more and more of a permanent nature, in the same proportion more independent of the original disease, and, on that account, more demanding the physician's careful attention. But with this passing observation our limits oblige us to leave them to be each considered under its proper head.

STRUMOUS DYSPEPSIA.

Under this title we are anxious to draw the attention of the profession to the form of dyspepsia which belongs to the scrofulous constitution, for in our opinion it presents a more characteristic feature of this habit of body than any physiognomical portrait which has yet been drawn of it. In this respect it is more to be depended on than either the fine skin, the clear delicate complexion, the light hair, large blue eyes, and dull sclerótica of one variety; or the foul, dull, swarthy-coloured skin, the sallow complexion and swollen countenance, the dark hair, and tumid upper lip of the other. It betokens, indeed, little familiarity with scrofula to connect it with any particular temperament, for it belongs to all temperaments, to the sanguine as well as the phlegmatic, to the nervous as well as the melancholic, and to all their varieties and combinations. But upon whatever temperament the disordered habit which we call scrofula may engraft itself, we venture to say that this form of dyspepsia will also there be found; and, therefore, being constantly present with it, preceding and accompanying the various symptoms which issue from it, it would be contrary to all reason to refuse to it an important share in the development of this disordered habit, and in the production of the local affections which have hitherto too much engrossed the attention, to the exclusion of a proper consideration of the constitutional disease.

Of late years, however, the constitutional affection has received more of the notice of physicians. It has been described by Malfatti of Vienna under the name of *latent scrofula*, by Dr. Ayre under that of *chronic marasmus*, and most faithfully by Dr. [Sir] James Clark under the term *tubercular cachexy*; it has also been sketched by Dr. Marshall Hall under the title of *disorder of the general health in tuberculous affections*; but we are not aware that any of these physicians have connected it with a special disorder of the chylopoietic function.

Form of the Disease.—In the offspring of scrofulous and also of dyspeptic, hypochondriacal, or cachectic parents, in the children of old men, in children who have been badly nursed, or who, brought up by hand, have been improperly fed, or reared in the impure air of crowded towns, symptoms of disorder of the function of digestion early manifest themselves, generally between the first and tenth year, often commencing with the first dentition, which is commonly painful and difficult. Though the child from time to time loses its appetite, it is generally morbidly craving or ravenous, even soon after a plentiful meal requiring fresh food, so that the nurse remarks there is no satisfying such children. The complexion loses its colour, the skin its tone, ceasing to compress the flesh; the flesh becomes soft and flabby, the appearance is languid, the belly generally tumid, and there is a want of the usual disposition to play, or to use the exercise common to that period of life. The little patient is soon tired, complains of aching of the legs and knees, desires frequently to be taken up; his temper is fretful, he is easily set a-cry, and his intellect is either precocious or unusually dull. His sleep is seldom calm and composed; he moans, talks, or grinds his teeth, sometimes screams and raves. His bowels are generally confined, and his evacuations are of a light grey colour, like pale brown paper, sometimes curdled with streaks of mucus; or they are of a greenish colour, frequently yeasty, of a sour and highly offensive smell, and very often the food is passed unchanged. Diarrhœa occasionally occurs, consisting usually of light-coloured or slimy stools, and the patient frequently complains of pain in the bowels or uneasiness of the stomach. The urine often deposits a whitish sediment; the breath is fetid or heated; there is some slight thirst, slight heat of skin, except on the extremities, which are colder than natural; the skin is harsh and dry, except during sleep, when there are frequently heavy but partial sweats. The tongue is redder than natural, and on its anterior part spotted with small points of a darker and brighter red colour than the general surface; it is seldom much furred, being either covered with a thin mucous fur, through which the red spots appear, or with a slimy brownish coat, or the fur is distributed in small circular white spots, more or less confluent, presenting altogether a dappled appearance. When irritation of the stomach supervenes, the tongue is dry and of a brownish red colour. These symptoms, seldom entirely absent, continue from time to time to recur, more or less severe in degree, as the causes of derangement, irregularities in diet, an indulged and pampered appetite, may present themselves, being always most remarkably manifest after any of the ordinary diseases of childhood. As the child grows, unless the most judicious management has interfered with the natural progress of the complaint, other symptoms begin to appear. The patient becomes subject to sore throat, the fauces are redder than natural, and the tonsillary glands are observed to enlarge; there is a frequent tickling cough, and itching and picking of the nose and lips. The hands and feet are usually very cold and damp, or on the least cold turn of a dark livid purple colour, and the child is extremely subject to chil-

blains, even sometimes in summer. The patient is liable to be troubled with various affections of the skin, very early with *porrigo furfurans*, *psoriasis guttata*, *achorous* pustules on the hairy scalp, (the *tinea mucosa* of Alibert,) with *pityriasis*, *herpes circinnatus*, with *lichen* and *purpura*, frequently the *lichen urticans* and *purpura urticans*, at a later age *ichthyosis*, *pityriasis versicolor*, *porrigo decalvans*, *erythema nodosum*, and *porrigo favosa*, sometimes spreading over the whole body, and at a still later period of life, *acne indurata*, one of the most characteristic signs of this habit of body. All these diseases of the skin, in their external appearances so dissimilar, have yet in their nature a close affinity to each other, and, frequently convertible into and succeeding each other, seem only different external manifestations of the various degrees and modifications of the irritations of the internal organs. The eye is frequently the seat of various troublesome affections; hordeola constantly recurring, inflammation or purulent discharges from the ciliary glands, falling off of the eye-lashes, &c. Occasional discharges of blood from the bowels, epistaxis at a much earlier age than usual; copious mucous discharges from the bowels, sometimes from the vagina, are not rarely observed in this disease. Sometimes the cellular system feels exclusively the effects of the internal disease, a succession of cold indolent abscesses occupying every limb of the body. Frequently the nervous system is the seat of the secondary irritation, sometimes in its membranes and vascular structure, giving rise to inflammation and hydrocephalus; sometimes in its functions, inducing chorea, epilepsy, idiocy. The bones very commonly manifest symptoms of disorder, but the ordinary termination of the disease is the formation of that morbid growth or deposit well known under the name of tubercle, which, most usually seated in the lymphatic glands, has almost exclusively received the name of scrofula.

In young females about the age of puberty this disease frequently undergoes a remarkable change; for habitual constipation becoming established, another form of dyspepsia is induced, which in this constitution very frequently leads to spinal affections.

In the adult age the symptoms present considerable modification. The patient's complexion becomes pale, of a slightly blueish or leaden colour, particularly under the eyes; in dark complexions it becomes of a pale sallow or yellowish colour; the body is more or less emaciated, the skin flaccid, the muscles flabby; there is an unusual sensibility to cold, the patient is very apt to shiver, and there is a constant tendency to coldness and lividity of the extremities. The appetite continues good; frequently it is craving, and the food does not appear to satisfy; sometimes there is a constant empty and sinking feeling at the stomach, only temporarily relieved by eating, the patient feeling after a meal as if he had long fasted, and is again desirous of taking food. The bowels are confined; more rarely they are loose, discharging copious light or drab-coloured stools, which are frequently more than usually fetid. The urine generally deposits a whitish sediment, sometimes mucus. The tongue is red at the

point, generally studded with enlarged papillæ, of a brownish red colour behind, but seldom coated. The pulse, always weak, is small and drawn, sometimes it is slow and weak. The sleep is seldom natural, the patient is restless during the first part of the night, and towards morning falls into a heavy unrefreshing sleep, during which he sometimes perspires profusely. He is listless and drowsy by day, and though the spirits are sometimes sufficiently cheerful, more commonly the patient is timid, nervous, torpid, or hypochondriacal. Frequently there is a great tendency to perspiration on the least exertion or the least excitement, and the palms of the hands and soles of the feet feel damp and clammy, frequently cold. The thyroid gland, the lymphatic glands of the neck and groin, are observed to be large and swollen, but not painful. In women, leucorrhœa, painful or deficient menstruation, in men, a disposition to hemorrhoids, is observed; but the usual progress of the disease is to *tabes mesenterica* or *phthisis pulmonalis*.

Pathology.—The phenomena of this disease, its whole complexion and character, sufficiently indicate a congestive state of the hepatic system; and were we to assume as the proximate cause of the disease a plethora of the *vena portarum*, both in its roots and branches, we should be furnished with the means of explaining all the symptoms of the disease; for we should readily understand how, in this state of the circulation of the abdomen, the mucous surfaces of the intestines should be full of blood, consequently subject to inflammatory irritations and disordered functions, whilst the peculiar office of the duodenum renders it especially liable to be the seat of them: how the function of the liver being deranged, all the other consequences of this disease may follow; for though we may not know precisely what share the function of the liver may have in the process of sanguification, we may easily understand how it may interrupt and interfere with this process, leading to a cachectic state of the fluids, from which result tubercles and other semi-vital and semi-organic productions. (For a further explanation of this opinion, we refer the reader to our account of the formation of tubercles in Dr. [Sir James] Clark's work on Climate.) Nor does it seem an improbable supposition that a disposition to abdominal plethora, or an organization which favours it, may be transmitted by parents to their offspring, more especially in dyspeptic and hypochondriacal persons, in whom the chylopoietic viscera, under constant irritation, are necessarily also in a state of congestion: we might thus explain how the strumous cachexy is continued, and how it is generated.

The foregoing view of the nature of this disease is also in conformity with the observation and opinions of other physicians. "In children," observes Dr. Wilson Philip, "the symptoms of inflammatory dyspepsia supervene early, and the disease in them commences in the liver rather than in the stomach." And Dr. Ayre has, in the following passage, confirmed our statement, though we have offered another explanation of it: "Diseased mesenteric glands occur in children from acrid condition of the duodenal contents; the liver, pancreas, and duodenal glands become dis-

eased from congestion, and irritation will be propagated to the brain, giving rise to hydrocephalus, spasms, convulsions, vomiting, contortions of the countenance, affections of the sight, violent headaches, faltering voice, chorea, palsy."

Treatment.—The plan of cure of this disease consists in the following indications: 1, to correct the morbid condition of body which we have stated to constitute the essential foundation of the disease; 2, to render the function of digestion easy of performance by a regulation of diet suited to the nature of the disease; and 3, to improve the general tone and strength of the body.

1. In the ordinary degree of this disease, it is seldom necessary to relieve the congestive state of the liver by the detraction of blood; but when there is much febrile excitement, with a red and dry tongue, with fulness or tenderness of the right hypochondrium, the application of a few leeches brings more immediate relief, and spares the necessity of much physic. In general, the direct antiphlogistic part of the treatment is accomplished by a light diet, by the nitrate of potass given in repeated small doses, either in saline mixture or in some carminative or bitter infusion, as the case may admit, whilst the intention of this indication is also obtained indirectly by increasing the secretion from the liver. We entirely agree with Dr. W. Philip in his high estimation of this remedy, the nitrate of potass. Of itself partly a substitute for mercury, when combined with it, it renders less mercury necessary; with purgatives, it renders their action more free, and with antimony tartarizatum it is invaluable in case of determination to the head. For promoting the secretion of the liver, mercury is the medicine most usually resorted to; as an occasional remedy for regulating the secretion of the liver, it is also probably the most safe and the most convenient. It should, however, be given only in interrupted doses, and should on no account be allowed to affect the system. The *hydrargyrum cum cretâ* combined with a few grains of subcarbonate of soda, and a minute quantity of *pulvis ipecacuanhæ*, or *pulvis Jacobi*, we consider the best general formula. If the bowels are too open, the mercury may be combined with the *pulvis ipecac. comp.*; if confined, with a little magnesia, nitrate of potass, or extract of aloes; but in either case this alternative should be followed every morning, or every second morning, by a tea-spoonful of castor-oil, by a little electuary of cassia or senna, or by a small dose of *sal polychrest*. The effects of the mercurial medicine will be also very much promoted by following it up with a course of *taraxacum* or *sarsaparilla*, or both united.

The action sought to be induced upon the liver, and through that organ upon the abdominal circulation, by means of mercury, may also be obtained by means of iodine, in our opinion more efficiently and more permanently; and where the inflammatory state of the mucous membrane of the duodenum exists in a slight degree, we think that it merits the preference. We have been in the habit of using the *tinct. iodin.*, and have had much satisfaction in its use in strumous affections, but we have always observed that its value has been invariably in the degree in which it acted on

the liver. We have made it a rule to commence in small doses, gradually increasing them; and though we have never seen any untoward consequences from its use, we have invariably observed the precaution of from time to time interrupting its exhibition for a few days. Where there is any hemorrhagic or scorbutic tendency, shown by eruptions of the nature of purpura, iodine is decidedly contra-indicated. It is probable that the muriate of lime has a similar action upon the liver, and may be advantageously used for this purpose.

In chronic cases we have seen the greatest advantage derived from a course of the Kesselbrunnen of Ems; and when there is any tendency to diarrhoea, we believe it to be preferable to every other form of medicine. The Obersaltbrunnen may be also used in similar circumstances.

When the state of the mucous surfaces admits of the exhibition of chalybeates they prove an alterative of very great value, and possess considerable power of correcting the congestive state of the abdominal circulation. This property of chalybeates has in our opinion been very much overlooked; for though they are usually administered in this disease, they are never exhibited with this intention. The chief obstacle to their use is the state of the mucous surfaces; for if they be not in a cool and secreting state, chalybeates are repugned by them as irritants. On this account it is most advisable to select the salts of steel the least exciting, as the ferrum tartarizatum, or to qualify the chalybeates by saline refrigerants, as by uniting the carbonate of iron with small doses of the nitrate or the sulphate of potass; or, best of all, by giving the remedy in the form of some saline chalybeate water, as the Eger. We have lately been in the habit of combining the iodine with chalybeates, and we think with very considerable benefit. They appear to correct and promote each other's action. This is our formula:—
R. Tr. muriat. ferri, tr. iodinii aa ʒii. aq. puræ ʒss. Guttae x. ad xxx. ter die sumendæ.

The congestion of the hepatic system may also be relieved by increasing the action of the kidneys and skin; that of the former will be promoted by the alteratives already mentioned; and that of the skin will be excited by the tepid sea-water bath, by sponging the body with vinegar and water, or salt and water, by the use of the nitro-muriatic acid lotion, by warm clothing, and by exercise; and, failing this, by gentle friction of the whole surface of the body for at least half an hour daily.

Unless a free and open state of the bowels be made to concur with the preceding remedies, they will prove abortive; but violent purging by irritating medicines is equally to be avoided. A soluble state of the bowels, procured by such mild remedies as have been already mentioned, is all that is to be desired. Sometimes a course of purging by the sal polychrest or the Harrowgate salts is of service, and when a sluggish state of the colon coincides with this disease, it is absolutely necessary that this intestine should be unloaded and preserved so.

2. Except under occasional febrile symptoms from an aggravated degree of the disease, the antiphlogistic regimen is unnecessary, and it ought never to be long-continued. According to our

experience a limited diet of animal food, nutritious and easy of digestion, answers best. The meals should be small, consisting chiefly of animal and farinaceous food; all vegetables and fruits ought to be avoided, or used very sparingly. Cows' milk seldom agrees well, and ought therefore to be considerably diluted; occasionally a little beef-tea or plain bouillon answers very well as a substitute for breakfast when milk is found to disagree. Wine, porter, ale, and beer are unnecessary, and therefore better avoided. In this disease fish is a very unwholesome food.

3. In ordinary cases, when the organs of nutrition are restored to a healthy state, the natural resiliency of the constitution can generally dispense with artificial assistance; but with feeble powers of body—a marked feature of the disease of which we are treating—some further help is necessary. We cannot, however, speak much in favour of internal tonics, excepting chalybeates, (which we do not view simply in the light of tonics,) and of them we have already said enough. More benefit is derived from tonics externally applied. Of these, unquestionably the most powerful is the cold sea-bath, and the most beneficial, unless it produces languor and chilliness. The shower-bath, cold ablution, exercise in the open air, in a dry free atmosphere, either by the sea-shore or in an elevated situation. The exercise should be moderate, chiefly on horseback, or for children, on donkeys. Amusing plays, moderate and agreeable occupation of mind; gentle friction over the whole surface for half an hour every evening; and lastly, occasional change of air and change of habits.

III.—FOLLICULAR DUODENAL DYSPEPSIA.

Synonyms.—Hypochondriasis pituitosa; (*Fraccasini*, cap. 4. p. 388;) *Auct. Var.*; *aurigo frigida* ab obstructione, *Sauvages*; *infarctus*, *Kämpf*; painful affections of the intestinal canal, *Powell*. (*Med. Transact.* vol. vi.)

General Character.—Symptoms of painful or difficult digestion, felt chiefly a considerable time after taking food, most frequently observed in phlegmatic habits; occasional alvine discharges of mucus in various morbid states; acute attacks of gastrodynia or jaundice sometimes intervening.

Form of Disease.—In persons of a cold temperament and relaxed habit, characterized by softness and want of elasticity of fibre, dark carbonized blood, a slow circulation, a soft pulse, low animal temperature, yellowish or chlorotic, and sometimes swarthy paleness of the skin, who are also much disposed to sleep, showing great languor, sluggishness, and apathy in their feelings, and betraying a want of decision and energy in their moral and intellectual character,—disorder of the duodenum assumes a particular form, depends upon a peculiar morbid condition, and manifests itself by certain characteristic symptoms.

The general progress of this species of dyspepsia is insidious, and can hardly be distinguished from the other forms of duodenal disease, except that the appetite is commonly much impaired, sometimes to loathing. There is great languor, lassitude, and incapacity for every exertion. The patient complains of a sense of load, distension, or pain, some hours after taking food, and the diges-

tion is accompanied with flatulence, oppression, anxiety, sometimes amounting to a feeling of suffocation. There is no remarkable loss of flesh, but the appearance of the skin is much altered; the complexion becomes bloated, loses its colour, is dull and cloudy, sometimes swarthy, frequently clammy, greasy, or waxy, as if covered with a thin film of melted wax; or the skin is sallow and somewhat jaundiced; it feels generally cold, moist, and clammy, the hands and feet particularly so. The lips and gums are generally pale; the tongue is moist, pale, and flabby, covered with a pearly white mucous coating, but seldom much loaded; sometimes there is a thick, shaggy, cottony fur. The mucous coating of the tongue often has the appearance of a false membrane, which, falling off in pieces, leaves patches quite clean, sometimes red, and morbidly tender. The bowels are almost always constipated, but diarrhoea is sometimes, though rarely, observed; the stools are light-coloured, porraceous and abundant, out of all proportion to the ingesta, and having often a faint mawkish smell; occasionally they are dry and dark-coloured, more frequently fluid and dark, of a greenish or brownish black colour, and not uncommonly dark, viscid, and pitch-like. But the characteristic features of the evacuation are considerable quantities of mucus, which are discharged in various morbid states and forms: sometimes it resembles transparent jelly, or is glairy like the white of an egg; frequently yellow and viscid like the yolk of an egg; sometimes it assumes the solid form, appearing in concrete masses varying in size and figure, frequently resembling small bits of tallow, wax, suet, or bits of the blanched kernel of walnuts; in other cases it appears in large shreds of a semi-transparent membrane of considerable tenacity; or large quantities of flakes mostly torn into irregular shapes, and appearing to have formed parts of an extensive adventitious membrane of no great tenacity or firmness; sometimes the membrane is passed in perfect tubes of considerable extent. Frequently it is passed in solid cylindrical forms like shreds of boiled macaroni or vermicelli, not rarely mistaken for the detritus of worms; and on some occasions considerable quantities of mucus of a purulent appearance are discharged at once, leading to the supposition that an abscess has burst internally. These discharges of mucus appear to take place periodically, and as it were critically, being in general preceded by considerable aggravation of the symptoms, whilst the recovery is attended with evacuations of quantities of mucous or glutinous substances.

In these attacks the patient is sometimes suddenly seized with acute spasmodic pain in the right hypochondrium, darting through to the back, frequently accompanied with vomiting or a hard dry cough, by either of which the pain is greatly exasperated. Often there is sudden and excessive pain towards the epigastrium, returning with vomiting, in violent paroxysms. These pains are occasionally rather relieved by pressure; but the parts are frequently so sensitive that the slightest touch cannot be borne, and even during the intervals of the pain the patient complains of great tenderness and soreness in these parts. The tongue, already coated with a white fur, becomes dry, the

pulse accelerated, the stools white, the urine turbid and of a dark red colour, like blood. As the pain remits, the patient is bathed in a profuse perspiration. After a day, sometimes longer, the skin becomes jaundiced, and on examining the evacuations, instead of gall-stones, as he expected, the physician finds copious flakes of mucus in various forms, which are passed with considerable relief to the patient. This mucus, sometimes fluid and approaching to pus in appearance, has, in connection with the foregoing symptoms, frequently imposed the disease upon the attendants for the rupture of an abscess of the liver; but the same symptoms and the same discharge occasionally occur without jaundice or any symptom of hepatic obstruction.

The urine, in the ordinary progress of the disease, is extremely variable; in the early stage it is rather pale and abundant, occasionally crude and transparent like water, and voided in considerable quantities; but during the severity of the symptoms this secretion becomes very deficient, high-coloured, and extremely loaded, sometimes of a deep orange colour, unless there be some obstruction of the biliary secretion, when, as has been already observed, it is of a dark blackish brown colour, like porter, or, mixed with a copious lateritious sediment, it almost resembles blood. The pulse, except during what may be called the acute attack, is always weaker than natural, generally slow and small, more rarely frequent and small, or wiry and fluttering.

The seat of the disorder may entirely escape the notice of the patient and even the observation of the physician; the chief complaint, frequently the only object of the treatment, instead of indicating any derangement of the function of digestion, may be an affection of another part of the body, some of the multifarious symptomatic diseases which originate in this disorder. Among the secondary affections which occasionally accompany this morbid state of the small intestines, (for we do not pretend to confine it strictly to the duodenum,) are, a remarkably altered state of the temper and feelings, languor, indifference to every thing, complete apathy, sometimes stupor or fatuity, sadness, great depression of spirits, obstinate melancholy, great irritability of temper, moroseness, obstinate silence and reserve. Sometimes the patient is oppressed with irresistible drowsiness during the day, and troubled with want of sleep at night, or the sleep is disturbed by dreams and incubus. The uterine functions seldom escape the influence of this disorder; menstruation is generally deranged, being either painful, irregular, or deficient, and the secretion pale-coloured; leucorrhœa is a very common attendant of the complaint in early as well as in protracted cases. Frequently the patient complains of uneasy sensations about the heart, of a sense of fluttering, of violent palpitation or syncope. The organs of respiration often suffer in consequence of this disorder; hence dyspnoea, short dry cough, frequently moist humoral cough with a grey viscid expectoration, or pain and sense of weakness of some part of the chest; in children a spurious form of croup is one of the most common symptomatic affections. The nervous system is often the chief seat of disorder, and chorea one of its most common forms; sometimes

it affects the whole body, less often only one half the body, generally the right, and on some occasions only one of the extremities, very commonly the right arm. Paralysis, generally partial, affecting one, seldom more, of the limbs, is another form of secondary affection. Painful local affections are often the chief subject of complaint, rheumatic paralysis, rheumatic gout. *Erysipelas*, *erythema*, *acne*, and *impetigo*, are the most common affections of the skin which originate in this disorder.

The unfavourable progress of the disease leads to a state of general cachexy, *cachexia pituitosa*, which sometimes terminates in anasarca.

Pathology.—This species of dyspepsia, noticed by some of the ancient physicians, has been more frequently concealed under the name and description of other disorders. Overshadowed by the secondary affections which originate in it, it is only to be found masked under the symptomatic forms of other diseases. But the morbid products of the mucous secretion have scarcely escaped the observation of any practical physician. Marcard (*Description de Pyrmont*, vol. iii. pp. 45, 90,) and Stoll (*Ratio medendi*, p. ii. pp. 319, 346,) have particularly described them; Theden (*Remarques et Expériences*, vol. ii.) and Hoffmann (*Med. Ration.* vol. v. de morb. infant. Obs. ix.) have considered them as not an unfrequent cause of sudden death; Bonnet, Morgagni, Vesalius, Brunner, and other pathologists worthy of every confidence, have discovered them in the dead subject; and the minuter researches of modern anatomy have traced them to their proper origin. But this morbid condition of body never received its due share of importance until the work of Kämpf, (*Abhandlung von einer neuen Methode die hartnäckigsten Krankheiten, die ihren Sitz im Unterleibe haben, zu heilen*, 1784,) a Dutch physician, by whom it was first professedly described under the name of *infarctus*, and who must be considered to have established it as a particular disease. Though this author was in some degree guilty of the common error of most original thinkers, of overstepping and overcharging his premises,—for he said he recollected few diseases which were not originally referable to *infarctus*,—it was not so much this fault as his singular method of cure, which failed to lead to a more general reception of his opinions, which, except in Germany and Holland, have been too little attended to. In our own country, as far as we are aware, the pathological condition of this disorder has never been accurately specified, though the secondary forms of diseases under which it masks itself have been frequently described. A few interesting cases of the primary disorder have been given by Dr. G. D. Yeats, (*Op. citat.*) but more particularly by Dr. Powell. (*On certain Painful Affections of the Intestinal Canal*, *Med. Transact.* vol. vi.)

It has been observed by those who have devoted much attention to morbid anatomy, (*Andral*, *Anat. Path.*) that the mucous glands of Peyer and the follicles of Brunner do occasionally present appearances very different from that of the healthy state. Sometimes they are found unusually developed; as large as mustard seeds; frequently they contain a whitish concrete matter, more or less friable, bearing a close resemblance to the caseous or lardaceous matter of tubercles;

at other times a great number of small white bodies are found disseminated over the surface of the intestines, corresponding to the grub or *emphragma sebaceum* of the skin; for they are nothing more than the follicles filled with concrete mucus. These bodies occasionally acquire considerable size, but seldom exceed that of a pea; sometimes they are elongated, projecting in the form of little excrescences or fungous papillæ; or on the contrary, the follicles are flattened and depressed, with their orifice more or less apparent, from which is thrown out a thin greyish mucus, which sometimes collects in astonishing quantities in particular parts of the intestinal canal, or, spreading itself in every direction, forms a thick mucous coat over a considerable part of the surface of the intestine, which on the first view might easily be mistaken for the mucous membrane itself, in a white and healthy state; sometimes it is a tenacious mucus of a dark brown colour; or instead of this greyish semi-transparent semi-fluid mucus, a concrete matter, equally secreted by the follicles, may spread itself in the form of a membrane, more or less dense, over the surface of the intestinal canal; or instead of being spread on the surface, this concrete matter may form solid masses, as occurred to the celebrated Justin Lipsius, who, though treated by his friend and colleague Heurnius, suffered for a long time from this complaint, and was not relieved till he had voided a viscid mass of the colour and form of the intestines.

It was the doctrine of the school of pathology just disappearing, to consider all these morbid appearances as the result of inflammation of the mucous surfaces. Dr. Parry observes that the appearance of the fibrous and curdled stools of children, and the consistent concrete membranes taking on the tubular form of the intestines in adults, which are often evacuated from the bowels in slight inflammatory affections of the mucous membrane of the colon and rectum, so often mistaken for worms, consist rather of coagulated albumen than of concrete mucus; but there does not appear any just reason for this opinion. We have observed these without the remotest sign of inflammation; nor did Dr. Powell observe any, but on the contrary, states that the most remarkable circumstance in the history of his cases was, the production of an effect usually ascribed to inflammatory action without its previous existence.

There will be little difficulty in understanding how all the various symptoms and sufferings described as originating in this morbid condition of the mucous follicles may be consequences of it, if we allow a due importance to these organs in preserving a healthy action of the membrane of which they constitute so essential a part. On comparing the various morbid appearances presented by a disordered state of the follicles, we may remark that they divide themselves into two classes; one in which the secretion is suppressed or retained, and another in which it is excessive or overflows, to each of which opposite states a more precise observation will in all probability ascribe its appropriate symptoms. In the mean time it may be easy to conjecture how the mucous membrane, not defended by its appropriate secretion, may acquire a preternatural sensibility and irritability

which, not only disturbing the function of digestion, and giving rise to most painful affections of the intestinal canal, but rousing the actions of its sympathetic organs, may induce any of the disorders which we have noticed; and how, on the other hand, the membranes, sheathed and muffled by the morbid envelope, and thus deprived of their sensibility, will induce disorder and excite sympathies of another character, and will also sometimes become mechanical causes of irritation and obstruction. The inconvenience of a dirty skin, as a writer on this subject observes, is felt, because its obstructed pores prevent the transmission of that insensible perspiration which is essential to health; languor, sickness, headach, and other inconveniences originate precisely in the same manner, from filthy intestines. And we know that the mucous membrane, either by sympathy or association, sometimes degenerates into a state relatively similar to that of the teguments of the surface of the body, which sometimes become hard, harsh, and rough; or glossy, smooth, and shining, like parchment; pale, weak, and withered, or covered with large thick scales of cuticle adhering to its surface, thus losing all its permeability; or, on the other hand, besmeared with an excess of sebaceous secretion, covering the skin with an oily, greasy, or waxy coating. When both these secreting surfaces, the skin and the mucous membranes, cease at the same time to perform their offices, it is not difficult to understand how the fluids become disordered, how nutrition becomes impeded, and how the most inveterate forms of cachectic complaints ensue.

Our pathology of this complaint receives considerable illustration and confirmation from considering its causes. It has been observed most frequently in females and children, in whom the mucous follicles are most developed; it prevails most in cold humid seasons, in cold humid climates, and therefore, prepared by the influence of winter, it often declares itself in early spring, and on the return of cold in autumn. Sedentary employment in confined and impure air, with neglect of personal cleanliness, are the circumstances most powerful in producing it; to which may be added unwholesome food. When the predisposing causes have been in operation, it is generally immediately excited by colds, errors of diet, drastic purgatives, fatigue, watching, anxiety, alarm, and bodily accidents. Constipation of the bowels, while it is a consequence, is also one of the exciting causes of this disease.

Method of Treatment.—The indications for directing us in the cure of this disease, are, 1, to render the function of digestion easy of performance by a proper selection of food, by preserving an open state of the bowels, and by proper exercise; and, 2, by endeavouring to correct the morbid condition of the follicles, which constitutes the proximate cause of the disease.

1. Having already so fully and so frequently considered the means of fulfilling the first indication, it will be unnecessary again to recur to that subject; we shall, therefore, content ourselves with referring to the treatment of *follicular gastric dyspepsia*, and shall for the present confine our observations to the means of fulfilling the second indication.

2. Some medicines appear to exert a particular influence upon the functions of the mucous follicles. According to our experience they consist of purgatives, especially rhubarb, senna, scammony, and aloes, of sulphurous and some neutral salts, as sal polychrest, muriate of soda, of alkalies, mercurials, chalybeates, of iodine, colchicum, gum ammoniacum, and ipecacuanha. Amongst several means capable of effecting the same object, it is a received principle of physic to select those whose operations are best known and most under control, having recourse to others only when their use cannot be dispensed with. Accordingly, some of the purgatives above enumerated, either alone or in combination, form the proper remedy of this complaint in milder cases; and where no signs are present indicating an inflammatory or excited state of the mucous membranes, rhubarb, with sal polychrest and a small proportion of ginger, the pulvis scammoniae compos., the infusion of senna; in cold habits, the vinum aloes, the decoct. aloes comp., and the baume de vie, are convenient combinations. Dr. Powell found, in his cases, that the infus. sennae with the infus. gentian, comp., and from x to xx minims of liquor potassae, repeated so as to produce four or more stools in the twenty-four hours, discharged the flakes of mucus better than saline aperients, and more efficaciously than mercurials. Where there were general torpor or coldness of the system with much pale urine, and dark stools with much mucus, Dr. Yeats observed very excellent effects from taking one drachm of the vinum aloes with xv minims of liquor potassae in a little infusion of chamomile every morning. It is not enough that these medicines be taken in isolated doses. To give them effect, they must be steadily persevered in for some time. But their effects must be watched. If they cause irritation, heat, thirst, or much griping, they are not indicated, and may induce the very state we are seeking to remove. The largest fistulous membranes that we ever recollect to have seen discharged by stool, we observed in two ladies who were in the habit of using the electuary of senna every day as an aperient.

The operation of purgatives is rendered much more efficient when the bowels are prepared for their action by one or two small doses of alteratives. Of these the most certain and most manageable are mercurials, and we believe calomel to be the best form of this medicine. One, two, or three grain doses are generally sufficient, and, according to the state of the patient's stomach, it may be combined with the pil. galban. comp., the pil. scillae comp., with a little prepared chalk if there be a disposition to diarrhoea, or with a minute quantity of opium or opiate confection.

Chalybeates, though in a less degree, possess the same alterative power over the follicles as mercurials, and united with their tonic properties, afford a means of cure applicable to another combination of circumstances; as for instance, when there exists a general torpor and coldness of the system, with much pale urine; when the patient is thin, pale, and weak, with a withered look, a peculiar dry state of the skin, and a small weak pulse, the appetite variable and capricious, the bowels slow, though easily regulated, and the

evacuations always of a remarkably dark colour, like mahogany, or almost black; or when the patient is pale, bloated, and chlorotic; in all such cases chalybeates are very useful remedies. The most suitable preparations are the sulph. ferri combined with pulv. aloes; the ferrum tartarizatum or ammoniatum with rhubarb, or the carbonas ferri with rhubarb and soda. It has been observed in these cases, contrary to what happens in general, that chalybeates, instead of rendering the faces darker, restore them to their natural colour, an observation which is in accordance with the experience of Nehr and Heidler, of the action of the mineral water of Marienbad.

Kämpf's method consisted in injecting frequent small enemata of strong decoctions of plants which he supposed to be endowed with resolving powers, as *taraxacum*, *saponaria*, *melilotus*, and such like; these he allowed to be absorbed from the intestines.

It is always desirable, as far as the case admits, to combine some tonic with the corrective treatment, and, as soon as the evacuations have assumed a healthy appearance, it may always be attempted. Chalybeates, as already observed, answer this purpose best; but when they are not admissible, or after their use, tar-water, lime-water, infusion of cascarrilla, nitric or nitro-muriatic, or muriatic acids, are very useful remedies.

It is unnecessary to observe that this direct method of cure must be assisted by all those means which tend to the improvement of the general health, and which at the same time correct and avoid those habits which form the predisposing causes of the disease. Amongst these the state of the skin deserves particular attention. The warm sea-water bath, the cold sea-bath, the cold shower-bath, cold sponging with vinegar and water, or salt and water, friction with a flannel glove, warm clothing, preserving the feet dry and warm, will be found most useful auxiliaries.

But a remedy superior to any or even all of these, we have found in mineral waters, by which every intention of the medical treatment, corrective as well as tonic, we have seen more efficiently, more fully, and more surely accomplished than by any other combination of remedies. Some of the most surprising cures effected by mineral waters have been chiefly in affections of this nature, as has been observed at Carlsbad by Becher, at Marienbad by Heidler, in the waters of the Pyrenees by Bordeu, at Pyrmont by Marcard, and also at Eger and Harrowgate.

III. COLONIC DYSPEPSIA.

The functions of the large intestines being chiefly disordered.

Alvine excretion forms so important a part of the function of digestion, that, in common language, the term indigestion is exclusively appropriated to the disorder of that function; and if it be impeded, interrupted, or otherwise deranged, it is rare that its other processes continue to be healthily performed. There may be some exceptions to this, as in the extreme cases mentioned by Heberden, where one person was in the habit of having his bowels relieved only once every month, and another person twelve times every day, yet both with the enjoyment of perfect health; and in all persons, what is called the regularity of the

bowels admits a certain latitude; but in ordinary circumstances the right performance of excretion is so essential to the health of the whole function of digestion, that any serious or long-continued irregularity of the bowels invariably leads to its disorder. We cannot, therefore, be said to have exceeded the limits of our definition in considering disorders of the functions of the large intestines as constituting species of dyspepsia.

The large intestines are very frequently, indeed most frequently, the part of the apparatus of digestion of which the functions are the first disordered; and the symptoms of their disorder often present the first perceptible link of the chain of the disorder of the whole apparatus; and though ultimately their disorder necessarily involves the whole apparatus, their derangement may so entirely predominate, that the healthy or unhealthy state of the other processes follows as a mere consequence of the state of the large intestines.

The disordered functions of the large intestines, considered only in reference to the part which they perform in digestion, without regard to the more positive diseases of which they may be the seat, are of themselves a source of great discomfort to the patient; but they deserve most consideration as being the medium through which the greater number of the disorders of the function of digestion become established, not only directly, by the impediment which they present to the function of the stomach and small intestines, but indirectly, by the stomach being made the recipient of the medicines which are necessary for their relief. The disordered function of the large intestines may, therefore, be considered as the means by which most of the noxious causes which disturb the healthy function of digestion produce their effect, and the principal secondary cause by which they extend their mischievous consequences.

The disordered functions of the large intestines afford almost the first symptoms of the derangements of the stomach and small intestines, which attract the attention of the patient, and have not seldom been improperly treated as a dyspeptic state of the stomach itself. This, as Dr. G. D. Yeats very justly observes, is not remarkable, it being recollected that the great arch of the colon lies close upon the stomach, whence a swelling or puffiness in the one may easily, without due care, be attributed to the other.

As long as the disorders of the large intestines continue to predominate over the disorders of the other parts concerned in the function of digestion, they have their own symptoms, and demand their own method of cure. When they have induced the disorder of the whole function, it is always important to know where the error originated; and as their disorders may be mistaken for those of other organs, it is necessary that a distinction should be made between them. Under every consideration, as the disorders of the functions of the large intestines admit of being ascertained, so they deserve being made a subject of special attention.

Like the other organs of the apparatus of digestion, the large intestines may be deranged in different ways; they may be disordered from atony, from morbid irritability, from inflammation of their mucous membrane, from disorder of its follicles;

all which morbid conditions afford the means of dividing colonic dyspepsia into a corresponding number of species.

I.—ATONIC COLONIC DYSPEPSIA.

Synonyms.—Obstipatio debiliū, *Cullen*; mimosēs; acute disorder of the general health; *Marshall Hall*; coeliacus affectus, *Celsus*; colica stercorea, *Etmüller*; colica flatulenta, *Sennertus*; lien verberans, *Bonetus*; stridulous affection of the bowels, *Bradlye*; (Observations on a Stridulous affection of the bowels, London, 1818.) tenesmus à scybalis; dysodia stomachalis, *Sauvages*; excrementitious plethora, *Barlow*.

General Character.—Bowels habitually confined, but alvine evacuations not remarkably altered; pain or uneasiness in some part of the colon, variable in degree, situation, and constancy; often stridulous noise in the abdomen. [See COLON, TORPOR OF THE.]

Though costiveness is the leading symptom of this disease, it would be a mistake to suppose that it consisted in costiveness alone, or that constipation of the bowels was the only symptom which an atonic state of the colon gave rise to.

Form of Disease.—This disease is not confined exclusively to either sex; it is most common in young females, and in delicate boys or young men. After there has existed for some time an habitually confined state of bowels, or a morbid state of them, in which, though evacuations occur daily, they are scanty and insufficient, the patient appears slowly and imperceptibly to fall out of health; but it is some time—several months, even years—before his ailments attract serious attention. The patient has no marked or distinct complaint, but the appetite is impaired, there is lassitude, loss of strength, weariness after any bodily exertion, a general, sometimes painful feeling of weakness, an aching over the whole body, or very distressing pains in the loins and lower extremities, attended with some degree of torpor, especially on walking or long standing; and hence the patient is constantly constrained to sit down or to rest on a sofa. There is frequent headach, great nervousness or susceptibility of impression, a tendency to perspiration on the least surprise or exertion, fluttering, faintishness, timidity, discomposure by the least hurry or agitation, sometimes tremor and vertigo. At first there is no loss of flesh, but the skin grows coarse, the countenance puffed and bloated, the complexion dull, foul, and greasy, and the lower eyelid becomes dark, sallow, or otherwise discoloured. But as the disease continues, there is considerable loss of flesh, the complexion loses its colour and turns pale, sometimes dead-pale, sometimes swarthy pale, sometimes rather chlorotic; the countenance becomes thin, the features sharp, and the lips, more especially the upper lip, are sensibly paler than any other part of the face; the surface of the face is somewhat shining and glossy, or is frequently affected with a slight degree of clammy or oily perspiration, especially about the nose; and the orifices of the sebaceous follicles appear as small black points disseminated over the surface; and the discoloration under the eye increases to sallowness or a greenish black colour.

Pain is frequently complained of in some part

of the colon, which, when it exists in an aggravated form, is various and irregular in its situation, course, degree, and duration; its approach is sometimes sudden, often slow and progressive; at first it is apt to change its situation from one side to the other, or from one part of the colon to another, and frequently appears to move up the chest or to the back, but by degrees it becomes more permanent in its situation; it is commonly observed in one of the iliac regions, frequently in the right iliac region in the course of the ascending colon, in which situation the pain on some occasions becomes very acute, aggravated by violent spasms returning in paroxysms, and not rarely attended by vomiting and great irritability of stomach, (the *colica stercorea* of some authors,) often the forerunner of stercoraceous tumours, and ultimately of that disease which has been described by Dupuytren under the name of phlegmonous tumours of the right iliac region, and which has been recently well described by Mr. Ferral. (*Edin. Med. and Surg. Journal*, 1831.) A common situation of the pain is in the left side just under the false ribs, and very often in the left iliac region in the course of the sigmoid flexure of the colon; in this last situation it is occasionally attended with a frequent desire to go to stool, accompanied with distressing tenesmus. Frequent though ineffectual efforts are made to obtain a stool for several days, and at length a number of small hardened and slimy lumps, or scybala, either separately or connected together, similar to sheep's dung, more rarely of a flattened or tape-like form, will be voided, sometimes preceded and sometimes succeeded by liquid and sanious stools of various colours and of a frothy consistence, always extremely offensive. This is the *tenesmus à scybalis* of some authors, and the dysentery of others, of which inflammation and ultimately ulceration of the mucous membrane, and occasionally stricture of the lower part of the colon, are the remote consequences. On some occasions the pain and soreness is felt about the middle and lower part of the hypogastrium; and a slight pain is also experienced on micturition. Sometimes there may be perceived in the course of the colon a distinct hardness or tumour, which appears to arise from a loaded state of the intestine, an occurrence particularly apt to take place in females, and more especially in the left iliac region. When the disease has made some progress, the hypogastrium is generally swollen, especially in the evening and fore part of the night, but in the morning the enlargement has nearly or altogether vanished, in some cases leaving a degree of soreness in that region.

One of the most common and most distressing, as well as unpleasant attendants of this complaint is a disagreeable noise, not unlike the croaking of a frog, heard in the bowels, proceeding more especially from the left side. The noise is very much under the influence of respiration, and also any state of excitement. For the most part, especially on inspiration, it is similar to the croaking of a frog; but on expiration it is somewhat less so, conveying the idea of the sound issuing, as it were, from water; often before it ceases, it is like the plaintive sound of a dying animal. *Dicitur gemere de turture, τρῖζεν τρῖζεν*. At every act of

inspiration, on laying the hand on the left umbilical region, about two inches or two inches and a half from the navel, in a transverse direction towards the spine of the ilium, a sensation is felt as if some liquid were forcibly spirted or dashed against the peritoneum; on expiration this is less perceptible. This curious verberation is not always confined to the same part of the abdomen, as it will often be found two and a half or three inches from the navel in the direction of the spleen. During its presence the patient seldom complains either of pain in the part or on any moderate pressure, or even from change of posture; but if the part be suddenly pushed by a moderate force, great pain is often felt in the region of the stomach, so much as to cause fainting, a circumstance which more particularly happens when the pulsation approaches the epigastrium. At first this stridulous noise returns at uncertain intervals in the course of the day, and is of no limited duration. The period of its continuance, however, seldom exceeds twenty minutes or half an hour; it is particularly marked whilst the patient is in an erect posture; on lying down it will almost instantly cease, and be no more heard as long as the body continues in an horizontal posture. Whatever is taken into the stomach, whilst the body is erect, has no inconsiderable influence in exciting or abating this stridulous sound. For instance, after the patient has sat down to a meal and taken a few mouthfuls, it will almost invariably ensue, and continue for some time, after which it becomes weaker, and intermits more and more until it ceases. In other cases, however, instead of food producing this effect, it oftener abates this noise, especially when the stomach is empty, and there is faintness and a sense of craving for food. In the advanced stage of the complaint, the noise frequently returns, even while the patient remains in the horizontal position. The varied state of the bowels seems to have little influence either in augmenting or diminishing the noise in the abdomen.

If the state of the organic functions be inquired into, they will be found to betray a considerable deviation from the state of health. The appetite is generally impaired, sometimes to loathing, but frequently without any symptom of gastric or duodenal dyspepsia; sometimes there is remarkable irritability of the stomach, the patient throwing up part of the little nourishment taken immediately on swallowing it; and this vomiting is often attended with pain or uneasiness in, or tightness across, the stomach; sometimes there is faintness with a sense of craving for food. The tongue always presents an unhealthy appearance, almost invariably it is loaded or covered with a white slimy fur; sometimes it will be found coated with a whitish fur, inclining to a yellowish tinge, and often dappled towards the root, especially of a morning; occasionally for a few days this incrustation is diminished, and the patient is more disposed for food, but this change is of short duration. Frequently the tongue is loaded, swollen, and cedematous, and marked by pressure against the contiguous teeth; it is frequently so large in proportion to the mouth, that from compression it is found more or less divided with sulci or folded into plaits. The teeth and mouth are foul; the gums

also are frequently coated and palish; the inside of the cheeks, like the tongue, is often impressed by pressure against the teeth; a vitiated taste is sometimes perceived, particularly in the morning; the saliva is viscid, the breath tainted and fetid, sometimes emitting a heavy strong smell, not unlike roasted meat, sometimes a putrid, even stercoraceous odour. The bowels are at first always constipated, afterwards constipation and diarrhoea occasionally alternate; in advanced cases the latter state becomes permanent. The *faeces* at first exhibit in general no unnatural appearance, except that they are scanty and indurated; afterwards they are occasionally fluid, scanty, dark-coloured, and extremely fetid, often accompanied with mucous and even blood; sometimes, as already observed, they are attended with tenesmus, bloody stools, and pain in the right iliac region, an occurrence very common in young females. In the commencement the urine is high-coloured and apt to be loaded, depositing a whitish sediment, and presenting a supernatant iridescent pellicle; afterwards it lets fall a mucous deposit, sometimes of a lateritious tinge; during the continuance of the disease the urine frequently becomes limpid, but slight exasperations of the complaint restore the deposit. The pulse is frequently nearly natural; sometimes it is quick or easily accelerated, or variable, and apt to become irregular and intermitting; it is usually soft and weak, sometimes small; it varies in point of fulness, and continues to increase slowly in frequency as the complaint advances. The skin is in general cool, rather moist and clammy, particularly the hands and feet, which are apt to be obstinately cold; the fingers are rather livid, and the nails assume a lilac hue.

It is remarked by Dr. M. Hall, from whose exact portrait of this complaint we have drawn a considerable part of our description of it, that the condition of the countenance, the tongue, internal mouth, and general surface, is peculiarly constant and uniform in almost every case and every period of the disease, but that the other symptoms are characteristically inconstant and variable.

These symptoms are—an unaccountable sensation of weakness and weariness, the patient suffering from a sense of aching after slight exertion; a considerable loss of strength, sometimes amounting to faintness in the upright posture, with a peculiar sense of fluttering at the heart and pit of the stomach; but the most frequent subjects of complaint are headach, vertigo, and nervousness. The headach, which is severe on rising from bed in the morning, insomuch so as sometimes to excite vomiting, will continue unabated for an hour or two, and is often proportionate to the degree and length of time which the patient has slept. The patient is flurried by the least hurry, agitation, or excitement, is very frequently affected with nervous tremour on the least surprise or least exertion, frequently manifested in a quivering of the lip or dimpling of the chin on speaking, or, when at all agitated, by tremour on holding out the hand, or carrying a cup of tea to the mouth, on attempting to stand or walk, or on being fatigued or hurried. Sometimes there is oppression, heavy sleep, or considerable stupor or obtuseness of intellect during the day, and during the night great wake-

fulness and restlessness, disturbed sleep, dreams, and incubus.

The patient is liable to violent and sudden attacks, generally induced by some improper article of diet, or a more than usually loaded state of the large intestines, such as sickness, vertigo, faintness with cold perspirations, paleness of the countenance, and coldness of the extremities. These attacks are sometimes accompanied with spasmodic or convulsive paroxysms, frequently assuming the form of hysteria, more rarely of epilepsy, and occasional temporary delirium, loss of memory, or absence of mind. Sometimes the attacks consist of spasmodic or anomalous pains about the heart or side, or in various parts of the abdomen; in fluttering, irregular action, violent palpitation of the heart, with syncope; in local pains more or less severe, occasionally so severe as to resemble tic douloureux, of longer or shorter duration, and in various forms and situations; in some cases resembling the passage of gall-stones, in others inflammation of the pleura, of the liver, spleen, kidneys, and intestines or peritoneum, and affections of the bladder. Sometimes there is an extraordinary loss of muscular power, especially of the lower extremities, which are so enfeebled as to appear affected with paralysis.

Curvature of the spine is not a rare complication and consequence of this disease, more especially in scrofulous constitutions. Its approach is very gradual, and long before any deformity can be observed, on forcibly pressing with the fingers on each side of the spinous processes of the third or fourth lumbar vertebra, considerable pain will generally be excited, insomuch as occasionally to produce a degree of sickness. The seat of this pain is, however, confined to no exact point. After a considerable time the patient experiences a further increase of weakness and derangement of the general health, and the spine, at the place above mentioned, will now be found giving way, either slightly projecting anteriorly or to the left side. In consequence of the curvature of the spine to the left side, the right hip has the appearance of being enlarged, by reason of the hollowness between the iliac and vertebral column being increased, whilst the left hypogastric region is more swollen than the right.

Dr. Bradley conceives that the disease of the spine is the primary affection, of which the stridulous sound and other derangements are only the consequences. We confess that to us his reasoning presents a very remarkable instance of a false induction; for on his own admission there is no constancy of conjunction between the affection of the spine and the stridulous noise, as every practitioner must be able to confirm. They are both accidents of a more general disorder, only connected together through their common cause.

Causes.—A certain period of life, from the age of ten to thirty, seems very much to favour the formation of this disease. It may be partly connected with the natural conformation of the body and the development of the constitution at this particular time of life; but perhaps it is more strictly dependent upon the change of habits coincident with it in the children of the rich, who are either unremittingly occupied with their omnifarious education, or, to obtain a graceful carriage,

steadfastly confined to one posture, the undeviating sedentariness of the body presenting a remarkable contrast to the desultory activity of the mind; and in the children of the poor, who are of necessity obliged to seek their bread in the sedentary occupations of needle-work, in the tedium and wearisomeness of manufactories, at the tambour, the stocking or the lace-frame. Hence females, who are under boarding-school discipline, and rigidly subject to it, being compelled to sit many hours of the day with the head erect and the shoulders thrown forward, are liable to this disease; hence governesses, sempstresses, milliners, mantua-makers, students, and all persons of sedentary and inactive occupations, are the chief sufferers from it. The effect of sedentariness is increased by any causes which have a relaxing influence upon the body; and hence the confined or impure air of apartments, the warm relaxing vapoury air of some occupations, as that which arises from working over ironing-stoves, or from the steam-engines of manufactories. But every circumstance which tends in any way directly or indirectly to impede the evacuation of the bowels is the most influential cause of this complaint. Hence not lending a ready obedience to the calls of nature, which often arises in children from indolence of habit, but more frequently from being placed in situations where their modesty checks them in doing so, and, at a later period of life, from the unbending restraint and thralldom of society; or amid the fatigue, care, and anxiety of life, from neglecting a due attention to the state of the body.

Pathology.—The explanation of the nature of this disease presents no difficulty. That it consists in a state of atony and insensibility of the colon, the most probable consequence of habitual over-distension of its muscular fibres, there seems to be little reason to doubt. The symptoms may be clearly and distinctly traced to this morbid condition of the colon, with which also it seems easy to connect the disorder of the general health which ensues. For, sometimes by continuity, sometimes by sympathy, deranging the function of gastric and duodenal digestion, sometimes by defective excretion changing the state of the circulating fluid and interfering with the process of nutrition sometimes by the sympathetic irritation of distension disturbing the functions of the nervous system, and by pressure impeding the circulation in the abdomen, (from which cause and continuity, the functions of the womb and pelvic viscera become disordered, and the spine loses the support of the antagonist muscles,) it seems all-sufficient for the effects which we attribute to it.

When the disorder of the colon is secondary, supervening upon gastric or duodenal dyspepsia, it appears to be merely a degree of languor or sluggishness in the bowel, causing delay in the passage of its contents, the consequence of the bile and other secretions being less adapted to support its action; but when its contents are longer delayed than usual, they become hardened, and irritate the surface of the intestine, causing tenderness on pressure, a feeling of hardness in the part, and all the symptoms of colonic disorder already described.

Treatment.—The indications for directing

the method of cure are, *a.* to remove any accumulation of feces by having the bowels fully and satisfactorily evacuated; *b.* to facilitate and promote the regular performance of the function of the colon; and, *c.* to correct the morbid condition of the colon, the proximate cause of the disease.

a. For fulfilling this indication, purgatives cannot be dispensed with; but though constipation is a constant attendant of this disease, they are not to be given with an unsparing hand. Rhubarb, combined with sal polychrest and a little ginger, the pulvis scammoniae comp. followed at a proper interval, if necessary, by a little infusion of senna, are the best description of purgatives. If the bowels are not easily acted upon, it is a bad practice to continue throwing in without discrimination any description of purgatives without allowing sufficient time for moderate doses to act. Mercurials are unnecessary unless the alvine evacuation does not resume its proper colour by means of the other class of aperients.

b. This indication may be fulfilled by the daily use of the warm water lavement, and, if necessary, by some mild-aperient medicines, just sufficient to solicit the bowels without irritating them. The object should be to induce a full and consistent evacuation daily, avoiding as much as possible the fretting and painful operation of medicines, by which the bowels are irritated. On the other hand, the power of the aperient must not be less than equal to obtaining a complete evacuation of the bowels; scanty evacuations will not suffice. Whilst, therefore, too considerable and too often repeated doses of medicines are to be guarded against, ineffectual medicines are equally to be avoided. Good forms of aperients are the pulv. aloes comp., decoct. aloes comp., or baume de vie in pimento water; a pill composed of equal parts of ext. colocynth. comp. and extract. hyoscyami: three, four, or five grains of this composition may be occasionally taken. The following formula affords a useful pill:—*R.* pulv. aloes, pulv. gambog. saponis, ext. hyoscyami āāʒi. fiant pilulæ xx. Una vel duæ horâ somni sum.

Though the use of the warm water injections in the loaded state of the bowels is frequently attended with pain in the course of the colon, or though they may not be at first successful, yet a perseverance in their use generally overcomes these obstacles, and occasionally restores the natural and spontaneous action of the bowels: by preventing the constant distension by accumulated feces, the opportunity is afforded the intestine of resuming its tone and sensibility. But whether clysmata or aperients are used for relieving the bowels, opportunity should be from time to time afforded for their natural action, by leaving off, or gradually diminishing, the medicines.

The diet should be mild, light, and nutritious, taken in moderate quantities, and frequently not less than three or four small meals daily, for the frequency of the meal appears to have a considerable effect in promoting the action of the bowels. It should consist of mild animal food, boiled or roasted, and should be well masticated; mutton, chicken, beef less frequently; stale pure bread, untoasted, mealy potatoes mashed, tea or coffee in moderate quantities. We have not known much advantage from using more aperient kinds of food,

as fruits, figs, medlars, stewed plums, stewed apples, brown bread, oatmeal porridge, and such-like. They generally disorder the first processes of digestion.

The function of the bowels will be also promoted by a system of regular walking exercise, apportioned to the strength; but violent efforts and fatigue are injurious. Sometimes easy, lounging exercise, with complete relaxation of mind, has considerable effect in promoting the evacuation of the bowels.

c. The means of fulfilling this indication are partly direct, partly indirect.

1. When the bowels have been preserved in a soluble state, the use of tonics or chalybeates may be advisable for correcting the morbid condition of the bowels. When chalybeates have a tendency to keep the bowels open without causing griping, they are often of great service, and we have had frequent opportunities of observing the superiority of the chalybeate mineral waters in this respect over the officinal chalybeates. But the state of the tongue must always be the guide for administering tonics, for as long as this is considerably furred, the most effectual means for removing such fur will prove the best tonic, and the utility of any tonic may be estimated by the return of appetite; therefore any stomachic tonic which does not effect its purpose by removing the fur is injurious.

Friction over the bowels with the flannel glove or flesh-brush, the galvanic circuit passed through the bowels and daily repeated, and in obstinate cases an occasional blister, are also direct means having the same effect in different degrees. But of all external means we have known the greatest service from the warm or cold douche upon the abdomen, continued for a month or six weeks, as so commonly practised in Italy.

2. The indirect means are sea-bathing, sponging the body with salt water or vinegar and water cold; change of air; country air; travelling; warm clothing; preserving the feet dry; relaxation from study, occupation, and business.

II.—INFLAMMATORY COLONIC DYSPEPSIA.

Synonyms.—κοιλιακή, *Græcorum*; ventriculosa passio, *Cæl. Aurel.*; enteritis colica, colica phlogistica, *Sauvages*.

General Character.—Pain in some part of the colon, prevailing most in one particular point, felt always more before an evacuation of the bowels, seldom increased on pressure; stools generally liquid, rarely formed, not always more frequent than natural.

Form of Disease.—We wish, without encroaching upon the subject of diarrhœa or dysentery, to characterize by this term a disorder of the function of excretion, arising from chronic or sub-acute inflammation of the colon. This complaint is manifested by pain in some part of the colon, and by sense of extreme weakness or of fainting after an evacuation of the bowels. The patient is always remarkably lowered, irritated, or made otherwise uncomfortable by the action of purgative medicine, and even by the spontaneous action of the bowels, which is always followed by more or less feeling of exhaustion; he feels always most strong and most comfortable when his bowels are confined. Sometimes the pain or uneasiness extends over the whole abdomen, and there is also a

certain degree of tenderness and an increased heat of the part; but more commonly the pain is referred to particular points of the colon, to which it is more or less confined—frequently to the caput cæcum coli and the ascending colon; sometimes to the arch of the colon; in young women to the sigmoid flexure. The pains of the colon are accompanied with a pulse somewhat accelerated and rather tense; there is some degree of thirst, but seldom much heat of surface. The motions present an unhealthy appearance; they are seldom formed, more commonly liquid or pultaceous; sometimes they are light-coloured, almost white, sometimes yellow and frothy, less frequently green or black; sometimes a tenacious puriform matter streaked with blood is discharged, which on some occasions alternates with healthy feculent matter, and at other times is mixed with it; the evacuations are always fetid in some degree, on some occasions most remarkably so. They are generally more frequent than natural, but often they are not so, an evacuation sometimes not occurring oftener than once in two days. The stools are frequently discharged with considerable force, but occasionally there is tenesmus without any excrementitious discharge. The appetite is seldom much impaired. The complexion is pale or whitish, sometimes of a remarkable greenish paleness, and the body emits more or less of a cadaverous smell.

The unfavourable progress of this disease is to hectic fever accompanied with œdema of the lower limbs and face, dejected features, and gradual exhaustion.

Causes.—This complaint is a common consequence of the preceding form of dyspepsia, more frequently of the medicines which have been improperly used for its cure; the effect of distension from remora of fæces, or of harsh drastic medicines. It is also on some occasions produced by the irritation of worms, and may arise from accidental colds.

Pathology.—The nature of this disease has been verified by repeated dissections, which have shown it to consist in various degrees of inflammation of the mucous membrane of the colon, sometimes very limited in extent, frequently terminating in ulceration, occasionally in thickening or induration.

Treatment.—Leeches or cupping to the painful parts used with caution and moderation; fomentations; covering the abdomen with a flannel roller moderately tight; light, bland, pultaceous diet; milk, if it is easily digested, or asses' milk; rest of body, sometimes confinement to bed or the recumbent posture, afford the only means of relief in this complaint.

III.—IRRITABLE COLONIC DYSPEPSIA.

Synonyms.—*Ερευνματώδης νόσος*, Hipp.; colica hypochondriaca, hysterica, Sydenham; flatulencia hypochondriaca, hysterica, Juncker; flatulencia convulsiva, Sennertus; hypochondriasis tympanitica, And.; colique nerveuse; enteralgie, French.

General Character.—Intestinal digestion accompanied with pain, uneasiness in some part of the abdomen, seldom fixed to one spot, but changing its situation, and intermitting.

Form of Disease.—There exists a certain

morbid condition of the intestines, referable only to irritability or morbid sensibility, without either proof or sign of an inflammatory state of the mucous membranes. It is certainly most frequently met with in persons of irritable and nervous temperaments, and is therefore probably a consequence of that constitutional state; but the symptoms show that this morbid condition is sometimes pre-eminently developed in the intestines, in which the patient is sometimes the subject of the most painful, distressing, and unnatural sensations. It is always attended with hypochondriasis, a constant watchfulness and attention to all bodily sensations, which depress and overwhelm the mind. These patients frequently complain of pain, or of a sensation of twisting at the umbilicus or in the course of the colon; occasionally of acute pain in the same situation, seldom augmented, generally relieved, by pressure; frequently a sensation of sinking or dragging of the bowels, giving the notion of the intestines falling out; some patients experience this uneasy feeling to such a degree that they are obliged to confine themselves to the recumbent posture. Sometimes, instead of pain, the patient feels in the intestines an indescribable uneasiness or peculiar sensation, similar to those which are perceived in the stomach in irritable gastric dyspepsia; occasionally the pain and preternatural sensation exist together, frequently they alternate with each other.

Frequently the chief subject of complaint in this disease is flatulence, which is generally accompanied with inodorous eructations, neither acid nor putrid, with stridulous noise in the bowels, borborygmi, with colic and spasmodic pains affecting different parts of the bowels, which are sometimes accompanied with ptyalism and copious discharges of limpid urine.

A very aggravated form of this complaint has been described under the term *flatulencia convulsiva*. It occurs in men, and has a strong affinity to the hysterical passion of females, the sexual organs being strongly affected. Early in our medical career we witnessed a case of this disease, the paroxysm of which a more experienced and now justly eminent physician arrested by the application of cold to the testicles.

The uneasy feelings in this disease return or are exasperated during the intestinal digestion, which is ordinarily difficult and laborious. They are frequently dissipated by travelling or agreeable occupation of the mind, and return with repose. They are sometimes, however, aggravated by the least motion, and are excited by a fit of passion, by anxiety of mind, by any disquietude, sometimes by the least effort of attention. The pains and colic often supervene upon stormy or unsettled weather. We recollect to have seen a case of this disease which co-existed with a remarkably painful sensibility of the retina.

Under these complaints the patient may preserve the appearance of health, and though the function of digestion is painful, it is yet satisfactorily performed, the nutrition being little affected, and the stools healthy, though the bowels are generally disposed to be confined.

Every form of this complaint is most obstinate, and rendered doubly so by the mutable and variable state of mind of the patient, who is contented

with no method of treatment, and is every day changing his physician. He has not patience to wait for the operation of any medicine, but is unceasingly fretting his body with every description of medicine, particularly with aperients, by which his complaints are invariably aggravated.

Pathology.—Concerning the nature of this disease, we refer to our pathology of irritable gastric dyspepsia. Bonetus gives the case of a person who had this complaint, marked by great pain and rolling of the bowels, attended with a morning sibilous noise, for three years, in consequence of plum-stones lodging in the colon.

Treatment.—The cure of this disease, always difficult to be obtained, is to be sought for by a mild bland diet, easy of digestion. If milk diet agrees, the patient should confine himself to it. He should avoid any thing heating and irritating, and should shun every form of medicine as much as possible. The bowels are to be kept soluble by the easiest means. The patient should live much in the open air, and take exercise, chiefly on horseback. Sailing, and even long sea voyages are very useful. Of direct medicines we can speak most in favour of chalybeates, and the other metallic tonics. We have known the Kesselbrunnen of Ems of considerable service, but the worst case we have known was benefited by the artificial Pyrmont water.

IV.—FOLLICULAR COLONIC DYSPEPSIA.

Synonyms.—Colica pituitosa; (Sennerti species tertia; *Fernel*. pathol. lib. vi. cap. 9; *Sal-muth*. centur. i. obs. 78. *Bonet*. Sepulchret. obs. 23;) scelotyrbe pituitosa; (*Pereywinger*;) chlorosis pituitosa; (*Sauvages*;) diarrhœa pituitosa, (*Id.*;) *Auct. Var.*; arthritis chlorotica, (*Musgrave*;) *Sauvages*; paraplexia rheumatica, *Id.*; infarctus, (*Etmuller*, p. 440,) *Kämpf.*; colique glaireuse, *French*.

General Character.—Pain, spasm, or uneasiness in the course of the colon, with the evacuations of considerable quantities of mucus in various morbid states.

Form of Disease.—In persons of sedentary habits, more frequently young persons, and most especially young females, who are generally subject to costiveness and accumulation of feces in the large intestines, the mucous follicles of those organs are liable to be disordered in the way we have already explained in the section on *follicular duodenal dyspepsia*, much to the aggravation and obstinacy of the other symptoms. Like that complaint, the present disease is most usually met with in cold phlegmatic habits, and its progress is insidious. After habitual costiveness and the establishment of that state of general disorder of the health which we have already considered under *atonic colonic dyspepsia*, the patient becomes subject to acute attacks of pain or spasm in some part of the large intestines, frequently amounting to regular paroxysms of colic. The pain is occasionally confined to one particular part of the colon, frequently the ascending colon and the sigmoid flexure. Relief of these pains is only obtained by copious discharges of mucus in some of the various morbid forms already described. *Etmuller* has observed that the pain in this species of colic is more confined to one part of the abdomen, and conveys the feeling of a perforating or

transfixing pain. But instead of this direct symptom of disorder, it is not unusual for the patient to be seized with a violent nervous affection. Children are frequently seized with convulsions, to which succeed chorea, and sometimes paralysis of the limbs. Young women in this complaint are often affected with hysteria, which may, however, be distinguished from the idiopathic form of that disease by the great variety of ways in which it attacks the patient, sometimes as catalepsy, at other times as imbecility of mind, neuralgic affections of the heart, convulsive asthma, loss of voice, loss of speech; it very frequently leaves paralysis of some member, most commonly of the lower limbs, differing from ordinary paralysis in the sensation of the limb being seldom impaired. Painful affections of the heart, violent headach, extreme restlessness and agitation, rheumatic gout, severe pain in some part of the spine, frequently at the bottom, may be enumerated amongst the secondary affections of this disease. In women the uterine functions are always painfully performed; and it is not unusual to see a metastasis of the function to other organs, to the lungs, appearing as hæmoptysis; to the stomach, as hæmatemesis; to the bowels, as melæna. These derangements of the natural functions are various. Generally the patient becomes pale and delicate looking, but sometimes preserves a natural appearance, or even good looks; the skin is cool, moist, and clammy, particularly the extremities; the lips and gums are pale, and the tongue is invariably large, moist, and covered with a thin clammy coating; frequently it is swollen and œdematous, divided laterally or transversely by deep cuts or fissures, and retaining the impressions of the teeth. The bowels are always constipated, often obstinately so, the most violent medicines having little effect; but when they do act, the stools are found to be abundant, gruelly, and light-coloured, frequently deficient of their natural smell, or having a faint musky smell, and, if mixed with water, leaving a greyish calcareous deposit: sometimes they are extremely fetid. Occasionally the stools are mixed with shreds of membranous substance, or with mucus in various morbid states and forms, frequently in perfect tubes, some of which have been observed full half a yard in length; an appearance which has not rarely imposed upon the ignorant the belief that a portion of the intestines has been actually discharged. The urine is extremely variable, being sometimes scanty and loaded, almost deficient, at other times copious and limpid like water. The pulse, except under the excitement of any violent attack, is always weak, small, and soft, generally slow; the circulation seems hardly to arrive at the system of the capillary vessels.

Pathology.—Under *follicular duodenal dyspepsia* we have already sufficiently inquired into the nature of the morbid condition of the mucous membranes which constitutes the proximate cause of this disease; a condition in which their surfaces are deprived both of their secreting and absorbing function as well as their natural sensibility, their vessels losing their permeability, and becoming, as it were, impacted and blocked up with viscid or concrete mucus—*emphragma mucosum*. This state is the consequence of the

membranes, either from atony or inflammation, losing the power of throwing off the mucus from their surface, and which, either accumulating or concreting in the follicles, gives rise to considerable tumours there; or, collecting, forms itself into the various forms of excreted matters already noticed. This unhealthy state of the mucous membranes, the consequence of a depraved function of secretion, is the proximate cause of many painful, even dangerous diseases, arising as well from the disordered function of the membrane as from the irritation of such unnatural substances in the alimentary canal, inducing different symptoms corresponding with the different situations they may occupy. The most common cause of this state is the habitual costiveness of sedentary persons, or the repeated irritation of the alimentary canal by crude and indigestible articles of food; but we have known it to be produced quite independently of these, by the long-continued use of laxative medicines, and these by no means of the most irritating kind.

Treatment.—For the general treatment of this complaint we must refer to the corresponding form of duodenal dyspepsia. We have only to observe that, as a purgative for evacuating these *infurctus*, we have found the oleum terebinthinæ superior to any other.

IV. GASTRO-ENTERIC DYSPEPSIA.

The disorder affecting the function of more than one organ of the apparatus of digestion.

The preceding orders present dyspepsia in the simplest forms in which it is capable of existing, either such as it has been observed to assume, or to which it may be reduced by a careful classification of its causes, its symptoms, and its remedies. It is, however, neither pretended nor meant to be understood that it is met with always in these definite forms. In diseases there is nothing absolutely definite. They are not like animals or plants, each of which, nature, to preserve the integrity of the species, has surrounded with a distinct barrier. In strictness of language, diseases may be described, but cannot be defined. They pass so gradually into one another, that all the pathologist can hope to attain is to mark their leading and most constant phenomena. In describing the different forms under which dyspepsia presents itself, this is all that we have either sought or professed to do; and though we are too well aware that not only the species or forms of the different orders, but that even the species of the same order, may be complicated with each other, we venture to assert that, however intimately the different species may be combined together, it is seldom that one will not be found predominating. A knowledge, therefore, of the elementary forms of dyspepsia gives the physician a most commanding advantage even in cases the most complex; enables him to decompose and unravel their complications, furnishes him with indications which, as it were, throw daylight upon his operation, simplify and assure his method of procedure, and afford him the means, if not of foreseeing, most certainly of early describing, the effect of his remedies.

The characters which we have assigned to the different species of dyspepsia, are the result to

which we have been conducted by the review of many cases in which the disease has been presented in its most simple as well as its most complicated forms, comparing the circumstances of one case with those of another, separating the constant from the contingent, referring each to the morbid condition with which it was found to be most constantly conjoined. And if any persons should be disposed to regard these morbid conditions as mere figments, or to regard the terms which represent them as mere empty words, we trust they will be reasonable enough to recollect that the name does not change the thing, and that if it serves to mark the constancy of conjunction of a group of phenomena, it matters not which word or what sign we may use for the purpose.

Were time or space allowed us, it would be the object of the present section to indicate and describe the complications of the different forms of dyspepsia, to trace the law of their combinations, and the order in which they coexist or succeed each other; circumstances well deserving the attention of the physician. But this task we must reserve for another occasion, and content ourselves at present with merely indicating some of the more common complications. We leave the full consideration of this part of the subject with the less reluctance, because we are convinced that a moderate attention to the elementary forms of this disease will render a description of their complications almost superfluous.

When the disorder of the function of digestion extends to the whole or to more than one organ of the apparatus—to the stomach as well as the intestines, the morbid condition may be the same throughout, or it may be dissimilar, thus giving rise to the division of *gastro-enteric dyspepsia* into what may be termed *enopathic* and *polypathic*.

The species of the first division must be necessarily limited, and determined by the morbid conditions which the organs are liable to assume. Hence they will be the four following:—

1. Atonic gastro-enteric dyspepsia.
2. Inflammatory gastro-enteric dyspepsia.
3. Irritable gastro-enteric dyspepsia.
4. Follicular gastro-enteric dyspepsia.

Even in these species it will seldom be found that the morbid condition exists in an equal degree in every organ of the apparatus; but, on the contrary, that it usually preponderates more in one than the other, thus approaching to some of the elementary species.

The second division admits of a much greater variety of species, co-extensive with the combinations into which the four morbid conditions are capable of entering. The following are those most frequently observed:—

5. *Atonic Gastric with Inflammatory Duodenal Dyspepsia.*—It is the constant tendency of long-continued dyspepsia of any form, whether it be atonic, irritable, or inflammatory, to localise itself, to attach itself to one part of the alimentary canal, which in consequence becomes the seat of morbid sensibility, morbid irritability, or of some modification of vitality, or of inflammation, or some other modification of its vascularity. Dr. Wilson Philip has observed that in atonic gastric dyspepsia this occurs most frequently at the pylorus or upper part of the duodenum. Hence one of the most

common forms of complicated dyspepsia is the species above indicated. It is deserving of remark that this localisation of the disease, this disposition to confine itself to one point, sometimes removes, frequently relieves, the original disease.

6. *Irritable Gastric with Inflammatory Duodenal Dyspepsia.*—This, also, is the consequence of the tendency just indicated, after irritable gastric dyspepsia has existed for a considerable time, or when it has been treated by heating or irritating remedies. It is met with commonly in persons of anxious, energetic, enthusiastic dispositions, in persons worn out and exhausted with cares, as for instance, in over-anxious mothers. The tongue is generally clean, small, and tremulous; its anterior edge of a smooth, glossy, light red colour; more rarely it is of deep red colour; or it presents a loose velvety appearance, like red plush; the lips are red, and there is a frothy saliva in the mouth. The patient complains of an uneasy gnawing sensation, a sense of fainting or sinking at the pit of the stomach; sometimes there is a constant excruciating pain in that situation. The uneasy feelings are much increased by medicines; they invariably irritate, produce discomfort, or disturb the digestion. The pulse is generally quick, wiry, and small, the skin dry and harsh, particularly the palms of the hand, which are rough; the urine is alternately pale and sedimentous.

7. *Inflammatory Gastric with Atonic Colonic Dyspepsia.*—This is a complication common in young scrofulous subjects, male as well as female.

8. *Irritable Gastric with Atonic Colonic Dyspepsia.*—Vomiting, more especially after meals, is the most leading symptom of this complication. It appears to arise from pressure of the loaded colon upon the stomach.

Of the complications of the different morbid conditions in the same organ of the apparatus of digestion, we must also reserve the consideration for another opportunity.

The only apology we have to offer for having occupied so large a share of the time and attention of the reader, is the importance properly attached to the disease which is the subject of the present article; for if considered in its almost universal prevalence and in its remote consequences, it is the source of more suffering to man than any other to which by his physical nature he is exposed, and, therefore, ought to precede all others in its claims upon the attention of the physician. It is, indeed, a very egregious mistake to imagine that this opinion, which attributes health to a pure digestion, and every species of disease to its disorders, is one of recent growth. It is one which has been sanctioned by the experience of the greatest physicians of every age and country. To the greatest of them all, the healthy state of the function of digestion seemed so important, that he has not hesitated to declare, if not exactly in so many words, certainly in equivalent terms, that he who shall have discovered the means of a healthy digestion (which he considered to consist in the exact adjustment of food and labour,) shall have discovered the great secret of health: *ἢν μὲν γὰρ ἦν ἐρετὸν ἐπὶ τοῦτοις, πρὸς ἑκάστην φύσιν, οἷον μέτρον, καὶ πόρων ἀριθμὸς, μὴ ἔχον ὑπερβολὴν, μήτε ἐπὶ τῷ πλείον, μήτε ἐπὶ τῷ ἑλάσσον, εὖροιτο ἂν ὑγιή τοῖσιν*

ἀνθρώποισιν ἀκριβῶς. (De dietâ, lib. i. sect. 3.) In this respect Aretæus has gone a step beyond the father of physic; for to a healthy digestion he not only attributes health of body, but also health of mind: *στόμαχος ἡδονῆς καὶ ἀνδρείας ἡγεμόν· καρδίας καὶ ῥιον γειτόνισμα, ἐς τόνον καὶ θυμὸν ἢ ἀθυρίαν, τῆς ψυχῆς συμπαθεῖν· ἥδε στομάχου πρῶτιστα ἐνάμις.* (De causis et signis diuturn. morb. lib. ii.) And to give this opinion only its full extent, we may add with all propriety, that sweetness of temper, clearness of intellect, vigour of understanding, correctness of judgment, firmness of character, power of self-control, are preserved by a healthy state of the digestive organs, and may be lost by their disorder; for as it is by the diseases of these organs that intemperance works its mischief, all that sages, all that philosophers have delivered in praise of the virtue of temperance, may, without stretching a point, be fairly predicated of the healthy state of the function of digestion. When will legislators stoop to consider, or when shall legislators be made to comprehend, the influence of physical causes upon moral conduct?

The state of the digestive organs has the greatest influence upon the state of the other organs of the body. Their disorders are frequently the cause, frequently the consequence, of the disorders of other organs. "Sur dix cas de maladies aiguës," says one of the most distinguished pathologists of the present day, "qui ont leur point de départ ailleurs que dans le tube digestif, il en est huit à-peu-près dans lesquelles on observe un dérangement plus ou moins prononcé, soit dans la texture, soit dans les fonctions du canal intestinal. Dans les maladies chroniques, quelle qu'en soit la nature, il est infiniment rare que le tube digestif ne subisse pas quelque altération." (*Andral, Anatom. Patholog.*) A similar opinion had been expressed by Cullen: "I am of opinion that we cannot bestow too much pains on the consideration of the affections of the stomach, as we find that, next to the pyrexia, they are the most frequent occurrences in practice." From these statements we might learn, did we not all already know, that there is scarcely a disease which afflicts the human body that can be correctly treated if the nature of the diseases of the digestive organs be not properly understood; and we may infer how much the difficulty of their treatment is increased, when, as Aretæus observes, the means which restore the health and recruit the strength in other diseases, are noxious in these; *ἢ ἐν τοῖσι ἄλλοιςι πάθεισι μετὰ τὴν θεραπείαν δίαίτα ἐς ἰσχυρὸν καὶ κράτος τοῦ σώματος εἰπεύλη ἀγαθὴ· στομαχικοῖσι δὲ μόνοις ἥδε γίγνεται πλημμελής.* (De curatione diuturn. morb. lib. ii.) A thorough knowledge of dyspepsia in all its forms and varieties may therefore justly be considered the key to the cure of many acute and of most chronic diseases.

The mischief which springs from the disorders of the function of digestion is not limited to the individual—it extends to the offspring; for the disposition to these diseases being hereditary, and increasing in virulence as it descends, the dyspepsia of one generation becomes scrofula, consumption, or some other malignant disease in the succeeding ones; hence the decay and extinction of families, and all the manifold attendant miseries. When will parents, besides, if not before, wealth

and honours, think of bequeathing health to their children?

Moreover, as the diseases of the function of digestion may be said to belong peculiarly, if not exclusively, to a state of civilization, following it as closely as the body is followed by its shadow, they may be considered as the physical process by which luxury and refinement work the deterioration of the species, and prepare its decay—the under-current, which, setting against, stays or frustrates the progress of society. When will the physical state of the body cease to be deemed an unworthy means of promoting our moral—our religious improvement?

T. J. TODD.

INDURATION, (*induratio*, from *indurare*, to become hard.) This term is employed to designate an increase in the natural consistence of organs, in contradistinction to that of *softening*, which is used to denote the opposite state, or a diminution of the same property.

GENERAL PATHOLOGY OF INDURATION.

1. *Physiological Modifications of Consistence.*—In order to form an accurate estimate of the modifications which take place in the consistence of tissues or organs in a state of disease, it is essentially necessary to possess an accurate knowledge of the degree of consistence which these tissues or organs respectively possess in the normal state, as well as of the remarkable modifications which this property manifests not only in the different periods of life, but also during the progressive development of animal organization. The changes of consistence which are observed to take place under these different circumstances, although sometimes great in degree and extent, are nevertheless to be regarded as physiological conditions, and which mark in a particular manner the intermediate stages and extremes of life. Thus, when the phenomena of organization are about to manifest themselves in the impregnated ovum, nothing is discovered but a colourless liquid; organs when first perceived in the embryo are a mere jelly; and during their development, and in proportion as they approach to the perfect state, do they acquire a gradual increase of consistence. This progressive increase of consistence keeps pace with their development, and does not acquire that degree which belongs to each tissue or organ in particular, until it has arrived at a perfect state of formation. Now, we cannot but perceive here that the degrees of consistence must serve some important end; that even the almost fluid state of parts is not to be looked upon as a mere consequence either of an entire want or of an imperfect state of organization, but that it is a condition of organs or of the materials of which they are composed, subservient—if we may so speak—to the elementary acts of life; a condition which facilitates the transitions of form which organs must present before they can attain their more permanent and perfect state. By means of this condition of organs, whether transitory or permanent, nutritive elements subservient to growth and development find a nidus fitted for their reception, and fluids every facility for passing in whatever direction they are wanted; organs are moulded to the forms of the parts destined to receive and protect

them; and numerous relations of bulk, position, situation, &c., are reciprocally adjusted between the containing and contained parts, as the changes which they undergo may render it necessary, in order to maintain the integrity and secure the well-being of each.

At the different periods of life, infancy, manhood, and old age, the consistence of the various tissues of the body, and consequently of organs, present great variety. In the first they are soft, spongy, largely imbued with fluids, easily torn or broken; in the second, firm, more compact; the fluids are less abundant, and the solids resist considerable efforts to tear or break them. In the last period, the proportion of fluids is still less, and the solids have arrived at their maximum of density and cohesion.

The consistence of organs varies likewise according to sex, constitution, and the various conditions of life in which the individual has been placed. The difference of consistence arising out of these states is, however, by no means equally marked in all, and least as regards sex, if we except the cutaneous and muscular systems, which, in the female, are more delicate and softer than in the male. Those states of the body which are connected with the predominance of the lymphatic system are characterized by a soft, flabby feel, the opposite of that which accompanies what is called a sanguineous temperament; and as an instance of the modifications of consistence which organs undergo in individuals submitted to the influence of external causes, we may refer to such as are the result of climate and various modes and conditions of life. The modifications of consistence, however, which depend on sex, constitution, or conditions of life, are, perhaps, never so great as to be confounded with those which constitute morbid states of this property of organs. It is far otherwise in the different periods of life; a degree of softness or induration equal to that which characterizes even the extremes of certain pathological states, constituting the peculiar character of certain parts at the periods to which we allude. Thus, the brain of the new-born infant, the mucous membrane, and even the muscles of organic life, are so soft as to be ruptured or broken down into a pulp by a slight degree of pressure or traction, just as we find to be the case in softening of these parts from disease, in after life. On the other hand, in advanced life, the cellular tissue; membranes, particularly serous and fibrous; the muscles and tendons; bone; the brain and nervous system; and particularly the uterus and ovaries, sometimes acquire a degree of hardness equal to that which is known to be produced by certain diseases, and which, by some pathologists, has even been described as a state of scirrhus of these organs.

It may not be unimportant to observe here, that numerous modifications of consistence similar to those which take place in man at the different periods of life, are found to exist in certain parts of some kinds of animals. In them, however, it is a primary condition, necessary for the accomplishment of important functions, and, generally speaking, in no way dependent on changes induced by subsequent development, as in man. The conditions to which we allude consist in an

increase of consistence, or a positive conversion of one tissue into another of a similar but denser kind; a change necessary to enable the animal to live in a manner suited to its wants and the place which it holds in nature. Thus, in some animals, the cellular tissue, instead of being soft, spongy, and highly extensible, is naturally firm, dense, and fibrous; the epithelium, an opaque, thick covering; the sclerotic, a cartilaginous or osseous case; the epidermis, a horny envelope, &c., &c. The analogous changes which take place in man constitute pathological states, and not only subvert but entirely destroy the properties and functions of the organ in which they are accidentally produced.

If the physiological changes in the consistence of organs which we have noticed are properly understood and applied, they will serve to explain many of the pathological changes which occur in man, whether we consider these in relation to the causes by which they are produced, the phenomena which accompany them, or the effects to which they give rise. These varieties in the physiological consistence of similar tissues in different animals show likewise, that when they occur as pathological states, they are in all probability subjected to the influence of the same general laws as the former; that the limits which separate the two states, that is, of health and disease, can be defined only by a reference to a change of structure or function as regards the particular tissue, system, or organ, in which it occurs, the age, sex, or kind of animal in which it is observed. Hence, in our examination of this, as well as of every other modification which takes place in the internal and external conformation and composition of organs, the necessity of taking as the point of comparison that state of each which is found to prevail at any particular period of life, and which constitutes the type of the condition whose changes we wish to describe.

II. Pathological modifications of consistence.—We have already observed that the opposite changes of consistence of organs are named softening and induration. The latter only will be examined in the present article. A greater or less increase in the consistence of organs, particularly of the softer ones, has always attracted the attention of the pathologist, and whether existing alone or in connection with other changes, has sometimes enabled him to determine the particular nature of a disease, more frequently to detect diseases at their commencement, even when no alteration of the bulk, form, colour, sensibility, or temperature of the part, was perceptible. Hence the importance which has long been attached to this physical alteration, but which, as regards its diagnostic value, may be fairly considered as having seldom served any higher purpose than a signal of alarm of present or of future danger. It is only within these few years that induration and inferior degrees of this state have been more successfully studied, and the knowledge thus obtained more usefully applied as a means of diagnosis. Several diseases, indeed, which were believed to consist simply in an augmentation of cohesion, in an increase of density of the solid materials of a tissue, are now known to depend on very different states; that a morbid increase of consistence

is much more frequently dependent on the presence of an accidental or new product, fluid or solid, external to or combined with the tissue which is so altered, and consequently, that it is in these cases merely an effect, and no index whatever of the nature of the disease on which it depends. Mechanical, microscopical, and chemical analyses have shown that this physical condition varies much in its nature in the same or different tissues; and observation and experiment have also shown that it is produced by causes of a very opposite kind, and that the modifications of function by which it is accompanied are no less diversified. Since, therefore, induration is, in general, to be regarded as a symptom of previous or co-existing diseased states, it would appear to us to be of great and essential importance to determine, before proceeding farther, what the diseased states are on which induration depends.

Every degree and form of induration may be referred to changes which take place in the conformation and composition of organs.*

1. *Induration depending on changes which take place in the conformation of organs.*—The only change comprehended under this head, which gives rise to induration, is that of bulk.

Under change of bulk we include hypertrophy and atrophy, and changes in the quantity of the fluids of nutrition and secretion, as conditions which are not unfrequently accompanied with an increase of consistence of the otherwise natural and healthy texture of organs. Hypertrophy, however, is the only state in which increase of consistence can be regarded as a simple disease, inasmuch as it does not depend on the presence of a foreign product; the increased consistence in such a case being a consequence of a superabundant, molecular deposit of nutritive matter of a homogeneous kind in a tissue, and arranged in the normal order. But, that an increase of consistence depending on these circumstances should follow, it is not necessary that it should be accompanied by any change of bulk of the organ in which it is observed; for there may be hypertrophy without change of bulk, from the mode in which the additional deposit takes place.

The most remarkable examples of morbid increase of consistence, depending on an augmentation in the quantity of healthy solid material which enters into the composition of organs, are met with in those which are naturally soft; as in the medullary and cortical substance of the brain and spinal marrow; in the lymphatic and salivary glands, and in the cellular and muscular tissues, and even in those tissues which are naturally firm and hard, as the fibrous and osseous, in which the induration is sometimes extreme. The brain has not unfrequently been found increased to twice and even thrice its natural consistence; that of glandular, cellular, fibrous, and muscular tissues, become so hard, that they occasion a particular grating sound when cut; and the walls of some hollow organs, naturally soft and flaccid, acquire such a degree of firmness, that they preserve, when empty, a globular or cylindrical form, and spring up with considerable force after sudden pressure: and parts of bones acquire that degree of hard-

* We employ this arrangement here, having adopted it as the basis of our classification of all organic diseases.

ness which has been called eburneoid or ivory-like induration.

Induration, as a consequence of a diminution in the quantity of the healthy solid material of an organ, is, perhaps, never observed, unless it is accompanied by other morbid states. It is only observed in soft, spongy, hollow organs, from which the fluids of nutrition have been removed, and for this reason we shall give examples of it under the following head.

Changes in the quantity of the fluids of nutrition frequently give rise to induration analogous to that which we have just now generally noticed, the one depending on an augmentation of the healthy solid, the other of the healthy fluid materials of an organ. The accumulation of blood in the vessels of the lungs, in the spleen, and tumours of a similar structure in various forms of congestion, produces sometimes a great degree of tension, hardness, and density of these organs.

Great diminution in the quantity of the same fluid is also followed by an increase of consistence of organs. Like the former, it is chiefly observed in the lungs and spleen, which feel as hard as liver, or even cartilage. It is, however, to be observed that the increase of consistence in this case does not follow as an immediate consequence of the removal of the fluids of nutrition of these organs, but depends on the subsequent collapse and approximation of the walls in their vascular and cellular textures. In order, therefore, that induration of this kind should be great or permanent, it is necessary that there should be, besides the primitive cause, (*viz.*, the removal of the fluids,) an external or compressing force. Hence it is that induration of the lungs, of this kind, is met with most frequently in pleurisy; the lung may simply be compressed by the effused fluid, as in the acute form of this disease, or it may in addition be permanently enclosed in a dense fibrous membrane of new formation, as in chronic pleurisy. When a lung in this state is examined, it is found to be indurated merely from the approximation of its solid textures, and may be made to assume by inflation its natural bulk and consistence when the accidental fibrous envelope has been removed from its external surface. The constricting force of such pseudo-membranes is, perhaps, nowhere so marked and so peculiar in its effects as when it covers a portion only of a lung or of a single lobe. When a whole lung is contracted, reduced to the bulk of the fist, pushed into the hollow summit of the chest, or flattened and fixed along the spine by a dense fibrous covering, the effused fluid is generally believed to be the sole cause of the diminution of bulk of the organ and of its subsequent condensation. Such, however, is not the fact. It is also owing to that very remarkable property possessed by accidental fibrous membranes, by means of which they contract during the last period of their organization, and thereby gradually compress, diminish in bulk or capacity, or entirely obliterate hollow organs. It is, as we have already observed, when pleurisy has been circumscribed, limited to a single lobe or a portion only of one, that the effects of the contractile property of the fibrous membrane are most strikingly illustrated. The portion of lung included in this membrane feels quite solid, hangs

pendulous, or projects outwards in the form of a small tongue or dog's ear; or it may have a conical or cylindrical form of various dimensions. The portion of lung so compressed and indurated is immediately recognised not only from its diminution of bulk and peculiarity of form, but by the pale, uniform, white colour of its accidental fibrous covering, instead of the mottled aspect of the lung under the transparent pleura; and the cause of its density is farther demonstrated from the absence of every external compressing cause, fluid or solid (for it is not necessary that effusion should be present in such cases), except the fibrous membrane, and from its bulk and consistence being restored in the manner already noticed.

Condensation and induration of the spleen are often effected in the same way, that is, from the constricting force of an accidental fibrous membrane.

The last form of induration which we shall mention here, produced by the fluid contents of organs, is that which is found to accompany an augmentation in quantity of the healthy fluids of secretion: as of the milk in the breasts, semen in the testes, bile and urine in their respective reservoirs. The inordinate accumulation of any of these secretions in their proper vessels gives rise to a degree of hardness sometimes equal to that of hard tumours,—a circumstance arising from the incompressibility of the fluids themselves, and the state of condensation of the walls of the organs in which they are accumulated.

2. *Induration depending on changes which take place in the composition of organs.*—The increase of consistence included under this head may be referred to the presence of accidental or new products. These may be either fluid or solid. Of the first kind we have the natural fluids of nutrition and secretion, and some anomalous fluid products; of the second, we have all the solid accidental and new products which are found in the different textures and organs of the body. By far the greater number of these products require only to be named in this place, inasmuch as the induration which they produce depends on the degree of consistence which they themselves possess, and not on any change induced in the texture of the organ in which they are formed. There are, however, others, some of the natural fluids, and various anomalous fluid products, which, when effused into natural or accidental cavities, occasion from their accumulation, or the rapidity with which they are effused, great increase of consistence of the containing solids. When blood, or serosity containing various proportions of albumen and fibrine, is effused into the cellular tissue or the cavities of organs, the distension which these fluids occasion is sometimes so great as to render parts naturally soft and flaccid, quite dense, and almost unyielding. Thus the parenchyma of organs and the cellular tissue in general, when they become the seat of hemorrhage, as pulmonary apoplexy, ecchymosis, &c., feel sometimes quite hard; and such is the state of the walls of the abdomen from the great accumulation of serosity in ascites, and of the cellular tissue of the extremities in œdema. The effusion of serosity into the intermuscular cellular tissue produces sometimes an extreme degree of induration, even when

the muscular organ is not submitted to the influence of any external compressing cause. This is particularly observed in œdema of the tongue, in which this organ becomes as hard as a piece of wood. The same state is met with in the heart, although in a much less degree; also in the brain, liver, salivary and lymphatic glands. What is called hepatization of the lungs is a modification of consistence of a similar kind, but is produced by the presence of coagulable lymph, pus, and blood, as well as serosity.

To complete the general view of the diseases from which induration may arise, we have only to add that the accumulation of gases in the cavity of the abdomen and digestive organs sometimes occasions an extreme degree of tension and hardness of the abdominal parietes, and that collections of pus, atheromatous, melicerous, and other adventitious products, constitute swellings which communicate to the surrounding parts various degrees of induration. We may also note in this place, as a cause of induration, the accumulation of the contents of the stomach and intestines so frequently produced in these organs, particularly from stricture. Thus fecal matter may be accumulated in the cæcum, and communicate to the hand the sensation of a hard tumour in that region; or the whole of the colon may be similarly distended from stricture of the rectum, and be seen as well as felt throughout its whole course of an enormous size and extremely hard; and the stomach may be so distended in stricture or obstruction of the pylorus as to occupy the greater part of the cavity of the abdomen in the form of a globular swelling, offering considerable resistance to pressure.

Although the state of induration which we have been considering has always been confined by pathologists to changes directly or indirectly induced in the solids, whereby their consistence is increased, we do not see any reason why the same alteration, when considered in a general point of view, and as implying merely a modification of consistence, should not embrace changes of a similar kind which take place in the fluids of nutrition and secretion. The various degrees of fluidity which these products are found to possess, appear, in fact, to present us with some of the most simple forms under which the various degrees of consistence of matter can be subjected to our senses, at least in so far as regards the material of organic composition. Various degrees of fluidity of the blood are observed, from a watery thinness to a state of inspissation approaching to coagulation, which last is, perhaps, a manifestation in an extreme degree of one and the same property. It is, indeed, highly probable that the consistence of the blood depends principally on the fibrine which it contains, and may vary in degree with the quantity and quality of this important constituent,—an opinion, the truth of which appears to be proved by the fact that coagulation of the blood is no other than spontaneous solidification of the fibrine. The opposite state, or extreme fluidity produced by frequent hemorrhage or bloodletting, reduces this fluid to the consistence of serosity, chiefly by the removal of the greater part of its fibrine—a further evidence of the influence which fibrine exercises on the consistence of the blood.

The consistence of the blood is always increased in a greater or less degree by whatever reduces the velocity of the circulation below that of the healthy state. The blood that first flows from a vein in phlebotomy is not only darker but thicker than that which escapes some time after, on account of its having been brought to a state of rest by the constricting force of the bandage; and as the buffy coat is generally increased under similar circumstances, it would appear that the fibrine had already assumed a disposition to coagulation; for cessation in the motion of the blood, even when very limited in duration, is always accompanied by a tendency to separation in its constituent parts and to coagulation of the fibrine. Hence it follows that ligature, tumours, and other mechanical obstacles situated in various parts of the body, and certain adynamic states, as local and general debility, which retard or arrest the motion of the blood, occasion, in the manner just stated, inspissation and coagulation of this fluid,—effects which often lead to other diseased states that sometimes terminate in death.

It may not be out of place to remark here, inasmuch as it is not our intention to discuss afterwards the changes which take place in the fluids of nutrition and secretion in the different organs of the body, that the study of this physical property, whether existing as a primary or secondary diseased state, seems to us to be one of considerable interest, and, as well as many other still more important changes of these fluids, deserves to be carefully prosecuted, and promises to those whose knowledge of animal chemistry enables them to do so, results of the highest importance. There was, indeed, a time in the history of humoral pathology when some of the physical qualities, and in particular the consistence of the blood and other fluids of the body, attracted almost exclusively the attention of the physician. But, whilst an acquaintance with the laws of fluids in motion enabled him to explain some of the changes which he observed to take place in the circulation of the blood, it was at the same time the great source of the many errors which were introduced into the humoral pathology at the period to which we allude. Nevertheless, not a few of the morbid states of consistence of the circulating and secreted fluids were known to the humoral pathologist, and suggested to him the use of various remedies for their cure. The doctrines of solidism, as exclusive as those of its now too much neglected predecessor, led away the mind of the physician from the study of the diseased states of the fluids, or induced him to ascribe the origin of those which he occasionally recognised to some previously existing disease of the solids, of which they were supposed to be merely effects, and to be removed by the cure of the primary disease. Such opinions contain much that is untrue as regards the origin of diseased fluids, and even when effects of disease of the solids, it by no means follows as a consequence that the cure of the one will necessarily be followed by the cure of the other. Facts are not wanting to prove the contrary, and to show the necessity of directing the operation of remedies in such a manner as to effect a salutary change in the pathological conditions of the fluids. But as regards the subject of our immediate

consideration—the increased consistence of the fluids of nutrition and secretion—we find not unfrequently examples of this change in the blood of certain individuals labouring under plethora from various causes, and also in many cases of great local congestion, as we have already observed.

Inspissation of the bile is a common occurrence, particularly in the gall-bladder; and here, as in the blood-vessels, the transit of the respective fluids must be more or less impeded by such a change. The formation of gall-stones appears in some instances to depend chiefly on this condition of the bile, which, being thus prevented from passing along the ductus communis choledocus, undergoes the chemical changes necessary for the formation of these accidental products.

Alarming and even fatal consequences arise from inspissation of the mucous secretion of the bronchi, larynx, and even posterior fauces, particularly in individuals debilitated by disease. In such cases the mucous secretion may be perfectly healthy, but having its fluid portion absorbed, it becomes thick and viscid, adheres to the mucous membrane, and accumulates to such a degree as to obstruct the passage of the air, and thus sometimes produces fatal asphyxia. We have ourselves seen the life of more than one individual saved by the removal of this viscid secretion from the posterior fauces and larynx, by mechanical means and change of position. The copious use of cold water given with a view to diminish the plastic property of the blood, is said to have prevented the deposition and formation of the false membrane in croup, or to facilitate greatly its subsequent removal. Are the beneficial effects obtained from the use of mercury in this disease to be attributed to a similar mode of operation?

From these general observations on the diseased states on which induration depends, we may now refer this increase of consistence of the fluids and solids of the body to the following heads:—

1. To a superabundant molecular deposit of solid nutritive matter of the same kind as that which enters into the healthy composition of a tissue—hypertrophy.
2. To an increase in the quantity of the fluids of nutrition and secretion—various forms of congestion, retention, &c.
3. To a diminution in the quantity of the fluids of nutrition—diminution of bulk from compression.
4. To the presence of solid, fluid, and gaseous, accidental and new products—scirrhus, cancer, &c., hemorrhage, dropsy, œdema, tympanitis, &c.
5. To changes which take place in the qualities or elementary composition of the fluids of nutrition and secretion—thickness, inspissation, coagulation.

It is hardly necessary to observe that several of these diseased states may exist at the same time, and by their combination give rise to compound forms of induration of one or several tissues of the same organ. The characters of each kind are, in this manner, much obscured, and can only be determined by a careful examination of the part, so as to discover the particular diseased state on which each kind depends.

Independently of this source of obscurity, the

characters of induration are frequently rendered still more obscure from the changes of bulk, form, and colour with which it is accompanied. The principal changes of bulk which accompany induration are already known to the reader. It is only necessary to remind him that induration may exist without any change in the dimensions of an organ, and that an increase is infinitely more frequently observed than a diminution of bulk.

The changes of form with which induration may be connected are extremely numerous; but as they are of no great importance in the present inquiry, we shall only observe that induration is not necessarily accompanied by any modification of this state.

Various kinds of colour are, perhaps, still more frequently found to accompany the induration of tissues, and modify the appearance which they present in a much more remarkable manner than changes of form or bulk. In the second, third, and fourth kinds of induration which we have enumerated, the sources of the greater number of the changes of colour which accompany these states are obvious. But there are others which are derived from the colouring matter of the blood deposited in tissues, or afterwards modified by the operation of external agents. Hence the colour of an indurated tissue may be quite healthy, diminished, or increased in intensity, or it may be entirely different in kind; examples of which are met with in hypertrophy, atrophy, congestion, hemorrhage, jaundice, and melanosis.

Changes in the weight, humidity, transparency, and sonorousness of organs, are not only complications, but frequently the immediate effects of induration. Those of weight, humidity, and sonorousness, are all strikingly exemplified in pneumonia terminating in hepatization; and those of transparency are not rare in membranous tissues.

Having pointed out these sources of complication, we should now proceed to describe the distinctive characters of each kind of induration; but having already entered sufficiently into this part of our subject, which we regard as embracing only the generalities of a morbid state, the physical, anatomical, and chemical characters of which belong to or are derived from other diseases, we have to refer the reader to these diseases, which we have named, for further information on this head. There are, however, certain modifications of function produced solely by the state of induration, and which may be regarded as constituting the physiological characters of this state. These are, modifications of sensation and motion. Thus pain, sometimes of the most acute kind, is produced by the hard unyielding nature of certain tumours compressing or constricting the nerves of sensation distributed to, or which pass in the vicinity of, the diseased organ. Similar effects on the nerves of motion give rise to paralysis. Motion of the solids is, besides, mechanically impeded by induration, which prevents the change of situation and bulk which ought to follow muscular contraction or that of elasticity; and the motion of the blood, bile, urine, and other fluids, may be greatly impeded, or even entirely arrested by the hard unyielding nature of accidental products. Having already pointed out the greater number of these facts which are of any degree of importance, we

shall conclude the general part of our subject with a few remarks on the symptoms, causes, and treatment of induration, considered as a morbid affection in the living body.

Symptoms.—The symptoms of induration, considered in a general point of view, are not to be separated from those of the diseases on which it depends; and although the modifications of sensation and motion which we have just noticed are the immediate consequences of this physical change, they do not furnish us with any positive sign of its existence, unless it be at the same time felt or otherwise perceived. Induration, therefore, is not to be detected during life, except in cases in which it is perceived by the touch, or the *mediate sense* of auscultation and percussion,—means which, together with the modifications of sensation and motion mentioned, and those of bulk, form, and colour, to which we have also alluded, will enable us, when properly employed and appreciated, to detect in certain organs the kind, situation, degree, and extent of this morbid state.

Causes.—The causes of induration are also, properly speaking, those of the diseased states on which it depends, and, therefore, anything we might say on this head would be foreign to the present inquiry. Much, however, has been said on the causes of induration, when employed as synonymous with the term *scirrhus*; but as we regard this state as something more than induration, or induration and hypertrophy united, we think it more consistent with the order which we have hitherto followed, to leave the etiology of *scirrhus* to be investigated in its proper place.

Treatment.—The principal part of the treatment of induration to which we have to direct the attention of the reader in this place, is that suggested by the modifications induced in the functions of sensation and motion as immediate effects of this physical condition.

When pain arises from induration, and the consequences which frequently follow this change, as weight and tension, it is seldom removed or even much mitigated when seated in internal organs, unless the exciting cause be a fluid. In this case the removal of blood is found to be sometimes followed by great diminution or even the entire cessation of the uneasiness, anxiety, or suffering, which its presence had occasioned; as in great congestion, for example, of the brain and lungs. The good effects of venesection in most cases of plethora are also in part to be attributed to the removal of a quantity of the same incompressible fluid, whereby the organs of circulation, respiration, and innervation are allowed more free and extensive action. The pain which always accompanies the vascular tension of an inflamed part, and more particularly that occasioned by the effusion of serum and pus in the cellular tissue, and beneath unyielding fibrous coverings, is still more remarkably relieved by the destruction of the constricting causes and the evacuation of the incompressible fluids. The relief which patients experience on the removal of the fluids collected in the cavity of the pleura and abdomen in acute inflammation of their respective serous coverings, in some forms of ascites and œdema, in retention of the milk, urine, &c. is to be attributed in no

small degree to the judicious application of the same principle.

When pain is occasioned by the pressure of a hard tumour, it may be mitigated or removed by the following means—change of position, warm fomentations, anodynes, extirpation, and other mechanical means. Change of position seldom accomplishes much in the way of removing pain, and has only been found to be occasionally suggested by patients themselves who have accidentally discovered that their sufferings were relieved when in certain positions; as in some cases of pendulous tumours contained in cavities.

Warm emollient applications, from the relaxing effect which they produce on the parts to which they are applied, are often of the greatest benefit. Independent of the benefit which for a time may be derived from the general administration of anodynes, more decided and more permanent advantage has of late been obtained from their local application, in the manner recommended by some French physicians, and called by them *la méthode endermique*. (Essai sur la Méth. Enderm. par Ant. Lembedt, Paris.—Trousseau, Journ. Univer. et Hebdom. de Méd. et de Chir. Pratique, tom. iv. p. 82.) This method, so far as we know, has not been employed to remove pain produced by the pressure of hard accidental products or tumours; but from its successful application in several cases of acute and chronic neuralgia in external parts of the body, we feel strongly disposed to believe that the continued and sometimes excruciating pain which accompanies certain sub-cutaneous and even deeper-seated tumours of the nerves would be greatly relieved or entirely removed by the application of the salts of morphia or belladonna (the remedies hitherto employed) to the denuded skin in the tract of the affected nerve. The cure of these cases and others of a similar kind belongs, however, to the province of surgery, and consequently we can only name the third mode, viz. extirpation, excision, and other mechanical means employed in that department of medicine.

With regard to the means to be employed with a view to facilitate the motion of solids and fluids, impeded by an abnormal increase of consistence, we have little to add to what we have already suggested on this head. The physician when compared with the surgeon is wonderfully limited in the means which he has to employ in many of these cases. Those remedies alone which exercise a special influence on the great function of nutrition in general, or on those of hematosis, circulation, absorption, and secretion in particular, seem sometimes to afford a well-grounded hope that many of the diseased conditions which give rise to induration are not altogether beyond the salutary influence of medicine.

SPECIAL PATHOLOGY OF INDURATION.

Having entered rather fully into the general pathology of induration, we do not think it necessary to discuss the special pathology of this disease, unless in the two following cases—induration of the cerebral substance, and induration of the cellular tissue.

I. Induration of the cerebral substance.—Perhaps no term has been more vaguely employed by

physicians to designate a particular diseased state of the brain than that of induration. There are, in fact, few accidental products which, at one period or other of their development, and formed in the substance or on the surface of the brain, have not been described as induration of this organ. Much of this ambiguity has, however, been removed by a more accurate knowledge of the anatomical characters of these diseases; and however obscure or uncertain may be the origin, nature, symptoms, and treatment of many of them, their being thus brought before us under a distinct and tangible form has already been productive of much good. It is, perhaps, owing to this circumstance alone that so much progress has of late years been made in the pathology of the brain.

The substance of the brain is, as we have already said, subject to an increase of consistence independent of the presence of any foreign product deposited within or upon it. It is only under such circumstances that we admit the existence of induration as a disease. Hence, it is only in certain forms of hypertrophy and atrophy that we find a simple increase of the consistence of this organ. It is, however, by no means easy in every case to determine that an increase of consistence depends alone on a modification of one or other of these conditions of nutrition; for colourless effusions, containing a greater or less quantity of albumen and fibrine, may take place in the fibrous texture of the brain, and produce various degrees of consolidation of the cerebral substance. But when such effusions are not to be detected; when there is no other morbid product present; when the brain or a portion of it is harder than we know it should be at the period at which it is submitted to our examination, we are then to consider it to be in a state of simple induration, whether its colour be altered or not. The degree and extent of such a condition of the cerebral substance may present very considerable variation. Sometimes the increase of consistence is so slight that we only admit its existence as probable; at other times it is so great as to be perceived even before it is touched, on account of the soft surrounding substance falling down when divided, and leaving the indurated portion more elevated. If, in the first case, the augmentation of consistence be circumscribed instead of being general, we have then in almost every case the means of determining how far it is a pathological state, by comparing the part supposed to be diseased with the corresponding healthy part,—a mode of examination which ought always to be had recourse to under similar circumstances in every organ of the body whenever it can be employed. We of course suppose that a previous knowledge has been acquired of the several degrees of healthy consistence of the brain in general, and of its parts in particular.

The several degrees of morbid increase of consistence of the cerebral substance may be represented to the mind of the reader by the changes of consistence which the brain itself undergoes after it has been submitted to the action of alcohol, acids, or boiling oil, for a given length of time. It then cuts like the white of a hard-boiled egg, the udder of the cow when boiled, or firm smooth cheese, such as that of Gruyère. It has been

represented to be sometimes as hard as fibrous or cartilaginous tissues; but such degrees of induration of the brain do not, we believe, exist as simple states, and depend on the presence of accidental tissues.

The greater the degree of induration, the greater the change of colour the affected part undergoes: this consists in a diminution or entire want of the natural colour of that part. Hence, the natural colour of the medullary substance being pale, a diminution of colour is principally observed in induration of the brown or cortical substance, which may become so pale as not to be distinguished from the medullary with which it is in contact.

The first as well as the succeeding degrees of induration may present this state of pallor, but it may likewise be redder than natural.—In the former the substance of the brain, when cut, is sometimes moistened with serosity, at other times drier than natural; in the latter it presents a greater number than usual of red points or streaks of blood. A thin slice of the indurated portion may be held out between the thumb and fore-finger, and, when pressed, sometimes snaps through like a bit of boiled albumen. It is only when this diseased state is circumscribed that it has been observed to be great in degree; and when it occupies the whole brain, it generally amounts to little more than what may be called a state of firmness.

An increase of bulk in induration of the cerebral substance is not easily ascertained unless the affected part be in the convolutions, in some of the circumscribed and distinct portions of it, or occupies the whole brain. A diminution of bulk accompanying the same state presents the same difficulties. Both, however, have been observed; but the former much more frequently than the latter.

The brain is far more frequently the seat of induration than the cerebellum; the cortical substance perhaps more so than the medullary; the peripheric portion of the latter more so than the central; the basis than the surface of the hemispheres.

The medulla spinalis, in which this change has also been observed in a circumscribed or general form, is much less frequently affected than the brain, and has seldom been seen to acquire the same degree of morbid consistence, except at its upper portion, and more particularly the medulla oblongata.

Symptoms of Induration of the Brain.—

Of the various authors who have observed and described induration of the brain and spinal marrow, some of them have regarded it, when general, as giving rise to ataxic or typhoid fever, and some forms of mental derangement, being in the former an acute, in the latter a chronic state of disease. Others have endeavoured to show that tetanus, epilepsy, and other nervous and convulsive disorders, may also sometimes originate in the circumscribed form of the same pathological state. Whilst we add our testimony to the truth of the anatomical part of the facts on which these opinions have been founded, we must at the same time say that we feel but little disposed to place much reliance on the diagnostic value of the symptomatic details which these authors have collected on this subject. In the present state of our

knowledge we believe that we possess no means of detecting the existence of induration of the brain and spinal marrow during life, the symptoms which have been found to accompany it—such as various modifications of sensation, motion, and intelligence—being common to many very different morbid states of the same parts. The derangements of function which follow as the immediate consequences of induration of the cerebral substance are, indeed, sufficiently obvious to the physician; but, for the reasons just stated, they afford him little or no assistance in determining the nature of the lesion on which they depend.

Causes.—The etiology of this morbid state is by no means so well understood as some pathologists would have us believe. That certain forms of it depend on a previous state of irritation, every one must admit; but that this state of irritation, or any modification of it, is the sole cause of induration, is by no means in accordance with the results of observation. In that firmness of the brain in general, observed in some forms of fever accompanied with more than ordinary excitement, and in some cases of acute hydrocephalus, in some kinds of mania accompanied or not with paralysis, irritation of the brain or its membranes may be regarded as at least the probable cause. Circumstantial induration of the cerebral substance may also originate in the same cause, inasmuch as we find it present and in juxtaposition with other diseased states, such as ulceration and abscess, having a similar origin. But for reasons equally cogent, we are led to reject the evidence on which it has been attempted to establish the general application of this principle to the etiology of this disease. When, as we have stated in the introductory part of this article, we find that portions of organs, and even whole organs, acquire a great increase of consistence without presenting any, even the slightest, modification of function as is observed to accompany irritation; that the same organ (the brain too) is soft at one period of life and firm at another; that an organ that is soft in one animal is hard in another; we cannot resist the conclusion that increase of consistence—that is, induration—when occurring out of the usual order of place and time, may nevertheless be something else than a consequence of any morbid state with which we are yet acquainted, however much we may pretend to be familiar with its ways of working. It would seem to us to be much more consistent with a sound philosophy to attribute the production at least of some of the forms of induration of organs to the influence of other and still more general laws than those of irritation, viz. those of organization; and, moreover, that instead of occupying the rank of a cause, irritation in this as well as in numerous other instances follows as an effect, and thence becomes a valuable evidence of the existence of the former.

Treatment.—As the causes of induration are obscure, and more particularly as we are unable to recognise the existence of this state during life, we have of course no indications or modes of cure to propose. We except, however, from this barren and unsatisfactory result that form of induration which we have stated may arise from an augmentation in the quantity of blood usually admitted into an organ. Such is the state of the

brain in congestion, the treatment of which is given in another place. It may not be unimportant to remark that the principal phenomena of congestion, loss of sensation and motion, seem to be the immediate effect of the state of induration induced in the cerebral substance by the accumulated blood: the degrees of density alone, which is thereby induced, being sufficient to unfit the organ for the accomplishment of its functions, independent of the other changes which we well know follow as a consequence of such congestion.

II. Induration of the Cellular Tissue.—*Syn.* Induratio telæ cellulose, sclerema; squirrhosarque; œdème concrète; œdème du tissu cellulaire des nouveaux nés; zellegewebsverhärtung; skin-bound disease.

The cellular tissue affords so many facilities for the formation and development of disease, that it has been regarded by several pathologists as the primary seat of almost all morbid products. Various circumstances, the exposition of which does not come within the scope of this article, concur to give rise to such a belief, but which is as little founded in fact as every other exclusive theory regarding the common origin of diseases. The pathological state which we have to examine furnishes a striking example of the fallacy of such generalizing principles, induration of the cellular tissue being, in point of fact, one of its most equivocal characters.

Induration of the cellular tissue constitutes a case of complicated induration, depending exclusively, as regards the local affection, on an accumulation of serosity or sero-albuminous fluid in the cellular tissue. It is therefore only in accordance with custom that we have introduced this state under the appellation of induration of the cellular tissue. We shall, however, employ the term *œdema* (instead of induration) of the cellular tissue, as it fully and accurately expresses the condition on which the induration depends, to which we may add of *new-born children*, to distinguish it from that which occurs at an after period of life. Although this affection is generally observed in children a very few hours after birth, it may occur several days later; and there are examples of children having been affected with it when born.

The subjects of this disease are for the most part feeble; sometimes imperfectly developed, and generally born before the full period. They do not seek the breast, but refuse to suck; they are agitated almost continually, and have a peculiar cry. The skin is dry, cold, as if stretched; generally of the natural red colour, but sometimes purple or livid. The soft parts feel firm, or even hard; when pressed they become pitted, and of a dull yellow colour; but the primitive form and colour soon return, unless the œdema be extreme. These appearances are generally observed to begin in the inferior extremities, passing from the feet upwards, and sometimes proceed with great rapidity, attacking the hands and arms; the inferior part of the abdomen, back, and face. Sometimes it appears to affect almost all these parts simultaneously, and nearly to the same degree. More rarely it is confined to the feet and hands. The bulk of the affected parts is increased, particularly that of the inferior extremities, but by no means

in proportion to the degree of induration which they communicate to the hand when pressed. The diminution of temperature of the affected parts follows in a descending ratio the progress of the œdema, and in some cases has been observed to precede it. The production of heat is rapidly diminished over the whole body; the inferior extremities become quite hard and stiff; the superior extremities and trunk less frequently to the same degree. In extreme cases the application of heat to the body only acts upon it as on dead matter, its temperature being suddenly raised or cooled as the warming medium is applied to or removed from it.

The other signs of functional derangement which accompany this affection increase in severity with the same rapidity. The respiration, at first imperfect, becomes difficult and laborious, and the pulse so feeble as sometimes not to be felt. In this state death supervenes from asphyxia, generally within the fourth day, sometimes on the first, and more rarely at the end of one, two, or even three weeks.

These are the most prominent and remarkable symptoms; those which may be regarded as proper to the disease. The symptoms of jaundice, although frequently present, are, however, perfectly distinct from those of this form of œdema. The same may be said of those of cerebral, gastric, intestinal, and acute pulmonary affections, which have been regarded by some as giving rise to the affection.

The characters of this disease are so well marked that it cannot be confounded, unless when circumscribed, with any other disease by the most careless observer; and even in this form it is only necessary to note the diminution of temperature which accompanies œdematous swelling, to distinguish it from any inflammatory affection of the skin which gives rise to a similar state of the cellular tissue, and in which the temperature of the affected part is always morbidly increased.

It is rare that the physician has the satisfaction of being able to pronounce a favourable prognosis in this affection after it has arrived at a certain stage. It is only when the œdema is limited in extent and not great in degree; when the circulation and respiration are not much affected; when the temperature has not sunk much below the natural standard, and when the strength of the infant can be supported by its taking the breast, that a favourable termination may be reasonably expected. In such cases, as well as in those of a severer kind which recover, the signs of a favourable issue are to be drawn from the amelioration which takes place in the state of the respiratory function, which becomes less embarrassed; the increasing strength of the pulse; the gradual elevation of the temperature of the skin; the diminution of the swelling, and particularly of the induration; the disappearance of the deep red or livid colour which it may have presented, and the supervention of a gentle moisture over its hitherto dry surface—the child becomes quiet, sleeps, and manifests a desire for food.

Before proceeding to examine into the causes of œdema of the cellular tissue of new-born children, we shall, in the first place, endeavour to give a correct statement of the facts which the

morbid anatomy of this disease has enabled us to collect.

The external aspect of the body is but little changed after death. The affected parts still preserve the same colour; the face and upper part of the trunk are even more swollen, and the induration in general is rather increased than otherwise; the softer parts, such as the face, evidently so.

When a section of an œdematous extremity, the leg for example, is made so as to expose fully the subjacent cellular tissue, instead of finding this tissue compact and indurated, we find on the contrary its cellular aspect much increased, from the cells being filled with a serous or sero-albuminous fluid, which is either quite limpid, of a citrine colour, or tinged with blood. The quantity of this fluid is in proportion to the degree of swelling and induration which accompanies it. If small in quantity, the cellular tissue requires to be pressed before its presence can be recognised; but when abundant, it distends the cells of the subcutaneous cellular tissue, and a part of it oozes or flows out from the compression which the divided skin exercises upon it, or by its own specific gravity. When the whole of this fluid is forced out by pressure from the subcutaneous cellular tissue, it then feels soft and extensible; and the skin, which was before stretched and fixed, becomes lax, and can be moved over it as in the healthy state. When examined narrowly, it is found to present no thickening, opacity, or change of consistence. Its colour may be natural, or reddened by a slight degree of vascularity. The intermuscular cellular tissue may present the same appearances, but in a much less degree.

When the serous effusion occupies the adipose as well as the cellular tissue, the feeling of hardness is increased. The granules of fat, so conspicuous and firm in the child, are in this way compressed between two forces. They appear whiter than usual, resemble the fat of meat, and are hard, as if frozen. This state of the adipose tissue does not necessarily accompany œdema of the cellular tissue, as it occurs frequently without it.

From these facts, the truth of which we have had ample opportunities of verifying in a large hospital set apart for the reception of new-born children—the *Enfants Trouvés* at Paris, it must appear obvious that the state of induration observed in these children is a purely mechanical effect, depending on the accumulation of a fluid in the subcutaneous cellular tissue. The term induration never could have been employed to designate such a morbid state, had those who first observed and described it submitted the affected parts to careful anatomical investigation. Denman, Underwood, and others since their time, have stated that the cellular tissue, in the cases which they observed, was not only hard but *dry*. As we have never met with one example of such a nature among the great many cases which we have examined, and as we know that the disease which they described is the same as that of which we are now treating, we feel disposed to doubt the reality of such cases. It would serve no good purpose to multiply facts to prove that those pathologists have been also deceived who have

described the cellular tissue in this disease as thickened and hardened; particularly Allard, who considered it in this respect as analogous to the elephantiasis Arabum, or what is commonly called Barbadoes leg. (See ELEPHANTIASIS.)

The presence of a greater or less quantity of serosity or sero-albuminous fluid in the subcutaneous cellular tissue constitutes the essential anatomical character of the disease we are describing; and in this respect it is to be regarded as œdema, differing perhaps little even in its nature from that which is much more commonly observed in adults, as a consequence of disease of the organs of circulation and respiration, and in whom it also presents to the touch the sensation of various degrees of induration.

Not satisfied with this simple explanation of induration of the cellular tissue of new-born children, some pathologists would have the effused fluid possess the property of becoming concrete, and to this circumstance they attribute the degree of hardness which the affected part communicates when pressed. For this reason, also, they regard it as different in its nature from the œdema of adults, and have on that account, and to distinguish it from the latter, called it *concrete œdema*. The results of some experiments made by Chevreul on the effused fluid taken by Breschet from the cellular tissue of children affected with œdema and jaundice at the same time, (a very frequent complication,) appeared to confirm the opinion that the induration depended on the coagulable nature of this fluid. Subsequent experiment, however, has shown that the inference drawn from the fact of the coagulable property of the effused fluid was by no means correct; for not only is this fluid not found in a concrete state in the cellular tissue of new-born children affected with œdema, but the property which it possesses of coagulating spontaneously when placed in a state of rest, and exposed to the influence of the ordinary temperature of the air, exists also in the fluid found in the cellular tissue of adults affected with ordinary œdema. In all cases, in fact, of œdema produced by an obstacle to the return of the venous blood, does the effused fluid possess this property; and so far as our experience enables us to judge, the more sudden the production of the œdema, the greater the spontaneous coagulability of the effused fluid. Hence the reason why in the œdema of new-born children, in whom the effusion generally takes place rapidly, this coagulable property is more marked than in the chronic œdema of adults. Notwithstanding these facts, we must repeat that the state of induration is neither caused nor increased by this circumstance, for we have never found the fluid coagulated in œdema of the cellular tissue after death. That it is not coagulated during life we know, from the fact that it flows out when the skin is punctured.

Besides the state of the cellular tissue which we have described, various morbid appearances are observed in different parts of the bodies of those who die of infantile œdema. Some of these are always present, and are therefore to be regarded as essential to the production of the disease; others are only occasionally met with, and on that account must be viewed in the light of coincidences.

The most remarkable among the constant lesions is a state of general venous congestion. The heart and great blood-vessels are filled or distended with blood; the lungs and liver, and indeed all the soft parts, are in a high state of congestion, particularly the former, which, when cut, discharge a great quantity of dark venous blood. There exists no mechanical obstacle in the heart, great blood-vessels, or lungs, to which this accumulation of blood can be attributed; and on that account it resembles plethora more than any other affection.

We need hardly observe that it is to this state of general congestion that the effusion of serosity in the cellular tissue is to be attributed, and that the same state of congestion, and the œdema which follows it to the lungs, are the causes of the difficulty of breathing which is present in this disease. The languid state of the circulation, and the stagnation of the blood in the capillary system in general, appear to us sufficient to account for the remarkable diminution of temperature which takes place in infantile œdema.

With this state of congestion there is, also, a greater or less degree of œdema of the cellular tissue of the viscera of the thorax and abdomen, and effusion of the same fluid into the serous cavities. The submucous cellular tissue in general is more or less œdematous; and it is this state of that glottis which occasions the cry peculiar to children affected with this kind of œdema.

These are the most remarkable of the constant lesions in infantile œdema. Those which occur accidentally, but which have been regarded by some pathologists as the causes of this kind of œdema, are numerous. The principal of them are acute affections of the lungs and liver, of the stomach and intestines, or of these and the subcutaneous cellular tissue at the same time; the non-occlusion of the foramen ovale; and a diminution in length of the intestinal tube.

Without denying that most of these morbid states, and some of them much more than others, contribute, when present, to increase the effusion into the cellular tissue, we are more disposed to believe that they are much more efficacious in retarding or rendering its cure impossible; and we are persuaded that they have no direct effect in producing it, since we have found it to exist in an extreme degree when there was no other appreciable morbid condition to be detected but the general state of congestion which we have described.

After these remarks we trust it will not be considered an omission, if we overlook most of the theories, or rather hypotheses, which have been entertained regarding the etiology of œdema of the cellular tissue of new-born children.

Andry and Auvity, the first who gave a good description of this disease, attributed its production to the action of cold; but although it occurs more frequently in winter than at any other time of the year, it is often observed in summer and under circumstances the most favourable as to external temperature.

The opinion of Breschet, that the effusion of serosity in the cellular tissue depends on the permanent opening of the foramen ovale, was soon shown to be unfounded. Indeed it is difficult to

conceive how this intelligent pathologist could have offered such an opinion as the result of his observation. "In seventy-seven children," says Billard, (*Traité des Maladies des Enfants Nouveaux-Nés*, &c., Paris, 1828,) "affected with œdema of the cellular tissue, there was in forty of them *complete occlusion* of the foramen ovale, and in twenty-eight of these even the ductus arteriosus was considerably contracted, and did not allow the passage of the blood through it. The explanation of Mons. Breschet falls, therefore, before the evidence of facts. If the foramen ovale is still found frequently open in *hard children*, it is because induration of the cellular tissue affecting particularly very young children, the changes which take place in the heart and ductus arteriosus of the new-born child, after the establishment of the independent circulation, have not had time to be completed when the œdema appears. I think, therefore, that there is no relation between the two phenomena in question."

The last opinion which we shall notice is that of Mons. Denis, who has endeavoured to show that an inflammatory condition of the cellular tissue which becomes affected with œdema, and of the mucous membrane of the stomach and intestines at the same time, are the causes of this disease. To characterize this complication, and no doubt anxious to do honour to the *Doctrines Physiologiques*, Mons. Denis has conferred upon it the appellation of *phlegmasie entéro-cellulaire*. Inflammatory affections of the gastro-intestinal mucous membrane are extremely common in infants, and must consequently be met with in those affected with œdema of the cellular tissue; and when we find œdema without them, and vice versa, we are not permitted to regard their simultaneous existence otherwise than as a coincidence. That the œdema of the cellular tissue is the consequence of inflammation, no pathologist who has examined it, and whose judgment is not biased by preconceived notions, will believe. Were such the fact, we should find sometimes, if not always, some of the products or effects of inflammation of the cellular tissue, such as coagulable lymph or pus, or softening; which we ourselves (or, we believe, anybody else, not excepting even Mons. Denis,) never once have met with.

Mons. Baron, who for a number of years has been physician to the *Enfants Trouvés*, regards the œdema of new-born children as analogous in every respect to that of adults.

An accurate observer and distinguished pathologist, Mons. Billard, who has had ample opportunity of studying this disease, considers its predisposing causes to be, 1st, a natural state of debility of the new-born infant; 2d, a state of general congenital plethora; 3d, a superabundance of venous blood in the tissues; 4th, a state of dryness of the skin before the exfoliation of the epidermis: and the direct causes, 1st, an obstacle to the course of the blood, resulting from the abundance of this fluid in the circulating system; 2d, its regurgitation in the cellular tissue, to which it furnishes an inordinate supply of the materials of secretion; and lastly, the action on the skin of external agents, which, without condensing, as has been said, the serous fluids, are capable of suspending the cutaneous transpiration, and

thereby favour the accumulation of the serosity in the cellular tissue.

(M. Valleix (*Clinique des Maladies des Enfants Nouveaux-nés*, Paris, 1838) from a consideration of the difficulty of breathing, which constantly exists, even in slight cases, along with the feebleness and slowness of the circulation, and the sanguineous congestion which is the result, is led to believe, that the development of the disease is referable to the disturbance in those two important functions, and to the stasis of the blood; hence, he has proposed for it the name of *Asphyxie lente* of the new-born; and MM. Desormeaux and Paul Dubois (*Dict. de Méd.* xxi. 161, Paris, 1840) believe that this term will ultimately prevail, in the place of the one most in use, which merely designates one of its symptoms and results.)

Treatment.—Reasoning on the evidence which we have endeavoured to lay before the reader on the nature and causes of infantile œdema, the curative indications which it suggests are but few in number. The state of general venous congestion that prevails; the diminution of temperature which accompanies this state; the dry atonic condition of the skin, and the state of debility of the little patient, constitute the chief points in the pathology of the disease to which the attention of the physician is to be directed. With a view to diminish the quantity of the blood, and thereby favour its circulation, leeches may be applied to the chest or œdematous parts; a practice which, although we have not seen it fairly tried, is said to have been remarkably successful in the hands of Paletta.

A more safe, and perhaps equally successful method of treatment employed to accomplish the same end, consists in the use of repeated friction with warm flannel, the body in the intervals being well covered with the same material, which is not to be allowed to become cool. The vapour-bath has been recommended; but it has not been found to answer the expectations of some physicians who had ample opportunities of giving it a fair trial. Mons. Baron has found friction and the application of warm flannel to the skin much more beneficial. The difficulty of breathing is sometimes greatly increased while the child is in the bath, and congestion and even sanguineous effusion have been known to take place in the lungs and brain soon after its administration.

If, under the judicious use of the means we have recommended, the pulse improves and becomes steadily more strong, the temperature soon rises, and the physician has the satisfaction to perceive that a gentle moisture breaks out over the surface of the skin. The œdema soon after begins to diminish, and with it the induration which it had occasioned; the motions of the child become more free, and the cry natural; the desire for food returns, and convalescence is complete, sometimes in a few days. Although we are not acquainted with any method of treatment so successful as that which we have recommended, it requires in many cases, either on account of their severity, the debility of the child, or the coexistence of other affections, much discrimination on the part of the physician, and a degree of care and patience not often to be found in those in whose hands it may be said the lives of these little sufferers are placed, to regulate

its application, and obtain from it its beneficial effects.

Acute affections of the lungs, stomach, and intestines, are, as we have said, extremely frequent at the same period, and when severe, destroy, perhaps, a greater number of children affected with them than the disease which we have described, and for which no mode of treatment can then be said to offer any reasonable hope of accomplishing a cure.

R. CARSWELL.

INFANTICIDE.—Before the end of the seventeenth century, medical men were not consulted in cases of infanticide. In the criminal code (*Beobachtungen und Abhandlungen von österreichischen Aertzen*, 3er. Band. Wien. 1823,) of the Emperor Charles V. it was merely directed that the breasts and parts of generation should be inspected by an experienced and sensible woman, and the delivery being, as it was supposed, ascertained, the proof of the death of the child at birth was imposed on the mother. We are told also by Bohn (*Dissert. binæ de partu enecato*, p. 336,) that a mother suspected of infanticide which could not be proved, was put to the rack to extort confession of her imputed guilt. In this country the statute of James I. was conceived in a similar spirit, for it concluded the mother to be guilty of the murder of her child, who could not prove, by at least one witness, that the child was actually born dead; a condition under certain circumstances obviously impossible, and thus rendering the statute unjust in its operation by confounding the unfortunate with the guilty. This act continued in force for nearly a century, but at length it became *customary* to require more direct proof of homicide; and by an act passed in the 43d of Geo. III. it was provided that trials for infanticide should be regulated by the same rules of evidence and presumption as were usual in other trials for murder; and thus the subject was brought more distinctly within the pale of medical inquiry.

Infanticide has been divided into *fœticide*, or the destruction of the fœtus whilst yet in the womb, commonly called *criminal abortion*; and *infanticide* strictly so called, or the destruction of the life of the child either newly born or in the course of parturition. The present article will treat of the latter division only; and the evidence respecting it naturally divides itself, 1st, into that which has reference to the child, and 2dly, into that which relates to the mother. The investigation of the following questions will comprise the most material points of medical evidence:

1. Was the child born living or dead?
2. What was the cause of its death?
3. Has the suspected mother been recently delivered?
4. Do the phenomena presented by the supposed mother and child confirm the suspected relationship?

[It may be proper to make a few remarks as to the meaning of the term 'born alive.' This is a question applicable not to infanticide only, but to other cases. According to the English law, where a man marries a woman, seised of an estate of inheritance, and has by her issue born alive, which was capable of inheriting her estate, in such case, he shall, on the death of his wife, hold the lands

for his life as *tenant by the courtesy* of England. It has, consequently, been a point of moment for the husband to show, that the child was born alive; and the said authorities have, with singular infelicity, attempted to define what shall be regarded as evidences of this condition. According to Blackstone, (*Commentaries*, B. ii. 127,) "Some have had a notion, that it must be heard to cry, but that is a mistake. Crying, indeed, is the strongest evidence of its being born alive, but it is not the only evidence." According to Coke, (*Institutes*, 30, a.,) "if it be born alive it is sufficient, though it be not heard to cry, *for peradventure it may be born dumb*. It must be proved, that the issue was alive; for *mortuus exitus non est exitus*: so as the crying is but a proof that the child was born alive, and so is motion, stirring, and the like." It need scarcely, by the way, be said, that the deaf and dumb cry at the moment of birth the same as other children. The *natural* cry is effected by them as well as by the infant that possesses all its senses. It is the *acquired* voice alone which they are incapable of attaining. Still, this blunder of Lord Coke does not materially concern the present inquiry; not so, however, the latitudinarian definition, contained in the latter part of the sentence cited from him. In a case that was tried before the Court of Exchequer in England, about forty years ago, the jury agreed that a child was born alive, because, although, when immersed in a warm-bath immediately after death, it did not "cry or move, or show any symptom of life," yet, according to the testimony of two females,—the nurse and the cook,—there twice appeared a twitching and tremulous motion of the lips; and this was sufficient to make it fall under Lord Coke's definition. It is manifest, as elsewhere remarked, (*Human Physiology*, i. 371, Philad. 1844,) that granting such motion to have actually occurred, it was of itself totally insufficient to establish the existence of vitality. On the application of appropriate stimuli, the muscles of a body may be thrown into contraction for hours after the cessation of respiration. Instead, therefore, of referring the irritability or contractility to the existence of life at the time, it must be regarded simply as an evidence, that the parts had previously and recently formed portion of a living system.

According to Mr. Taylor, the English law authorities will admit evidence of life in a child before the establishment of respiration. In the case of *R. v. Brain*, Judge Park properly said, that a child might be born alive, and not breathe for some time after birth. (*Archbold, Crim. Plead.* 367.) The same thing was admitted by Mr. Justice Coltman, in the case of *R. v. Sellis*, tried on the Norfolk Spring Circuit, in 1837. In this instance, it was alleged, that the prisoner had murdered her child by cutting off its head. The judge told the jury, that if the child were alive at the time of the act, it was not necessary, in order to constitute murder, that it should have breathed. Respiration is regarded as one but only one evidence of life.

In England, some decisions have been made as to the legal meaning of the term 'born alive,' in connection with infanticide. According to Dr. Guy, (*Principles of Forensic Medicine*, p.

120, Lond. 1843,) it has been decided, in more than one case, that to constitute live birth, the child must be alive after the whole body has been brought into the world. (*R. v. Poulton*, 5 *Carlington and Payne's Reports*, 329; *R. v. Crutchley*, 7 *C. and P.* 814; *R. v. Sellis*, *Ibid.* 850; cited by Guy, *loc. cit.*) and that it must have an independent circulation. (*R. v. Enoch*, 5 *C. and P.*, 539; *Reg. v. Wright*, 9 *C. and P.*, 154.) It would appear, however, that it is not necessary, that the umbilical cord should be separated, for the child may still be connected with the mother by the cord, and yet the killing of it will constitute murder. (*R. v. Crutchley*, 7 *C. and P.* 814; *Reg. v. Reeves*, 9 *C. and P.* 25, cited by Guy, p. 121. See also on this subject, M. A Taylor, *Manual of Med. Jurisp.* p. 472, Lond. 1844.)

Writers on infanticide, in proceeding to discuss the first question in the inquiry, have generally deemed it necessary to prefix a statement of the development of the fœtus at the different periods of utero-gestation, a knowledge of which is requisite in proving the *viability* of the child, that is, its capability of supporting extra-uterine or independent existence. Some difference of opinion has existed concerning the precise period from which the viability of the child should be dated; but it is generally agreed on among medico-legal writers, that no well-authenticated examples are recorded of children living which had been born before six months of utero-gestation. (Beck's *Elem. of Med. Jurisprudence*, Dunlop's ed., p. 119.) An exception to this opinion may be thought to have occurred in a case recorded by Dr. Rodman, (*Edin. Med. and Surg. Journal*, vol. xi. 445,) who describes his patient as having been delivered at the end of the 19th week of pregnancy. The feebleness of the child would appear to justify the correctness of Dr. Rodman's opinion, for when three weeks old, it measured but eleven inches in length, and weighed two pounds and a half avoirdupois, the clothes forming eleven ounces of this weight. But a case has subsequently been published by Mr. Baker, which renders it probable that Dr. Rodman was mistaken, for the child described by Mr. Baker (*Transactions of the Med. and Phys. Society of Calcutta*, vol. ii.), although born undoubtedly at the full period of utero-gestation, corresponded pretty closely with the one alluded to by Dr. Rodman. The absence of all allusion to the external characters of the child in the latter instance prevents any reliance being placed on it. If the membrana pupillaris had existed, it may be reasonably presumed that it would not have eluded Dr. Rodman's observation, nor escaped remark.

A description of the leading phenomena which the organization of the fœtus presents from the fourth to the ninth month will include everything on the subject which can be interesting in relation to infanticide; and these phenomena relate to its length and weight, the proportional length of its parts, the state of the skin and its appendages; of the pupil of the eye; of the internal viscera, particularly of the abdomen; of the organs of generation; of the brain; and lastly, the progress of ossification. The weight and absolute length of the body furnish but uncertain data, since they vary much in different fœtuses of the same age.

But Chaussier (*Médecine Légale*, &c. par Lecieux, &c. 1819, p. 17,) has pointed out an excellent criterion, founded on a very extensive examination of subjects, in the comparative length of its several parts at different periods. If in a well-proportioned adult a line be drawn from the top of the head to the heel, its centre corresponds with the upper edge of the pubis. But in the fœtus this central point is situated much higher; for in a mature child it corresponds with the umbilicus or a little above it; at the end of the eighth month it is about an inch higher; at the end of the seventh still nearer to the sternum; at the end of the sixth it falls just at the end of that bone.

The average weight of the fœtus at four months is from five to seven ounces; at five months, about a pound; at six months, two pounds; at seven months, from three to four pounds; at eight months, from four to five pounds; at nine months the average weight in this country is about seven pounds (*Phil. Trans.* vol. lxxvi. p. 394; *Hunter's Anatomy of the Gravid Uterus*, p. 68), the most frequent range being from five to eight pounds. Lecieux and Bernt have remarked that the length of children at the full period is less liable to variation than the weight. The following is a transcript of the table of the former.

Months.	Inches.
4	5 to 6
5	9½
6	12
7	14
8	16
9	18

And he agrees with Baudelocque in stating the extremes in mature children to be from sixteen to twenty-two or twenty-three inches. (*Médecine Légale ou Considérations sur l'Infanticide*, p. 11.)

At the *end of the fourth month* the skin is rosy and moderately dense. The pupillary membrane is very visible; the meconium a little coloured, and occupying the commencement of the small intestines. The brain exhibits the interlobular furrow. There is a commencing ossification of the vertebrae of the sacrum. The kidneys are very voluminous, consisting of from fifteen to eighteen lobes, the suprarenal capsules being as large as the kidneys.

At the *end of the fifth month*, the scalp is covered with short silvery thinly scattered hair; the skin is of a deep red colour, but without sebaceous covering; the adipose membrane is but little developed; the nails are scarcely perceptible. There is commencing ossification of the first bone of the sternum, of the pubis and os calcis. The volume of the lungs is small, the heart is large, the ventricles little distinguishable from the auricles; the liver very large and near the navel, consisting of two equal lobes. The gall-bladder contains a little, almost colourless, serous fluid; the spleen is little developed and close to the stomach; the meconium is in small quantity, and only occupies the cæcum and a small portion of the colon. In the male fœtus the testicles are situated beneath the kidneys, near the lumbar vertebrae. In the female the ovaries are small, soft, elongated, very distinguishable from, and in a similar situation to, the testicles in the male. The brain on the surface is smooth, but several deep furrows

and convolutions are now visible on the inner aspect of the hemispheres where they are applied to the falx cerebri.

At the end of the sixth month, all the external parts are very distinct. The skin is very fine, of a deep red or even purple colour, particularly in the palms of the hands and soles of the feet, face, lips, ears, and breast. The stomach is filled with mucus; a part of the large intestines with meconium. The colon begins to exhibit its sacculated character. The testicles are still in the abdomen under the peritoneum. The bladder, hard, pyriform, and above the pelvis, has but a small cavity. About this period two points of ossification are formed in the second cervical vertebra; near the seventh month the superior point, which answers to the odontoid process, is larger than the inferior, which relates to the body of the bone. According to Tiedemann, the posterior lobes of the cerebrum now cover the corpora quadrigemina, and almost the whole cerebellum. The three cornua of the ventricles are quite distinct. The choroid plexus is very voluminous. The laminae of the septum lucidum are joined so as to form the fifth ventricle. The corpus callosum extends further backward, but does not yet cover the thalami and third ventricle.

At the end of the seventh month the skin is dense and fibrous, and is covered with the *vernix caseosa cutis*, unequally thick in different parts of the body. The pupillary membrane has disappeared. The hair is longer and of deeper hue; the nails are firmer, but do not extend to the ends of the fingers. The bile is yellowish and bitter. The meconium occupies a considerable part of the large intestines. The valvulae conniventes begin to appear. The testicles and ovaries are nearer the pelvis. The posterior lobes of the cerebrum now cover and extend beyond the cerebellum, and several furrows and convolutions are observable on the surface. The corpus callosum covers the thalami, and consists of transverse fibres passing from one hemisphere to the other. The corpora quadrigemina are divided by a transverse line or furrow rendering them complete and distinct, the two superior, or nates, being somewhat longer than the two inferior, or testes, and their parietes so thick that the iter a tertio ad quartum ventriculum may be considered perfect.

At the eighth month the skin becomes covered with very fine short hairs, the skin itself is denser and whiter, and the nails are firmer and more elongated. The sebaceous covering is more general. Oftentimes the breasts are projecting, and a milky fluid may be expressed from them. In the male the testicles are generally engaged in the abdominal ring. About this period the transverse processes have begun to ossify in the first lumbar vertebra. The structure and configuration of the interior parts of the brain, already completely formed, have only to be augmented in volume, the surface to be farther developed. The two hemispheres of the cerebrum extend backward considerably beyond the cerebellum. The hemispheres on each side are traversed with furrows, into which the folds of the pia mater enter, but these furrows, or the convolutions which they produce, are nowhere so marked as on the anterior and middle lobes.

At nine months ossification is more complete. The descending ramus of the os pubis and the ascending ramus of the ischium are consolidated. Ossification has commenced in the first cervical vertebra, and also in the first bone of the coccyx. The body of the fourth lumbar vertebra, which is the most voluminous, is three lines in depth and six in breadth. The lateral portions of the six superior dorsal vertebrae begin to unite so as to form a ring posteriorly to the bodies of these bones. The bones of the cranium, although movable, are in contact at their margins. Generally the testicles have passed the abdominal ring, or even descended into the scrotum. The nails are thicker and firmer, and are prolonged to the extremities of the fingers. Capuron states that the grey matter is now visible in the brain, but Tiedemann asserts that at no period is it possible to distinguish between the cortical and medullary substance in the foetus.

We shall not be understood to pretend that the preceding details will be found precisely to indicate the age of the foetus. Much variety is found in different children at the same age; but an attention to the criteria now laid down, particularly as they relate to the progress of ossification; to the development of the brain, and relation of the umbilicus to the centre of the body, for which we are indebted to Béclard, Tiedemann, and Chaussier, will enable the inquirer to form a tolerable approximation to the truth.

[In another work, (*Human Physiology*, 5th edit. ii. 470, Philad. 1844,) the writer has drawn attention to the wide discrepancy that exists amongst observers in regard to length, weight, &c., at different periods of foetal existence. Nor are they more agreed in regard to the test proposed by Chaussier. Of 500 children examined by M. Moreau, at the Maternité, in Paris, the umbilicus corresponded to the centre of the body in four only. In the majority of cases, it was eight or nine lines below the centre; and he found that in some children, born about the sixth or eighth month, the cord was inserted at the middle point of the length. (*La Lancette Française*, 1837.) Among many cases, too, of mature children, which Mr. Alfred L. Taylor had an opportunity of examining, the umbilicus was found to be generally from a quarter to half an inch below the centre of the body. (*Guy's Hospital Reports*, April, 1842; and *Manual of Medical Jurisprudence*, p. 489, Lond. 1844.)]

The advantage arising from the investigation of the anatomy of the foetus is, that it enables the inquirer to decide on the maturity or immaturity of the child, and to set at rest its capability of being born alive. If the child were mature, the greater is the probability of its having been born living; if immature, the likelihood of death from natural causes is considerable. And in either case it is creditable to the investigator, and indeed necessary in drawing up a medico-legal report on a child found dead, to indicate with some precision the age of the subject under examination.

I. At the time when concealment of birth and evidence of the life of the child were allowed to form conclusive proofs of the commission of infanticide, the inquiry, whether the child was born living or dead, was of paramount importance;

and it is still one of considerable interest to the medical jurist and lawyer. The proof of the child having been born alive forms, in trials for infanticide, presumptive evidence in favour of the charge; whilst evidence of its having been still-born will confine the investigation to the proofs of death from criminal violence during parturition,—a species of child-murder commonly requiring the aid of an accomplice, and hence an infrequent form of infanticide.

The proofs of the survival of the child after delivery must be drawn from the phenomena of *respiration* and *circulation*, as it is chiefly by the performance of the former, and the changes which take place with respect to the latter, that the commencement and continuance of extra-uterine life are indicated. These phenomena relate principally to the *colour of the lungs*, their *consistence*, *specific and absolute weight*, and their *volume*; to the *contraction of the ductus arteriosus Botalli*, and its diameter in relation to that of the pulmonary artery and its two great branches.

1. *Colour*.—The colour of the fetal lung is dark red, sometimes inclining to the brownish red of the liver, or the blueish red of the thymus; but in those parts of the lung in which respiration has had an influence, it is pale red or scarlet, unless they are gorged with blood, in which case it may be brownish or blueish red. From the experiments of Bernt (*Experimentorum Docim. Pulmon. Hydrost. illustrantium Centuria I. curante Jos. Bernt, M. D., &c. Viennæ, 1823.*) it results that artificial respiration in a dead child, if it changes the colour at all, causes a pale or greyish red tint. In children who have breathed imperfectly, or only for a short time, the lungs on the anterior surface are of a pale red, on the posterior surface dark red, whilst in different parts of the lungs patches of scarlet red are visible. In children who have breathed perfectly and lived a longer time, the lungs are pale red with numerous patches and stripes of cinnamon or scarlet red; posteriorly they present a dark red colour, owing to the subsidence of the blood.

2. *Consistence*.—The lungs, in the fetal state compact, become from respiration looser and expanded. They are vesicular on their surface, and air-bubbles or froth may be squeezed out of them. These are circumstances to be determined by the touch and sight, and result from their mechanical distension by the air. Three sources have been enumerated, besides natural breathing, from which air found in the lungs may be derived, namely, artificial inflation, putrefaction, and emphysema. The two latter produce vesicles which are superficial, large, and irregular, and which may be pressed out, so that the fetal lung will sink, which can never happen when the lungs have been distended by natural breathing or insufflation.

A general presumption only can be drawn from the consistence of the lungs. If they are soft and have a regularly vesicular appearance, respiration either natural or artificial must have taken place, and a reference to the other tests of independent life will show which of the two has happened.

[According to Dr. Guy (*Op. cit.*, p. 123,) the smallest quantity of air, received into the lungs by respiration or insufflation, serves to develop some of the air-cells on their surface, and these developed air-cells form the best proof of the admission of

air in one of the two modes mentioned. The air-cells, thus developed, present, he remarks, an appearance not to be confounded with any other. If the lungs are fresh and filled with blood, the position of these developed air-cells is marked by brilliant vermilion spots; if the lungs contain less blood, the spots are of a lighter colour; and if they be examined some days after the birth of the child, they will be found to have lost their bright vermilion hue, and to have assumed a light rose colour. In the lungs of children who have survived their birth some days, the air-cells have very nearly the colour of those of the healthy adult lung.]

3. *Specific Gravity*.—It was known to Galen that the fetal lung sank in water, but that after respiration it floated, and these facts form the foundation of the hydrostatic test. Swammerdam affirmed that the lungs would float if only one inspiration had taken place, in which assertion he has been followed by Haller, Daniel, and Dr. W. Hunter.

But subsequent experience has shown that the specific gravity of the lungs before and after birth does not observe an uniform ratio. It has been ascertained, first, that newly born children may live some time without respiration; secondly, that after respiration has been carried on for some time, the lungs are not uniformly dilated, and occasionally to so trifling an extent only, that they sink in water, or sometimes that the lungs are unequally dilated or diseased; and thirdly, that in some still-born children the specific gravity is less than that of water, which may arise from breathing before complete birth, from artificial inflation, or extrication of air through other causes; and objections to the conclusiveness of the hydrostatic test have been alleged for these several reasons.

a. It is a fact familiarly known to all obstetrical practitioners, that children occasionally do not breathe till they have been born for some time; but there are no means of determining whether a child found dead could have been animated had the proper measures been resorted to. And the proof that a child so circumstanced had been murdered must rest on the evidence of existing mortal injuries, which it was morally impossible could have been the consequence of accident, but must have resulted from criminal violence. In short the evidence of murder in such a case must be similar to the proofs of infanticide during parturition.

b. But the lungs may sink, although the child have breathed for some time, owing to their imperfect dilatation. Craanen (*Commentatio de Infantum nuper natorum Umbilico et Pulmonibus, Auctore G. F. Daniel, Hallæ, p. 100.*) described it as a frequent occurrence, and had the merit of pointing out how the fallacy might be obviated. He recommended that each lobe of the lungs be cut into small portions and thrown into water. If all sank, he inferred that the child died in utero; but if a few fragments floated, he concluded that the child had survived delivery. The imperfect dilatation of the lungs after respiration has been usually found in immature children, but cases have been related by Schenkus, Bernt, and others, of children born at the full time, and who had lived one or more days, whose lungs sank in water; and we recollect an example of the same kind which occurred to the late Dr. Wm. Cullen of Edin-

burgh; [and a similar case is related by Mr. A. Taylor, (*Guy's Hospital Reports*, No. V.)] The proceeding recommended by Craanen is, no doubt, applicable to all such cases; and the conditions of the ductus arteriosus Botalli and pulmonary arteries, to be hereafter noticed, would, in conjunction with other proofs, remove all doubts concerning the conclusiveness of the hydrostatic test in similar instances.

c. A diseased condition of the lungs may also prevent their floating after respiration, but it is extremely rare to find the foetal lungs in such a state of disorganization as to admit so little air that the whole lung will sink in water. Such a pathological state must be quite conspicuous, and the proceeding recommended by Craanen would easily obviate the fallacy, for if life had been maintained at all, some portion would float.

d. Hoffmann, (*Tom. vi. p. 213.*) Bohn, (*Dantel*, op. cit. 108.) and Hutchinson, (*Essay on Infanticide*, 1820, p. 52.) have related examples of lungs which have sunk from congestion of blood in consequence of suffocation. The best informed pathologists, Meckel for instance, have doubted the possibility of such an occurrence; but the fact has been attested by the three authors just named. This is an objection to the hydrostatic test easily corrected, for after gently pressing out the blood, the lung will float. Thus, although the lungs may sink in a child which has outlived birth, the circumstances under which this may happen are known, and can be readily detected and allowed for.

It has been further observed that the lungs in children notoriously still-born will sometimes float, and the circumstance has been adduced as a ground of objection to the hydrostatic test. Such floating has been ascertained to depend, first on breathing before delivery, the child nevertheless dying before complete expulsion; and secondly, the lungs may be rendered specifically lighter than water by artificial inflation, by putrefaction, or by a species of emphysema, first noticed by Schmidt, (*Neue Versuche und Erfahrungen*, &c. S. W. Wien, 1806.) and subsequently more distinctly characterized by Chaussier. (*Lecieux*, op. cit.)

e. The possibility of uterine respiration was denied by all writers down to the time of Bohn. (*Daniel*, op. cit.) He first maintained, in 1700, that in difficult labours a child may draw in air enough to suffice for the distension and floating of the lungs, and yet die before delivery. Brede-noll has related a remarkable example in Siebold's *Journal für Geburtshülfe*, Band I. It was a case of twins; the first child had been delivered by the forceps, the membranes ruptured, and the hand introduced to turn the second, whom he heard distinctly to cry for at least a dozen times. Bernt has mentioned four somewhat analogous cases. In a child delivered by turning and destruction of the brain, every fragment of the lungs floated. (*Edin. Med. and Surg. Journ.* xxvi. 371.) Of the other three cases, two foetuses were extracted after the mother's death, the vagina in the one and the neck of the womb in the other having been ruptured; and the third was extracted by the forceps on account of tedious labour. In these the lungs sank when entire, but many fragments floated, and in all the four examples every other test coincided with the hydrostatic to justify

the inference that the children had respired. Until recently the evidence in favour of uterine respiration had been altogether supplied by German authorities; lately, however, Professor Marc has recorded an unequivocal example of the kind communicated to him by M. Henry, which has removed the scepticism formerly entertained on the subject by the learned professor, and others also we presume. A woman, having a deformed pelvis, and pregnant for the third time, was in labour on the 10th of October, 1827. M. Jobert was in attendance, and called in M. Henry to his assistance. Having ascertained that the deformity occasioned an obstacle to delivery, M. Henry observes,—“M. Jobert and I thought that it might be necessary to turn the child, but as the head did not appear to be very voluminous, we hoped to be able to disengage it by means of the forceps. That instrument was applied; and as soon as M. Jobert commenced the attempts at extraction, the foetus uttered repeated cries during a dozen seconds, so distinct as to be heard by all the assistants. But as the head remained impacted in the pelvis, notwithstanding the efforts made with the forceps, we were obliged to desist from this attempt.

“Whilst we were discussing the necessity of turning the child, these cries were renewed as distinctly as on the former occasion, and in such a manner as could only take place in consequence of repeated inspirations. Finally, when introducing my hand to seize the feet, the moment it passed over the left shoulder the foetus for the third time uttered cries, less prolonged than the preceding, yet sufficiently loud to be heard by all present.

“The delivery was completed with much difficulty, and the child did not breathe after its expulsion; but as the pulsations of the heart were pretty strong, we tried various means to resuscitate it, among others insufflation of the lungs. Our attempts were fruitless, for at the end of some minutes the circulation had ceased. I regret that I cannot describe the state of the lungs, but as insufflation was practised, an examination of them could not have afforded precise and unexceptionable information.” (*Dict. de Médecine*, xii. 154.)

But the case now to be related proves incontrovertibly that these cries may be uttered by a child in utero, and subsequently born alive without assistance. It is described by Dr. A. F. Holmes, Lecturer on Chemistry and Materia Medica, McGill College, Montreal. (*Edin. Med. and Surg. Journal*, No. cii. 215.) “On the 29th of November, 1828, I was called to a lady in labour of her sixth child. The fontanelle presented, but the pelvis being capacious, and her labours generally easy, no attempt was made to change the position. The head continuing to descend, the mouth lay on the pubis, and the examining finger could easily be introduced into it. The occiput did not yet occupy fully the cavity of the sacrum. At this time I heard sounds like the cries of a child whose mouth was muffled by some covering, but not being very distinct, and not being at all prepared for them, I thought, when they ceased, that they must have been produced by flatus in the intestines of the mother. In the course of a short

time, however, the cries were repeated, and with the greatest distinctness, so as not to admit of a doubt that they proceeded from the child. The mother, much alarmed, inquired the cause of these noises, and required to be assured that they were not indicative of any danger. The pains being brisk, the head was soon forced down and expelled. The child was a female, and is still (August, 1829,) alive and thriving." [See, also, an undoubted case, on the authority of Dr. Collins, of Dublin, in his *Practical Treatise on Midwifery*, &c. Lond. 1835.]

The evidence for vaginal respiration is equally conclusive. Formerly Professor Marc (Manuel d'Autopsie Cadaverique, traduit par C. C. H. Marc) endeavoured to show that, from the compression of the fetal thorax in the passages, it was impossible; but his reasoning must yield to the unquestionable testimony of Schmidt, Oslander, and Capuron, each of whom has witnessed it. In relation to infanticide it has been usual to disregard the vagitus vaginalis, as occurring only under circumstances which could not lead to doubt in the decision; either because it was only heard after the expulsion of the head, when there could be comparatively but little difficulty on the part of the mother, and as little danger to the child in the accomplishment of complete expulsion; or that it occurred in presentations of the face and feet, in which delivery could not be completed without great difficulty or foreign manual assistance, and was therefore not likely to occur in medico-legal practice.

The experience of practitioners will not completely justify this view. It is undoubtedly for the most part true, that when the head is expelled, the complete birth of the child is attended neither with difficulty nor danger; but the case related by Dr. Hosack (Beck's Med. Jurisprudence, p. 164) proves that a child may perish after the expulsion of the head and before complete delivery, and that in the interval it may breathe and cry. The editors of the London Medical and Physical Journal (Vol. lxii. p. 423) have observed a similar occurrence; and every practitioner of experience must have met with presentations of the face and feet, in which delivery has been completed by the unassisted expulsive efforts of the uterus. (Heath's Baudelocque, ii. 224.)

Uterine and vaginal respiration appear therefore to constitute a possible objection to the determination of the life of the child after birth, which may sometimes be insuperable. The correct objection to oppose to it, is the rarity of such a conjunction of circumstances as is indispensable for the occurrence; and the full expansion of the lungs, if present, would render such a plea more than doubtful.

The lungs may float from insufflation or artificial respiration, and Bohn (Beobachtungen und Abhandlungen von Oesterrischen Aerzten, u. s. w. iii. Band, S. 45) and Camper (*Daniel*, op. cit. p. 163) have quoted instances in which it had been successfully practised by blowing air into the lungs with the mouth. Schmidt (Neue Versuche, u. s. w.) has investigated the subject of artificial respiration, and established the facility with which it may be practised. According to his experiments crepitation is always present, and the dis-

tension of the thorax is permanent, but the ratio of the weight of the lungs to the rest of the body remains as in dead-born children. The results of the *static* test, the colour of the lungs, and the unaltered conditions of the ductus arteriosus Botalli and pulmonary arteries would distinguish insufflation of the lungs in a dead child from respiration, either natural or established artificially in a living one.

It is impossible to conceive, however, that a woman charged with infanticide, who had attempted to resuscitate her child by insufflation, could fail to produce satisfactory proofs of her innocence; for it may be reasonably presumed that a child subjected by a mother to such an attempt would not exhibit any signs of criminal neglect or wilful ill-treatment, whilst the attempt to inflate the lungs would form a presumption in favour of the accused. Morgagni (*De sedibus et morborum causis*, Epist. xix. art. 47) and Dr. W. Hunter have suggested that insufflation may be practised by another person from a malicious motive towards a mother; but were such an apparently incredible occurrence to happen, the results of the other indications of life would demonstrate by what means the lungs had been expanded.

"Medical jurists," says M. Devergie, (*Dict. de Méd. et Chir. pratique*, vi. p. 345, [and *Méd. Lég.*]) "have endeavoured to represent the expediency of drawing positive conclusions from the evidence under consideration, by alleging that a woman may have inflated the lungs of her own child for the purpose of restoring it to life; or that another person may have done so from a criminal motive towards the mother. Such observations are just, but a multitude of cases occur where the circumstances in which the body of the child and the author of the crime are found, totally exclude them from consideration. For example, a child has been thrown alive upon the ice of the Seine, undoubtedly *living* at the time, for it presents all the signs of injury which can result from such a fall; another is found in the water, inclosed in a bag firmly sewed up; a third is thrown into the street, the mouth and pharynx filled with linen, so as to produce suffocation; a fourth floats on a river inclosed in a paper box, and so enveloped in linen as to prevent the access of air; a fifth has been thrown into a privy; a sixth dismembered and buried in an unfrequented situation. Certainly none of these proceedings could have been the act of a mother who had practised insufflation in order to restore her child to life, nor could it be attributed to a person, who, having wickedly simulated a crime, would have an obvious motive in proclaiming its apparent existence."

[M. Devergie (*Méd. Légale*, 2de édit. art. INFANTICIDE, Paris, 1840) affirms that in many cases he could determine, whether the distension of the lungs with air had been the effect of respiration or of insufflation. In the case of air introduced by respiration, he states, there is a minute injection of capillary vessels on the surface of the air-cells, which injection does not take place in the case of insufflation. It is properly remarked, however, by Dr. Guy, (*Op. cit.*, p. 125), that although this distinction may be well founded, it deals with parts so extremely minute, and according to M. Devergie's statement is to be relied on

only in *many*, but not in *all* cases, that it may be fairly set down as unfit for the use of those who have not taken the pains to examine the lungs carefully and minutely for themselves; and he adds, that there is one case in which the distinction laid down by M. Devergie would entirely fail; that is, where lungs that have respired contain but a very small quantity of blood; in such case, the capillary vessels would, in all probability, present no strong signs of injection.

It has been affirmed, too, of late years, (Mr. Alfred Taylor, *Lond. Med. and Phys. Journ.*, Nov., 1832, and Jan. and May, 1833; and Mr. Jennings, *Transactions of Provinc. Med. and Surg. Association*, for 1833,) that if air be introduced into the lungs by insufflation, it may be always forced out by pressure, so that the lungs will sink; whilst no pressure will force the air from lungs that have respired. It would seem, however, that the test does not distinguish imperfect respiration from imperfect insufflation; and on the other hand, the experiments of Dr. Guy (*Op. cit.*, p. 138,) would seem to have proved that lungs completely distended by insufflation, cannot be made to sink by a degree of pressure short of that which will destroy the texture of the lung; and that lungs so distended with air differ from those which have breathed completely only by requiring somewhat more pressure to make the latter sink; and he infers from his experiments, that where portions of lungs that have been inflated are submitted to the same amount of pressure with portions of lungs that have respired, the only difference observable is one of *degree*, the inflated lung, like that of the lung which has breathed, not sinking until its texture is destroyed, but a less amount of destruction being necessary in the former than in the latter.]

An objection to the hydrostatic test has been drawn from the putrefaction of the lungs, and the consequent floating from the air thus disengaged. Although this is an objection of very little practical importance, it has occasioned much controversy. Heister, (*Bernt*, in *Abhandlungen und Beobachtungen*, S. 56,) in 1722, observed the lungs of a child which had died in the womb, to float both whole and in pieces, and the known circumstances of the case proved that insufflation could not have been practised. Haller (*Bernt*, *Abhandlungen und Beobachtungen*, S. 56) instituted experiments on the subject. He allowed the lungs of a dead-born child to become putrid in water, and saw them float after seven days in the same water. The colour was changed from dark to light red, and they were covered with air-bubbles. A dark-red compact-feeling lung out of another body, already powerfully offensive, sank both entire and in pieces. He concluded, therefore, that considerable putrefaction was necessary to cause the floating of the lungs. Camper had previously made the same remark, and had found that, when the whole body was so far advanced in putrefaction that the joints separated with the slightest touch, the lungs had only begun to decay, and would not float in water. Jaeger, from experiments and observations on the difference between sound and putrid lungs, drew the following conclusions: a lung which floats from putrefaction is distinguished from one which does so

from breathing, by the situation of the former against the spine, by its dark red colour, and by the air being found under the outer membrane in the form of bubbles, (See *Hunter*, *Med. Observations and Inquiries*, vol. vi. p. 284,) and by the easy escape of the air after cutting into the lungs and the subsequent sinking of them. The air developed by putrefaction he found to escape with much facility by means of incisions and gentle pressure; not so in those which floated from respiration. Mayer (*Schlegel's Collectio Opusculorum*, vol. i.) also engaged in an extended series of experiments on the putrefaction of the lungs. He found that on placing the lungs of still-born children in water, in the course of two or three days their colour changed, and they increased in volume. By the eighth day at latest they floated, both whole and cut into pieces, in the water in which they became putrid, but, transferred to clean water, although they still floated, yet on the slightest compression they sank. The rays of the sun accelerated the putrefaction, but a current of air retarded it, so that they did not float until the tenth or eleventh day. After having once floated, they continued to do so, emitting daily a more offensive odour and acquiring an increased volume, until the twenty-first or at latest the thirty-fifth day. After that period they gradually sank down, without a single exception, to the bottom of the vessel, nor did they afterwards in the least float, although kept for seven weeks or even longer. Beck (*Medical Jurisprudence*, p. 157) and Orfila have confirmed these results of Mayer, to which M. Devergie has added the following interesting practical correction. Referring to the above experiments, M. Devergie observes, (*Dict. de Méd. et Chir. prat.* vi. p. 342, [and *Méd. Lég.*]) "Although the above experiments appear incontestable, an accidental circumstance may completely change their results, so true is it that practical deductions drawn from experiments are frequently liable to error. In the number of the *Annales d'Hygiène et de Médecine Légale* for Oct. 1830, I published two cases of infanticide submitted to my examination, in which putrefaction of the lungs with development of gas was evident. The children had been thrown into the Seine, remained in the water seven or eight days, and subsequently exposed to the air from twenty-four to thirty-six hours before being opened.

"It is ascertained that, whenever a person drowned is taken out of the water after having been submersed for ten or fifteen days, if the temperature of the atmosphere ranges between 15° and 25°, a considerable development of gas takes place in the body immediately on its exposure to the air. In consequence of this disengagement of aeriform fluid, which takes place not only in the subcutaneous tissue, but even in the internal organs most protected from the agency of the atmosphere, the fluids of the body are conveyed to the surface, bullæ are formed, sanies exudes from the cutaneous pores in general, and escapes also by the natural openings. In a great number of bodies the development of putrid gas is so considerable as to effect an alteration in the posture of the limbs, and even to change the general position of the body. Thus, it has been found necessary to secure the bodies, publicly exposed at

the *Morgue*, to the tables on which they are placed. Before this precaution was adopted, the bodies occasionally fell to the ground; and strangers frequently hastened to inform the porter that an individual placed there was not dead, for they had seen him move.

"The phenomena observed in the body of an adult found drowned, develop themselves with equal or greater rapidity, under the same circumstances, in the foetus. Now it is very rare that a medico-legal examination of a body takes place, before the *procureur de roi* (in England the coroner) has been informed of it; hence at least twenty-four hours generally elapse, during which period the body is undergoing the changes indicated above, and the lungs become as emphysematous as possible."

We have said enough, however, to show that air developed in the lungs by putrefaction must be an extremely rare event, that it is easily recognised, and any fallacy arising from it readily avoided.

Alberti (*Daniel*, op. cit. p. 120) in 1728 threw out a hint that the lungs sometimes contained air which was derived neither from putrefaction nor respiration. In 1806, Schmidt (*Neue Versuche*, u. s. w.) confirmed the observation, remarking that bubbles of air appear in the lungs which do not betray the least trace of putrefaction, and that they are thereby rendered capable of floating. The same phenomena occurred to the observation of Chaussier, (*Lecieux*, p. 56,) who suggested the following method of obviating the fallacy: "In these instances," says he, "the aeriform fluid is contained in the cellular tissue of the lungs, whence it may be expelled by pressure, after which the lungs thrown into water immediately sink. This does not happen if the air was contained in the minute air-cells."

The preceding observations include all the objections alleged against the conclusiveness of the hydrostatic test as a proof of extra-uterine life. If we except the rare and barely possible occurrence of uterine or vaginal respiration, it must be evident to every candid mind that these objections possess neither conclusiveness nor force; and that the circumstances on which they depend can be so easily and fully appreciated as to avoid any error which could lead to the crimination of the innocent. Of the considerations to be opposed to the *vagitus uterinus* we have already spoken, and shall again advert to them before the conclusion of this article.

4. *The difference between the weight of the lungs before and after natural respiration.*—This constitutes the *static test* first proposed by Ploucquet* in 1777. Experience, however, soon showed that this test was limited in its practical application, since, in some children who had lived several days, the weight of the lungs proved to be less than that frequently observed in still-born children.

[The recent experiments of Dr. Guy (*Lond. Lancet*, Oct. 1, 1842, and *op. cit.*) have shown in a signal manner the limited application of the absolute weight of the lungs as a test; for, of 34 cases, there was not a single one in which it could

have been pronounced, by means of this test alone, that respiration had or had not taken place; whilst in this instance the great weight of the lungs would have led to the inference that respiration had been effected, although the children were still-born.]

It was, therefore, suggested to substitute as a criterion, the *relative* weight of the lungs, before and after natural respiration, to the whole body. But the experiments and observations of Chaussier, Schmidt, and Bernt, have shown the inutility of this modification of the static test, by pointing out that in many still-born children the ratio was a lower one than the average for children who have breathed, and vice versa. Schmidt, seeing therefore that this method was not an improvement, proposed to return to the original mode of judging by the *absolute* weight of the lungs, and to confine the application of the static test in this form to those cases in which the weight is such as is never attained by the natural and healthy *fœtal* lung. In twenty-four still-born children examined by Bernt,† the greatest weight of the healthy lungs was 993 grains, and he states the medium at about 550 grains. The form of the static test recommended by Schmidt is very limited in its application for the lungs of children who have outlived delivery; not more than one in six or seven equal their former weight. When the *fœtal* lungs, being naturally formed and of healthy structure, exceed 1000 grains, such weight may be considered as constituting decisive proof that the floating of the lungs and their loose and expanded appearance do not result from insufflation practised on a dead child, but must be a consequence of the continuance of respiration and of the circulation of blood through them, and therefore of life; and even if the weight exceed in any considerable degree 550 grains, the same inference is a reasonable presumption.

5. *Size of the Lungs.*—As respects the volume or circumference of the lungs, it is observed by Bernt (*Handbuch*, 266) that naturally formed and healthy *fœtal* lungs which have not respired, occupy the posterior part of the thorax, merely touching the pericardium with their anterior borders. The posterior half only of the arch of the diaphragm is covered with them: the edges are sharp, the margins of the right, middle, and left upper lobes forming small pointed, tongue-shaped elongations. If, however, the child have lived a very short time after birth, and breathed only imperfectly, the lungs are found to occupy the lateral parts of the thorax also; their anterior borders and the tongue-shaped elongations of the right, middle, and left upper lobes are become round either partially or altogether. After full and complete respiration the lungs entirely fill the lateral cavities of the thorax; their anterior borders cover the sides of the pericardium, and their concave surface the whole arch of the diaphragm; their borders are everywhere rounded, and the tongue-shaped prolongations of the right, middle, and left upper lobes are short and obtuse.

6. *State of the Ductus Arteriosus.*—Passing

* *Abhandlung über gewaltsame Todesarten*, L. 153—156.

† *Experimentorum Docimasiam*, &c. Edinburgh Medical and Surgical Journal, p. xxvi. p. 375. *Handbuch der gerichtlich. Arzneikunde*, u. s. w. von J. Bernt. Wien. 1828, s. 256.

over the changes which take place in the foramen ovale, the ductus venosus, and umbilical vessels, changes which take place at too late a period after birth to supply satisfactory evidence in trials for infanticide, we come to the consideration of the comparative state of the ductus arteriosus Botalli, and the branches of the pulmonary artery before and after respiration. Previous to the investigation of Bernt no minute observations had been made on the changes which these vessels undergo soon after delivery. It might have been anticipated that the occlusion of the ductus arteriosus must be rapid, since its perviousness would form an impediment to the perfecting of the child's new mode of existence; but it had not occurred to medical jurists to seek for any indication of extra-uterine life from this source.

In the fœtus the ductus arteriosus proceeds from that part of the trunk of the pulmonary artery where it divides into its two great branches, and running parallel with the arch of the aorta and in contact with it, joins it at a very acute angle. It is about half an inch long, cylindrical, equal in diameter to the trunk of the pulmonary artery, and almost three times the diameter of its two branches, each of which branches is about the thickness of a crow-quill. (*Experimentorum Docimasiam, &c. Proleg. p. xiv. Handbuch, 277.*)

If the child, says Bernt, have breathed for a few moments only, the aperture by which the duct enters the aorta becomes oval; if a little longer, it loses its cylindrical form, and assumes the shape of a cone, the apex being at the aortal end, but sometimes, though much more rarely, at the opposite extremity; the diameter is diminished so as to be smaller than that of the trunk, but about equal to that of the two branches of the pulmonary artery, the latter, owing to the establishment of the pulmonary circulation, having already increased in diameter.

If the child have lived for some time, and breathed perfectly, the ductus arteriosus Botalli resumes the complete cylindrical form, but has become shorter, and is not thicker than a crow-quill, whilst the two pulmonary branches are thicker than a goose-quill. As these comparisons are determined by the relative size of objects situated close to each other, an observer would not be liable to fall into error, as he is otherwise apt to do in estimating relative magnitude. (*Edinburgh Medical and Surgical Journal, vol. xxvi. p. 378.*)

The observations and experiments on which the preceding inferences relative to the blood-vessels are founded, were made previous to the year 1823; and in the Manual of Medical Jurisprudence published in 1828, Professor Bernt adheres to the same conclusions, and informs us that they have been confirmed by the observations of Kilian (*Abhandlung über den Kreislauf des Blutes im Kinde welches noch nicht geathmet hat, Karlsruhe, 1826*), a writer of authority on the foetal anatomy. As we have attentively examined these observations and experiments, which are seventy-five in number, and not been able to concur with Bernt in his inferences in every particular, we shall briefly state those which appear to be conclusive, and of practical application in medico-legal inquiries.

In every instance of respiration whether natu-

rally accomplished or the effect of resuscitation from insufflation, a general or partial diminution of the diameter of the ductus arteriosus was found. But a diminution in general diameter (so that the natural relative diameter between the ductus arteriosus and the trunk and branches of the pulmonary artery did not exist) was sometimes found in children notoriously still-born, and who had not breathed artificially; hence a smaller relative diameter of the duct cannot be relied on as a proof of extra-uterine life. But the contraction of the extremity (either aortal or otherwise) of the duct, though sometimes absent in children who had respired, was never present unless respiration had been carried on; so that, if the ductus arteriosus represent a cone in figure, it may be regarded as a decisive indication of the continuance of the pulmonary circulation, and hence of breathing.

[It may be desirable to cite from M. Devergie (*op. cit.*) the various changes that take place in the organs of circulation, the cord, and the skin, at different periods, beginning with the first and ending with the thirty-fifth day, which may enable some judgment to be formed of the age of the child.

First day.—Cord beginning to wither; foramen ovale, ductus arteriosus, ductus venosus, and umbilical vessels open.

Second day.—Withering of the cord complete; foramen ovale closed in two out of eleven cases; partially closed in one out of seven; ductus arteriosus beginning to close; umbilical arteries obliterated to a greater or less extent; umbilical vein and ductus venosus still open.

Third day.—Desiccation of the cord; foramen ovale sometimes closed; ductus arteriosus obliterated in one in eleven cases; umbilical arteries very often obliterated; umbilical vein and ductus venosus still open.

Fourth day.—Cord beginning to fall off; foramen ovale closed in about one-third of the cases; ductus arteriosus still open in the majority of cases; umbilical arteries closed, but sometimes open near the iliacs; umbilical vein and ductus venosus much contracted.

Fifth day.—Separation of the cord with rare exceptions; foramen ovale closed in more than half the cases; ductus arteriosus closed in about half the cases; umbilical vessels closed; vein occasionally open; separation of the cuticle advanced.

Eighth day.—Entire separation of the cord, with commencing cicatrization; foramen ovale closed in three-fourths of the cases; ductus arteriosus completely obliterated in half the cases; vessels closed.

Ninth to eleventh day.—Cicatrization of the umbilicus often complete; sometimes, however, there is an oozing of mucus from the cord for many days, so that the cicatrix is retarded; separation of the cuticle in the trunk, chest, and abdomen, and at the articulations.

Twentieth to twenty-sixth day.—Separation of the greater part of the cuticle.

Thirtieth to thirty-fifth day.—Separation of the entire cuticle, excepting that of the hands and feet, which is often delayed until the 40th day. (See, on the same subject, Billard, *Maladies des Enfants*, and Guy, *op. cit.* p. 149.)]

Having now investigated the evidences of independent life, which may be supplied by the examination of the body of a child found dead, we proceed to arrange the inferences of practical value in a compendious form. The state of the stomach, bowels, and urinary bladder, and of the umbilical cord, has been purposely omitted, as in a large majority of cases they do not furnish any indications which can be relied on.

First.—A child may be concluded to have been still-born who does not present the signs of having arrived at the sixth month of uterine life: or

The colour of whose lungs is uniformly dark-red, or verging towards the brown-red of the liver or the bluish-red of the thymus:

If they are of a fleshy compact structure, somewhat like liver, presenting no traces of cells on the surface, nor yielding a crepitating sound when cut, nor bubbles of air when portions of them are pressed beneath the surface of water:

If the whole lungs and every fragment when they are cut into small pieces immediately and rapidly sink in water; and when the weight of the whole lungs (being naturally formed and healthy) is below five hundred grains:

If the lungs have occupied the posterior cavities only of the thorax, merely touching the pericardium with their anterior borders, and covering with their concave surface the posterior half of the arch of the diaphragm, the edges being sharp, and the margins of the right, middle, and left upper lobes forming small tongue-shaped elongations: and if the ductus arteriosus is cylindrical throughout, being of equal diameter with the trunk of the pulmonary artery, and two or three times the diameter of the two pulmonary branches.

Secondly.—It may be concluded that a child has lived a short time and breathed imperfectly,

Whose lungs being for the most part dark-red, brownish, or bluish-red, present, here and there, in one or both lungs, but particularly on the edges, insulated scarlet or cinnabar-red spots or streaks; when there are visible, particularly in the upper lobe and edges of the right lung, insulated groups of cells surrounded by portions retaining the compactness of liver; when this cellular portion yields a crepitating sound on being cut, and bubbles of air if pressed under water; when the lungs occupy more or less the lateral cavities of the thorax, and their margins, particularly the prolongations of the right middle and left upper lobes, are partially or altogether of a rounded form:

When the lungs, with or without the heart, sink in water, but some fragments of them, when divided, float, even after having been subjected to pressure; and when the absolute weight of the lungs much exceeds five hundred grains:

If the ductus arteriosus is smaller in diameter than the pulmonary trunk, and about equal to the pulmonary branches, and particularly if with these signs it is contracted either at the aortal or other extremity, so as to assume a somewhat conical shape.

Thirdly.—A child may be concluded to have lived for some time and breathed perfectly,

If the lungs are of a pale-red colour generally, but with numerous spots and streaks of scarlet; the posterior surface only being dark-red, in consequence of the gravitation of the blood to that part:

If the lungs completely occupy the lateral cavities of the thorax and cover the sides of the pericardium, and if their lower concave surface cover the whole arch of the diaphragm, their edges being everywhere rounded, and the tongue-shaped elongations of the right middle and left upper lobes short and obtuse: if insulated groups of innumerable cells distended with air are visible with the naked eye in the substance of the lungs; if they are everywhere expanded and spongy in texture, crepitating audibly when cut, and yielding on pressure under water, numerous bubbles of air or bloody froth:

If the lungs connected with the heart, or separated from it and each separate lobe, project above the surface of the water, and every fragment when they have been divided and subjected to strong pressure, float; and if their absolute weight exceed one thousand grains:

And if the ductus arteriosus is short and much contracted in diameter, so as to be as small as or smaller than the branches of the pulmonary artery; or if it be decidedly contracted at the aortal or other extremity, so as to represent in form a truncated cone.

To every indication, hitherto adduced, of the extra-uterine life of the child, the possible occurrence of uterine or vaginal respiration presents an objection which deserves farther consideration. In the preceding remarks we have adverted to cases of this kind, which refute the opinion hitherto entertained that this species of respiration cannot come in the way in medico-legal investigation, because it can only occur in cases requiring instrumental or, at least, foreign manual assistance. Although there can be no doubt of the general correctness of this opinion, it is manifestly not true in all instances; for the cases of Dr. Hosack and Dr. Holmes (see page 681) prove that it may be met with in instances of delivery capable of completion by the natural efforts only.

Admitting, however, the possibility of intra-uterine and vaginal respiration, we must contend on the other hand for the extreme rarity of the occurrence; so rare, indeed, that, until very recently, it has been regarded with the greatest distrust by European practitioners in general with the exception of the Germans: and it is doubtful whether any other positive evidence than that recorded in the present essay, exists in the writings of French and English authors in its favour. Ought, then, so rare an occurrence to be admitted as a decisive reason for uniformly rejecting the conclusiveness of the indications of life which we have hitherto been discussing? We think not, and doubt extremely whether the signs of *perfect* respiration which we have just detailed are ever to be met with in such cases; whilst we have every reason to believe that they are commonly found in the bodies of children who have died from criminal violence or neglect.

Vaginal respiration may occur in natural presentations, but the delivery in such a case must be *delayed* to admit of it, and thus the labour would become "difficult." In every such case the tumour of the vertex would plainly indicate its nature. Face presentations, in which vaginal respiration may occur, are capable of proof from the absence of the tumour just named, and from the tumid

and distorted features; and footling presentations are recognisable, if death have taken place soon after birth, by signs not difficult of detection. Such are the cases most favourable to the possible occurrence of vaginal respiration; and although they demand full consideration, they seem nevertheless capable on careful inquiry of tolerably easy detection. Should there be no proofs of difficult labour, whilst indications of full and complete respiration are found, and conjoined with these there exist signs of fatal injury, which could not have been accidental, and must have been inflicted during the continuance of the circulation, the proofs of infanticide would be indubitable; for to reject them would be to disallow the force of the strongest circumstantial evidence.

II. In proceeding to inquire into the *cause of the death of the child*, we may remark that it may have died in the womb previous to the commencement of labour; or during the act of parturition, or after birth; and in each case death may have been produced by natural or criminal causes.

1. The death of a fœtus in utero criminally induced in the early periods of utero-gestation, falls under the head of criminal abortion; at a later period death arises most frequently from natural causes, from disease in the mother, in the fœtus itself, or in the secundines; but it may result from premature labour brought on artificially by puncturing the membranes.

A fœtus having died in utero, may remain there an indefinite time, and even be converted into adipocere. Generally it is expelled in from five to twenty days, exhibiting unequivocal signs of putrefaction; the members are relaxed, the muscles flabby, the epidermis detached by the slightest touch, the skin is of a purplish or brownish-red. Frequently there is a sanguineous or serous infiltration of the whole subcutaneous tissue, particularly under the hairy scalp. The umbilical cord is thick, soft, brittle, and infiltrated. The chest is sunken or flattened. The head is deformed, falling flat by its own weight; the pericranium and dura mater are separated from the bones, which are nearly, if not altogether, disunited, and the cerebral substance is converted into a putrilaginous mass. Jaeger observes that these signs are quite peculiar, and that their concurrence distinguishes this state from death by injury, and every thing else. (*Schlegel, Opuscul. Collectio V. 48. Le-cieux.*)

2. Capuron, (*La Médecine Légale relative à l'art des accouchemens*), who has given the best summary of the causes of death during parturition, has divided them into innocent and criminal.

Of the former kind are difficult labour with premature evacuation of the liquor amnii; total or partial separation of the placenta; premature expulsion of the funis; presentation of the feet; detention of the body from mal-position after the expulsion of the head; and the "entortillement," or turning of the funis around the neck of the child.

The effects on the child of difficult labour with premature evacuation of the liquor amnii, are such as result from severe and continued pressure; and the death of the child takes place in the way of apoplexy. The signs which indicate it are the

sero-sanguineous tumour of the vertex; if the head have presented, deformity and elongation of the head, attended even with fractures of the bones, tearing of the membranes, or separation of the pericranium, and effusion under it. (*Foderé, iv. 503.*) The position of the injuries of the head, and the absence of any distinct sign of impingement from a bruising body, combined with the absence of the signs of respiration, would satisfactorily elucidate these phenomena.

In the case of total or partial separation of the placenta, the death of the child is of course from hemorrhage, and the body would present the signs of anæmia. It might be confounded with death from hemorrhage from the umbilical cord; but the absence of the signs of respiration would be a decisive means of discrimination. The mother would also present signs of anæmia.

In premature expulsion of the funis, the death of the child is from asphyxia. No sign of injury would be present, nor would there exist any proof of respiration.

Presentation of the feet, with all but the head expelled, and the delivery tedious: in such a case a woman might assist herself, and in so doing inflict so much injury on the child by her injudicious attempts, as to excite strong suspicion against herself; and the more particularly, as this is a conjunction of circumstances under which vaginal respiration may occur. Such a case would require a circumspect observation of all the particulars; but there are circumstances which could scarcely fail to lead to its correct elucidation. The indications of difficult delivery and of the presentation of the feet would be easily observed, and an examination into the situation and nature of the injuries would show whether they were of a kind which a woman might be expected to inflict on her child in promoting her own delivery. If death were not the result of injury, it would take place in the way of apoplexy, and the corresponding signs would be found.

In retention of the body from mal-position or otherwise after the expulsion of the head, death results from asphyxia, from the compression of the funis, if the child have not breathed; and if it have, from impediment of the free expansion of the thorax. In the former the absence of the signs of respiration, with the want of proof of criminal neglect or violence, would rebut the charge of infanticide; in the latter, imperfect respiration would be recognised by its appropriate indications, the severity of the labour would be proved by the tumour of the vertex, and other signs, and the want of proof of criminal act or intention would render the charge of murder untenable.

The only other innocent cause of death during parturition deserving of particular attention, is the "entortillement," or turning of the funis around the neck of the child. If this circumstance lead to fatal consequences, it is either by inducing apoplexy or asphyxia, according as respiration have or have not been carried on. Should any sign of injury be left, it will consist of a spiral impression, or (if the cord have passed round more than once) of the circular and spiral line discoverable on the neck. The epidermis is never puckered, nor the cartilages of the trachea injured. If it were al-

leged that the cord have passed round the neck more than once, it should be ascertained whether it was sufficiently long for that purpose.

It is proper to add that fractures of the bones sometimes take place in the uterus, of which Chaussier (*Bulletin de la Faculté de Médecine*, tom. iii. See also Otto's *Handbuch de Pathologischen Anatomie*, 394) has related a remarkable instance. In this example each of the long bones presented one or more fractures, some of which were recent, others beginning to unite, and others had united.

The criminal causes of death during parturition are various, and for the most part evidently betray the intention with which they were employed. They almost always imply the aid of an accomplice, and hence are of comparatively infrequent occurrence. Of these the following are the most usual:—puncture of the brain through the fontanelles or sutures, or of the spinal marrow between the first vertebra and the occiput; torsion or compression of the head; detraction; strangling and suffocation.

Belloc (*Cours de Méd. Lég.* 101) has reported an instance of child-murder in which the brain was punctured through the interior fontanelle. The external wound did not exceed half a line in length. On examination it was discovered that it penetrated the brain to the depth of two inches. At this point the cerebral substance was lacerated in several directions. Blood was effused both between the membranes and in the left lateral ventricle. Gui-Patin, Alberti, and Brendel have cited similar examples; and in the article *Accusation* in this *Cyclopædia*, reference is made to a trial in the "*Causes Célèbres*" for the same horrible offence. It is doubtful, however, whether these means would prove so rapidly mortal as to destroy life before the expulsion of the child. In the case related by Belloc, death appeared to have been produced by suffocation, the laceration of the brain not having been effectual.

In torsion of the neck the injury inflicted on the spinal marrow might be immediately fatal. The marks of violence presented by the ligaments of the vertebra and neighbouring muscles would indicate the nature of the case; and it is highly probable that the marks of the pressure of the fingers would be visible.

Foderé (*Vol. iv. p. 524*) has related the trial of a widow, who destroyed her child in the act of parturition, by compressing its head between her thighs till it was dead.

It is doubtless possible that a child may be strangled or suffocated before complete respiration has taken place; but the nice accomplishment of such a purpose requires a more refined application of injury than is almost ever practised; and without such caution the remains of intentional injury would be demonstrable. If strangulation were attempted whilst the circulation was proceeding vigorously between the mother and child, continued pressure would be necessary for its accomplishment, as death would take place in the way of apoplexy; and for such continued pressure a longer intermission of the uterine pain would be required than is usually found to occur.

3. The causes of death after delivery are natural or criminal; and the latter are subdivided into

those which are fatal by omission and by commission.

The following is a general summary of the natural causes of death after delivery: immaturity, disease, malformation; omission of the usual and necessary attentions; injuries from severe labour or from sudden expulsion; sudden and simultaneous expulsion of the placenta, and consequent hemorrhage; prevented respiration from envelopment in the membranes; or suffocation in the discharges. The two causes last enumerated are not distinguishable from the same causes of death intentionally applied. Of the others, injuries from severe labour and from sudden expulsion are most likely to be confounded with the effects of criminal violence, and hence demand the most careful and deliberate examination. With reference to the former, it should be recollected that "fluid blood effused at the base of the brain is met with in all children, when the head *has been long* in the pelvis, and the child has died in that situation." (*Foderé*, iv. p. 503.) The cerebral ventricles of newly-born children, Foderé adds, usually contain much reddish serum, and the brain much blood. And when the superior aperture of the pelvis is narrowed by deformity, even fractures of the bones may occur with depression of them into the brain. But all these effects require for their production a disproportion between the size of the head and dimensions of the pelvis. The state of the former should indicate the difficulty of the labour by its deformed and elongated appearance, and by the unusual size of the sanguineous tumour at the vertex. Signs of laceration and contusion ought not to exist.

Injuries arising from sudden expulsion are very rarely fatal, or even dangerous; and they are less likely to be confounded with the causes of infanticide, inasmuch as they are of infrequent occurrence in first labours, on which occasions the crime is for the most part perpetrated. No instance of the death of a child from sudden expulsion has come within our knowledge. Suffocation in privies under such circumstances is of course possible, and Hutchinson (*Dissertation on Infanticide*) says instances are reported; he has not, however, supplied any reference to them. Several years ago Chaussier (*Lecieux*, Op. cit.) experimented on dead children to ascertain the effects of falls from a given height, and also of blows, on the cranium. These experiments, neither very refined nor conclusive in their character, are superseded by the more recent observations of M. Klein (*Dict. de Médecine*, tom. xii. p. 188) of Stutgardt. M. Klein, taking advantage of his situation of Member of the Superior Council of Health, caused a circular to be addressed to the midwifery practitioners of the kingdom of Wurtemberg, requiring reports of the cases of sudden expulsion of the fetus which might be observed by them. Returns were made of one hundred and eighty-three cases. Of these, one hundred and fifty-five children were expelled whilst the mothers were in the upright posture, twenty-two when sitting, and six when on the knees. Twenty-one happened at the first labour. Of the whole number not one child died; no fracture of the bones took place, nor any other severe injury. Two only suffered temporary in-

sensibility, and one an external wound with sigillation over the right parietal bone. Not one suffered from umbilical hemorrhage, although in several the cord was ruptured at four, three, and two inches, and even one inch from the umbilicus. In twenty-one children it was torn off close to the abdomen, yet no serious hemorrhage followed. We are entitled, therefore, to conclude that in accidents of this kind the death of the child, if not impossible, is highly improbable; and if it should occur, we have no reason to think that it would be immediate.

The criminal causes of death *by omission* are, the neglect of removing the child from under the bed-clothes, or from the state of supination; the want of suitable warmth; neglect of nourishment; and the neglect of the ligature of the umbilical cord.

Death has resulted not unfrequently from the first of these causes; but the medical man possesses no peculiar means of determining whether this has happened from design or from the mother's inability to render the usual succours. Dr. William Hunter has mentioned a case which shows how readily neglect of this kind may prove fatal.

Death from want of suitable warmth, which is almost always conjoined with public exposure, is proved by the evidence of respiration and circulation; by sanguineous congestion in the large vessels, with comparative absence of blood in the superficial ones; by the position of the body; and most conclusively perhaps by the *cadaveric congestion* or *lividities* (*Chaussier*, *Recueil de Mémoires*, &c., 424) which are met with in the depending parts of the body.

Neglect of nourishment is also generally combined with public exposure; under which circumstances death may be attributable to the combined causes. It would be very difficult to prove the death of a newly-born child from neglect of nourishment only, because to establish that it would be requisite to show how long the child had lived, which there are no means of determining with strict accuracy. The changes supervening in the umbilical cord would furnish the best evidence; and being applicable on other occasions, we shall describe them in this place.

The umbilical cord varies in different children considerably, (*Traité des Maladies des Enfants*, &c., par Billard, p. 18): in some it is slender and comparatively firm, in others thick and soft; the thickness varying from the greater or smaller quantity of the albuminous fluid, called the gelatinous fluid of Warton. The changes which take place in the cord are, first, flabbiness, then desiccation, and lastly separation from the abdomen; and all these processes occur at different periods of time in different children, according to the thickness or thinness of the cord. Immediately after birth, or at farthest in a few hours, the flabbiness commences, and it is complete in the course of a day, or at most in two days. Desiccation, which commences after the fading of the cord is complete, begins generally at the end of the first day, and is completed on the fourth or fifth, when the separation takes place. The desiccation is a purely physiological phenomenon, for it does not take place in children born dead; in them the cord remains soft and flexible, and then becomes

putrid. The desiccation of the cord is more speedy when it is thin; and it is rare that separation of a slender funis is attended by suppuration, or even inflammation. When it is thick, the case is otherwise; suppuration at its junction with the abdomen takes place, with a red and thickened base. The slowness of the separation appears to occasion the inflammation.

A consideration of these circumstances will indicate the age of a child approximatively within the first four or five days after birth.

The neglect of the ligature of the umbilical cord may be accidental or intentional. The absence of it is unfavourable to the accused, and more particularly if the funis be cut. The effects of the absence of the ligature of the umbilical cord have been a fruitful source of controversy; many, Capuron among others, having doubted whether fatal hemorrhage could result if the ligature were not applied. (*Daniel*, *Commentatio de Infantum nuper natorum Umbilico*, &c., 1780.) Foderé (*Tom. iv. p. 516*) has related a case which we deem quite conclusive in the affirmative; and the signs he has described will no doubt be generally met with under similar circumstances. They were the following:—extreme paleness of the whole body; no wound or external sign of violence; the umbilical cord flaccid; floating of the lungs with or without the heart; complete vacuity of the heart and great vessels, of the vena portarum, of the ductus venosus, and even of the capillary vessels. All the blood which could be collected did not weigh two ounces. The child lived long enough to be carried three leagues; hence death from this cause is not speedy, and the signs of respiration would be certainly found.

Roderer has remarked that the ligature may be applied to the cord after fatal hemorrhage for the purpose of deception, but the proofs of anæmia would elucidate the case. If three ounces of blood can be collected, it may be presumed that the child has not died of hemorrhage. In Foderé's case, not two ounces could be collected.

We now pass to the consideration of the causes of death after delivery *by commission*; and it is commonly in this manner that infanticide is perpetrated in this country. They may be as various as those of homicide generally; but there are some which are more easily or more commonly employed than others. The following enumeration embraces the more usual and important varieties. Suffocation from division of the frænum linguæ and turning back of the tongue; stoppage of the aerial passages; asphyxia by strangulation or by deleterious gases, or by plunging into privies; torrefaction; drowning; wounds and bruises about the head or in different parts of the body; crushing of the head; punctures per rectum or in the region of the heart: to which may be added some of the causes mentioned under the criminal means of death during delivery. The criminal intention in many of these injuries would be self-evident. A recent case of infanticide in Guernsey was perpetrated by laceration of the frænum linguæ and puncture per rectum. (*Edin. Med. and Surg. Journal*, No. cvii. p. 548.) The proofs of murder were unquestionable.

The effects of injuries about the neck demand the strictest scrutiny; for strangulation is perhaps

the most frequent of all causes of infanticide by commission. The fallacies by which it is beset are the "entortillement" of the umbilical cord; supposed injury from compression by the os uteri and vagina; or from the assistance which a woman might endeavour to render herself; possibility of post-mortem injury; and livor, or spontaneous sugillation.

The turning of the umbilical cord around the neck requires that the funis should be of a certain length; (See Scott's Case of Infanticide; Edinb. Med. and Surg. Journal, vol. xxvi. p. 75;) and the mark, if any remain, cannot be circular unless it have made a second turn. No abrasion or puckering of the skin ever takes place from this cause. (*Plouquet*, Ueber die gewalt. Todesarten. 378.) M. Klein, (*Dict. de Médecine*, tom. xiii. p. 183.) who has made special observations on the subject, denies that any sugillation or even impression ever occurs from compression of the neck by the cord, by the os uteri, or vagina. He has seen many children who have died from the first of these causes; and in none did he observe any mark left about the neck. But in infanticide, as in homicide generally, criminal efforts to extinguish life are executed most frequently with characteristic violence, and accordingly injuries of the tracheal cartilages or of the deep-seated muscles of the vertebræ are sometimes found, or plain impressions of the fingers. A few years ago we had occasion to examine the body of a child which had been destroyed by strangulation with the fingers. The impressions were distinctly perceptible on each side of the trachea, and the mark of the fingers gradually increased in distinctness from the back of the neck forwards. The trachea was not injured, but on each side of it coagulated blood was found.

The assistance which a woman might have endeavoured to afford herself would be generally recognisable by the nature, situation, and direction of the marks. The case of Marguerite Granger, related by Foderé, (*Op. cit.* tom. iv. p. 502.) affords an excellent, perhaps an extreme illustration of the kind of injury which might be expected in such a case; and his report shows that, though such injuries may be numerous, they will be superficial.

Chaussier (*Recueil de Mém.* p. 470,) asserts that injuries have been inflicted on the dead body for the purpose of determining an accusation against an individual. If such wounds or bruises have not been inflicted for twenty-four hours after death, there is no difficulty in deciding that they were not received during life. The lips of wounds are pale, without swelling or retraction. There is no clot of blood adhering to the surface, nor, in the case of contusion, is coagulated blood found in the surrounding cellular texture: hence there is no tumour. The characteristics of blows inflicted during life are tumour from extravasation of blood and serum; or clots of blood in the subjacent cellular tissue without tumour, or "incorporation of the blood with the whole thickness of the true skin, rendering it black instead of white, and increasing its firmness and resistance."

"In respect to external contusions," says Dr. Christison, (*Cases and Observations in Med. Jurisprudence*. Edinb. Med. and Surg. Journal, No.

xcix. p. 247,) "experiments show that for some hours after death, blows will cause appearances which in point of colour do not differ from the effects of blows inflicted recently before death; that the discoloration generally arises like lividity, from an effusion of the thinnest possible layer of the fluid part of the blood on the outer surface of the true skin, but also from an effusion of thin blood into a perceptible stratum of the true skin itself; and that dark fluid blood may be even effused into the subcutaneous cellular tissue in the seat of the discolorations, so as to blacken or redden the membranous partitions of the adipose cells, but that this last effusion is never extensive."

"It is impossible," continues Dr. Christison, "to fix absolutely the limit of the interval beyond which contusions cannot be imitated by violence applied to the dead body. It appears to vary with the state of the blood, and the time which elapses before the body cools and the joints stiffen. Sometimes the appearance of contusions can hardly be produced two hours after death; sometimes they may be slightly caused three hours and a quarter after it; but I should be inclined to think this period very near the extreme limit."

The testimony of Chaussier (*Recueil de Mém.* p. 471,) corresponds with what has just been stated. "If," says he, "the injuries have been inflicted soon after death, whilst the muscles preserve their contractility, there will neither be tumefaction, nor infiltration of blood into the cellular tissue, or the blood will only form a clot without adhesion to the divided surfaces."

Lividities or livor, which are the terms employed to express the nature of discolorations occurring spontaneously after death, may be easily distinguished from ecchymoses, which are the result of injury during life. Livor is generally found on the back and thighs, or on the parts of the body on which it has remained when becoming cold. Sometimes it extends more particularly to the head or neck or genital organs. Lividities assume varieties of appearance, but they are confined to the skin, and are greatest when the blood has long retained its fluidity. Infiltration or effusion of blood into the cellular tissue never occurs from them, nor are they ever attended by tumour.

Ecchymosis or sugillation, on the contrary, is characterized by a true effusion of blood, which has formed a coagulum, and this coagulum is intimately adherent to the meshes of the cellular tissue, and frequently forms a tumour. In the progress of putrefaction, indeed, the blood resumes its fluidity, escapes from the vessels, and collecting under the skin forms soft fluctuating tumours, which, on being opened, are found to contain a dark sero-sanguineous fluid. But it would be impossible for any person of moderate information to confound such appearances with the phenomena of true ecchymosis.

Death from torrefaction or burning is of rare occurrence in criminal cases, yet we are informed by Dr. Ryan, (*Manual of Med. Jurisprudence*, p. 169,) that an instance of this crime has been recently perpetrated in London. The circumstances to be investigated by the medical jurist would be, whether the child was killed by burning, or the

body was thrown into the fire after death from other causes. Some late experiments of Professor Christison (*Edin. Med. and Surg. Journ.* No. cxvii. p. 323,) show that "a line of redness near the burn not removable by pressure, and likewise the formation of blisters filled with serum, are certain signs of a burn inflicted during life." The application of a cauterizing iron ten minutes after death did not cause redness, although vesications were produced; which vesications, however, did not contain serum, but were dry and filled with air.

Instances of infanticide by drowning are infrequent. The proofs would be found in the signs of extra-uterine life, the absence of other efficient causes of death, and the presence of phenomena which are usually observed in asphyxia from submersion. (See *ASPHYXIA*.) We may observe that the presence in the bronchi of a portion of the fluid in which the body was found is no proof of death by submersion; for fluids will pass into the bifurcations of the bronchi if the body have been thrown into water after death. If, however, any of the fluid, and particularly any foreign matters contained in it, were found in the stomach, death from submersion would be unquestionable, as it could only have arrived there from deglutition. The indications of struggling which are sometimes met with in adults destroyed by drowning, could not be expected in a newly-born child under such circumstances.

Death from criminal injuries of the head are distinguishable by the fracture of one or more bones in situations which, neither in the course of natural parturition nor in the case of sudden expulsion, are liable to them. Ecchymoses and wounds almost always accompany them.

In injuries of the head from violent compression criminally applied, it is highly improbable that the marks could be confounded with those which sometimes, though very unfrequently, occur during labour. The unusual situation, severity, and complications of the injuries, with the indications of extra-uterine life, would, in the absence of the signs of difficult labour, dissipate all doubt as to their origin. We shall here detail the marks of difficult labour which are usually met with.

In a first labour, even when there is no unusual disproportion between the head of the child and pelvis of the mother, and the delivery has been accomplished with moderate celerity, we observe in the presenting part of the child a tumefaction of uncertain extent and size. On dissecting this tumefied part, a serous infiltration, sometimes with sanguineous engorgement, is found under the subcutaneous cellular texture, and which does not exist in other parts of the head.

In a woman who has borne several children, whose pelvis is large, and the os uteri soft and yielding, this impression is so slight as to be scarcely perceptible, especially if the child is small, and the delivery have been quick. On the contrary, when the head of the child is large, the bones firm, and the labour slow and painful, so that the head have been delayed in the pelvis, the tumour is large, prominent, and unyielding. When cut into, we not only find a sero-sanguineous effusion into the subcutaneous cellular

tissue, but the pericranium is detached and elevated by a collection of dark fluid blood, the bone is brownish, and the connecting membranes are more or less elongated. These changes are still greater when the superior aperture of the pelvis is narrowed by an unusual projection of the promontory of the sacrum. Then the head is deformed, elongated in its greater diameter, flattened in the transversal. Sometimes even a depression or fracture, longitudinal, angular, or starred, of one or both parietal bones, may occur. All these phenomena are distinguishable from those produced by accidental or criminal violence, by the nature and position of the tumour, and of the other injuries which result from the unnatural projections of the pelvis. Such deformity of the pelvis is ascertainable at any period after delivery; and where the usual proportions between the head of the child and pelvis of the mother exist, the appearances above adverted to are never met with.

We here terminate all the remarks we have to offer on the causes of the death of a newly-born child,* and venture to state that the indications afforded by them will be found applicable to the solution of the difficulties which can be reasonably anticipated on trials for infanticide. Undoubtedly instances may occur in which it will not be possible to demonstrate the causes of death, but such is the case also in other varieties of homicide. In infanticide the victim is incapable of resistance, and hence some of the ordinary proofs of homicide may be absent; but the kind and degree of injury necessary for the destruction of the life of a child are very rarely nicely measured by the perpetrator of the crime; and the violence committed is most frequently such as to leave no doubt as to the cause of death, and to constitute, at the same time, the most indubitable evidence of extra-uterine life. It is unquestionable, however, that medical evidence on trials for infanticide has not influenced the decisions of juries in the same degree as on trials for other kinds of murder. By some this has been attributed to the doubtful and hesitating manner in which medical witnesses have generally delivered their testimony, (*Edin. Med. and Surg. Journal*, vol. xxvi.); by others, to the impression that the killing of a new-born child, when perpetrated under the impulse of injured honour and fear of disgrace, should not be classed with the other varieties of murder. The latter question we shall not attempt to discuss; but as regards the former explanation, we unhesitatingly express our conviction that the anatomical, physiological, and pathological phenomena on which medical evidence is founded on these occasions are as susceptible of positive conclusion as any other facts within the sphere of medical investigation. Nevertheless, we are not surprised that medical men should frequently be unprepared to deliver their testimony with clearness and decision in criminal trials. The facts and information connected with these subjects are rarely applicable in the discharge of the ordinary duties of medical practice; and general practitioners in active occupation have, therefore, no great inducement, and seldom

* For the signs of death by poisoning and deleterious gases, see *TOXICOLOGY*.

sufficient leisure to devote to the literary and experimental researches which investigations in medical jurisprudence demand, whilst it is to this class of practitioners that reference is generally made in medico-legal proceedings. The custom which prevails in Germany and other northern countries of Europe of appointing a medical officer for each district, whose especial duty it is to investigate all cases which become the subject of juridical proceeding, seems worthy of imitation in this kingdom. The establishment of such an office creates individual responsibility, and ensures a due preparation for the faithful discharge of it; and the concentrated experience thus acquired has contributed to the exactness and extension of medico-legal knowledge. Under existing arrangements in this country, the infrequency with which individual practitioners are called on to act, constitutes perhaps the chief reason why this department of professional study has hitherto been comparatively neglected.

III. We next proceed to inquire into the proofs whether the suspected mother has been recently delivered.

As collateral evidence, it is advisable to ascertain whether the general symptoms of pregnancy have pre-existed. It is evident that no conclusive opinion can be formed in such a case, auscultation and the *ballotement* supplying the only positive evidence of pregnancy. But if the menses have been suddenly suppressed, the mammae and abdomen have enlarged, and no other symptoms of disease than inappetency, irritability of the stomach, and dyspepsia have followed, it may be reasonably presumed that the woman has been pregnant.

The proofs of recent delivery are furnished by an aggregate collection of signs, which, separately considered, do not admit of positive inference. In a woman recently delivered, particularly of a first child, the following appearances are very generally met with: the face is rather pale, the eyes are sunken and surrounded with a dark circle; the pulse is rather quick, full, and undulating; the skin soft, with some heat and moisture, having a peculiar acid odour. The breasts are tumefied, distended, and painful, yielding on pressure or suction a fluid having the characteristic properties of milk; the belly is soft, and the skin is wrinkled and marked with short red or white lines passing in different directions, chiefly towards the umbilicus; a separation of the *linea alba* is perceptible, particularly towards the umbilicus. The uterus is felt above the pubis. There is a discharge from the vagina either of a red, greenish, or light colour, and of peculiar odour. The genital organs are more or less tumefied, and considerably dilated in their whole extent; the fourchette is lacerated; the *os uteri* is soft and relaxed, so as easily to admit of the introduction of the fingers, and a discharge similar to what has been just mentioned flows from it.

There is no known disease which will produce the concurrence of signs now enumerated, whilst after parturition, and particularly after a first labour, they almost uniformly occur.*

* A curious application of the knowledge of the signs of recent delivery has been mentioned by Capuron, *Med. Légale*, p. iii. A young woman simulated pregnancy,

But the discovery of such a series of symptoms will depend altogether upon the period of time at which the examination was made. Zacchæus long since observed that the proofs of delivery were uncertain after the tenth day. (*Quæstiones Med. Legal.* ii. lib. 7. quæst. 2.) After the fourth or fifth they become less distinct, gradually diminishing, and at the end of a fortnight are indecisive. The possible fallacies are the sudden cessation of dropsies; the expulsion of hydatids or moles. The *Foreign Quarterly Journal of Medicine and Surgery* contains a case of the sudden disappearance of dropsy, in which the water was discharged per vaginam by passing down the fallopian tubes. In *Rust's Magazine* (Vol. 21) a case is related of the discharge of a "mole" preceded by the general symptoms of pregnancy, and accompanied by flooding and other signs of parturition. The discharge of the menstruous fluid after long retention might simulate some of the symptoms of recent delivery, but many of them and those the most decisive, would be absent in all such cases; whereas, after delivery, and particularly of a first child, almost all would be found to concur.

IV. Do the phenomena presented by the supposed mother and child establish the suspected relationship?

The solution of this question is almost always easily determined in cases of infanticide by moral evidence; and indeed it is by moral evidence alone that it can be positively settled. Medical testimony must be confined to showing that there is an agreement of the phenomena presented by the child with the indications of delivery observable in the woman. The data thus derived can be of a general nature only, and are confined chiefly to a comparison of the state of conservation or decomposition in which the body of the child was found, with the presumed period of delivery.

If the inquiry were not instituted for some days after delivery, it would be necessary to take into consideration the circumstances capable of accelerating or retarding decomposition. For instance, putrefaction proceeds most rapidly when the atmosphere is humid and still, and the heat ranges between 60° and 80° Fahr. It proceeds most rapidly in parts of the body which have sustained injury either before or after death.

It is important to remark that in bodies plunged into privies, putrefaction does not commence so soon as when they are exposed to the air; but having begun, it proceeds more rapidly in such a situation. Decomposition is retarded by submersion in water, so that two or three weeks generally elapse before, in bodies so circumstanced, putrefaction commences.

Some remarks on post-mortem examination, and on the drawing up of medico-legal reports with reference to the present subject, would furnish practical information of value, and hence form an useful appendix to this essay. It already, however, occupies the limits which can be assigned to it in the *Cyclopædia*, and we content ourselves

and pretended to have been delivered, in order to obtain from her lover the execution of a promise of marriage. The latter claimed the child, which could not, of course, be produced. A charge of infanticide was brought against the pretended mother, who was compelled to show that she had not been delivered. This was attested by the medical examiners.

with referring the reader to the Thesis of Lecieux, where the points now adverted to will be found admirably exemplified.

ROBERT ARROWSMITH.

INFECTION, *infectio*, (not classical,) *infectus*, and *infectere*, Lat.—The meaning of this word has been, and perhaps still is, unsettled. It will be employed in this article to signify the deleterious or offensive qualities which certain matters designated by the terms malaria, matter of contagion, emanations, and effluvia, communicate to the air and other inert bodies; and likewise the pernicious effects which some of these substances produce on the human constitution. This description comprises, if we mistake not, all the physical senses in which the word is usually employed. It will be observed that, according to one of them, it is to a certain extent synonymous with contagion, and it is likewise made so by the custom of the majority of the profession; a custom which is in a great measure owing, we believe, to the word *contagion* being destitute of the verbal form, whence the phrases *to infect* or *to be infected* become convenient modes of expression. A good deal of confusion has resulted from an attempt to discriminate between contagion and infection, when the latter term is employed to express the transmission of disease from man to man; and in the article **CONTAGION** we have expressed an opinion that in this case the words should be regarded as strictly synonymous; but it will be observed that infection possesses a wider sense than contagion, being applied to cases of contamination which are never designated by the latter word.

Deleterious qualities may be communicated to certain bodies either by matters known only by their effects on the human constitution, or by those which affect perceptibly the sense of smell. Of the former an account will be found in the article **CONTAGION**, and in those on **MALARIA** and **MISASMA**. The latter consists of hydrogen and its compound gases, carbonic acid, azote, and perhaps other gaseous matters which are the result of animal and vegetable putrefaction aided by the presence of moisture. Their sources are various, such as cemeteries in which bodies are deposited at an insufficient depth from the surface, or from which it has been found necessary to remove the accumulated remains; slaughter-houses; dissecting-rooms; neglected privies and drains; stagnant waters, in which organic recrements are undergoing decomposition, as is often exemplified in noisome swamps, or at low water on the banks of rivers near their mouths, when in the vicinity of populous towns; human beings accumulated into a small space with deficient ventilation, &c.

The two genera of infecting substances frequently co-operate in producing an effect on the human system. Thus it is commonly observed that contagious diseases are more generally diffused and assume a worse character in an atmosphere abounding in manifest impurities than in one which is free from them. During the prevalence of typhus at Paris in 1814, the mortality was observed by M. Jadioux to be frightful in those wards of the Salpêtrière which are situated near the sewer of the hospital; and it were very easy indeed to multiply examples of this description.

The bodies which are sensibly contaminated by infecting particles are various, and differ much in their power of receiving and retaining the contamination. Confined masses of atmospheric air receive it readily and retain it long, as likewise do solid bodies which possess the property of holding air in a quiescent state within their interstices, such as cotton, wool, cloths fabricated from these substances, fur, feathers, &c. On the contrary, smooth and polished surfaces are tainted with difficulty, and are readily cleared of the pollution. These facts are illustrated by the well-known experiment of Mead, who placed a portion of carded cotton near a morsel of putrefying meat under an inverted bell-glass, and thus ascertained that the downy substance became strongly impregnated with the odour, and retained it long, whilst the contrary was the case with the smooth surface of the glass. The same rule is observable with respect to certain infecting particles of which our senses are unconscious, for the downy substances named retain contagious matter long, and hence become powerful fomites; but there is no reason to think that the species of marsh effluvia called malaria adheres to them so as to render them the media by which it is communicated to the human system.

Action of Infecting Substances on the Animal Economy.—We now come to the second branch of our subject, the consideration of the mode in which infecting agents operate on the human constitution, and the kind of change which they produce there.

If common odorous infecting matters are freely diluted with atmospheric air, we find that persons do not suffer from exposure to them, as is exemplified in the case of butchers, tanners, &c.; but in a more concentrated state they produce very deleterious effects, and occasionally instant asphyxia, which was illustrated by the well-known case of the exhumations in the cemetery of the Innocents at Paris, and is not unfrequently exemplified in attempts to empty privies which have been long neglected. The slower but yet pernicious effect of the same cause is shown in the unhealthy aspect of the inhabitants of filthy and ill-ventilated alleys in large cities of which the police is neglected. Those agents whose existence is recognised only by their influence on the animal economy are likewise found to be affected by admixture with pure air. The effect of dilution is very conspicuous in the case of human effluvia, which have their intensity much diminished in a free and pure atmosphere. Marshy emanations retain considerable noxious power at a distance from their source, but there is a point beyond which they are inoperative, showing that diffusion in the atmosphere is ultimately destructive of their agency.

There are two hypotheses regarding the mode in which these matters act injuriously on the economy. According to one, their operation is on the nerves of the part to which they are applied; the other supposes them to be absorbed from the same part into the circulation. In the present state of our knowledge, it is impossible to decide in favour of one or the other of these modes, or to say that either of them is that which is uniformly operative. The very rapid action of certain me-

phitic gases leads to the supposition that an impression on the nerves of the air-passages is sufficient for the production of *their* poisonous effect on the system. The cutaneous surface, the mucous membrane of the air-passages, and the corresponding surface of the alimentary canal, have each of them been supposed by different medical reasoners to be the channel by which noxious agents find access to our system. Lancisi, who first reasoned with any degree of accuracy on this subject, conceived that such agents might be transmitted by all these media to the interior; and we believe that he was correct in supposing that any of them might be the channel through which the system is contaminated. When the epidermis is entire, the absorbing power of the cutaneous surface is so very feeble, and its nerves are so protected by an inert covering that it is probable that gaseous matters of a noxious nature rarely act in this way; but more concentrated substances often do so when the surface is broken, as in inoculation or injuries from dissection, which last certainly produce a species of infection. The first impression from infecting matter diffused in the atmosphere was supposed by the late Dr. Jackson to be made on the alimentary canal; and it is very probable, at least, that by the act of deglutition, which persons are almost incessantly performing to swallow their saliva, noxious particles may be conveyed thither, and whether we regard its mucous membrane as an absorbing or sentient surface, it is one through which such particles are very likely to act on the animal economy. But the most ready access for atmospheric poisons to the system is afforded by the air-passages. The experiments of Nysten and Edwards have proved that hydrogen, azote, and other gases, are rapidly absorbed by the lungs; and analogy would lead us to attribute a similar susceptibility of absorption to contagious and other miasmata; whilst if we reject the necessity of absorption, and assume that a nervous impression is all that is required, we find a widely extended and sensible membrane on which the deleterious corpuscles may operate.

The local operation of these poisons has been considered as far as our present knowledge of the subject admits. It remains that we should notice their more general effect, or their operation on the animal economy, if we are to take such a view after they are absorbed into the circulating mass. To discuss the various changes which odorous infecting matters effect in the system—the modes in which they destroy life or impair its vigour, would lead to a very lengthened disquisition, and one which perhaps belongs rather to the physiologist than the practical physician. But the agency of the morbid poisons by which what is strictly called infection of the human constitution is produced, and diseases are engendered ranking among the most important of our nosologies, demands some notice in this place. To whatever parts of the body morbid animal poisons or marshy effluvia may be in the first instance applied, and however various the diseases ultimately engendered by them, we believe that their primary constitutional effect is on the nervous system. The period which generally intervenes between the application of a contagious or paludal poison and the full development of the disease engendered by it, is not one

of health; and the slight signs of indisposition which exist are referable to the nervous system solely, excepting in a proportion of the cases arising from marsh effluvia, where some disorder of the bowels is after a time associated with the indications of nervous affection. These indications are extreme debility, inertness in motion, irritability and despondency of mind, incapacity of continued attention, noises in the ears, occasional giddiness, inappetency or morbid appetite, and extreme susceptibility of the impression of cold, the vascular system being during this period free from manifest disturbance. The first symptoms of the invasion of the actual disease partake of the same nervous character. They are giddiness of the head, pain there and along the spine, marks of irregular distribution of heat, rigors, inappetency, nausea, and in a proportion of the cases of some diseases, the exanthemata for instance, convulsions. One morbid poison, that of hydrophobia, appears to confine its whole operation to the nervous tissue, an extraordinarily erethismal state of this tissue giving rise to all the phenomena of the disease, and at its fatal close there being no traces of local affection of uniform occurrence or of such importance as to be considered as the source of the symptoms witnessed during life. In most diseases the vascular and other systems are ultimately involved, but accurate observation will always discover preceding indications of an affection of the sentient portion of the frame.

For the mode of purifying infected substances, see DISINFECTION.

JOSEPH BROWN.

INFLAMMATION, from *inflammo*, to burn; hence, also, *phlogosis*, *phlegmasie*, *phlegmon*, &c. from φλέγω: a name given on account of the resemblance of spontaneous inflammation to the effects of the application of fire to the living body.

There has hitherto existed so much diversity of opinion respecting the proximate cause or nature of inflammation, and it is a disease assuming such an infinite variety of forms, that it is scarcely possible to give a strictly correct and scientific definition of it. The following, proposed by Peter Frank, is the most comprehensive and accurate which has hitherto appeared:—"Calor partis, tensio, moles, ac durities acuta; ut plurimum cum sensu doloris fixi, nunc ardentis, nunc pungentis, pulsantis, nunc gravativi, aliquando nullæ, cum colore vivido, nunc profundius rubro; sæpissime cum febre, pulsu frequenter pleno, forti ac duro, sæpe contracto ac parvo, aliquando naturali; ac tumoris evidenti, aut in suppurationem, aut in gangrenam nisu, dicitur inflammatio." P. Frank, however, judiciously adds that the presence of all these signs is not necessary to constitute inflammation, and that frequently some of them are wanting.

So large a proportion of the diseases which affect the human frame are of an inflammatory nature, that the study of the pathology and treatment of inflammation has at all times been considered a subject of interest and importance. The opinions entertained by professional men at different periods on this branch of medical science have necessarily varied with the prevalent theories of the day. The writings of the older authors abound with speculations, more or less ingenious, respecting

the nature, causes, and treatment of inflammatory affections; and although they do not supply much information founded on the sober and rigid deductions of experimental philosophy, a brief review of the theories of inflammation may prove both interesting and useful, as an occasional ray of light sometimes glimmers forth in the midst of much obscurity, and the errors into which those who have indulged in visionary conjectures have fallen, may serve as beacons to protect us from a similar danger.

The general principles respecting the nature of diseases, promulgated by Hippocrates, exercised a considerable sway over medical science for above two thousand years, holding a more or less prominent station in the systems of almost every sect down to the close of the last century. These views laid the foundation of the Humoral Pathology, in which the first material innovation, and especially in the theory of inflammation, was made by Paracelsus in the fifteenth century, who, having bestowed considerable attention on the study of chemistry, endeavoured to account for all diseases by changes in the chemical composition of the animal fluids. This gave origin to the sect of *chemical physicians*, who violently opposed the doctrines of the school of Hippocrates and Galen. There was a strong tendency in the physiologists of that period to ascribe exclusively the phenomena of life to the influence of the same laws as those which regulate the motions of inanimate matter; and some conceiving they could satisfactorily explain all the operations of the animal economy on the principles of mechanics, founded a sect of *mechanical physicians*.

The ignorance which had hitherto prevailed respecting the circulation of the blood contributed, no doubt, very materially to prevent the introduction of more correct views of pathology: it was very generally believed that the liver was the centre of the vascular system, from which the blood went forth by day to the extremities, returning again by night; if any peccant matter irritated the liver, the blood was sent out more forcibly; and if, at the same time, any part of the body were either weakened or irritated, a swelling was produced by the flow of humours to this place: fluxions might therefore happen either from weakness or irritation; the peculiar nature of the swelling was supposed to be modified also by the nature of the humour: blood produced the true phlegmon, bile being the supposed cause of erysipelas, &c. The blood and humours were imagined sometimes to stagnate in a part from want of expulsive power, and this was termed congestion; whilst fluxion or defluxion denoted a sudden flow of humours from a distant part.

The discovery of the circulation of the blood by Harvey in the beginning of the sixteenth century, was not followed by such an immediate improvement in the theory of inflammation or of other diseases as might perhaps have been expected. Although the course of the blood in the large vessels, and the connection between the lymphatic and sanguiferous systems through the medium of the receptaculum chyli and thoracic duct, were facts clearly ascertained, the functions of the capillary circulation and of the nervous system, which are more immediately connected with the

proximate causes of inflammatory affections, were yet very little understood.

Böerhaave, one of Stahl's contemporaries, a professed eclectic, endeavoured to select whatever appeared most valuable in all preceding systems, and to combine the whole into a uniform body of medical science. He took the humoral pathology as the basis of his theory of disease, and especially of inflammation, but adopted also many of the opinions of the chemical and mechanical sects. He considered that the blood and humours were vitiated in disease either by an excess of acid or of alkali, or by becoming too viscid and glutinous, or too thin and watery; that the circulation of the fluids might be too rapid or too slow; that the fibres of the solids were either too feeble and relaxed, or too rigid and elastic; that there were also separate diseases of the large vessels and of the capillary system.

The following summary will afford a connected view of the fanciful speculations of the different sects whose opinions we have thus briefly noticed. The propelling force of the heart having been ascertained, and microscopic observations having been made on the capillary vessels, and on the size of the globules which pass through them, the mechanical physicians imagined they could satisfactorily explain many of the phenomena of disease by the effects of friction, pressure, and trituration, and by the relative dimensions of the vessels and of the globules which they circulate: these globules were described by Leeuwenhoek as conical; so that, when forced into very small vessels, they became fixed like a wedge. The combinations and decompositions of the chemists added to the preceding theory that of the acrid and inflamed, the inspissated, fermented, or putrid state of the humours. They were thus heated by the excess of friction, of motion, or of pressure, or rendered acrid, irritating, and inflammatory by an excess of acid; they distended the vessels by their rarefaction, were condensed by evaporation, becoming then corrupt and dissolved; or when too viscid and inspissated, they stagnated in the vessels, which were too feeble to expel them, and became cold and concrete, until some strong reaction took place by which the crude morbid humour was concocted, and the tumefaction resolved either by the formation of pus or the elimination of the concocted humour through some of the excretory organs. At other times, the solids being too lax and weak for the perfect elaboration of the fluids of nutrition, became corrupted and dissolved, acquired an excess of alkali, and gave origin to putrid diseases. Their treatment was adapted to these views of the nature and causes of diseases, and we consequently find in their therapeutics refrigerant remedies, delayants, inspissants, antiseptics, resolvents, depuratives: and some slight share of influence in the production of disease being allowed to the solids, there were also remedies intended to increase the tone and cohesion of the fibres; others to relax and lessen rigidity, and others to allay excessive sensibility.*

The contending sects of chemical and mechanical pathologists were completely overthrown in the beginning of the seventeenth century by the

* For a full account of all the leading medical theories, see Broussais' *Histoire des Doctrines Médicales*.

opinions of the celebrated Stahl. Having noticed that the changes which the components of the body undergo during life, differ greatly from those that take place after death, he conceived, like Hippocrates, that there must necessarily exist some additional principle during life, by which the action of the mere physical laws is counteracted and modified, and from which the body thus derives its distinctive character of vitality. He imagined this agent, which he called *anima*, to be something distinct from the body, possessing a species of intelligence which enabled it to act the part of a rational being, and to superintend all the operations of the animal economy. There is an apparent analogy between the *anima* of Stahl, and the *φύσις* of Hippocrates: the latter, however, only proposes his term as a rational manner of explaining the facts he observed, whilst the former considers his principle as an abstract metaphysical spirit, capable of acting independently of the state of the body, and without any physical necessity arising from that state. In other respects Stahl adopted most of the opinions of Hippocrates, and engrafting on them some of the doctrines of the chemical school, his pathology turned chiefly upon the opposite states of plethora and cacochymy.

Van Helmont, one of the most distinguished of the Vitalists, proposed a more rational theory of inflammation than any of his predecessors. According to him there were two circumstances indispensable to the development of inflammation—the action of a stimulus on parts endowed with sensibility, and an increased activity of the arterial system, followed by redness, pain, heat, and swelling in the part thus stimulated. He not inaptly compared the action of the stimulus to that of a thorn thrust into living flesh: this excited the alarm of his *archæus*, who immediately caused an increased flow of blood to the part, and set up a defensive and reparatory process. He adopted also many of the chemical opinions, conceiving his ideal inflammatory thorn to be generally acid, &c.

The humoral pathology, after keeping for a long period almost exclusive possession of the medical schools, began to receive a serious check from the doctrines taught at the University of Halle by Hoffmann; who contended strongly against the long-established notion that a vitiated state of the fluids was the primary cause of the great majority of diseases, and maintained that it was much more rational to attribute their various phenomena to morbid conditions of the solids, by which the fluids themselves were contained, elaborated and kept in constant motion. There were, according to him, two principal morbid states of the solids, *spasm* and *atony*; and as the motions of the solids seemed to depend in a great measure on the influence of the nerves, he ultimately referred most diseases to affections of the nervous system: he attributed to the nervous principle the functions which Stahl ascribed to his *anima*, and Hippocrates to his *φύσις*. These views of disease were zealously embraced by Baglivi in Italy, Barthé at Montpellier, and Cullen in our own country: the latter applying them with great talent and ingenuity, as will be seen presently, to the theory of inflammation. The humoral pathology soon became completely exploded, and a totally

opposite system was substituted in its place, called that of the *Solidists*. The introduction of this system was greatly favoured by the labours of the celebrated Haller, whose important discoveries in anatomy and physiology have contributed so much to our knowledge of the intimate structure and functions of the different organs, and particularly of the nervous system.

Dr. John Brown of Edinburgh, adopting some of the opinions of the Solidists, founded on them a most fanciful system of physiology and pathology, which, although less noticed in this country, was eagerly adopted in France and Italy, and partially also in Germany, and had a most baneful effect over the practice of medicine in these countries. According to Dr. Brown, life is only sustained by the action of either external or internal stimuli on the body through the medium of the nervous system: this susceptibility of impression he calls *excitability*. If the action of stimulants be too much increased, this gives rise to diseases with excess of action (*sthenic*), and, when deficient, to diseases of debility (*asthenic*.) Asthenia is subdivided into *indirect*, when the excitability is exhausted by excessive excitement, and into *direct* when the deficiency of excitability arises from a want of adequate stimulus. Dr. Brown attended more to the state of the general excitability than to the condition of the organs: there were thus two deviations of the excitability from the standard of health, constituting the *sthenic* and *asthenic* diatheses, and only two great classes of diseases: he maintained, moreover, that both *sthenia* and *asthenia* could never exist together in the same individual; so that, if an individual presenting signs of general debility was seized with pneumonitis or hepatitis, the local affection, however severe, was attributed to debility, and treated by stimulants: inflammations were thus divided into two classes, the *sthenic* and *asthenic*; and idiopathic fevers, hemorrhages, congestions, convulsions, plethora, &c. were classed among the diseases of debility. He asserted that the diseases of direct and indirect debility so greatly preponderate over those of the opposite class, that out of every hundred cases there were scarcely three of genuine inflammation: there were accordingly only two classes of remedies, and these pernicious principles necessarily led to a most incendiary system of practice. The apparent simplicity and plausibility of this theory unfortunately obtained for it numerous adherents.

The Italians, after adopting Brown's theory, discovered at last its fundamental errors, and engrafted on some of his physiological principles a new system called the *contro-stimulant*; they admit two opposite diatheses, one of *stimulus* and one of *counter-stimulus*, and have founded a third class of diseases consisting of local irritations, which may give rise to either of the two preceding morbid states of the constitution: they accordingly adopt only two classes of remedies, the stimulants and counter-stimulants; the latter being supposed to remove directly, and without even any evacuation, the excess of stimulus in the system, whilst stimulants act in a manner directly the reverse: the animal fibre, it is also supposed, will tolerate the action of stimulants or counter-stimulants exactly in proportion to the

strength of the existing diathesis, either of stimulus or counter-stimulus. Venesection is, however, considered as an active counter-stimulant. Counter-stimulant remedies include above nine-tenths of the *Materia Medica*; we have thus tartar-emetic, bark, mercurial and saline purgatives, preparations of iron, all kinds of bitters, &c. classed together as suited to combat inflammation. The really stimulating remedies are limited to a very small number, such as opium, fermented liquors, &c.

Several distinguished physicians introduced about this period the more practical and judicious method of investigating carefully the symptoms, course, varieties, and post-mortem appearances of diseases. A number of highly valuable monographs of disease were the result of this course of proceeding. Among these we must first mention, as particularly deserving of notice, the works of the great Sydenham. He was the foremost to perceive the necessity of descending from the engaging but profitless regions of fanciful speculation, to the more laborious task of a rigid and accurate observation of the phenomena of nature; and his example had a powerful influence in giving a new and better direction to the investigations of medical science throughout Europe. Many excellent descriptions of the inflammatory affections of separate organs, and of the alterations of structure which they induce, are also to be found dispersed throughout the writings of Grant, Stoll, De Haen, Morgagni, Bonetus, Wagler, Ræderer, &c. Bordeu, in his work on chronic diseases, gives a very minute and faithful account of the irritative and inflammatory affections of the digestive tube, and lays considerable stress on the sympathetic influence exercised by the abdominal viscera over every other part of the animal economy.

Inflammatory diseases had not, however, hitherto formed the subject of any special and separate inquiry; and the merit of having contributed the first scientific work on this important class of diseases belongs to our talented countryman Dr. Carmichael Smith, who in 1788 published an admirable paper on this subject, (*Medical Commentaries*, vol. ii.) in which he took a comprehensive view of the peculiarities of inflammation as they are observed in the principal elementary tissues that enter into the composition of the body: this was laying the foundation of the morbid anatomy of tissues, from the cultivation of which medical science has since derived such incalculable advantage.

The next separate treatise on inflammatory diseases was one on chronic inflammations by M. Pujol, of Castres in Languedoc, which obtained a premium from the Royal Academy of Medicine of Paris in 1791: in this valuable work the author first considers the chronic inflammatory affections of the surface of the body, and next those in succession of the three splanchnic cavities.

The preceding writers had confined themselves to a general description of the different varieties presented by inflammatory diseases, and of the changes of structure they induce. The celebrated John Hunter instituted an experimental inquiry into the essential nature and proximate cause of the process of inflammation, an undertaking for

which he was particularly well qualified by his admirable knowledge of the minute anatomy of tissues; and his great work on the *blood, inflammation, and gun-shot wounds*, appeared in 1794: this was the first experimental and scientific treatise on the theory of inflammation ever published;* it is distinguished for depth and accuracy of observation, acuteness of reasoning, and original and enlarged views of the laws which regulate the functions of life, and must ever be considered as a lasting monument of the author's genius. We shall frequently have occasion to refer to it in the course of this article.

The modifications occasioned in disease by the structure of the part affected, were beginning to excite more general attention, as appears by the writings of Dr. Wm. Hunter, John Hunter, the two Monros, and Dr. Cullen, as well as by the splendid collections of pathological preparations made by the four former. M. Pinel, sensible of the many advantages that might be derived from a more comprehensive study of the influence of texture in modifying disease, made this the ground-work of his valuable *Nosographie Philosophique*, which was first published in 1797. Although some imperfections must necessarily attach to every nosological arrangement in the present state of medical science, the plan followed by this distinguished pathologist was infinitely superior to that of any of his predecessors, and had a highly favourable influence on the medical opinions of the time. The phlegmasiæ constitute the second class of the *Nosographie Philosophique*, and are divided into five orders, founded on the five principal animal tissues—inflammations of the cutaneous tissue; of mucous membranes; of serous membranes; of the cellular tissue and parenchymatous texture of organs; of the muscular, fibrous, and synovial tissues: this is exactly the division that had been adopted several years before by Dr. Carmichael Smith.

It was the *Nosographie Philosophique* that suggested to Bichât the plan of his great work on the anatomy of tissues. This justly celebrated work may be considered as having laid the foundation of the improvements made in France in every department of anatomical and physiological science, since the beginning of the present century: it is only necessary to refer in proof of this to the labours of Laennec, Bayle, Magendie, Broussais, Andral, Louis, Lallemand, Rostan, &c.; and as relating more exclusively to the subject of the present paper, to the *Histoire Anatomique des Inflammations* of M. Gendrin, by far the most comprehensive and practical work that has yet appeared on inflammation; and to another valuable work, entitled *Recherches Experimentales sur l'Inflammation*, by M. G. Kaltenbrunner, published in the *Répertoire Général d'Anatomie et de Physiologie Pathologique*.

[On all this subject, most valuable information is contained in Dr. Alison's *Outlines of Pathology and Practice of Medicine*, Amer. edit. Philad. 1844; Dr. Williams's *Principles of Medicine*,

* A small treatise was published at Florence by Dr. Vacca in 1765, entitled *Liber Inflammationis morbosæ quæ in humano corpore fit, natura, causis, effectibus, et curatione*; but although containing some excellent observations, the work was chiefly speculative.

Amer. edit. Philad. 1844, and Mr. T. Wharton Jones's *Report on the Present State of Knowledge of the Nature of Inflammation*, in *Brit. and For. Med. Rev.*, April, 1844, p. 567.]

The cultivation of physiology and pathology has, during the same period, been pursued with great success in our own country. Among the many contributions to general or special pathology, may be mentioned those of Baillie, Thomson, Hunter, Philip, Hastings, M. Hall, Abernethy, Astley Cooper, Lawrence, Travers, Parry, Cheyne, Bright, James, Elliotson, &c.

Before concluding this brief historical sketch, we must notice the views respecting febrile and inflammatory diseases promulgated a few years since by Broussais, and very generally adopted in France. Although carried beyond their just and reasonable limits, Broussais' opinions have been the means of introducing a highly beneficial change in the system of practice of that country, by exploding Dr. Brown's phlogistic method of treating diseases, which was previously in almost general use.

Whilst Brown committed the great error of referring most diseases to a morbid state of the general excitability, overlooking in a great measure the constitutional effects of local diseases, Broussais, influenced probably by his more extensive acquaintance with pathological anatomy, founded his system of *Physiological Medicine* on the principle that all diseases affecting the general health have a local origin. Instead, also, of considering a morbid condition of the nervous system to be the proximate cause of all diseases, and the great majority of them as the effect of debility, he maintains that they depend much more generally on affections of the vascular system; that they originate in various degrees of irritation, congestion, and inflammation in some one organ, disturbing by morbid sympathy the functions of all the others; and that the great majority of diseases are, in fact, of an inflammatory nature. Local irritations and morbid sympathies constitute thus the fundamental principles of Broussais' system; many debilitating agents, he conceives, excite inflammation, and the deficient action of one organ may excite a sympathetic irritation in others. To the affections of the mucous membrane of the alimentary canal he attributes an inordinate degree of importance, more particularly the sympathy of the digestive with the other vital organs. He asserts that fever is always the effect of an irritation of the heart, either primitive or sympathetic; that every form both of continued and intermittent fever has for its primary cause inflammation of the mucous membrane of the stomach and bowels, which he terms *gastro-enterite*; he completely repudiates the notion of there being any such diseases as idiopathic or essential fevers, maintaining that they are all to be explained exactly on the same principles as the symptomatic fever of pneumonia: all the exanthemata, hepatitis, pyrosis, and a vast number of other diseases, are, according to him, complicated with *gastro-enterite*; and we heard him even boldly assert in his lectures, that hydrophobia was only a *gastro-enterite*, frequently complicated with some degree of inflammation in the pharynx and brain!—a most remarkable instance of the dangerous extent to

which the distortion of facts may be carried by an immoderate love of theory. An exposition of the fallacy of Broussais' opinions respecting fever will be found in the introduction to the article *FEVER*.

In writing upon a branch of pathology which has been the subject of so much investigation as inflammation, we cannot avoid repeating a great deal that has often been previously stated by others: as a reference to authorities on all points respecting which there can be no difference of opinion would be endless and inconvenient, we think it preferable to state here generally, that the sources from which we have chiefly derived assistance in the composition of this article, are the works of John Hunter, Thomson, Travers, Craigie, Elliotson, Andral, Gendrin, and Kaltenbrunner. Whenever we have occasion to mention opinions which possess any degree of novelty or originality, we shall either quote the author or refer to his work.

Physiological and Pathological Considerations on the Circulation.—There are three of the elementary parts of the body that appear to be primarily and more essentially affected in inflammation: these are the blood-vessels, the nerves, and the blood. As every rational theory of disease must be founded on a correct view of the healthy phenomena of life, we shall offer a few observations on the action of each of these parts in the living body, before proceeding to the details of the theory of inflammation.

The minute ramifications of the arteries and veins, and the capillary system of vessels, being the principal seat of the morbid phenomena of inflammation, it is important, therefore, to attend to the peculiarities of the circulation in these vessels. It is now generally admitted that the arterial branches acquire a greater power of contractility in proportion as they become smaller, and that the arterial trunks are less contractile and more elastic. That the minute ramifications of arteries are endowed with a high degree of contractility, in virtue of which they are enabled to carry on the circulation independent of the action of the heart, is proved by a variety of circumstances. It is by this order of vessels that the functions of nutrition and secretion are performed, and it is absolutely necessary for the uniform and uninterrupted accomplishment of these varied and highly important functions, that they should have the power of controlling the motions of the fluid circulating within them. The relative momentum of the blood in different parts of the body, or the quantity of the blood and its velocity, are perpetually varying from the influence of external stimuli or internal causes; and this variable state of the momentum of different portions of the arterial system is a decisive proof of the vital contractility of its vessels. We thus observe the minute vessels of the cheek, in the act of blushing, acquiring increased activity and admitting more blood; while under the influence of depressing passions, such as fear, they are suddenly emptied, and the countenance becomes pale. Local inflammation is stated by all pathological writers to be characterized by a rapid throbbing pulsation of the vessels in the part affected, while the action of the heart and arteries of other parts of the body is not increased. If a person having inflammation in

one hand be blooded in both arms at the same time, twice or thrice as much blood will flow from the diseased side as from the other. It is partly by the contractility of the extreme vessels in animals which have no heart, that the fluids in the lymphatics and lacteals are absorbed and moved. The minute arteries, like muscular tissues, retain the power of contracting after breathing has ceased; this is the cause of the empty state of the arterial system after death, for the small arteries and capillaries continuing to contract, empty their blood into the veins, while they receive no fresh blood from the heart. When death is rapidly occasioned by lightning or any violent narcotic poison, the action of the arterial and whole muscular system being suddenly destroyed, the arteries are found filled with blood as well as the veins.

The preceding facts respecting the active and independent power of the small arteries and capillaries over the circulation of the blood, have been strongly confirmed by the interesting microscopic observations of Dr. Thomson, Dr. Wilson Philip, and Dr. Hastings, for an account of which we must refer the reader to the writings of these distinguished physiologists.

It is, in the mean time, evidently impossible not to admit that the action of the heart and large arterial trunks, or *vis à tergo*, must assist in carrying on the capillary circulation. A constant supply of fresh blood is transmitted by each contraction of the heart, which must have the effect of distending and stimulating the action of the smaller vessels. When the contractions of the heart are unusually violent and rapid, the blood will no doubt be propelled through the small vessels, and especially through those within its vicinity, with a degree of force that will completely overcome the contractility of these vessels, and give them the appearance of passive canals; but this circumstance does not appear to us by any means sufficient to prove that under a quiet state of the circulation, and especially in parts of the body remote from the heart, the extreme vessels and capillaries have no control over the course of the blood: the reverse of this has, in our opinion, been satisfactorily established by the facts and experiments already adduced. We conceive, therefore, that it is more reasonable to admit the influence of both causes in the circulation of the extreme vessels, and that the advocates on each side of the question have been much too exclusive.

The preceding are highly important facts, which will require to be taken into consideration in investigating the nature of inflammation. It should also be stated, that according to the latest experiments, it would appear that the arteries do not terminate in exhalants, but that both exhalation and absorption take place through the pores of the thin coats of the vessels. (Magendie's Physiology, p. 353, 479, Dr. Milligan's translation.)

While we consider the independent vitality of the minute arteries as the most efficient agent by which they carry on the circulation, it is but reasonable to admit that the laws of capillary attraction may afford some degree of assistance; for the living body is never completely exempt from the influence of physical laws. Dr. Marshall Hall has lately made some interesting microscopic ob-

servations on the action of the capillary vessels. He describes them as a network of pellucid vessels, differing from the small arteries in the circumstance that they subdivide without becoming smaller, and freely anastomose with each other, like nervous plexuses, forming thus an intermediate system of vessels between the arterial and venous systems. He states several reasons for inclining to the opinion that they are rather passive than active canals, through which the blood is circulated by the impulse of the arteries, the absorbing action of the veins, and also by capillary attraction. The facts brought forward in support of this opinion do not, however, appear to us sufficiently conclusive to controvert the numerous proofs we have already mentioned in support of the opposite opinion; and we consider it, therefore, a subject requiring further investigation. Dr. Marshall Hall fully admits the contractility of the small arteries. (On the Circulation of the Blood, by Marshall Hall, M. D. &c.)

Dr. Reus, of Moscow, published, some years ago, an account of experiments tending to show that galvanism exercises a locomotive effect on the circulating fluids. This singular property has been more fully investigated of late by M. Dutrochet, (*Nouvelle recherches sur l'Endosmose et l'Exosmose*, &c. par M. Dutrochet, 1828,) who has made some very interesting discoveries respecting the circulation of fluids, and has applied them with considerable ingenuity to the functions of vegetable life. M. Dutrochet has ascertained that when two fluids of different densities are only separated by a thin bladder, they exercise a double power of attraction over each other, which leads to the formation of two currents passing through the bladder in opposite directions and of different strength: the necessary result is a greater accumulation of fluid on one side of the bladder, in the direction of the strongest current, and a diminution of fluid on the other side. He conceives this property to depend on differences of density, of chemical composition, and of states of electricity. He has demonstrated the existence of a double current of this description through the vesicular texture of vegetables, and he calls the introduction of fluids into the vesicles *endosmosis*, and their expulsion *exosmosis*. He endeavours to account in this way for the ascent and descent of the sap, and for the circumstance of the roots of plants taking always a direction downwards, and the stems a direction upwards. This property is shown to differ from capillary attraction. May not *endosmosis* and *exosmosis* be reasonably supposed to have some influence over the circulation in the extreme vessels in animals as well as in vegetables? This has already been made the subject of some highly interesting experiments by Dr. Faust* and Dr. Mitchell (*On the Penetrativeness of Fluids—American Journal of Medical Sciences*, vol. vii.) in America, and Dr. Stevens (*Observations on the Healthy and Diseased Properties of the Blood*) in our own country. These gentlemen have clearly proved that gases are subject to the singular laws of *endosmosis* and *exos-*

* Experiments and Observations on the Endosmose and Exosmose of Gases, and the Relation of these Phenomena with the Function of Respiration—*American Journal of Medical Sciences*, vol. vii. Philad. Nov. 1830.

mosis as well as fluids, and they have deduced from the facts they have observed a completely new and very ingenious theory of the function of respiration.

The connection and mutual influence of the two great systems, the vascular and nervous, on which mainly depend the functions of life in the higher classes of animals, has often been an interesting subject of inquiry with physiologists, and is one that involves considerations of the highest importance also to the pathologist. It may be necessary to premise that there are two great divisions of the nervous system, the first including the cerebro-spinal organs and their nerves, and the second the ganglionic system of the great sympathetic; and that the vascular system may be also divided into two sections—the circulation of the heart and large vessels, and that of the smaller and extreme vessels.

The heart and larger vessels receive but few nerves directly from the cerebro-spinal portion of the nervous system, their nerves being principally supplied by the ganglionic system of the great sympathetic, which appears to have the organic or nutritive functions of life more especially under its influence. The two divisions of the nervous system are, however, intimately connected by the numerous branches the great sympathetic receives from the spinal marrow, and by a few smaller branches coming from the brain.

There has been much difference of opinion among physiologists respecting the degree of influence exercised by the brain and spinal marrow over the organs of circulation; some concluding from their experiments that the action of the heart and blood-vessels is wholly independent of this portion of the nervous system; while others adopt, as the result also of experiments, a directly opposite opinion. The medium between these contradictory views approaches probably the nearest to truth; and the following facts may, we think, be considered as satisfactorily established by the joint testimony of experiment and pathological observation.* The action of the heart and large vessels is not immediately dependent on the influence of the cerebro-spinal nerves, for these organs continue to carry on the circulation after the brain and spinal marrow have been completely destroyed; they preserve, however, this independent power only for a short time, as their contractions gradually become weaker, and completely stop at the end of a few hours. It is evident, therefore, that the functions of these organs, although partially removed from the direct influence of the brain and spinal marrow, cannot be continued in full vigour and activity after the destruction of this important portion of the nervous system. We see, likewise, these positions clearly illustrated by the natural phenomena both of health and disease. The action of the heart is not perceptibly affected by the ordinary operations of the mind, while it is frequently either quickened, depressed, or totally suspended, on the occurrence of sudden and powerful emotions; the functions of the heart are also not disturbed by partial diseases of the brain or spinal marrow, but

very extensive lesions of these organs lead inevitably to some alteration in the state of the circulation.

The circulation in the extreme vessels (arteries, capillaries, and veins) is also in a great measure independent of the direct influence of the cerebro-spinal portion of the nervous system, for when the communication of a part of the body with the brain and spinal marrow has been destroyed, as, for instance, in paralysis, the function of nutrition is still carried on, although with diminished activity. The blood-vessels are chiefly supplied with nerves from the great sympathetic; the nervous filaments follow the ramifications of the arteries, subdividing most minutely around them, forming plexuses and penetrating their coats; the nerves of the cerebro-spinal system are also largely distributed, along with the blood-vessels, throughout the texture of many organs, conveying additional stimulus, although, as just stated, not absolutely indispensable to the action of the vessels. It may therefore be truly said, that wherever there are blood-vessels there are also nerves, and that there is scarcely a particle of organized animal matter without nervous tissue.

It is not, therefore, surprising that the varied and important functions of the extreme vessels should be under the immediate and powerful influence of the nervous system, and more especially of the ganglionic nerves of the great sympathetic. This is rendered obvious by innumerable facts both in physiology and pathology. The activity of the circulation in these vessels, and the various changes which the circulating fluid undergoes in the process of nutrition, secretion, &c., are, it is well known, accelerated, retarded, or otherwise altered, according to various modifications of sensibility. A striking proof of the important offices performed by the nervous system in these functions is also afforded by the result of Dr. Wilson Philip's experiments on the influence of galvanism over the function of secretion. (Wilson Philip on the Vital Functions, c. v. p. 119.)

Some physiologists have conceived that the nervous system has even a direct influence on the blood in the extreme vessels, an opinion which Andral is inclined to favour, as will be seen by the following extract from his pathological anatomy:—"Barthez has said a great deal about a direct influence exercised by the nervous system over the blood: I grant that such an idea seems unfounded if we consider the blood only as it is in its great vessels; but in the capillaries, where it comes in contact with the solids and is confounded with them, where it manifests signs of vitality, and where in conjunction with the nerves it gives life to the organs it traverses;—in these, I say, who will venture to deny the influence of the nerves over it? In the capillaries is exerted in full force that law of mutual dependence that connects all the parts of the system, and makes of so many different elements but a single whole, of so many partial lives a single life. In them the nerves must act on the blood, as the blood acts on the nerves." (Andral, Pathological Anatomy, p. 660.)

It should be remembered, on the other hand, that the nervous system is immediately dependent on the stimulus of blood for the preservation of its power, for this is completely destroyed the moment

* This is the conclusion Dr. Marshall Hall has adopted after repeating the experiments. An account of the whole controversy will be found in his valuable little Treatise on the Circulation of the Blood.

the nervous centres are deprived of arterial blood : there is, therefore, no fact in physiology better established than that of the intimate connection and mutual influence on each other of the vascular and nervous systems. They are the two that are first developed in the embryo, and they fulfil the most important offices in all the phenomena of life. These considerations are of considerable importance to the investigation of disease, as it will be seen that the various morbid conditions of the sensibility constitute one of the essential features of the process of inflammation.

We have next to consider the properties and uses of the blood. The ancients were so little acquainted with the structure and formation of the body, that perceiving the secretions and excretions generally vitiated in disease, they naturally considered the morbid conditions of the blood and other animal fluids as the primary and exclusive source of all diseases. After the humoral pathology had prevailed for many centuries, the rapid progress made in the science of anatomy and physiology about the time of Haller, led pathologists into the opposite extreme of referring exclusively all the phenomena of life, both in health and disease, to the action and various conditions of the solids; the humoral pathology became then completely exploded by the speculations of the solidists. A more careful and impartial investigation, however, of the properties and uses of the various constituent parts of the animal economy in modern times, has been followed by the adoption of more comprehensive views of the operations of life; and it is now satisfactorily proved that the animal fluids, and particularly the blood, exercise an influence fully equal, if not superior, to that of the solids. In consequence of the imperfect state of animal chemistry, no very satisfactory results have yet been obtained from the analysis of the blood in disease. There can be no doubt, however, from numerous recent observations, that it presents in many diseases a variety of remarkable changes in its physical characters: we must refer the reader for an account of these to the article *BLOOD, MORBID STATES OF THE*. Various alterations have also been discovered both in the chemical composition and physical properties of the other animal fluids as the effect of disease, and the *HUMORAL PATHOLOGY* is beginning to obtain, once more, the degree of attention to which, within rational limits, it is unquestionably entitled.

The blood has at all times been considered the chief support of life, and on this account, according to many, the seat of the vital principle. This is an opinion recorded in the most ancient books. We find in the Old Testament the following remarkable declarations of the inspired writers on this interesting point; "But flesh with the life thereof, which is the blood thereof, shall ye not eat." (Genesis, ix. 4.) "For the life of the flesh is in the blood." "For it is the life of all flesh; the blood of it is for the life thereof; therefore I said unto the children of Israel, Ye shall eat the blood of no manner of flesh, for the life of all flesh is the blood thereof."*

* Leviticus, xvii. 11-14. This is the reason of the Jews refusing at the present day to eat the flesh of any animal which has not been bled to death, and of their having their own butchers.

This opinion was embraced by Harvey, and in modern times has been warmly advocated by John Hunter. He considered, like some of the ancients, the principle of life to be a kind of distinct agent, independent of the conditions of matter, and endowed as it were with consciousness; he believed, however, this principle to reside chiefly in the blood, and made a great many ingenious experiments tending to support this opinion. Hunter's arguments in favour of the independent vitality of the blood, were its property of spontaneous coagulation, and of assuming under certain circumstances the most complete organization. When blood is drawn from the vessels, the globules, which consist of pure fibrine, are attracted together and disposed to arrange themselves in lines or fibres, constituting the crassamentum. This fibrous arrangement bears a great analogy to the fibres of muscles, which consist also chiefly of fibrine.† Many causes of sudden death, such as lightning, the bites of venomous animals, some acrid and narcotic poisons, by which the nervous action is suddenly paralysed, have also the remarkable effect of suddenly changing the composition of the blood, preventing its coagulation, and rendering it incapable of supporting life. Under similar circumstances, the muscles are also found relaxed and incapable of being excited by the accustomed stimuli. These facts have been supposed by Hunter to prove an identity between the property of muscular contraction and that of the coagulation of the fibrine;‡ this idea seems to be further supported by the circumstance of the chemical composition of the fibrine and of muscle being nearly the same.

There have been many speculations on the cause of the spontaneous coagulation of the blood, some ascribing it to its death, and others, like Hunter, to its life, whilst some have attributed it to the escape of carbonic acid gas. The remarkable property of spontaneous organization which has been so frequently observed in coagula of blood, seems directly opposed to the idea of its coagulation being the effect of its death; on the other hand, if blood is frozen and then thawed, it coagulates the moment it becomes liquid. We must admit that the blood was dead when frozen, and its coagulation after being thawed cannot therefore be reasonably attributed to its life. (Elliotson's Lectures, Med. Gazette, Dec. 1831.) The opinion of the coagulation depending on the escape of carbonic acid, which has been advanced by Sir C. Scudamore, is proved to be equally fallacious by the fact, that no carbonic acid has been

† Dr. Hodgkin, having made numerous microscopic observations on the minute structure of various tissues and on the composition of some of the animal fluids, denies that the particles of the blood have a globular form, and gives a description of them totally different from that of preceding physiologists. (Catalogue of the preparations in the anatomical museum of Guy's Hospital, observations on section xi.)

‡ Dr. Stevens, who has made many experiments on the coagulation of the blood, mentions the following remarkable fact: "If at a certain period after the coagulation has commenced, we add muriate of soda or a saline solution to the coagulating blood, the moment that the fibrine feels the stimulus of the salt, the whole of it becomes suddenly solid; and I have seen the fibrine of inflammatory blood, which had been drawn during the hot stages of the marsh fever, contract on the application of salt with almost as much rapidity as the muscles, when we apply the same stimulus to the fibres in the living body."—Stevens on the Blood, p. 183.

detected in the blood by the most accurate chemical analysis. Dr. Stevens has attempted to prove that the fibrine partly owes its fluidity within the body to the circumstance of being held in solution by the saline substances contained in the serum; that this saline solution, together with the influence of the living principle and of constant motion, contributes to preserve its fluidity in the vessels, but becomes insufficient to hold it in solution when removed from the body. The insurmountable objection, however, to this hypothesis is, that fibrine is found to be totally insoluble in solutions of neutral salts. Dr. Bostock's explanation of this property of the blood appears to us on the whole the most rational. He states in his valuable *System of Physiology*: "Perhaps the most obvious and consistent view of the subject is, that fibrine has a natural disposition to assume the solid form when no circumstance prevents it from exercising this inherent tendency. As it is gradually added to the blood, particle by particle, while the fluid is in a state of agitation in the vessels, it has no opportunity of concreting; but when it is suffered to be at rest, either within or without the vessels, it is then able to exercise its natural tendency. In this respect the coagulation of the fibrine of the blood is very analogous to the formation of organized solids in general, which only exercise their property of concreting or coalescing under certain circumstances, and when those causes, either chemical or mechanical, which would tend to prevent the operation, are not in action." (*Elementary System of Physiology*, vol. i. p. 444.)

[It is proper, however, to remark, that the blood may remain fluid in the vessels, and coagulate when removed from them long after the death of the body. In a case observed by the author, it flowed freely from the vessels of the brain, and coagulated fifteen hours after the total cessation of respiration and circulation, (*Proceedings of the American Philosophical Society* for May, June, and July, 1840, p. 216, and *Amer. Med. Intelligencer*, Aug. 1, 1840); and many such cases have been observed by others, (Dr. J. Davy, *Researches, Physiological and Anatomical*, Amer. Med. Lib. edit., Philad. 1840.) These facts would favour the idea, that the coagulation of the blood is a purely physical phenomenon.]

But the great argument in favour of the vitality of the blood is its property of spontaneous organization. When the fibrine and albumen [*liquor sanguinis*] are exuded in the form of coagulable lymph, it frequently happens that, although not in immediate contact with any of the surrounding solids, blood-vessels are seen shooting in every direction through the mass of concrete lymph, and it is gradually transformed into a new and perfectly organized living solid, having blood-vessels, lymphatics, and nerves, and performing all the functions of an original texture. The blood and the solids, when submitted to chemical analysis, are found to consist of the same proximate principles, and a similar analogy is observed in their physical structure, both consisting of globules variously united; these different circumstances made Bordeu apply to the blood the expressive appellation of liquid flesh, *une masse de chaire coulante*.

It must, therefore, be admitted that the blood

contains within itself the elements of organization, whether or not it be the exclusive seat of the vital principle. The powerful influence of the blood on the vital properties is further proved by the fact, that the degree of vigour and activity of animal life depends in a great degree on the qualities of this fluid. If the blood contains a large portion of fibrine and red matter, the animal presents every sign of florid and exuberant health, and is predisposed to inflammatory affections: when the crassamentum of the blood is deficient and pale, and the serum preponderates, a languid state of health is the consequence, and a predisposition to diseases of debility. These opposite qualities of the blood are observed to depend in a great measure on its being brought into contact with either an ample or deficient supply of oxygen, provided always that a due quantity of nourishment is also received through the digestive organs. The vigour and activity of life can thus be partly estimated by the quantity of oxygen consumed, and also by the consequent degree of development of the animal temperature. This has led some to conjecture that oxygen was the principle of life; it can scarcely, however, be considered in any other light than that of a secondary agent; for if oxygen did not meet in the living body with some specific power modifying its action, there is no satisfactory reason why its influence on living animal matter should lead to results differing so remarkably in many respects from those it is observed to produce on inanimate matter.

Theory of Inflammation.—After the phenomena of inflammation had for a long period been referred to a vitiated state of the fluids, and to mechanical or chemical causes, pathologists began to perceive the impossibility of giving a rational explanation of all the morbid changes that mark the inflammatory process by any supposed state of the blood alone, and turning their attention to the condition of the vascular system, they fixed on an increased action of the blood-vessels as its proximate cause. It was found difficult, however, to reconcile the swelling of inflammation, which necessarily requires an increased capacity of the vessels, with the notion of an augmented vital action, which would imply an increase of their contraction. Boerhaave endeavoured to solve the difficulty by attributing the swelling and obstruction to a change in the texture of the blood itself, which, he imagined, became more thick and viscid, acquiring what he called a state of *lentor*; he supposed also that the increased action of the arteries forces the larger particles of the blood into vessels too small to receive them, which constituted the *error loci* of the mathematical pathologists; they conceived that the structure of the globules was very complicated, each red one consisting of six serous, and each serous of six lymphatic globules, for the conveyance of which, vessels of three different kinds and sizes were provided as channels of communication between the arteries and veins, so that if a globule got into a wrong vessel, it might obstruct all those behind it.

For this mechanical theory of Boerhaave, Cullen substituted his hypothesis of spasm and constriction of the small vessels, which, he believed, was sometimes the effect of direct debility, and connected with a diminished energy of the nervous

power of the whole system, arising from the action of certain deleterious causes on the brain. The necessary consequence of this general spasm of the extreme vessels was a reaction of the heart and large vessels, which had the effect of solving the spasm; this was his theory of idiopathic fever. He conceived also, as another principle in the pathology of inflammatory affections, that there was a peculiar condition of the whole vascular system, which predisposed to and might be induced by local inflammation, and which constituted what he termed the *diathesis phlogistica*; that this consisted in an increased tone or contractility of the muscular fibres of the whole arterial system, which existed generally in persons of the most rigid fibres. The obstruction of the blood in inflammation was thus attributed to spasm; but it was obvious that a state of spasm would be directly exposed to tumefaction; and that, if the first effect of local stimuli were spasm, the very reverse of swelling and redness would take place, the blood being expelled from the vessels of the part, as is seen in convulsions, where it is driven from the surface to the centre of the body; that if also the spasm were the consequence of a previous congestion of the vessels, this congestion should be received as the proximate cause, and the spasm merely as an effect.

Although there exists, no doubt, a habit of body corresponding to the *diathesis phlogistica*, which may predispose to inflammation, it is likewise satisfactorily proved by general experience, that inflammation occurs much more frequently in constitutions characterized by lax, mobile, and irritable, than firm and rigid fibres; the inflammatory diathesis cannot, therefore, be always considered synonymous with the *diathesis phlogistica* of Cullen.

The great difficulty in all the theories of inflammation having been the manner of reconciling the increased action of the vessels, which supposes an increased contraction, and consequently a diminished capacity, with the swelling, which requires an augmented diameter of the inflamed vessels, several pathologists have had recourse to another hypothesis, by which the idea of increased action is set aside, and local inflammation is attributed to a diminished action of the vessels. This hypothesis was originally proposed about the middle of the last century by the Italian physiologist Vacca, and first advocated in this country by Mr. Allen of Edinburgh. According to him, the redness, heat, pain, and tumour are to be ascribed to an increased quantity of blood which the vessels contain in consequence of their relaxed state; he attributes those symptoms which had been usually accounted for by increased action, to this partial stagnation of the blood, together with a kind of struggle between the loss of power in the part, and the unusual stimulus to which it is thus exposed. (Thomson's Lectures on Inflammation, p. 68.)

This view of the subject had been adopted in a modified form by John Hunter, who supposed inflammation to be a disturbed state of parts which requires a new but salutary mode of action to restore them to their healthy state; inflammation is therefore rather to be considered a salutary operation than a disease. He describes the act of inflammation as an increased action of the vessels,

which at first consists simply in an increase or distension beyond their natural size, this increase apparently depending on a diminution of the muscular power of the vessels, at the same time that the elastic power of the artery is increased in the same proportion: this is, therefore, something more than simply a common relaxation, and Mr. Hunter calls it an act of dilatation—an hypothesis, however, devoid of proof. He says that, owing to this dilatation, there is a greater quantity of blood circulating in the part, and that it passes more rapidly through the vessels; the swelling is also partly produced by an extravasation of coagulable lymph with some serum, the lymph differing from the common lymph in consequence of passing through inflamed vessels.

The theory of a diminished action of the vessels was embraced also by Dr. P. Wilson, [Philip.] (Treatise on Febrile Diseases,) Dr. Thomson, and Dr. Hastings, who all performed a variety of experiments in its support. Dr. P. Wilson first showed that he could create increased action in the capillaries without exciting inflammation; but whenever inflammation was established, he found the capillaries in a state of preternatural distension and debility; whilst the larger arteries experience an increase of action, which, by keeping up a strong *vis à tergo*, tends to augment the inflammation. If, however, the inflammatory action continues, the vessels immediately preceding the inflamed capillaries become also distended, and consequently debilitated: in short, according to Dr. P. Wilson, inflammation seems to consist in the debility of the capillaries, followed by increased action of the larger arteries, and is terminated by resolution, when the capillaries are so far excited, and the larger arteries so far weakened by the preternatural action of the latter, that the power of the capillaries is again in due proportion to the *vis à tergo*. He refers many of the more general phenomena of inflammation to the sympathetic influence of the nervous system.

Dr. Thomson draws from his experiments inferences rather at variance with those of Dr. P. Wilson, for he conceives that it is not necessary to the establishment of Mr. Allen's hypothesis to admit that the capillary circulation is slower in inflammation. "I am inclined to believe," says Dr. Thomson, "that a diminished velocity of the blood in the capillary branches is by no means a necessary, constant, nor even the most common effect of incipient and moderate degrees of inflammation." (Op. cit. p. 75.) He considers that the velocity is sometimes increased and sometimes diminished.

This difference in the statements of these two gentlemen induced Dr. Hastings to repeat their experiments, in order, if possible, to reconcile them: and he came to the following conclusion: "that certain stimuli applied to living parts produce an increased velocity of the motion of the blood and a contraction of the blood-vessels. During this state of excitement the part affected is so far from giving anything like the appearances of inflammation, that the size of the vessels is diminished and the part paler. But if the stimulus be long-continued or increased in power, the small vessels, which in the natural state admit only one series of globules, become so dilated as to allow

an accumulation of a much less fluid and redder blood in them, which loses its globular appearance, and moves much more slowly than that which previously passed through these vessels: the part now appears inflamed; if the stimulus be removed, the vessels do not soon regain their original state; time is necessary to allow them to recover their contractile power, so as to prevent the impetus with which the blood is propelled by the heart and large arteries from keeping up the dilated state of the capillaries." "It may be logically inferred, therefore," says Dr. Hastings, "*that inflammation consists in a weakened action of the capillaries, by which the equilibrium between the larger and smaller vessels is destroyed, and the latter become distended.*" Dr. Hastings argues that Dr. Thomson's belief in the excitement of the capillaries in some cases of inflammation, arises from his having denominated a state of inflammation that which ought not to be so called, being only that temporary excitement of the capillaries generally preceding their debility, which is inseparable from inflammation. (On Inflammation of the Mucous Membrane of the Lungs.)

The late Dr. Parry of Bath, whose researches on the functions of the vascular system have deservedly attracted so much notice, necessarily rejected the opinion of diminished action of the capillaries in inflammation, since he denied that the capillaries possess any independent muscular power, asserting that the blood was propelled through them by the contraction of the heart alone. He attributed inflammation to an increased momentum of the blood in the part affected, and therefore to an increased passive action of the capillaries. This hypothesis has been strongly advocated by Mr. James, of Exeter, in his treatise on inflammation. The facts brought forward, however, in support of the opinion that the extreme vessels possess a contractile power, appear to us so convincing and satisfactory as to set aside completely the opposite theory.

In all the preceding theories the contractility of the vessels only seems to have been taken into consideration, whilst the other great vital property—the sensibility of the part—has been almost entirely overlooked. Sufficient attention also does not seem to have been paid either to the changes of the blood or to the modifications both in the structure and functions of the part which characterize inflammation, and vary considerably in its different periods. Each theory appears to contain much that is true, especially that of Dr. Hastings, but to be constructed on too narrow a basis, incapable of satisfactorily accounting for all the facts.

We have repeated the experiments with care, availing ourselves of many valuable suggestions gathered from the researches of some of the continental pathologists, especially those of Gendrin and Kaltenbrunner. The former has investigated with considerable attention the whole pathology of inflammation, and has given a luminous description of several important phenomena, especially those of suppuration; he adopts the opinion of an increased action of the vessels being the primary cause of inflammation. Kaltenbrunner's microscopic researches have been much more minute, accurate, and conclusive than those of any of his predecessors, and afford an excellent speci-

men of an experimental inquiry conducted in a truly practical and philosophical spirit; he confines himself, however, to a description of the obvious phenomena, without entering upon any theoretical reasoning. We have verified by our own observations the correctness of nearly all Kaltenbrunner's facts; but as the limits of this article do not admit of a detailed account of experiments, we must reserve this for some future occasion, and shall proceed to give a description of the various phenomena of the inflammatory process, and of the conclusions we have adopted respecting their nature, founded upon the facts observed.

When a stimulus is applied to a living part, the first effect produced is an excitement of the sensibility of the part, and with some exceptions, a consequent degree of pain: this, however, soon subsides if the irritation be only slight or temporary; but when the effect of the stimulus is either severe or prolonged, the contractility of the vessels of the part is next roused into increased action; the necessary result of this morbid excitement of the sensibility and contractility of the vessels is a more rapid flow of blood to the part, which, acting itself as a stimulus, tends still more to quicken the circulation: there is consequently a considerable influx of blood in all the vessels, capillaries, and veins, to the amount, perhaps, of double or triple the usual quantity: and as the vessels of the surrounding parts do not partake of this increased action, the blood of the irritated vessels is not carried off as quickly as it arrives, and must inevitably soon accumulate. Blood-vessels, like all other contractile and elastic tubes and tissues, are capable of having their capacity and other dimensions increased within certain limits, without any sensible diminution of their power of contraction or of their mechanical strength; the stimulated vessels thus adapt themselves to the increased flow of blood by becoming enlarged, whilst they still preserve their control over the circulating current. Vessels, which in their natural state were scarcely perceptible, owing either to the admission only of a thin colourless blood or to their extreme tenuity, now become dilated and visible, a red and more viscid blood being propelled through them. Boerhaave and the mathematical pathologists had accurately noticed this admission of the red globules into vessels from which they were previously excluded, calling it an *error loci*.

The pressure of the blood is sometimes greater, however, than the vessels are able to resist; this more particularly happens when the irritation has extended to the larger arterial branches and to the heart, so as to excite a strong *vis à tergo*. The strength and action of the smaller vessels diminish as their distension increases; the circulation, which was at first accelerated, now becomes gradually slower, and may continue in a languid and oppressed state for a considerable length of time without being completely interrupted. Under these circumstances the healthy functions of the part are necessarily more or less impeded; the blood ceases to undergo its usual change from arterial to venous; the red globules which were before confined to arteries, are now seen circulating in the small veins; these globules are more

numerous and of a more vivid red; the viscosity and coagulability of the blood seem augmented by a decrease in the proportion of its serum; and the globules, having a tendency to unite together, become less distinct; the functions of nutrition and secretion are also partially or wholly suspended.

The part affected now presents the following morbid conditions: an increased influx of blood and turgid state of the vessels—some degree of swelling and pain—an increase of heat, and, in certain textures, of redness, which disappears on pressure—the circulation either much quickened, or slow and embarrassed, with suspension of the healthy functions. These changes constitute a distinct period of disease, which has too often been mistaken for inflammation, but which it is highly important should always be distinguished as its previous stage only, and may be named *active congestion*. The existence of a morbid state, such as we have just described, is of common occurrence in a variety of diseases, and frequently subsides without passing into inflammation. When, however, by the increase of the diseased action, inflammation supervenes and is fully developed, a series of perfectly new and distinct morbid phenomena are observed, which will be presently noticed.

Congestions are sometimes formed, however, in a different manner. If the vessels of a part (arteries and veins) have been much weakened, as happens from a variety of causes, or if there be any obstruction to the return of the blood through the veins, an accumulation of blood, a languid embarrassed circulation, vascular turgescence, and several of the other symptoms of congestion, will necessarily follow, without requiring the previous application of a stimulus. The increased influx of blood sometimes proves a sufficient stimulus to excite a reaction in the vessels of the part, an accelerated circulation, and a state of active congestion, which may lead to inflammation. In other cases, however, no reaction takes place; the vessels remain in a turgid, loaded, debilitated condition, with a languid circulation, constituting a *passive* form of congestion. The characters of these and of some other varieties of congestion will be more fully examined in another place.

When congestion begins to subside, a diminution in the activity of the circulation and influx of blood is first observed at the circumference; the blood seems to reflow from the circumference towards the centre; the swelling, pain, heat, and other symptoms gradually disappear. The resolution of congestion is generally promoted by critical discharges. In some cases there is a slight exhalation of a serous or sanguineous fluid either on the surface of the part or in the interstices of the vessels; an exudation of small red scales is sometimes perceptible through the microscope. The congested vessels may be relieved by a profuse flow of the natural secretions, as is frequently seen on the surface of mucous and serous membranes, or else by spontaneous hemorrhage.

It is important not to mistake for congestion or inflammation various changes in the state of the circulation, that sometimes immediately follow the application of certain stimuli to a living part, and are only of a temporary nature. Simple compression is sufficient to cause a momentary interruption

of the circulation, and stagnation of the blood; the application of muriate of soda to the web of a frog's foot is followed by a diminution of the velocity or a complete stoppage of the circulation, and a remarkable increased redness of the blood; the immediate effect of a slight wound is an accelerated circulation, an increased flow of blood, redness, and other symptoms of incipient congestion; alcohol produces similar results, and sometimes a constriction of the vessels. All these changes, however, are only the immediate consequences of the mechanical or chemical action of the stimulants on the vessels, and of temporary nervous irritation, and do not of themselves constitute congestion or inflammation. When the irritation is slight, the increased activity of the vessels and influx or stagnation of blood soon disappear, after the removal of the irritating cause; but if the irritation has been prolonged or severe, and particularly if it has occasioned any extensive and permanent injury to the texture of the part, a reaction takes place soon after the changes just described have subsided, and a new process, *essentially vital*, is set up, intended to remove the irritating cause, or repair the injury it has inflicted; the circulation is consequently observed to assume again an increased activity, and the regular symptoms of congestion or inflammation are gradually developed. This is an important circumstance attending the process of inflammation, which had been noticed by Dr. Hastings, but has been since more clearly and accurately defined by Kaltenbrunner; and mistakes have no doubt been made in several accounts of the theory of inflammation from its having been overlooked.

The interval between the application of a stimulant and the development of the regular congestive or inflammatory process, may be considered as a period of *incubation*. The duration of this period is very variable; on the edges of wounds, where it is well marked, it may last several hours. The inflammation, however, does not always show itself in the part to which the exciting cause has been first applied, but in some other more or less remote; a variety of medicinal and poisonous substances applied to the external or internal surfaces of the body, frequently excite irritation or inflammation either in some of the secreting surfaces and organs, in the brain and nervous system, or in the heart and large vessels; and they produce this effect either by being absorbed and conveyed with the blood, or by their direct impression on the nervous system. Some animal poisons excite inflammation both in the part to which they are immediately applied, and in remote organs, as happens with the virus of hydrophobia, variola, &c. This secondary or sympathetic inflammation is not always the effect of irritating but frequently of depressing agents, acting on distant parts; a state of debility, or the suppression of the functions of one organ, becomes thus a very common cause of congestion and inflammation in another. All causes that operate in lessening the circulation on the surface or at the extremities of the body tend to produce determination of blood, and an inflammatory reaction in some of the internal organs. The slow and long-continued influence of such causes often gives rise to continued fever; or, when more sudden and active, to local inflammation,

In all these cases a greater or less period of time may elapse between the application of the exciting cause and the development of the disease; this is particularly the case with certain animal poisons, which may remain for some time circulating with the blood before they produce their specific effects. The consideration of the symptoms, duration, and treatment of the period of incubation, embraces some highly interesting questions, especially with respect to contagious diseases, as Dr. Marsh has shown in an excellent essay on this subject, published in the Dublin Hospital Reports.

We are next to consider the morbid changes that occur when congestion passes into true inflammation. If the action of the irritant be either violent or repeated, the appearances characteristic of active congestion extend from the centre to the circumference over a larger surface; the swelling and other symptoms increase in intensity, until the vessels are at last so gorged with blood that the strength and activity of their contractile fibres are overpowered: the vessels become therefore less and less able to resist and propel the current of blood, until its motion completely ceases; the blood then stagnates in the vessels, where it undergoes certain changes in the composition. This stagnation of the blood does not take place in the whole extent of the inflamed surface at once; the circulation first becomes slower, and the blood stagnates in some of the vessels at the centre; it then stops in others, forming sometimes several small nuclei of stagnation, which decrease in number and size towards the circumference, where the circulation continues more accelerated, and the part is in a state of active congestion. These changes occur first in the weaker vessels (the capillaries and veins), and afterwards in the arteries.

The following are the alterations observed in the composition of the blood; as the heat and other symptoms increase, the blood becomes less serous, more viscid and coagulable, and of a more vivid red; its course is altered, and a number of the globules are seen agglutinating together so as to form minute cylindrical clots; these are pressed in small columns from the capillaries into the veins, and move slowly in various directions, oscillating backwards and forwards until they become motionless; the blood is then evidently decomposed, so that the globules and serum can no longer be distinguished from each other, and it presents a red homogeneous coagulated mass, a part of the serum being generally expressed and effused around it. Motion, it is well known, is indispensable to the preservation of the globular appearance of the blood. A momentary vacuum is sometimes observed in the vessels between these coagula.

Another important occurrence, at this stage of the inflammatory process, is the bursting of a number of the over-distended vessels, and the extravasation of the blood in the surrounding texture, from which it is inferred that a diseased state of the coats of the blood-vessels is one of the immediate effects of inflammation, not less important than the changes in the composition of the blood. The acute inflammation of a large blood-vessel is characterized by redness, rugosity, thickening and softening of its internal membrane; the coagulated blood either adheres to it immediately, or through the intervention of a layer of effused lymph; the

middle and outer coats are also injected, thickened, and much more friable; and the whole texture of the vessel having lost its density and elasticity, is very easily torn. We may safely conclude that the inflammation of smaller vessels will be attended with nearly similar changes of structure.

The points of stagnation are easily distinguished by their more vivid red colour, and the redness differs from that of congestion in not being removed by pressure. The colour varies, however, considerably, according to the intensity of the inflammation, the texture of part, and the nature of the exciting cause. In very intense inflammation there is a livid red, which becomes black in gangrene. Muriate of soda produces a dark purple red; alcohol a bright clear red, and muriate of mercury a brown dusky red. The rapidity with which the course of the blood is interrupted, the number and extent of the points of stagnation, depend likewise on the same causes. When the inflammation is intense and the circulation very rapid, the blood does not stagnate so soon; but the points of stagnation are more numerous and extensive. When alcohol is applied to the web of a frog's foot, the circulation is quickened, and after some time a few points of stagnation may be seen; a fresh application of alcohol to the same part is followed by an increased activity of the circulation; the small coagula previously formed are sometimes again set in motion by the increased force and velocity of the current of blood, and the obstruction of the vessels is thus removed. Any new interruption in the course of the blood will take place more slowly, in proportion as the activity of the circulation is kept up by fresh applications of alcohol. The same results follow the infliction of wounds of different degrees of severity, and the application of other stimuli. It has been ascertained by Kaltensbrunner, that in highly vascular organs, in which the circulation is very rapid, such as the lungs and the mesentery, more time is required for the perfect development of the inflammatory process, than in organs whose circulation is more slow, such as the liver; but that when the inflammation is once established, it is much more intense in the former than in the latter. In cold-blooded animals, the susceptibility to the influence of stimulants being comparatively feeble, the circulation is only moderately increased under their application. Inflammation is on this account quickly established by the stagnation of the blood, but seldom violent. It may be stated as a general principle, that the rapidity with which the inflammatory action is fully developed is in the *inverse* ratio, and the violence and extent of the inflammation in the *direct* ratio, of the activity of the exciting cause.

It has already been observed that the blood ceases to undergo its change from arterial into venous during congestion and inflammation, and that the functions of nutrition and secretion are also completely suspended. There is sometimes also an apparent absorption of certain portions of the inflamed tissue; the stellated black spots of the frog's web gradually disappear, when the blood is kept for some time in rapid circulation through its vessels, and small particles of the pigmentum may be seen carried away by the current of the blood. The fat of the mesentery and the

earthy matter in bones is removed in a similar manner.

[On the inner surface of the walls of the dilated vessels, colourless corpuscles are seen to accumulate during the retardation of the flow of blood; and these have been regarded by Dr. Williams (*Op. cit.*) as new formations occurring at the moment. Mr. T. Wharton Jones, however, who has directed special attention to this point, ventures to maintain, that the colourless corpuscles, which are observed to accumulate on the walls of the vessels are no new formations called forth at the moment; and that they already exist in the blood,—that when the velocity of the stream of blood is great, the colourless corpuscles are mingled, and carried along, with the red corpuscles, but when the velocity of the stream is diminished from any cause—whether one of a temporary nature or that leading to inflammatory congestion—the colourless corpuscles become extricated from among the red ones, and come in contact with the walls of the vessels, where, rolling slowly along or actually remaining stagnant, they accumulate in great numbers. (Report, in *Brit. and For. Med. Rev.* for April, 1844, p. 593.)]

Another striking phenomenon is the formation of new canals or vessels by globules of blood bursting through the sides of a vessel and forcing a passage for themselves through the cellular texture into another vessel. A considerable number of new canals are sometimes formed by this mechanical process, through which the blood continues to circulate. This interesting phenomenon has been frequently observed by Kalténbrunner in the inflamed mesentery of the rabbit. We have not had an opportunity of verifying it; but it is easy to conceive a number of the small delicate cells of the cellular tissue being united together by the forced passage of the blood, and forming new tubes. This is strictly analogous to what takes place in the organization of coagulable lymph, where the globules of the blood may be seen forming new passages for themselves by shooting in every direction through the mass of soft lymph.

Beside the extravasation of blood into the parenchyma of the inflamed part, already noticed, there is also a certain degree of interstitial effusion. In all animal tissues, during health, there is a constant exhalation of a fluid in the form of vapour between their fibres or laminae. Gendrin gives the following description of the section of an inflamed part. Towards the centre it exhibits an infiltration of nearly pure blood, disposed in small coagula, and having sometimes a globular appearance, these coagula being surrounded with a gelatinous fluid. In some cases, instead of red blood, there is found a yellowish semi-concrete fluid resembling fibrine, and when inspected with the microscope, apparently partly composed of globules. On the outside of this concrete deposit, there is a reddish fluid half serous and half gelatinous, containing only very few globules; and quite at the circumference there is found pure œdema, with which almost all inflamed parts are more or less surrounded.

We have thus given an account of the various local effects which have been ascertained by observation and experiment to follow the application of stimulants to the living body, from the slightest

degree of irritation to the perfect development of inflammation. It has been shown that a morbid excitement of the sensibility is the first effect arising from the application of stimulants, and that from which all the other phenomena of inflammation seem to derive their origin: the diseased action, moreover, never completely subsides until the sensibility has been restored to its normal state, so that this morbid condition of the sensibility may be considered as operating in a manner strictly analogous to the *ideal thorn* of Van Helmont. Other morbid agents act in depressing the sensibility and causing a diminished vascular action and a stagnation of blood, which is often followed by inflammatory reaction. This primary influence of the sensibility over the phenomena of inflammation is a circumstance which does not appear to have received hitherto the degree of attention it deserves. It will be seen hereafter that all the modifications of inflammation may be traced to some of the infinite variety of morbid conditions which the sensibility is capable of assuming. The intimate connection between the vascular and nervous functions, and the influence especially of the nervous system over the circulation of the extreme vessels, strongly corroborate the accuracy of the preceding views.

In considering the action of stimulants on the animal economy, it appears also that sufficient attention has not been paid to the fact that they excite a series of distinct morbid changes, passing gradually into each other, and whose characteristic differences have not been hitherto well defined. Genuine inflammation is never established instantaneously, but is always preceded by certain deviations from healthy action, which constitute preliminary stages. We conceive, therefore, with Kalténbrunner, that the morbid changes which lead to inflammation may be divided into the three following periods.

1. A period of *incubation*, variable in its signs and duration. A better knowledge of the pathological condition of the system during this period might lead to the adoption of means capable of preventing the development of disease, and of destroying it as it were in embryo.

2. A period of *congestion*, characterized, first, by an increased activity of the vessels and influx of blood—various degrees of turgescence, swelling, heat, redness, and pain—interruption of the healthy functions of the part—and, secondly, as the congestion increases, a laboured slow circulation arising from the over-distension of the vessels, and increased thickness and viscosity of blood. There is yet, however, no change of structure in the part, nor formation of new products; the circulation, although slow, is still carried on or only very partially interrupted, and the affection may subside by critical secretions and hemorrhage.

3. The period of *inflammation*, which is characterized by an entirely new order of morbid changes. The circulation is completely interrupted—the blood coagulates, clogs the vessels, and stagnates in several points of the inflamed part—the coats of the vessels are diseased—some of the vessels are ruptured, and there is extravasation either of blood or coagulable lymph in the parenchyma—lymph and serum are also exuded, and the deposition of these new products leads to

a decided change of structure—the healthy functions of the part are completely suspended, and some of its constituents, such as the pigmentum and adipose matter, are sometimes absorbed—new vessels are also mechanically formed by the blood forcing itself a passage through the delicate areolæ of the cellular texture. All these changes are attended with a considerable increase of the swelling, heat, redness, and pain.

Congestion and inflammation pass so gradually into each other, that they are necessarily always combined, and it may often be extremely difficult to draw an exact line of demarcation between them. The stagnation of the blood, effusion of blood, lymph, or serum, either by exudation or rupture of the vessels, the changes in the structure of the part, and formation of new products, may generally be considered, however, as the pathognomonic signs of inflammation. The interruption of the circulation and extravasation of blood are not sufficient of themselves to constitute inflammation, since they are observed to take place in many cases of local or general vascular debility, the very opposite of inflammation, as, for instance, in ecchymosis, scorbutus, &c. It is only when these symptoms have occurred in conjunction with a series of certain other morbid actions, both preceding and following them, that they can be said to indicate inflammation.

It is assuredly neither rational nor philosophic to apply to these varied morbid phenomena of the inflammatory process but the one hypothesis of either increased or diminished action. It appears also incorrect to describe vessels, which performed their functions efficiently during health, as affected with *direct* debility, because they are unable to perform double their usual labour with equal efficiency in disease, as is the case with the vessels of an inflamed part. It is impossible to deny that, unless under peculiar circumstances forming exceptions to the general rule, the action of the vessels is at first greatly and powerfully increased, and it is only when they become clogged and over-distended by an excess of blood, and by blood less thin and fluid than that which they contain in health, that being no longer able to contract, they become passive. Direct debility of the small vessels cannot, therefore, correctly be admitted as the primary cause of inflammation, since we only see debility occur as a *secondary effect*. Weak and relaxed vessels are themselves susceptible of increased action, and often in a much greater degree than vessels in the opposite state; for it is well known that constitutions in which the fibre is lax and delicate are generally characterized by a much higher degree of mobility and irritability, and are much more predisposed to inflammation than constitutions endowed with a more firm and rigid texture of the solids. While delicate and sensitive vessels are easily roused into excessive action, they are less able to sustain it, and are, therefore, more readily overcome by the increased flow of blood, and more quickly affected with inflammation: this is fully exemplified in infants. But although the weak and delicate structure of vessels predisposes them to inflammation, still increased action is a primary condition necessary in most cases to its development. We may also add, in opposition to the hypothesis of direct debility

of the vessels, that the exciting causes and treatment of inflammation coincide better with the idea of excessive than defective action.

The following summary gives a condensed view of the series of morbid changes that have been described as occurring in the inflammatory process:—Increased sensibility of the part, followed by increased action of the vessels—quickened circulation—increased influx of blood—dilatation of the small vessels and capillaries—admission of red blood into vessels previously colourless—turgescence—swelling—and sometimes a slow and embarrassed circulation—*active congestion*. If the diseased action continues, the contractility of the vessels is paralysed by their over-distension—blood stagnates and undergoes changes in its composition—disease of the coats of the blood-vessels—rupture of many of the vessels—extravasation and effusion of blood, coagulable lymph, and serous fluid—changes in the structure of the part affected—*inflammation*.

This view of the theory of inflammation has the advantage of accounting in the most satisfactory manner for many of the modifications of common inflammation. The exciting cause may be of such a nature as at first to stimulate both the sensibility and vascular contractility of the part, and induce a degree of congestion. But if its action be increased beyond a certain point, it may have an opposite effect in lessening both the sensibility and vascular contractility, and inducing a state of torpor; the blood will then stagnate, not from excessive irritation and over-distension of the vessels, but in consequence of their deficient vitality and relaxed condition. This is frequently the mode of operation of cold, and of several stimulating narcotics and animal poisons, which excite a peculiar form of low sub-acute inflammation, requiring a specific mode of treatment.

In another variety of inflammation, the sensibility is directly weakened or completely paralysed, without previous irritation. There is at first no increased action of the vessels, or greater influx of blood; but the contractility and sensibility of the vessels being lowered or nearly paralysed, the current of the blood becomes extremely languid, and finally stops; reaction is generally excited in this case by the *vis medicatrix nature*, and a low kind of inflammation supervenes, which may terminate rapidly, either in unhealthy ulceration or gangrene. The living parts are then separated from the dead by a line of acute inflammation. The nervous power and vascular action of a part may be impaired or destroyed, as just described, by causes acting more immediately through the medium of the nervous influence, such as electricity, galvanism, intense cold, some very active narcotics, the ligature of large nerves, &c.; or by noxious substances taken into the blood, and materially altering its properties; or else by a deficient supply of arterial blood in consequence of the ossification and other organic diseases, or the pressure or ligature of large arteries. It remains, however, yet to be decided, whether the blood may not be considered the sole vehicle of all morbid agents, without its being necessary to have recourse to nervous agency in order to explain their effects. The great rapidity of action of some deadly poisons

seemed to favour the opinion of the nervous influence being exclusively the medium through which they operate. It would appear, however, from some recent observations, that morbid principles can be conveyed by the blood to remote parts of the body much more rapidly than was formerly imagined. This is an intricate but highly interesting question, requiring to be submitted to further investigation.

The preceding theory of inflammation enables us also to give a satisfactory explanation of the opposite mode of treatment often required in the different stages and modifications of inflammation. It is thus easy to explain, for instance, why local and general depletion are useful in the first stage of inflammation, in lessening the irritation and increased action of both the nervous and vascular systems; in reducing the quantity of the blood, and thus preventing the over-distension and obstruction of the vessels, and the extravasation consequent upon their rupture; in lessening, moreover, the viscosity, thickness, and coagulability of the blood, which is the constant effect of free depletion: why, on the contrary, in cases in which the exciting cause has more directly weakened the nervous and vascular action of the part, as is the effect of cold and of a variety of poisons, stimulants may be required from the beginning;—how, also, stimulants, when cautiously used, may in the latter stages of inflammation assist in restoring the weakened or oppressed action of the nervous and vascular systems, and in this manner facilitate and hasten the elaboration and expulsion, or the absorption of the morbid products, by which means the sequelæ of the disease are removed:—and why, also, the application of a stimulus, different from that which produced inflammation, will sometimes bring on resolution.

Having followed the changes that attend the inflammatory process up to its full development, we proceed to trace them in its ulterior stages. Before the inflammation has reached its greatest height, and any considerable change of structure has taken place, it may gradually subside. The frequency of the circulation begins to decrease at the circumference, and there is a reflux of the blood towards the centre, there are critical exudations through the sides of the vessels, consisting of a thin serous or sanguineous fluid, poured out on the surface or in the cellular texture of the part similar to those already described in congestion; there may be profuse exhalation of fluids on the secreting surfaces; the small coagula of lymph and blood contained within the vessels, or deposited in the parenchyma, are softened and removed, either by the impetus of the current of the blood within the vessels, or by interstitial absorption. The tumefaction, heat, redness, and pain, gradually subside: this is the most favourable mode of termination of inflammation, called resolution.

In more severe inflammation, when the texture of the part has suffered greater changes, it is frequently restored to its healthy state, and the effects of the disease are removed by a different process, which leads to the formation of a new fluid called pus. For a long period suppuration was believed to be the result of a dissolution of the living solids after they had been broken down by inflammation, and pus was supposed to possess a corroding

power, by which it continued the dissolution. These opinions were, however, completely set aside by the more rational theory of this fluid being formed by a process of secretion. The origin of this morbid fluid has been traced still further by Laennec and Gendrin, who consider suppuration as the result of a direct conversion of the coagulable lymph of inflammation, and of the fibrine of the blood, into pus. Laennec believed pus to be simply softened coagulable lymph; coagulable lymph is found by analysis to consist not only of the fibrine of the blood, from which it differs by its lesser consistency, but also of a small proportion of albuminous serum; it is supposed therefore to be formed of an intimate combination of the fibrine of the blood with a small portion of albumen, rendered more viscid and coagulable by the vital influence of the inflammatory action, and deprived also of the colouring matter. The opinion that pus is formed directly from the blood by the fibrine simply undergoing some slight modifications in its properties during inflammation, is supported by the following interesting experiments of Gendrin, which will require, however, to be repeated by others before the important conclusions to which they lead can be considered as fully established (*Histoire Anatomique des Inflammations*, vol. ii. p. 470.)

If any portion of an artery or vein be included between two ligatures, the intercepted blood at first coagulates; a portion of the serum is absorbed; a slight degree of inflammation is excited in the inner membrane; the globules of the coagulum lose their colour; a thin stratum of coagulable lymph is deposited on the sides of the vessel, forming a medium of adhesion between the clot and the internal membrane; and the clot itself becomes gradually organized. There is in this instance adhesive inflammation, and organization of the blood, without suppuration. But if a stimulating injection be thrown into a portion of a blood-vessel, the circulation having been previously suspended by means of ligatures, and if, after it is withdrawn, blood be again admitted and retained within the vessel, a more violent degree of inflammation is excited on the internal membrane, instead of the coagulable lymph, and the entire clot becoming organized, they are observed to acquire less consistency; small yellow globules are soon perceived between their layers, and they gradually undergo a more or less complete conversion into genuine pus. It is stated that these successive changes can be very distinctly watched with the aid of the microscope, and that they may sometimes be observed in cases of aneurism and phlebitis. If blood taken from one dog be injected into the cellular texture of the axilla of another, it soon coagulates, a slight degree of inflammation takes place, and the injected blood is gradually absorbed; but if a higher degree of inflammation is excited by any stimulating injection, or the passing of a seton, the blood, instead of being absorbed, is rapidly converted into pus: it would appear, therefore, that a certain degree of inflammation is indispensable for the transformation of extravasated blood lymph into pus.

It is deserving of notice that venous blood appears to possess a greater tendency to conversion into pus than arterial, while the latter is much

more disposed to become immediately organized; and likewise that suppuration is favoured by a high degree of inflammation, whilst immediate organization is more generally the result of moderate inflammation: these considerations point to a variety of important practical precepts.

Suppuration, however, is not merely the result of the conversion into pus of a mass of extravasated blood or coagulable lymph, but takes place both on the surface and in the interior of inflamed organs by a regular process of secretion, through the medium of vessels either previously in existence or newly formed. It constitutes in this manner a new function, which sometimes persists for a considerable period after the inflammation has subsided, as is seen in fistulous sinuses, chronic ulcers, setons, &c. Gendrin has minutely investigated the nature of this process by exciting violent inflammation in the web of a frog's foot and in the mesentery by means of a seton, the actual cautery, or boiling water, and watching its progress with the microscope. The following interesting account of the result of these experiments is favourable likewise to his opinion of the globules of fibrine being directly converted into globules of pus. (Op. cit. vol. ii. p. 477.)

After the inflammation has attained its height, the circulation remains for some time stagnant, the vessels and intermediate cellular texture being both filled with coagulated blood and lymph; the colouring matter gradually disappears, the part assuming more and more an opal tint; small yellow, soft molecules may be seen interspersed through the coagulum, and some of them agglomerating in large globules evidently purulent. A slow degree of motion gradually becomes apparent by the oscillation of some of the globules in the old vessels; whilst a passage seems to be made for others through the mass of softened lymph by the formation of new canals, especially near the surface. It is stated, moreover, that the various alterations which the globules of the blood undergo during their conversion into pus can be distinctly followed by the eye, especially in the blood-vessels of the mesentery; that the globules are first seen corrugating themselves and separating from their colouring envelope; that they then lose their transparency, becoming, as they approach the edge of the wound where the irritation is the strongest, more opaque, larger, softer, and completely converted into purulent globules. Small lacerated portions of the substance of the part are in some cases apparently dissolved by and carried along with the pus. The vessels soon become more distinct and numerous, and the circulation more regular, although it continues very slow as long as the vessels convey pus. As the swelling subsides by the discharge of the pus, the vessels in the centre re-admit red blood, and their circulation becomes more active. As soon as the suppuration ceases, a coagulable globular lymph of a pale flesh colour, and covered with red streaks, is exuded on the surface of the wound instead of pus; the red streaks are converted into vessels, by means of which the stratum of lymph becomes organized, and the cicatrization is completed. When suppuration is prolonged and rendered habitual by artificial means, the vessels secreting

pus are increased in size and number, and assume a more regular action.

Gendrin concludes from his experiments that the conversion of the fibrine of the blood into pus takes place independently of the action of the vessels or of any vital influence of the inflamed part, and by a mere chemical process not yet well known. This is an opinion, however, which we think scarcely admissible, for it would be extremely difficult to account for the great varieties observed in the qualities of pus in different forms of inflammation, and especially for its *specific* properties in certain diseases, on any other principle than that of referring them to the vital influence of the diseased vessels, as at least one of their essential causes.

The preceding, which is the most simple form of the suppurative process, usually attends mild inflammation. In violent inflammation, when the parenchyma has been much lacerated by the extravasation of blood and coagulable lymph, instead of the pus being entirely collected in vessels, it accumulates towards the centre of the tumour, where it is mixed with loose fragments of cellular tissue and coagulated blood. When the loss of substance has been considerable, the circulation is only partially restored, and the parts destroyed may undergo a degree of putrid fermentation; the pus itself assumes a dark livid colour and an acrid unhealthy character, and this leads to gangrene or sphacelus. Suppuration in this case takes place more by a process of decomposition than of regular secretion; it is a species of imperfect suppuration.

The alterations which the blood and other fluids undergo in different textures during inflammation, correspond in general to those just described as occurring in the cellular texture; they present, however, a few modifications, which we shall notice in this place, in order to give a complete and connected view of the nature of the inflammatory process.* When a serous membrane, as, for instance, the pleura, is slightly inflamed, there is, first, an effusion of a yellowish serous fluid, slightly viscid and alkaline, and consisting almost entirely of a small portion of albumen held in solution by water. As the inflammation increases, the surface of the membrane is lined with a thin layer of a soft viscid substance of a greyish colour, consisting of a semi-transparent jelly, interspersed with small globules of a yellow tint, and characterized by the property of spontaneous coagulation. This coagulated substance increases in thickness, viscosity, and density with the inflammation, constituting on the third or fourth day a distinct plastic, laminated, pseudo-membrane. When submitted to analysis, this membrane is found to consist of fibrine with a small proportion of albumen, and corresponds in every respect with the coagulable lymph of phlegmonous inflammation; it is insoluble in water, otherwise it would be dissolved by the serous fluid contained in the cavity of the membrane, instead of adhering to its surface. The serous fluid poured out at this period of the inflammation loses its transparency, becomes turbid, viscid, and more alkaline; its albumen is

* See Gendrin, Op. cit. *Alterations des fluides*, &c. vol. ii. p. 492, from which the facts contained in the following account have been partly derived.

considerably increased, and it deposits a greyish flocculent coagulable matter, exactly similar in its properties to false membrane, containing only a larger proportion of albumen and aqueous fluid. When the inflammation has lasted several days, the liquid assumes a yellow or greenish tint, and there is added to the coagulable lymph a yellow viscid matter, which is deposited in a pulverulent form, is soluble in alkalies when dried, and when examined by the microscope, presents all the appearances of globular pus. A large proportion of this last-mentioned matter is formed in violent inflammation, giving the effused fluid a well-marked purulent appearance, and a quantity of pus is sometimes deposited, as pure and genuine as that coming from an abscess. The inflammation of all serous membranes is followed by similar results. In the inflammation of synovial membranes the viscid, oily, albuminous synovia is likewise converted into coagulable lymph or pus, according to the intensity of the inflammatory action.

The fluid secreted by mucous membranes consists, in health, of animal mucus held in solution by an aqueous fluid, and containing a small quantity of saline matter; the proportion of these ingredients varies in the different mucous membranes, and other elements are added to them in some, such as muriatic acid in that of the stomach, a sebaceous matter in that of the ear, &c. In active congestion or commencing inflammation, there is generally more or less increase of the natural secretion; it has in ophthalmia the appearance of thin viscid yellow mucus; in coryza it is more fluid and of a yellow white; in bronchitis it is transparent and viscid, like the white of an egg mixed with water; in diarrhoea it is very watery and copious, with white flakes floating in it; it is also more or less tinged with bile. In inflammation of the vagina and urethra it is thin, white, and transparent; in inflammation of the urinary bladder it is mixed with the urine, in which it floats in the form of viscid flakes. In all these cases the mucus has been found slightly alkaline, except that of the digestive tube, which remains acid. This alkaline property is owing to the presence of a small quantity of soda. These copious secretions of thin mucus often prove critical, in relieving attacks of congestion or slight inflammation.

In more acute inflammation there is excreted in the beginning a very acrid sero-mucous fluid, which excoriates the lips in coryza, the cheeks in ophthalmia, the anus in diarrhoea, and the internal surface of the thighs in leucorrhoea; this thin acid mucus is sometimes streaked with blood, as in bronchitis and dysentery. It differs from the mucus of congestion or mild inflammation by coagulating in boiling water and containing albumen; its acidity is due to the presence of alkali (soda); the quantity of albumen is sometimes so considerable that it floats in the thinner part of the fluid in white lumps, differing in no respect from the albumen contained in the serum of the blood, but that there is mucus incorporated with it. At this period of the inflammation there is sometimes an exudation of fibrine as well as of albumen, and this leads to the formation of the false membranes frequently found in the larynx, the trachea, or in some portions of the alimentary canal. As the inflammation advances, the secretion lessens in quantity, and

it becomes completely suppressed when the inflammation has reached its height; there is only then exhaled a very small quantity of a thin viscid fluid, frequently more or less tinged with blood.

When the inflammation begins to abate, the secretion returns, becomes very copious, and assumes new characters and properties, having a striking analogy with the favourite hypothesis of *coction* of the ancients. In ophthalmia it is effused in considerable quantities on the surface of the conjunctiva under the appearance of a yellow opaque viscid fluid, distinctly globular, and still a little acrid; it presents nearly the same characters in coryza. In acute bronchitis the expectoration, which consisted first of a thin mucus mixed with some albumen, now assumes the appearance of opaque, yellow, conglomerated masses, surrounded with some mucus, and constituting well-formed sputa, such as was termed by the ancients *well concocted*. In diarrhoea there is a greyish, yellow, viscid fluid, containing small portions of coagulated albumen; in blenorragia a profuse secretion of a viscid opaque fluid of a yellow colour, inclining sometimes to green. All these secretions, when analyzed, separate into two principal fluids; one, of a milky colour and transparent, floats on the surface of water, or is suspended in it in small flakes; the other, which is of a greyish yellow, and presents all the characters of genuine pus, sinks to the bottom of the vessel. Puriform mucus floats on the surface of water, if the mucus preponderates; but if the pus be in larger quantity, it sinks to the bottom. In very severe inflammation the secretion consists of very little mucus, but almost entirely of pus, and the viscosity of the expectoration diminishes with the increase of the latter.

In chronic inflammations of mucous membranes, and especially in old catarrhs, if the inflammation is very moderate, the secretion is often purely mucous and not purulent, it separates into two parts, one transparent, slightly viscid, and chiefly serous; the other more opaque, greyish, flaky, grumous, and consisting of pure mucus: it is sometimes streaked with black from the secretion of the bronchial glands. If an acute inflammation supervenes on the chronic, the expectoration becomes more thin, abundant, acrid, or frequently purulent, and does not resume its usual qualities until the inflammation abates. These exacerbations of old catarrhs are generally attended with great irritation. Profuse mucous or sero-mucous secretions of long standing must not be supposed always to indicate chronic inflammation, as they sometimes occur spontaneously by a mere increased activity of secretion. When, however, the secretion is both purulent and mucous, it is always a sure sign of the presence of inflammation either acute or chronic: profuse purulo-mucous discharges of this description occur sometimes in coryza, bronchitis, and colliquative diarrhoea, and are attended with considerable debility.

The alterations of the bronchial secretions in pneumonia are also striking and important. In the first stage of inflammation there is expectorated a white viscid frothy fluid, containing a good deal of saliva; it gradually acquires a yellow and then a green tint; its viscosity increases so much that it separates into two parts, the one a thin

frothy fluid, the other a thick viscid ropy substance, which sinks and adheres to the vessel. About the third or fourth day the expectoration is often slightly tinged with blood, either uniformly or in streaks, and of a bright red or iron dusky colour; it has generally a saltish taste; the blood is, however, closely incorporated with the sputa, and not free, as in hemoptysis. The expectoration at this stage is found to contain mucus, albumen, and a certain proportion of fibrine, united with some of the colouring matter of the blood; it is the combination of albumen and fibrine with the mucus that renders the expectoration so plastic, adhesive, and ropy.

In the second stage of pneumonia, or that of red hepatization, the expectoration presents the same characters, only that the thinner fluid becomes also tinged with blood, which gives the whole expectoration a dirty pale-red colour; there is, however, a considerable decrease in its quantity. In partial and interlobular pneumonia the expectoration may continue purely catarrhal, or be only very slightly coloured.

In the third stage, or that of the grey hepatization, the secretions being suspended, there is for some time little or no expectoration; but as soon as the inflammation, having reached its height, begins to decrease, the expectoration returns. From being viscid, adhesive, and sanguineous, as described in the second stage, it becomes yellow, opaque, less tenacious, and also less tinged with blood; it sinks in water, and possesses all the characteristics of pus. As the resolution advances, the expectoration gradually becomes less purulent, and assumes again the plastic, viscid, sanguineous appearances of the second stage of inflammation; it then passes from this state to that of pure mucus, until, on the complete restoration of the pulmonary function, it finally disappears.

The transition of the tenacious bloody expectoration into purulent can be very distinctly traced by dissection in the bronchial tubes of an inflamed lung. If the inflammation be arrested in the second stage by active treatment, the expectoration, instead of assuming a purulent character, loses its viscosity, becomes more sanguineous and very frothy: this change is favourable, as it indicates a more free admission of the air into the inflamed pulmonary texture, and an exudation of blood on the surface of the mucous membrane—a kind of bronchial hemorrhage which tends to relieve the pulmonary congestion and inflammation. It is evident, therefore, that the formation of pus requires that the inflammation should have attained a certain height, and the blood have been submitted to a certain elaboration; this corresponds exactly with the notion of *coction* entertained by the ancients, which, however ridiculed by some, was founded on a correct observation of nature.

In chronic pneumonia the expectoration consists of thin transparent mucous fluid, and of a yellow purulent matter, which sinks to the bottom. In chronic catarrh and bronchitis we have already seen that the expectoration is sometimes purulent, but consists in other instances of mucus, more or less viscid or diluted. Purulent sputa always sink in water; mucous sputa sink in water when very thick and viscid, but float on the surface

when thin and flaky, and pure pus floats on water when mixed with a large proportion of mucus.

It has thus been seen that in the inflammation of mucous membranes, the component parts of the blood undergo distinct changes, by which all the morbid phenomena can be explained as satisfactorily as in phlegmon. The serous portion of the blood, which has acquired increased coagulability, is exhaled with some of the fibrine, and frequently tinged with the colouring matter; the albumen of the serum, and the fibrine, supply the materials for the secretion of pus; and all these fluids are mixed in various proportions with the natural secretions of the membrane, which have themselves undergone certain changes both in quantity and quality.

The secretions of the skin experience corresponding alterations in inflammation. The skin, when inflamed, secretes at first a serous fluid analogous to the serum of the blood, but containing an increased quantity of albumen, which gives it a gelatinous appearance; as the inflammation advances, a portion of fibrine is added, increasing the tenacity of the secretion, and forming sometimes a plastic membrane. These changes may be observed in the bullæ arising from blisters, sinapisms, burns, &c. When the inflammation has reached its acme, the gelatinous layer becomes more dense and friable, acquiring a yellow opaque colour, and all the properties of pus. In chronic erythematic affections the pus is sometimes greenish, tinged or mixed with pure blood. The secretions of the inflamed sebaceous glands are sometimes incorporated with the sero-albuminous or purulent fluid, giving it a peculiar fetid odour, varying in different parts of the body. It is by the concretion of these various fluids that the scales and crusts of cutaneous diseases are formed, as observed in herpes, tinea, psoriasis, &c., and it is also from the sebaceous matter that these crusts derive their peculiar odour.

The changes which the blood undergoes in inflammation, and its mode of conversion into pus, are the same in all textures; the intimate composition of the pus is also identical in all, presenting only such modifications as necessarily arise from the character and degree of intensity of the inflammation, and from the intermixture with other fluids. As the composition of the pus and its various modifications will be more fully considered in the section *Suppuration*, we shall only remark that its globular appearance, and its being composed chiefly of albumen and fibrine, are striking proofs, in addition to those already advanced, of its being derived immediately from the blood.

The exudation, in the inflamed part, of coagulated blood or lymph, and of other materials more or less concrete, proves sometimes so completely critical, that the inflammation subsides, leaving the swelling behind it. The inflammatory products may then remain in the part for a considerable time without undergoing any change, constituting various forms of induration and infiltration. These swellings may at a later period terminate by absorption or suppuration, or else take on some form of specific and unhealthy inflammation, such as the cancerous, syphilitic, scrofulous, &c. The dispersion of the inflammatory deposits without suppuration is partly accomplished by the impetus

of the current of the blood gradually removing the cause of obstruction from the clogged vessels, and partly by interstitial absorption, as already stated in describing the phenomena of resolution.

It is important to remark that, besides the tumefaction resulting from the deposit of *morbid* products, inflammation, when much prolonged or often repeated, causes sometimes an enlargement of parts, by exciting an exuberant action of the nutritive powers, and a consequent excessive nourishment termed *hypertrophy*; there is in this case merely an increased activity of the healthy functions, and a preternatural enlargement of the healthy structure, without the occurrence of any morbid process, or the production of morbid deposits. Hypertrophy is more frequently induced by chronic than by acute inflammation. On the other hand, one of the frequent effects of inflammation, as already stated, is to interrupt the healthy functions of a part; it may cause in this manner a waste of parts from deficient nourishment, and reduce them to a state of *atrophy*; this is more generally a consequence of acute inflammation. These opposite results of inflammation are sometimes observed in parts composed of different structures; an exuberant nourishment of one tissue is generally attended with a deficient nourishment of the other tissues of the same organ. We sometimes see a considerable thickening of the investing membrane of an organ, and a wasting of the substance of the organ itself.

The nutritive powers may not only deviate from the healthy standard by being increased or diminished, but are sometimes also perverted; and this leads to *transformations* of texture. One tissue may thus be changed by a mere aberration of nutrition into a structure corresponding exactly with some of the tissues already in existence in the body, such as bone or cartilage; and these transformations are called *analogous*. But parts that have been long exposed to chronic inflammation frequently acquire a new structure in consequence of a vitiated nutrition, totally different from any in the healthy body; and these transformations are called *non-analogous*. They give origin to a variety of tumours, simple or compound, hard or soft, benign or of a malignant nature. Acute inflammation generally lessens the cohesion of tissues, and often reduces them to a remarkably pulpy state, by a peculiar process termed *softening*. Chronic inflammation, on the other hand, has a greater tendency to cause parts to become indurated.—There are many exceptions, however, to these rules. Softening and induration are sometimes combined in the different textures of the same organ; but we must refer to the articles *INDURATION*, *SOFTENING*, *HYPERTROPHY*, *ATROPHY*, for fuller details of these important changes.

When the sensibility and vascular action of a part are so completely destroyed that all vital motion ceases, the dead animal tissues are soon affected with putrefaction, and this constitutes what is termed mortification. When this occurs as the direct effect of inflammation, it is to be attributed either to its excessive violence causing the rupture of a great many vessels and a considerable extravasation of blood, or to the nature of the exciting cause, or to some obstruction of the circulation. We shall not, however, enlarge here upon this and

some other effects of inflammation, such as ulceration, effusion, &c., as our only object in this section is to describe those morbid changes which are best calculated to illustrate the theory of inflammation, so as to enable us to define it accurately from all other morbid actions. We must, therefore, refer the reader for further details to the articles *MORTIFICATION*, *ULCERATION*, &c.

Although the preceding changes of structure are frequently the consequence of inflammation, it is necessary to remember that they may occur without any inflammation: the preternatural growth of a part presupposes some increased action of its vessels, but this may take place within the limits of healthy action, and the increase of growth does not at all require that it should be carried to such an extent as to become morbid. It is obvious that atrophy is more likely to be the effect of deficient than of increased action; and both induration and softening are frequently seen to take place under the influence of debility rather than of irritation. A perverted state of the nutritive functions will sufficiently account for all transformations of texture, without the necessity of admitting any increase of action; when they are attended with inflammation, this is much more generally to be considered as an ultimate effect of the irritation they have excited in the surrounding parts, than as an exciting cause; there is, however, no doubt that a state of long-continued irritation is one of the most powerful predisposing causes of these changes of structure.

It is important also to observe that many of the other common effects of inflammation sometimes occur without any inflammatory action: that increased secretions, effusions, hemorrhages, adhesions, suppuration, ulceration, and mortification may be the result of a state even opposite to inflammation, is a fact fully established by numerous pathological observations. There are numerous examples of large adhesions in the pleura in persons who had never experienced inflammation of the thoracic organs. Ulceration occasionally occurs in the skin and in the mucous membranes of the alimentary canal and of the throat, without any perceptible inflammation, and when the parts, on the contrary, are quite pale: this frequently happens also in scorbutus. Collections of pus are sometimes found in parts which do not exhibit the least trace of inflammation. Cases of this description, however, are of rare occurrence, and may be considered as exceptions to the general rule. The mortifications of the extremities arising from ossification of the arteries is an example of its occurrence independently of inflammation; and we have occasionally seen instances of the same kind in gangrene of the lungs.

After inflammation and its consequences have been completely removed, the vessels of the part frequently remain weak, relaxed, and irritable; and greatly predisposed, therefore, to a return of the inflammatory action.

Besides the local effects resulting from the application of stimulants to a circumscribed part of the living body, of which we have given an account, they sometimes also excite perturbations in all the functions of the animal economy; this is illustrated by the following experiments, first performed by Kaltenbrunner, and which we have re-

peated. When a stimulant is applied to the web of the foot of a frog, in the course of a few hours all the symptoms of congestion, such as quickened circulation, increased redness, and slight tumefaction, are not only observed in the part first subjected to the irritation, but nearly to an equal extent also in the web of the other extremity. The irritation has, therefore, spread by sympathy to the whole circulating system, producing an increased redness and coagulability in the entire mass of blood, an increased activity and turgescence of all the vessels, analogous to that observed in the original point of irritation. In fact, a species of general congestion has taken place, constituting fever; this sympathetic fever subsides with the local congestion. If a very acrid and poisonous stimulant, such as a solution of muriate of mercury, be used, the following remarkable results occur:—signs of severe pain; great acceleration of the circulation in the webs of both feet; the globules of the blood, instead of a vivid red, assume a dark brownish colour, and the blood shows a tendency to decomposition; the texture of the webs is tumefied, but rather pale; the skin of the whole body is pallid and covered with a thin mucus; after some time the vessels become less turgid; they contain but a small column of blood and are relaxed, their contractions continuing rapid but feeble. Small ulcers appear on different parts of the body, and the animal finally dies. [In repeating these experiments, however, we have not been able to distinguish the ulcers alluded to.] In this instance we first see a local inflammation followed by sympathetic fever, and next the fever itself becoming the cause of secondary inflammation in various other parts of the body. The essential characters of fever are, therefore, increased quickness of the circulation, alterations in the quality and quantity of the blood, general turgescence of the blood-vessels, and, as aptly remarked by Kaltenbrunner, a species of inflammatory erethism. In secondary fever the local effects of stimulants are propagated to the whole vascular system, whilst primary fever itself may become the exciting cause of local inflammation.

The character of the fever may vary according to the previous state of the constitution, and the activity and nature of the stimulant. If a powerful stimulus be applied to a constitution in which there is a redundancy of rich blood and great activity in all the functions of life, the reaction will be strong, and the fever of a highly inflammatory nature. If, on the contrary, the mass of the blood be deficient in fibrine and red matter, and the vital powers low and little excitable, there will be less tendency to symptomatic fever. It has been observed that the lower animals are less subject to fever than the higher, but sink more rapidly under it. If there be a predominance of the nervous system, a great mobility of fibre and spare habit of body, the fever will be characterized rather by nervous irritability than great vascular action. If the irritating cause be of such a nature as to act chiefly on the nervous system, by first exciting and then depressing it, as is the case with various animal and other poisons, the fever will also assume an essentially nervous character. If a vitiated state of the blood and fluids be combined with an exhausted and irritable nervous power,

we shall have the most formidable and pernicious kind of fever, characterized by an alarming combination of nervous and inflammatory symptoms: this is still more likely to occur if the exciting cause itself be of a depressing nature, such as animal and other poisons, the putrid matter of dissection, over-exertion of mind; depressing passions, &c. Finally, the exciting cause may operate on constitutions characterized by a specific morbid diathesis, such as the scrofulous, rheumatic, gouty, cancerous, &c.; in which cases the fever assumes a variety of well-defined modifications; all these varieties of constitutional fever will be more particularly considered in their proper place. (See *Constitutional Symptoms*.)

General Inflammatory Appearances of the Blood.—Besides the various alterations in the composition of the blood that have been described as occurring in local inflammation, the qualities of the entire mass of the blood are liable also to be affected in certain states of the constitution, which either predispose to, or are consequent upon local inflammation; there is, it may be said, a general inflammatory condition of all the fluids of the animal economy, and this is especially true with regard to the blood, the inflammatory characters of which we shall proceed to describe.

When blood is drawn from an individual affected with an inflammatory disease sufficiently severe to disturb the constitution, the nature and appearance of the coagulum differ very materially from those of healthy blood; it contains a larger proportion of fibrine than healthy blood, and the fibrine at the top of the coagulum forms a layer of a yellowish white or slightly greenish colour, varying in thickness from less than a line to one or two inches; this layer has received the name of *size*, *buff*, or *buffy coat*; the surface of the coagulum is also frequently contracted, puckered up at the edges, and concave in the centre; the blood is then said to be *cupped*.

According to the researches of Hewson, Dowler, (On the products of acute inflammation, by M. Dowler, Med. Chir. Trans., vol. xii.), Gendrin (*Histoire Anatomique des Inflammations*, vol. ii.) and others, the buffy coat consists of pure fibrine, deprived of the colouring matter, and mixed with a certain quantity of serum, which is found to contain much more albumen than the serum of the rest of the blood. There is a great analogy, therefore, both in appearance and in chemical composition, between the buffy coat of the blood, and the coagulable lymph that constitutes false membranes. Besides the buffed and cupped appearances just described, the coagulum is in general of a greater density than in health, and less easily broken; it is firmly contracted and dry, in consequence of the serum being more completely pressed out of it, and it appears for this reason smaller in proportion to the quantity of serum; it has an ovoid truncated shape, and is frequently found floating in the centre of the vessel on a level with the serum. The cupped appearance, however, and the firmness both of the buffy coat and of the entire coagulum, are usually proportionate to the strength of the patient and severity of the inflammation, and are also greater in the inflammation of certain textures than of others, such as serous membranes, aponeuroses, tendons,

ligaments, and other fibrous tissues. But it should be remembered that there is sometimes considerable firmness of the coagulum without any buff or cupping.

When the buffy coat is soft, the coagulum is less cupped, softer and larger, adheres to the bottom of the vessel, and contains more serum; the layer of buff is also thinner, and there is in reality a larger proportion of serum, although this may not be apparent at first, in consequence of its not being so completely separated from the coagulum: the blood is then sometimes described as being *sizy*. Whenever there is an excess of the serous portion of the blood, the coagulum will be found soft.

The serum of inflammatory blood is also proved, by the researches of Drs. Traill and Gendrin, to be altered in quality, and to contain nearly twice as much albumen as in the healthy state. Gendrin has sometimes observed, especially in cases of chronic and suppurative inflammation, a *mucous layer*, either at the bottom of the serum, or suspended in it like a cloud; the buffy coat in these cases was also of a more obscure white, less transparent, and softer.

The following are the appearances presented by the blood under different degrees of inflammation, according to numerous experiments made by Gendrin. (Op. cit. vol. ii. p. 430.)

In cases of very severe inflammation the blood coagulates rapidly. The buffy coat is thick, greatly cupped, firm, and elastic; the coagulum has the form of an oval, truncated at both extremities; it is dense and elastic (containing little serum), and floats on the surface of the serum, to which it bears the proportion, in point of volume, of one to one and a half, and sometimes two. The serum is viscid, colourless, and a little turbid at the bottom, but contains no colouring matter. In some rare cases of extreme inflammation, the proportion of serum is less than that of coagulum; the buff is very thick and dense, the coagulum adheres to the bottom of the vessel, where it is broader than at the top, having the shape of a truncated cone.

In cases of moderate inflammation the buffy coat is not so thick; there is little or no cupping; the coagulum is firm, cylindrical, and floats in a yellowish serum, equal in quantity to twice the volume of the coagulum; there is also a slight layer of colouring matter at the bottom of the vessel.

In sub-acute inflammation the coagulum may be slightly buffed, but more generally presents on its surface a layer of a bright red colour, and one or two lines in thickness; it is dense, slightly ovoid, and floats in the serum, although it sometimes either adheres to the vessel, or sinks to the bottom. The serum is viscid and limpid, but of a reddish colour at the bottom of the vessel, in consequence of the precipitation of some of the colouring matter; the serum equals in quantity at least twice the volume of the coagulum.

There may occur, of course, many modifications in degree between each of the preceding divisions; but this general outline will be sufficient to guide us in estimating the character of the inflammation, as far as we can depend upon the appearances of the blood.

It is important to notice that the blood may present all the inflammatory appearances just described, without the actual existence of any inflammation. Ratier and Belhomme ascertained by numerous experiments, that the blood of individuals in a state of sanguineous plethora was often buffed and cupped; this circumstance affords an additional proof, if any were wanting, that the general state of the blood may become a primary cause either of inflammatory fever or of local inflammation. The same inflammatory appearances are frequently observed also in pregnancy; the constitution of a pregnant woman bearing the closest analogy to the inflammatory diathesis, for the extraordinary increased activity of the circulation in the uterus borders on inflammation, and the general circulation of the mother is in a state approaching to symptomatic fever. The buffy coat has also been found in individuals who were in the habit of being bled, as a measure of precaution, at certain periods of the year.

The buffy coat and cupped-like form have been observed in the arterial blood during inflammation. Dr. Tweedie has seen it on two occasions; one was a case of inflammation of the chest, in which the temporal artery was opened in consequence of failure to procure blood from the veins; the other was a case of cerebral fever, in which blood was also taken from the temporal artery. Gendrin says that, on the only two occasions in which he opened the temporal artery, he observed a thin layer of buff, slightly coloured, on the surface of the blood.

The presence of the buffy coat may generally be considered as a correct indication either of the actual existence of inflammation, or of a strong predisposition to it; and when the obscurity of the other symptoms leaves any doubt respecting the inflammatory nature of a case, a buffed and cupped appearance of the blood will tend greatly to confirm us in the opinion of the disease being inflammatory. The degree of buffiness is not, however, in proportion to the danger of the inflammation; for, as already stated, in the inflammation of fibrous tissues, the blood is in general more intensely buffed and cupped than in that of vital organs. The absence of the buffy coat is not, on the other hand, to be taken as conclusive evidence of the non-existence of inflammation. We have seen that in sub-acute inflammation the buffed and cupped appearances are often wanting, and that they accompany the inflammation of certain tissues more constantly than that of others. In some inflammations of the mucous membranes, for instance, such as bronchitis, the blood frequently exhibits no buffiness or cupping. In weak or phlegmatic subjects also, whose blood is impoverished and whose constitutions are not very susceptible of sympathetic irritation, an important organ may be affected with dangerous inflammation, although the blood exhibits no indication of such a state of disease, and has, on the contrary, a dark red, jelly-like, and decomposed appearance. This has been observed in cases in which the inflammation has run rapidly to gangrene, or when the fever was of a typhoid character. It has also sometimes occurred in these cases, that when the typhoid symptoms have subsided, and the fever has assumed a more acute character, the blood

has then become buffy. Whenever, therefore, there are other well-marked symptoms of inflammation, we are not to attach much weight to the fact of the blood not exhibiting the usual inflammatory appearances.

The immediate cause of the formation of the buffy coat is obviously the circumstance of the colouring matter of the blood beginning to subside before the coagulation is complete, so that the upper part of the coagulum loses its redness. There have been numerous speculations respecting the *remote* cause of the buffiness, none of which, however, can be considered as satisfactory. Hewson, Dowler, and some others, thought that the fibrine of inflamed blood became lighter; the latter states that he found the fibrine of the buffy coat to contain a larger proportion of serum, which, by diminishing its viscosity, facilitated the precipitation of the red matter. Hunter took an opposite view of the subject, conceiving that the red matter was squeezed out by the firmer coagulation of the fibrine: this is probably in part correct, as we find the coagulum of inflamed blood much firmer than in its healthy state. Hewson and other writers have also affirmed that inflamed blood coagulates more slowly than healthy blood, and that more time is thus allowed for the subsidence of the red particles. This opinion, however, is controverted by Drs. Davy and Gendrin; the latter maintains, as the result of many experiments, that the coagulation of inflamed blood commences sooner, and is completed more quickly than that of healthy blood. That the slow coagulation of the blood is not sufficient to account for the formation of the buffy coat is clearly proved, moreover, by some experiments related by Dr. Stokes, in his *Pathological Observations*. He made twenty-seven experiments, in fifteen of which a buffy coat was formed, and in the remainder it was wanting. No coagulation took place in three of the latter class of cases, in less than from twenty to forty minutes, and in four there was no coagulation for eight minutes; there was, therefore, ample time for the red particles to have separated from the fibrine; while in twelve out of the fifteen, in which there appeared a buffy coat, coagulation took place in five minutes, and was only delayed for fourteen minutes in the three others.

Although the comparatively slower coagulation of inflamed than of healthy blood cannot be admitted as the cause of its buffy appearance, it is nevertheless certain that every circumstance favourable to an *unusually rapid* coagulation of the blood has the effect of preventing altogether the formation of a buffy coat. These circumstances are principally the following: a narrow opening of the vein, so that the blood trickles down slowly in a small stream; being thus exposed to the cooling influence of the air, it coagulates almost instantly on reaching the vessel, so that there is necessarily no time for the separation of any of its constituent parts. We may sometimes account in this manner for the first cup not exhibiting any buffiness, while, if the blood is made to flow afterwards more freely, the buff may form in the second cup, in consequence of its coagulating more slowly. The formation of the buffy coat may also be prevented or very much lessened by the blood being

received in a flat vessel, and especially if cold; for by warming the same vessel so as to delay the coagulation, the buff has made its appearance. It is likewise prevented by letting the blood fall into the vessel from a height of three or four feet, or by keeping the blood for some time in a state of agitation, or by adding a solution of caustic potash.

The formation of the buff is, on the contrary, favoured by making the blood flow from the vein in a full stream, and by receiving it in a deep and narrow vessel. A narrow vessel is also the most favourable to the blood assuming the cupped appearance, which it very seldom does in broad and shallow vessels. Some have advanced that the mere acceleration of the circulation was sufficient to impart to the blood its inflammatory characters; but this is denied by others, and Sir Charles Scudamore says that he has never observed any buff in cases of simple fever, or after violent exercise. (Elliotson's *Lectures*, Med. Gaz. Dec. 3, 1831.)

It is evident, therefore, that although the buffiness and cupped-like form peculiar to inflamed blood may be influenced in a certain degree by the various accidental circumstances just mentioned, these are wholly insufficient to account for this remarkable property, and that it must depend on some other cause with which we are unacquainted. The following remarkable facts would tend, however, to show that this property is immediately connected with some peculiar influence exercised by the vital powers of the system over the mass of the blood. The first cup of blood is often buffy, when the second is much less so, and the last one not at all. Now bleeding is frequently attended with an immediate diminution of the violence of the inflammatory symptoms, even while the blood is flowing; and the rapid change in the appearance of the blood may therefore be justly attributed to the amendment in the state of the patient. If at the end of some hours the inflammatory symptoms increase, and blood be again drawn, it will be found to have re-assumed the buffy appearance. Gendrin has observed on several occasions, that if blood was taken immediately after recovery induced by syncope, it not only had lost its inflammatory character, but that the clot was much softer; and the effect of syncope in rapidly subduing the inflammatory diathesis is well known. We have already stated that the fibrine is more abundant in inflamed than in healthy blood; it has been found, moreover, that the quantity of fibrine varies with the buffy appearance in the different cups, the blood of the first cup containing more fibrine than that of the second, so that the relief afforded by the bleeding is attended also with an immediate change in the proportions of the constituent parts of the blood.

In some diseases of debility in which the blood and other fluids are greatly vitiated, the blood is often extremely deficient in colouring matter, and the coagulum appears of a dirty yellow or greenish colour. This must not be mistaken for the buffiness of inflammation, from which it will easily be distinguished, by the great softness of the coagulum, turbidness of the serum, and general dissolved appearance of the blood.

[The state of the blood in inflammation has

been long attended to, so far as regards the buffy coat, and the shape and character of the crassamentum. The causes of the buffy coat in inflamed blood are presumed to be its slow coagulation, and the increased quantity of fibrin. We can thus understand, that in anæmia, in which the proportion of the red globules to the fibrin is diminished, the buffy coat may exist; and it is not uncommonly seen in chlorotic cases. The cupped form of inflammatory blood is owing to inequality of contraction. The upper surface being freer from intervening red particles contracts more powerfully than the under, and a concavity of the upper surface is the consequence. When, however, the contraction is weaker, the weight of the subjacent red clot, which forms a part of the same mass with the upper colourless portion, weighs this down, and keeps it in a horizontal position. (B. Babington, art. BLOOD, MORBID CONDITIONS OF THE, in *Cyclop. of Anat. and Physiol.* i. 415.)

The condition of the blood, which gives occasion to the buffy coat, when it occurs in inflammatory diseases, has been considered by M. Piorry (*Traité de Diagnostique, &c.*, § 781, Bruxelles, 1838) an inflammatory one of the fluid itself, and has received the name *Hémite*. Positive hæmatological experiments have shown, that inflammatory blood contains an increase of its fibrinous element. The experiments of various observers have been detailed elsewhere. (*Practice of Medicine*, 2d edit. ii. 534, Philad. 1844.) It will be necessary here to refer only to the recent investigations of MM. Andral and Gavarret. (*Archiv. Général. série 3*, tom. viii., p. 501; and Andral, *Hématologie Pathologique*, Paris, 1843; or Amer. Translation, Philad. 1844.) In another article, (BLOOD, MORBID STATES OF THE,) it is stated by the writer, that healthy blood consists, in the average, in 1000 parts,—of fibrin, 3; red corpuscles, 127; solid matter of serum, 80; and water, 790;—the proportion of fibrin probably varying, within the limits of health, from $2\frac{1}{2}$ to $3\frac{1}{2}$ in the thousand. In acute inflammatory affections, M. Andral invariably found an increase in the proportion of fibrin, the increase being proportional to the intensity of the inflammation, and the degree of symptomatic fever accompanying it; and he affirms, that if we find more than five parts of fibrin in 1000, in the course of any disease, we may assert positively, that some local inflammation exists. The average augmentation of fibrin in inflammation he estimates at 7; the lowest at 5; and the maximum at $10\frac{1}{2}$. Pneumonia and acute rheumatism are the only diseases in which he has found the proportion of fibrin rise as high as 10. M. Andral hence approves of Meckel's definition of inflammation—"congestion with tendency to new production"—the new production being, according to M. Andral, an excess in the quantity of fibrin. He found, however, considerable difference in the increase of fibrin according to the seat of the inflammation. In inflammation of the cellular tissue, it did not exceed 5; in pneumonia, it rose occasionally to 10 and more. In inflammations of the mucous membranes, when slight, and unaccompanied by fever, it remained in the usual quantity; but when they attained a certain degree of intensity, and were accompanied by

febrile reaction, the fibrin invariably rose in amount. In inflammation of the serous membranes, the increase was marked; and in acute rheumatism it rose as high as in pneumonia. The increase in the proportion of fibrin appears in the blood from the time the inflammation commences. In no case was it perceived before the modification of the solid that characterizes the phlegmasia was present. He properly, however, considers the question yet unsettled as to which of the two phenomena is primary, or whether they do not arise simultaneously. In the case of a burn, the blood clearly becomes affected secondarily, and analogy might lead to the belief, that the same may be the case with other inflammations.

Dr. C. J. B. Williams (*Principles of Medicine*, Amer. edit., by Dr. Clymer, p. 227, Philad. 1844) thinks it is pretty clear, that the increase of fibrin, and its more contractile and separating quality, originate in the vessels of the inflamed part, and must be regarded as an augmentation of the vital process of nutrition developed by inflammation.

If oleaginous or finely-powdered substances be injected into the blood-vessels, they may circulate freely until they reach the extreme vessels; but there they become the source of obstruction and consequent inflammation. Viscidity of the blood may likewise arise spontaneously from disease, and in all such cases some serious lesion of the lungs has to be apprehended.

On the other hand, experiments have shown, that if blood be deprived of its fibrin, and be injected into the vessels, death speedily results; and in such case, the blood has been found to have become so utterly unfit for circulation in the capillary vessels, that it was extravasated into the various tissues, and especially into the parenchyma of the lung. If the fibrin of the blood be removed in small portions, local lesions are induced, the origin of which cannot be mistaken. (Magendie, *Lectures on the Blood*, Amer. edit., Philad. 1839.) It would appear, consequently, that whenever the blood becomes much thinner than in health, it ceases to be adapted for the vessels in which it circulates, and transudation takes place through their parietes. In this mode—as the writer has repeatedly remarked—bleeding in many cases of hemorrhage proves detrimental, especially if watery fluid be freely allowed at the same time.]

Uses of Inflammation.—Inflammation may generally be considered as a salutary process, instituted by the powers of the constitution, or the *vis medicatrix nature*, for the purpose of preventing, repairing, or removing the consequences of injury and disease; but, like all other salutary efforts of the system, it not unfrequently becomes a source of serious injury, and leads to fatal results, in consequence either of its excessive violence, or of the importance of the part affected.

The salutary effects of inflammation in preventing more serious disease are well illustrated by the process of adhesion. When an opening is made in any of the hollow viscera, either by ulceration or violence, the escape of their contents into the surrounding cavities is likely to prove fatal by exciting violent and very extensive inflammation. This, however, is frequently prevented by a slight inflammation set up spontane-

ously on the outside of the organs, and near the edge of the ulcer or wound; coagulable lymph is effused, and firm adhesions are thus contracted between the opening and the surrounding parts. Adhesive inflammation is often useful in preventing the spreading of disease, as, for instance, of suppuration or ulceration. Both adhesive and ulcerative inflammation assist materially in the removal of foreign substances or collections of matter, which are deeply seated; thus, in cases of hepatic abscess, there are sometimes firm adhesions first contracted between the liver and the large intestine, or the stomach, and then a passage is opened for the pus, by a process of ulceration, into either of these organs, and its escape into the cavity of the abdomen, which would inevitably prove fatal, is thus effectually prevented. A similar process attends the pointing of all abscesses of internal organs towards the parietes of the cavities in which they are contained, and the passage also of foreign substances through important parts of the body.

The advantages of inflammation in repairing the effects of injury or disease are illustrated by the reunion of divided parts, and the restoration or reproduction of some which have been partially destroyed, as is the case with bone, skin, cellular membranes, and vessels; there are structures, however, such as the nervous, muscular, and fibrous, which are not susceptible of being reproduced.

When the consequences of injury or disease are to be removed, this is effected either by suppuration, ulceration, or increased secretions. When a part of the body has become useless and injurious in consequence of mortification, and when the mortification has a tendency to spread, this is prevented, and the separation of the living from the dead parts effected by a circle of inflammation being excited at their point of contact, which is followed by a gradual process of ulceration, whereby the dead parts are completely cast off.

When, after severe injuries, parts have been so much lacerated and contused that reparation becomes impossible, they are removed by suppurative inflammation. Suppuration is also sometimes of use in the removal of noxious substances and of foreign bodies; this may likewise be effected by increased secretions, or by the effusion of lymph, which afford relief, moreover, by sheathing and protecting the parts from the action of the irritating cause.

Inflammation is sometimes excited spontaneously in various parts of the animal economy, independently of any external cause, for the purpose of getting rid of some noxious or infectious matter which irritates, oppresses, or otherwise disturbs the operations of life; as is exemplified in the exanthemata, in several forms of fever, &c. We see, therefore, that various modes of inflammation are excited, according to the particular object that is to be obtained.

It is evident from the preceding considerations that inflammation is the most frequent of all diseases; it may exist singly, but is often combined with other diseases. When excited for a beneficial purpose, it is always susceptible of assuming a dangerous degree of violence, and this often depends on the state of the constitution. It fre-

quently, however, occurs as a morbid process, not intended to answer any salutary end; and when it affects certain parts, such as vital organs, it is the most dangerous of all diseases.

Congestions.—The morbid phenomena of the second stage of the inflammatory process, which we have described under the name of active congestion, occur in a variety of important diseases which run their course without passing into inflammation, for which, however, they have not unfrequently been mistaken. Some melancholy instances of the injury done by the adoption of a violent course of treatment in congestive affections, in consequence of their having been erroneously considered as inflammatory, have come under our observation. We think it, therefore, desirable to devote a separate section to the consideration of congestive diseases.

The important distinction between inflammation and congestion was clearly defined by the celebrated Laennec in his admirable discourses on the practice of physic, delivered at the *Collège de France*, in which he devoted several lectures to the consideration of congestive affections. This distinction has also been kept prominently in view by Andral in his excellent *Pathological Anatomy*, and especially in the section *hyperæmia*, to which we have been indebted for material assistance in this division of our subject.

Between the slightest increase of vascular action and that which constitutes decided inflammation, there are many intermediate degrees. Some of these are so slight and momentary that they do not interrupt the healthy actions of the part, and may be considered as physiological; such as the flushing of the cheek produced by moral emotions, &c. But in many diseases characterized by disturbance of the functions of nutrition, secretion, or innervation, there is a state of congestion more or less active, which is truly pathological. A congested state of the liver, lungs, or any of the secreting surfaces, may be attended either with a suspension or excessive flow of their secretions. Congestion at the origin of the nerves, in the brain or spinal marrow, is frequently the cause of a variety of nervous affections; it may also be induced by long-continued nervous irritation of the brain itself. A sudden congestion in some organs may be the cause of instantaneous death, as in sanguineous apoplexy and spontaneous hemorrhages. Many of these diseases, although attended with very serious disturbance of the general health and considerable suffering, leave behind them no trace whatever of any change of structure, or else appearances only of an increase of vascularity, quite inadequate to account for the severity of the symptoms. It is evident, therefore, that there is a state of increased activity of the circulation, not amounting to inflammation, which may become an extensive source of disease; and we think this state may be appropriately distinguished from true inflammation by the name of *congestive irritation*. The study of this morbid condition is of considerable importance; for besides constituting of itself an important class of diseases chiefly *functional*, it may lead to inflammation, and lay a foundation for the development of many *organic* diseases; so that it may almost be laid down as an axiom in medicine, that dis-

eases of function always precede diseases of structure. It should be remembered, however, that these morbid actions are closely linked together, passing by imperceptible gradations into each other; and that it is often as difficult to draw the exact line of demarcation between the healthy and pathological species of congestion, as between the latter and inflammation.

Congestive irritation may be more particularly limited to the arteries, the veins, or the lymphatics. Arterial congestion occurs most frequently in children, and venous congestion in old people. The scrofulous diathesis is peculiarly subject to congestive irritation of the vessels and glands of the lymphatic system. The vessels carrying only the colourless or serous portions of the blood, and those destined to the function of secretion, may be affected with congestive irritation as well as the vessels containing red blood, as is seen in sudden attacks of diarrhoea, cholera, &c. Congestions, however, may also occur without previous irritation, depending on debility of the vessels, mechanical obstructions to the circulation, or some alteration in the qualities of the blood. Congestions may, therefore, be divided into active, passive, and serous.

Active congestions.—These may be the effect, as already stated, of a primary irritation either of the nervous or vascular system, or of both conjointly; they are characterized by various degrees of increased activity of the circulation; injection and enlargement of the minute vessels; slight tumefaction, and in certain textures, redness, pain, and heat. Or when the congestion is very considerable, there is a languid oppressed circulation from over-distension. Active congestions differ, however, from inflammation, as already stated, by the circumstance of there being no rupture of the vessels or extravasation of blood, no exudation of blood, coagulable lymph, formation of new products, or decided change of structure. Almost every part of the body may be affected with active congestion, but it is of most frequent occurrence in organs of a highly vascular structure, or having numerous direct communications with the heart and large vessels. We shall briefly notice the effects of active congestion in some of the principal organs.

In the brain, which it is obvious must be greatly predisposed to active congestion, it may occasion severe headach, delirium, drowsiness, vertigo, convulsive and other nervous affections; and it may lead to apoplexy, meningitis, or encephalitis: these symptoms are the result either of the stimulus of an excessive quantity of blood, or of its pressure on the cerebral mass and origin of the nerves. The cause of the congestion may not be seated in the brain, but depend on its morbid sympathy with some other organ, or on the general state of the circulation.

The lungs are perhaps more liable than any other organ to be affected with active congestion, either of their parenchyma or mucous membrane.

This is a frequent source of embarrassed breathing, and of a variety of other symptoms of pulmonary irritation; as, for instance, the dyspnoea attending asthma, chronic suffocative catarrh, and diseases of the heart. There are many other circumstances capable of causing a sudden determi-

nation of blood to the lungs; it sometimes happens that while portions of the lung are engaged in chronic inflammation, the rest of the organ is in a state of congestive irritation. Active congestion is one of the frequent causes of hemoptysis.

Congestion of the heart and adjoining large vessels is of frequent occurrence; any obstruction to the circulation from organic disease in the lungs, brain, or large vessels in the neighbourhood of the heart, or any circumstance repelling the blood from the surface and extremities of the body towards the centre, must necessarily cause it to accumulate in the heart; and this may induce either symptoms of quickened and irregular, or slow and oppressed action. Organic disease of the heart is also a frequent consequence of a long-continued state of congestion.

There are many hepatic affections depending on a state of congestion of the liver, not amounting to inflammation. The great vascularity of this organ, and the peculiarities of its vascular system, consisting of a large proportion of veins in which the blood circulates slowly, greatly predispose it to congestion. The majority of hepatic diseases in this climate are functional, the liver not being so subject to active inflammation as in tropical regions. A congested state of the liver sometimes causes sudden jaundice by obstructing the biliary canals; at others it gives rise to an excessive flow of bile, which is ejected by vomiting or diarrhoea, as in cholera; in some cases it has been followed by ascites, an unusual quantity of blood being thrown into the vessels of the peritoneum, in consequence of the obstruction of the branches of the vena portæ. Some remarkable cases of this description have fallen under our observation, and they have in general yielded readily to an appropriate treatment.

The great extent of the mucous surface of the alimentary canal, its high vascularity, and numerous sources of irritation, sufficiently account for its being frequently the seat of active congestion. The pathology of these viscera, which was for a long period almost entirely overlooked, has been diligently investigated of late years, and its general importance fully established. The influence of a partial congestion and inflammation of this membrane in many diseases, and especially as the proximate cause of continued fevers, has, however, been much overrated. It is particularly with respect to these organs that some pathologists have frequently described appearances as inflammatory, which belonged only to the increased vascularity of active or passive congestion. We have sometimes seen, whilst on the continent, patches of mere redness and injection found in the stomach or intestines, noted down as decided inflammation by disciples of Broussais.

Continued and intermittent fevers, and some of the exanthemata, are generally attended with congestive irritation of several of the internal organs, which sometimes assumes the character of sub-acute, and more rarely of active inflammation. Various degrees of vascular injection and redness are often found in patches in the stomach and intestinal canal of patients who die of fever. In the yellow and some low forms of fever, characterized by violent and irregular determinations

of blood, large portions of the mucous membrane present sometimes a uniform dark injection, and the patients in the last stage of these fevers frequently discharge blood by the mouth and anus. The hemorrhagic affections of the alimentary canal, such as hematemesis, melæna, the hemorrhoidal flux, are usually preceded by some degree of congestive irritation, which seldom amounts to inflammation. In melæna the congestion, however, is in general rather passive than active. There is often an unusual quantity of blood forced into the vessels of the alimentary canal in diseases of the heart and liver, giving its mucous coat a highly injected and uniform red appearance: the same may occur when the last struggles of life are violent and much prolonged, but in these cases the congestion is also frequently passive.

The uterus is always in a state of congestion at the approach of the menstrual period. This organ is peculiarly subject to congestive as well as nervous irritation, which sometimes leads to profuse hemorrhage. The morbid irritations of the uterus exercise a most powerful influence over all the other functions, and especially those of the nervous system. The kidneys are affected with congestive irritation in some cases of hematuria, especially after scarlatina: the only morbid appearance these organs present in diabetes is a dilated and injected state of their blood-vessels. The spleen is frequently found excessively distended with dark blood after continued and intermittent fevers.

We have well-characterized instances of active congestion of the skin in a variety of cutaneous diseases. Erythema and erysipelas may be considered as holding a middle station between active congestion and inflammation, presenting the characters of the former when mild, and of the latter when severe. Petechiæ sometimes depend on congestive irritation, though they seem more generally connected with a passive condition of the vessels. The mucous membrane of the nose, mouth, and pharynx is often affected with active congestion: and there is in some individuals an habitual congested state of the pharynx and tonsils, that greatly predisposes them to reiterated attacks of cynanche. Sudden congestion of the pharynx occurs also sometimes in hysteria. Several diseases of the bones, such as necrosis, extensive caries, spina ventosa, are occasionally attended with great vascular congestion and profuse hemorrhage. This is also the case with cancer, fungus hæmatodes, erectile, and other tumours.

The preceding general, though imperfect, sketch of some of the principal varieties of active congestion is sufficient to show that it is a pathological condition of extremely frequent occurrence, and that it includes a number of most important diseases.

Considerable vigour in the powers of life, a great development and activity of the vascular system, with a large proportion of rich blood, will no doubt strongly predispose to active congestions. They, however, frequently occur also in an opposite state of the constitution—one of great general debility. The irritability of both the nervous and vascular systems being considerably increased by weakness, very slight causes are then sufficient to induce severe local congestions. The

nervous sympathy existing between the different organs has a remarkable and important influence in the formation of active congestions; the morbid irritation which attracts the blood to one organ is often transferred through the medium of the nervous system to other organs, and disturbs their functions. The occurrence of any considerable change in the circulation of one organ, either in excess or deficiency, frequently tends also to destroy the balance of the circulation in others, constituting in this manner a species of sanguineous sympathy; we accordingly find that a primary congestion is sometimes followed by secondary congestions in other organs, whilst it sometimes has a contrary effect in depriving other organs of their usual quantity of blood. Thus, in congestions of the mucous membrane of the alimentary canal, the skin may be either hot and red, or pale and cold; the brain either violently congested, or in the opposite condition. The occurrence of these secondary congestions depends of course on the extent of sympathy existing between the several organs, and this accounts for many of the important combinations of symptoms in disease; as, for instance, the cerebral symptoms accompanying active congestions of the stomach and intestinal canal; the occurrence from a similar cause of paroxysms of asthma, or of disordered action of the heart. The morbid irritability of the uterus, either with or without congestion, is a most prolific source of active congestion in either the digestive, the respiratory, the circulating, or the cerebral organs, and gives rise to an endless variety of anomalous and distressing symptoms. A diminution in the usual quantity of blood, and a deficiency in the vitality of one organ, may also become, as before stated, the immediate cause of congestion in others; as, for example, the sudden suppression of the perspiration, or an habitually torpid action of the skin from long-continued exposure to cold and damp; the suppression of the catamenia; of the urinary or alvine excretions; the application of cold and wet to the extremities, &c. If any one organ is in a state of disease, or has previously been so, that organ has the greatest disposition to be affected with either primary or secondary congestion.

When congestion exists in several vital organs at the same time, there is often a combination of most dangerous and alarming symptoms, many of them, however, of a purely nervous character, and leaving no morbid appearances beyond very slight traces of increased vascularity in some of the organs. A secondary congestion has sometimes the effect of aggravating the primary disease, at others it supersedes it; and in some cases there are singular alternations of disease called *metastases*, as is often observed between the brain and the stomach, or the brain and the lungs. These irregular determinations of blood may be traced in a great measure to the influence of the nervous over the vascular system, and especially over the functions of the minute and capillary vessels, for they occur particularly in debilitated subjects, whose nervous system is highly susceptible, and endowed with great mobility: the just balance and harmony of the circulation is easily destroyed under this feeble and unsteady action of the nervous power; points of irritation are excited in various organs

from the influence of slight causes, inducing a sudden, unequal, and temporary flow of blood towards these organs, and a consequent train of anomalous symptoms, frequently of a formidable description. It is remarkable how trifling a degree of local irritation and congestion is often sufficient under this state of weakness and irritability to cause violent pain, delirium, convulsions, or syncope; this class of patients, moreover, very frequently exaggerate their symptoms. An incautious perseverance in very active remedies in such cases is only calculated to aggravate their condition, and it is often necessary to combine, in their treatment, moderate local depletion with the administration of tonics, and to depend sometimes altogether on the restoration of the general strength. This important principle did not escape the attention of the great Hunter, for in the treatment of severe ophthalmia, in highly irritable constitutions, he often found bark and a generous diet more successful than depletion and purgatives. It should be observed, however, that long-continued disturbance in the nervous action of an organ has a great tendency to induce active congestion, and lay the foundation of organic disease; and this important consideration should never be overlooked in the regulation of the treatment.

The state of the mass of the blood, both as to quantity and quality, is a very frequent cause of active congestion. There is sometimes a greater quantity of blood formed than is required for the purposes of life, and this creates a state of overdistension of the whole vascular system, a sort of general congestion called *plethora*. There is a tendency in some constitutions to make blood more rapidly and in greater quantity than in others; this is favoured by high living and little exertion either of body or mind. There is also a much greater natural development of the vascular system in some individuals, constituting the sanguineous temperament; and the blood is then generally rich in fibrine and red matter. This excess in the quantity and nutritive quality of the blood keeps the solids in a state of permanent excitement highly favourable to the development of active congestion and inflammation. When this excitement is carried to a considerable extent, it ceases to be healthy; every portion of the animal economy is stimulated into inordinate action; the functions both of the nervous and vascular system become generally disordered; the pulse increases in strength and frequency; the temperature of the body is raised; the secretions are variously modified; and all the symptoms of general fever, without any marked local affection, are developed.

This fever from plethora may be mild and soon subside, or else there may be a strong general reaction, giving rise to a variety of alarming symptoms, and sometimes to an apparent prostration of strength from oppression of the powers of life. When this form of fever terminates in death, the only morbid appearance to be discovered is a certain degree of congestion in the minute vessels of the different organs, without any one being more particularly affected than the rest. It has been remarked by Andral, that since wherever the blood is distributed, derangement of function is found, the first cause of the disease resides indisputably in the blood, the lesion of the solids being

only secondary. That cases of fever exactly corresponding with the preceding description do sometimes occur, is a fact as well established by the concurrent testimony of many experienced pathologists, as any in medicine. We have had the opportunity of examining several hundred bodies of persons who have died of fever, and in some of these, although certainly but a small proportion, we have been unable to detect any morbid appearance worth noticing; the assertion, therefore, of Broussais and his followers, that fever is always the effect of a sympathetic irritation of the heart depending on the irritation or inflammation of some other part of the body, and that essential or idiopathic fever has no existence but in the imagination of some pathologists, is directly opposed to general experience. There are few, we believe, who would venture to deny that all the organs are sometimes found perfectly healthy in other acute diseases which have come unexpectedly to a fatal termination; and it may well be asked, why should not the same occur in fever?

A plethoric condition of the system is, however, most generally combined with a great tendency to accumulation of blood and active congestion in the different organs. When the brain is thus affected, a variety of cerebral symptoms, such as have already been described, may manifest themselves, and even a fatal termination be the result, without leaving any other trace of disease than a highly injected state of the vessels. The congestion may more particularly affect the thoracic organs, and occasion distressing symptoms of dyspnoea, cough, palpitations, &c. The digestive and hepatic viscera are frequently the seat of active congestion from plethora, in which case the digestion may be impaired, the secretions increased or vitiated, and indirect debility induced by the oppressed action of the different organs. It is justly observed by Dr. Barlow, in the article *CONGESTION OF BLOOD*, that this condition of the system has often been mistaken for common dyspepsia, and a more formidable and permanent disease been excited by the adoption of a tonic course of treatment; whereas, if the mass of the blood be diminished, and the vessels unloaded by means of venesection, by remedies tending to increase the secretions, and by abstinence, the oppressed organs soon recover their free action. The kidneys, uterus, and cutaneous surfaces may be similarly affected, and a natural cure sometimes takes place by spontaneous hemorrhage. The ancients were well acquainted with this state of the system, and were by no means in error when they laid it down as an established pathological principle, that many acute and chronic diseases, especially of the digestive, hepatic, and excretory organs, were to be considered as critical efforts of the constitution tending to rid it of various sources of oppression or irritation, and to re-establish the just balance of the functions. The late Mr. Abernethy has accurately pointed out the great importance of attending to this principle in the treatment of surgical diseases, and he is on this account justly entitled to the merit of having introduced a new era in this department of pathology.

A state of great obesity induces sometimes a form of plethora more dangerous, perhaps, than any other in its consequences, and more difficult

to obviate. When a great quantity of fat is deposited under the skin and round important viscera, the small vessels become so compressed, that the blood necessarily accumulates in the heart and larger vessels, in which case those organs destitute of fat, such as the lungs and brain, are often oppressed by excessive plethora, and strongly predisposed to active congestion; the action of the heart itself is frequently impeded by the mass of adipose substance surrounding it, and its muscular tissue is even sometimes partly converted into fat: this condition of the system is generally characterized by an extremely embarrassed, slow, and irregular circulation, and great disorder in the functions of the brain, lungs, and heart; in one instance we observed the pulse frequently so low as 28 in a minute, and it never rose to 40.

There may be an habitual excess of blood in one organ, a state of local plethora, whilst the other parts of the body have even less than their natural quantity. This may be the effect of natural conformation. When the thorax is narrow or deformed, the lungs are compressed, and the circulation through them is so impeded, that a slight acceleration of the action of the heart will be sufficient to cause an accumulation of blood in their texture. The same may occur in the brain when the head is small in proportion to the size of the trunk, and especially of the thorax. Large men with a small head and short neck often suffer severely from cephalic affections, especially when the heart is large and its action naturally vigorous; on the other hand a very large head and contracted chest may be attended with the very same result, especially in children: in fact, any great disproportion in the natural development of different parts of the body, must necessarily predispose to unequal distributions of blood, and this is one source of those peculiarities of constitution termed *idiosyncrasies*.

Plethora may exist more exclusively either in the veins or arteries; and this difference is in a great measure connected with the period of life. The arterial system being most developed and in greater activity in childhood and youth, active arterial congestion is most common at these ages. As the rigidity of the solids augments with age, the arteries in particular acquire a greater degree of density, and a greater number of the minute arteries become obliterated; a larger quantity of blood is consequently thrown into the veins, whose coats offer less resistance than those of the arteries; and the venous system becomes in this manner gradually more distended with blood towards the decline of life, and more liable to be the seat of congestion. (See the *Physiological Speculations* of Sir Clifton Wintringham; Cullen's *Nosology*, book iv. chap. 1.) The different periods of life are characterized also by a greater tendency to plethora and active congestion in certain organs than in others; thus, in childhood and youth the brain and thoracic viscera are principally affected, the abdominal viscera in adults, and the brain and abdominal viscera in old age.

Local plethora may be the result of habits of life and modes of employment. Intense study creates habitual plethora in the brain; occupations requiring a low position of the head and

great straining of the sight produce a similar effect. The people employed in Italy in the manufacture of mosaics suffer greatly on this account from congestive and inflammatory affections of the brain and eyes; and the same is observed in a variety of other trades. The seasons and climates exercise a considerable influence over the distribution of the blood. Heat stimulates the activity of the circulation, and creates a tendency to plethora in the skin and superficial parts of the body during spring and summer, as is shown by the prevalence of the exanthemata and other cutaneous affections: this is likewise the case in tropical climates, where some cutaneous affections assume a highly inveterate character. Excessive heat is known also to create a strong predisposition to hepatic congestions and disordered biliary secretions. The application of cold to the surface lowers the activity of the circulation, and repels the blood towards the centre; and hence the great tendency to congestions in the lungs, brain, and mucous surface of the alimentary canal, during winter and in cold climates. The sudden exposure to intense cold has often been instantaneously followed by an attack of apoplexy: the influence of variations of temperature is greatly increased by their occurring suddenly. These changes in the circulation are not the effect merely of the heat of the atmosphere, but also of the different degrees of pressure it exercises on the body according to the variations in its density. Thus, a condensed, pure, and cold atmosphere adds by its pressure to the power of the solids to resist the impulse and distension of the fluids; and the quantity of blood on the surface of the body being thereby lessened, a certain degree of *internal* plethora is the result: whilst in a heated, rarefied, damp, and impure atmosphere, the vessels of the surface being subjected to less pressure, are more relaxed, admit a larger quantity of fluids, and there is a consequent tendency to *external* plethora.

Some ancient pathologists conceived that there were certain conditions of the body independent of the effect of heat and cold, which give rise to alternate states of condensation and rarefaction of the fluids, and which they referred to some particular influence of the nervous system. They explained in this way various sudden congestions whose occurrence could not be traced to any irritation or mechanical cause; they accounted in the same manner for the great extrication of gaseous fluids observed in some nervous diseases, such as hysteria. The motions of the fluids, and their degrees of rarefaction and density, have been supposed by some modern pathologists to be partly regulated by electricity; but these speculations, however interesting, do not yet appear to rest on sufficient evidence to be applied to practical purposes.*

The last of the causes of local plethora to which we shall allude, is of a mechanical nature,—that arising from tight bandages habitually worn over different parts of the body. Every medical

* See the researches of Dr. Reuss of Moscow, published some years ago; the more recent experiment, also, of Dutrochet in France, and Faust and Mitchell in America, on the endosmosis and exosmosis of fluids and gases.

man must have had numerous opportunities of witnessing the highly injurious consequences of this pernicious practice, especially in women; they are too obvious to require further illustration.

The introduction into the animal economy of a contagious virus, or of any other deleterious principle, such as putrid miasmata, &c. has generally the effect of exciting congestions more or less active in several organs at the same time, as is observed in a number of infectious diseases, such as measles and scarlatina, typhoid and malignant fevers; or after the administration of poisons. These deleterious principles vitiate the quantities of the blood, disturb the whole nervous system by either irritating or depressing it, and thus create active congestions in the brain and alimentary canal.

One of the frequent terminations of congestive irritation of the blood-vessels is hemorrhage, either within the texture of the part affected, or on its surface. When there are no means of escape for the blood, the consequences are often extremely dangerous; as in apoplexy, and likewise in hemoptysis, when the blood is only partially expectorated, and a portion retained within the pulmonary texture. Where, however, the blood can issue freely, the hemorrhage frequently relieves the congestion, as in epistaxis, hematemesis, menorrhagia, &c. This timely hemorrhage often prevents the congestion from passing into inflammation; whilst the repression of the hemorrhage, whether spontaneously or by artificial means, has been sometimes immediately followed by formidable symptoms of inflammation. Hemoptysis has in this way been converted into pneumonia; hematemesis into gastritis; menorrhagia into metritis. The hemorrhage may also prove hurtful by causing an excessive loss of blood, either in one or successive attacks; there is a great tendency to hemorrhagic action in certain constitutions, depending most probably on some condition of the blood-vessels leading to congestive irritation; other constitutions being more predisposed to serous effusions. It should be observed, however, that hemorrhage may occur without any previous congestion of the blood-vessels, either active or passive, the parts after death not presenting the slightest morbid appearance; this must be owing to some modification in the texture of the parietes of the vessels, or to some peculiarity in the qualities of the blood; as, for instance, when reduced to a thin watery state, so that it escapes from the vessels as fast as it arrives. This species of hemorrhage is observed in scorbutus and in the hematuria of old age.

Inflammation is one of the most natural and important consequences of congestive irritation. The development of many formidable diseases may be prevented if the congestive stage of the inflammatory process can be removed by the timely application of appropriate remedies. Active congestions are sometimes only temporary, and quickly subside: when of long duration, they frequently occasion various alterations in the nutrition and secretions of the part, which they either increase, diminish, or vitiate. They sometimes assume an intermittent and periodical character, as in some forms of cephalalgia, dyspnoea, &c.

Passive Congestions.—It has been already

stated that congestions are frequently formed without any previous irritation or increased activity of the circulation, and that they may be the effect of a relaxed state and deficient activity of the vessels, of a vitiated condition of the blood, or of some mechanical obstruction to its course: in these cases the congestion is termed *passive*. Passive congestion is characterized by various degrees of redness and sometimes tumefaction, but is distinguished from active congestion by the absence of pain and heat.

The accumulation of blood in the passive congestion sometimes becomes a source of irritation, and the congestion then assumes an active character. On the other hand, a congestion, which was at first active, may after some time become passive. There are, therefore, two forms of passive congestion, the one *primary*, and the other *secondary*.

The principal causes of passive congestion, viz. relaxation of the small vessels, languor of the general circulation, and a thin vitiated state of the blood, are combined in the scorbutic constitution; there is consequently a remarkable tendency in scorbutus to passive congestions and extravasations of blood in all vascular textures. In cases of general debility of the powers of life, and deficient energy of the capillary system, the blood has the greatest tendency to accumulate in those portions of the vascular system the most remote from the propelling influence of the heart, and in which the circulation is chiefly carried on by the contractility of the extreme vessels; and this is still more likely to occur where the blood in its passage from the capillaries into the veins has to overcome the force of gravitation. The lower extremities of old people are sometimes affected, owing to the operation of these causes, with spots presenting an injected, dark-red, marbled appearance, sometimes varicose or in a state of ecchymosis. (*Andral*, Op. cit. vol. i. p. 50.) In some cases there is a complete stoppage of the circulation, stagnation and coagulation of the blood; the vitality of the part is destroyed; it becomes cold and insensible; assumes a dark livid colour; and a form of gangrene frequently supervenes, called the *gangrene senilis*. A similar affection is of frequent occurrence in certain forms of fever, and other diseases attended with great nervous debility and a vitiated state of the blood; the application of any slight irritation to the skin, especially in the dependent parts of the body on which the patient lies, such as the back, sacrum, and nates, is followed by the appearance of red patches of congestion; these, at first acute, soon become passive, and assume a gangrenous appearance.

All the internal organs are subject to passive congestion. When death is attended with violent struggles, as is the case from the convulsions of tetanus, of asphyxia, by strangulation, or from the effects of certain poisons, many of the internal organs, and particularly the brain, are found loaded with blood, and more or less injected. When after protracted diseases death occurs very gradually, the lungs are sometimes found gorged with blood and serum, although there was no previous symptom of pulmonic affection. These changes occur more particularly in the posterior portion of the organ, when the patient lies constantly on

the back. They can only be referred to debility of the capillaries and passive congestion, as they were not preceded by irritation. After the inflammation has been subdued in acute pneumonia, and convalescence is established, there remains in some cases a certain degree of dyspnoea and crepitating rhoncus, although the thorax has recovered its natural sound on percussion, and these symptoms resist the continuation of antiphlogistic remedies, whilst they yield readily to the employment of tonics. The congestion of the bronchial membrane in chronic catarrh frequently requires a tonic plan of treatment, and it may be fairly concluded in both these cases that the vessels are in a relaxed and passive condition.

There is a great predisposition to passive congestion in the mucous membrane of the alimentary canal. This is not surprising when we consider how largely it is supplied with blood-vessels, their subdivision into numerous arches supported only by a loose membrane, and, above all, the peculiarities of its venous circulation; for the venous blood of the alimentary canal being distributed to the liver by veins deprived of valves, the slightest obstruction to the circulation of that organ, which is naturally slow, must have the effect of retarding the return of blood from the intestines, and creating an accumulation in their venous system. This accounts for the frequency of hemorrhoidal affections, diarrhoea, and dysentery, in chronic affections of the liver. In fevers of a low, nervous, and malignant type, the mucous membrane of the intestines, and chiefly of the colon, is sometimes found of a uniform dark-red colour, turgid and soft, in consequence of an intense venous injection of a passive character, the black pitchy secretions of the membrane resembling decomposed venous blood. (Dr. Armstrong made these congestions the foundation of one of his divisions of fever, which he termed *congestive*.) In a case of this description the mesentery was covered with large dark-red blotches, giving it the appearance of a leopard's skin, and arising from a state of intense injection of the mesenteric veins with extravasation of blood, the congestion having fallen on the mesentery instead of the coats of the intestines. The mucous membrane presents frequently similar appearances in melana; and in a case of recent occurrence we found it impossible to discover the least difference between the black sanguineous fluid contained in the intestines, and the blood taken from the vena portæ.

Mechanical compression or obliteration of any portion of the venous system, is necessarily followed by passive congestion in all the parts whose blood is returned to the heart by the obstructed vessels. When this obstruction occurs either in the lungs or heart, it produces passive congestion in all the organs of the body. This is particularly well exemplified in asphyxia, in which the face becomes livid and swollen, the lips purple, the tongue tumid, the eyes red and staring, and the whole surface of the body injected with dark blood. The lungs, right cavities of the heart, and entire venous system are found distended with venous blood, whilst the left cavities of the heart are nearly empty; the mucous membranes of the lungs and alimentary canal are also deeply injected. When the obstruction in the pulmonary cir-

culation takes place gradually, as in pulmonary consumption, the same general congestion is not observed, because the absolute quantity of blood in the whole system is diminished by long-continued imperfect sanguification, deficient nutrition, and increased excretions. A nearly similar state of general passive congestion is sometimes produced by diseases of the heart, whether congenital, as in the morbus cœruleus, or acquired.

Serous congestions.—The order of vessels which convey only the colourless or serous portion of the blood, are liable also, as before stated, to be affected with congestive irritation. These vessels exhale in health a sero-albuminous fluid or vapour, which constantly lubricates the areolæ of the cellular tissue, the cavities lined with serous membranes, the mucous and cutaneous surfaces, and, in fact, every part of the body. It can be satisfactorily shown, by a variety of experiments, that this fluid is supplied by the serum of the blood. If, for instance, a solution of prussiate of potash be injected into the veins, it can be immediately detected in the fluid of the serous membranes by means of sulphate of iron. (*Andral*, Op. cit. vol. i. p. 379.) Serous and sanguineous congestions are not unfrequently combined; the former may, like the latter, occur without previous irritation, and be passive.

Congestive irritation of the colourless vessels is generally followed by an increased exhalation of serous fluid, which is either retained in the areolæ of tissues and closed cavities of membranes, constituting different forms of effusion, or, when poured out on the mucous and cutaneous surfaces, is carried off in the form of increased excretions.

Those portions of the cellular tissue, the texture of which is loose and the position dependent, are the most frequently the seat of serous effusions. The dense cellular tissue lining mucous membranes is not, however, exempt from serous infiltration; the membrane is then raised, loose, and flaccid, as is well exemplified in that fatal disease, œdema of the glottis. When serous effusions occur in the membranes investing vital organs, they often give origin to various formidable and fatal diseases. The investigation of their causes is, therefore, deserving of some consideration. These causes may be divided into increased action of the vessels, debility of the vessels, alteration in the qualities of the blood, and mechanical obstructions to its circulation.

Serous effusions may take place from irritation and increased activity of the secreting vessels, without the cellular tissue or serous membrane undergoing any alteration of texture, or presenting even the slightest appearance of sanguineous congestion. If the irritation be slight, the effused fluid corresponds exactly in its composition with the serum of the blood, consisting of a large proportion of water (900 in 1000 parts), a small quantity of albumen (80 in 1000), and the remainder made up of soda, various salts, and an animal matter analogous to mucus. (*Andral*, Op. cit. vol. i. p. 389.) Under certain circumstances not connected with irritation, the effusion contains also a substance called extracto-mucus, either uniformly combined and giving it a slight turbid appearance, or floating in the midst of the fluid in small filaments or flocculi. As, however, the irritation in-

creases, the proportion of albumen becomes considerably greater, and this substance is therefore a good test of the violence of the irritation. When the congestive irritation reaches the point of true inflammation, the disease is characterized by other morbid changes; there is an exudation of coagulable lymph and pus, which, being mixed with the serous fluid, gives it a turbid appearance; the surface of the membrane itself is lined with layers of lymph; its blood-vessels and those of the subserous cellular tissue are deeply injected, and blood is sometimes extravasated by their rupture. The absence, however, of any trace of vascular injection in a serous membrane, after effusion has taken place, must not always be considered as a sure proof that it never existed; for there may have been considerable sanguineous congestion in the first period of the disease, which has disappeared after the turgidity of the vessels has been relieved by the exhalation of the distending fluid. We accordingly often observe the symptoms of local and general irritation in acute affections of the cellular tissue and serous membranes, completely subside the moment the effusion has taken place; and we may frequently predict an accession of effusion by the return of these symptoms. It may, therefore, be received as a general rule that a state of congestive irritation, both of the sanguineous and serous vessels, especially when long-continued, is more favourable to acute dropsical effusions than active inflammation; that active inflammation is attended with a greater disposition to the formation of adhesions and false membranes, or to the exudation of pus and blood, than to copious serous effusions, the function of secretion being rather suspended than accelerated during the inflammatory process. The fever and other constitutional symptoms which precede effusions into the cavities of the head, chest, and abdomen, are accordingly, in the majority of cases, rather of a sub-acute than highly inflammatory character; and it is extremely important to keep this circumstance in mind, as the mild and insidious nature of the symptoms has frequently concealed the real danger of the disease. Serous effusions take place also, no doubt, in the course of severe attacks of inflammation; but effusion is then almost always combined with suppuration and the formation of pseudo-membranes, and it generally occurs when the inflammatory action is on the decline. We have examples of this in pleurisy and peritonitis.

In recent cases the texture of the serous membranes is generally unaltered; but when serous congestion has been of long standing or frequent recurrence, the membrane becomes thickened and of an opaque white, in consequence of the infiltration of the serous fluid between its layers. A similar infiltration takes place into the subjacent cellular tissue, which on this account adheres to the membrane when raised, and increases its thickness; this happens more especially where the subserous cellular tissue is loose and abundant, as, for instance, between the arachnoid and pia mater. The free surface of the membrane loses also its smoothness and polish, becoming rough and granulated. In some severe and very protracted cases, the membrane is thickened and even cartilaginous, in consequence of vitiated nutrition. The serous fluid may be either colourless or of a green, yellow,

or reddish tint, owing to the presence of a portion of the colouring matter of the blood; it is sometimes mixed with a yellow colouring matter analogous to that of the bile, and has in some cases been found to contain uric acid.

The effusion may be occasioned by a primary irritation of the tissue in which it is formed, or a secondary irritation propagated from a neighbouring part. (*Andral*, *Op. cit.* vol. i. p. 393.) Hydrocephalus is in most cases to be attributed to irritation in the brain; ascites is sometimes consecutive to peritonitis; erysipelas, phlegmon, and all extensive and deep-seated inflammations, are attended with œdema of the adjacent cellular tissue. Effusions depending on congestive irritation are characterized by local and constitutional symptoms more or less acute; when they occur in the subcutaneous cellular membrane, as in œdema and anasarca, there is swelling and some degree of heat, pain, and tension; this corresponds with the diffuse inflammation described by the late Dr. Duncan. When the effusion takes place within any of the splanchnic cavities, or in the texture of important organs, there are a variety of local symptoms more or less severe according to the impediment occasioned in the functions of the organ. The constitutional symptoms vary considerably, being sometimes violent, at others mild, obscure, and insidious; this depends very much on the suddenness of the affection, as well as on idiosyncrasy, and other circumstances. A slight degree of congestion and effusion occurring suddenly may give rise to very violent symptoms and prove rapidly fatal; whilst a higher degree of congestion, and the effusion of a larger quantity of fluid, if it only takes place gradually, is sometimes attended with comparatively little inconvenience, there being time for the parts to accommodate themselves to the distension occasioned by the fluid.

The following enumeration of the diseases in which effusion occurs as a consequence of congestive irritation of the serous vessels, will show the importance of attending to this species of diseased action. It affects both sides of the arachnoid, the pia mater, the lining membrane of the ventricles of the brain, and the medulla spinalis, in arachnitis, hydrocephalus, and hydro-rachitis; the pleura in pleurisy and hydrothorax; the pericardium in pericarditis and hydrops pericardii; the peritoneum in ascites; the ovaries in hydrops ovarii; the tunica vaginalis in hydrocele; the joints and surrounding parts in hydrops articulo-rum, and also the bursæ mucosæ of tendons; the cellular tissue in œdema and anasarca; the globe of the eye in hydrops oculi. The parenchyma of several organs may also be the seat of serous congestion and effusion; the white softening of the brain seems to depend on a species of serous infiltration; there is a serous congestion of a sub-acute character called œdema of the lungs, which is in general very obscure and intractable, and a frequent, though unheeded, cause of anasarcaous swellings in different parts of the body.

Serous congestion and effusion depend sometimes, as already stated, on debility of the vessels without previous irritation, being what is termed *passive*. In order to give a connected view of the pathology of these affections, we shall offer a few observations on this and some other causes of

serous congestion, although not immediately connected with inflammation. When the powers of the constitution have been considerably reduced after protracted diseases, excessive evacuations of blood, or in old age, especially in temperaments naturally leucophlegmatic, serous effusions sometimes occur, to all appearance, from mere debility: the lower extremities, where the blood has to overcome the greatest degree of gravitation, are most commonly first affected. Effusions from mere vascular debility are, however, by no means so frequent as was formerly imagined. It more generally happens that there is combined with debility some other cause, such as alterations in the quantity or qualities of the blood, or obstruction to its circulation.

Since the fact of absorption being actively carried on by the veins as well as the absorbents has been fully established by the experiments of Magendie, nothing can be more obvious than that the distension of the venous system by an excess of blood must have a special influence in the production of serous congestions and effusion, by retarding the current of the blood, causing an accumulation in the minute vessels, and lessening the activity of absorption. There are cases of œdema and anasarca which can be attributed to no other cause than extreme plethora; a remarkable one, which terminated fatally, is related by Andral. That effusion may occur from this cause is clearly proved by the fact of our being able to produce it at will by injecting into the veins a large quantity of water, so as to create a state of artificial plethora. That the absorption of the veins is greatly accelerated when in a condition opposite to that of plethora is also satisfactorily proved; for if in the same animal we remove the plethora by abstracting blood from the veins, the serous effusions soon disappear: this explains the good effects that follow venesection in acute dropsical affections.

A diminution in the proportion of fibrine and red matter, and a corresponding increase in that of the serosity of the blood, greatly favours serous congestions and effusions: this state of the blood is induced by copious and repeated venesections, which are sometimes followed by dropsical effusions. The long-continued use of a poor and watery diet produces similar results, although the mass of the blood may be diminished in quantity. The coagulating property of the blood is destroyed also by some poisons, especially those of reptiles; its fluidity is thus increased, and it assumes a decomposed appearance; the unhealthy malignant inflammation excited by these poisons is accordingly combined with serous infiltrations.

Any obstruction to the venous circulation has a tendency, for the reasons already stated, to induce sanguineous congestions and serous effusions. The obliteration of the principal veins of a limb from inflammation, the pressure of a tumour, or other causes, is generally followed by œdema of the limb below the obstruction. The obliteration of the inferior vena cava causes dropsy of the lower extremities: obstacles to the circulation of the vena portæ, arising from diseases of the liver, are among the most frequent causes of ascites. Several diseases of the kidneys, which have been well described by Bright, Christison, and Gregory, produce a similar effect. When the cause of obstruc-

tion occupies the central organs of circulation, as in diseases of the heart and lungs, the dropsical effusions affect every part of the body.

Impediments to the circulation in the lymphatic vessels, which may be considered as a species of veins, are sometimes followed by serous effusions in consequence of a diminished absorption; this is exemplified in *tabes mesenterica* and in obliterations of the thoracic duct. In some cases of chronic serous effusions, Dr. Hodgkin has found the lymphatic glands enlarged and indurated without any evident change of structure, but in a state rather analogous to hypertrophy.

Besides the primary causes of serous congestion and effusion that have been enumerated, there are various secondary causes, amongst which may be noticed the suppression of secretions, and especially that of the skin and bronchial membrane. Dropsical affections are very common in low and damp situations, which is chiefly to be attributed to the action of a moist atmosphere in lessening cutaneous and pulmonary perspiration. Copious serous effusions disappear sometimes with surprising rapidity; the fluid is in some cases transferred to another part, giving rise to a new train of symptoms; it is frequently, however, carried off by copious excretions. But there are instances of the general health being re-established without any such evacuations.

When the *mucous* and *cutaneous* surfaces are affected with congestive irritation of their serous vessels, it generally induces profuse serous excretions. These surfaces secrete two kinds of fluid, one in the form of a vapour or thin serosity exhaled by the serous vessels, such as the cutaneous and pulmonary perspiration and the watery evacuations from the bowels; the other consisting of the mucus and other secretions supplied by the mucous and sebaceous follicular glands. Very large quantities of these various secretions proceed sometimes from the skin and mucous membranes, without any morbid change in the structure of these parts, or such slight deviations only from their healthy appearance as are in no way proportionate to the severity of the symptoms. These profuse discharges can only therefore be referred to a degree of congestive irritation not amounting to inflammation. If, however, the secretions be checked, either by astringent remedies or spontaneously, the congestive irritation may be converted into active inflammation; and in this manner dysentery and enteritis have sometimes supervened on an attack of diarrhœa. (*Andral*, Op. cit. vol. i. p. 412.) These profuse evacuations, when occurring in mucous membranes, were called by the ancients *phlegmorrhagiæ*, *phlegmorrhagiæ*, or *fluxes*. Pyrosis, and some forms of coryza and pulmonary catarrh, have been classed by several nosologists among the *phlegmorrhagiæ*. At the invasion of coryza and pulmonary catarrh there is sometimes a very copious discharge of a watery fluid, either from the nose or by expectoration. The pituitary membrane is tumefied, but without increased redness, and the entire nose sometimes swollen. The quantity of serous fluid proceeding in some diseases from the mucous membrane of the stomach and bowels is enormous; it has amounted to several quarts thrown up from the stomach in some cases of pyrosis, and much

larger quantities have been discharged by stool from the bowels in attacks of cholera and colliquative diarrhoea. These profuse excretions generally induce symptoms of as great prostration of strength as from excessive loss of blood; the skin becomes cold and clammy; all other secretions are suspended; the rapid sinking of the strength brings on paroxysms of syncope and convulsions; the blood also assumes a dark red colour, being deprived of its serum. These serous fluxes have sometimes supervened on the sudden disappearance of dropsy either of the abdominal or thoracic cavity, and have in this way proved critical; they may occur also at the termination of febrile and inflammatory diseases, whose resolution they seem to favour.

The cutaneous perspiration is exhaled in health under the form of an imperceptible vapour. But in many diseases there is a state of congestive irritation of the skin, either primary or sympathetic, characterized by a morbid heat, and the excretion of a profuse serous fluid constituting sweat. These perspirations may likewise be critical in a variety of inflammatory and febrile diseases; in the *morbus sudatorius* they constitute the prominent symptom. They are sometimes passive, being then cold and clammy, as at the approach of death. A remarkable alternation of action is observed in some cases between the skin and mucous surface of the alimentary canal, the suppression of a profuse sweat being followed by diarrhoea, and *vice versa*. The diarrhoea which attacks the crews of whalers on entering the regions of ice is of this nature. The skin is generally dry and rough in chronic gastritis. In pulmonary phthisis, and other organic affections of the lungs in which the pulmonary perspiration is diminished, there is generally an increase of the cutaneous perspiration, which may be considered as its substitute. The qualities of the perspiratory fluid are modified in several diseases, as is manifest by peculiarities in its odour and flavour, and by the action of chemical tests.

All glandular structures, such as the follicles of the skin and mucous membranes, the salivary glands, liver, kidneys, &c., may be affected with congestive irritation of their secreting vessels leading to increased excretions, without any change of structure or appearance even of vascular injection. In all catarrhal affections there is an increased secretion of mucus from the different mucous surfaces; this, no doubt, is sometimes the effect of inflammatory action; but in numerous cases there is merely a congested state of the serous vessels, and not the least appearance of increased action of the blood-vessels, as is clearly demonstrated by numerous post-mortem examinations. Nothing, therefore, can be more erroneous than the opinion of some modern pathologists, that all catarrhal affections are to be referred to inflammation. Andral very justly observes "that it would be a great error to suppose that the fever which accompanies certain acute mucous fluxes is an infallible proof of their inflammatory nature: for the simple fact of an organ being deranged in its nutrition, secretion or innervation is sufficient to generate fever, no matter whether that derangement be attended with the augmentation, diminution, or perversion of the vital powers of the or-

gan; the bare circumstance of a part of the living body being in a state of suffering, whatever the nature of that suffering be, is sufficient to light up the various sympathies which constitute fever. The existence of fever does not, therefore, necessarily imply the idea of stimulus or of excessive action; and, consequently, the object of the practitioner should not, in every case of fever, be to combat this stimulus; but in some cases it should be to relieve a derangement, either circumscribed and purely local, or affecting generally the blood itself, or the centres of the nervous system." This view of the subject is the most consistent, certainly, with sound reasoning and general experience. It is, moreover, now generally admitted that many of these catarrhal affections, when the period of irritation that attends their invasion has subsided, are aggravated by perseverance in an antiphlogistic plan of treatment, and are speedily relieved by tonic remedies and a nourishing diet. This is particularly evident in chronic pulmonary catarrh and in mucous diarrhoea, to which complaints persons of a relaxed phlegmatic temperament, and much exposed to wet and cold, are particularly predisposed. The secretions of the lachrymal and salivary glands, of the liver and kidneys, may likewise be considerably increased in consequence of congestive irritation of their secreting vessels.

All the affections that have been described as depending on congestive irritation of the sanguiferous or serous vessels, may assume a continued, intermittent, sporadic, or endemic form. The various secretions are in general considerably under the influence of the nervous system, and may be suddenly increased or diminished by strong mental emotions; we need only mention, in proof of this, the well-known effects of fear on the secretions of the bowels and kidneys.

It is evident, from what has been stated in this section, that the morbid condition of the vessels which we have termed *congestive irritation*, includes a great variety of diseases, some of a formidable character, and the exact nature of which has not always been clearly understood. Many of these diseases originate in a high state of congestive irritation closely allied to inflammation; the danger, however, is not always in proportion to the degree of irritation, for we have seen that some diseases characterized by only slight congestive irritation, may in certain constitutions lead to a fatal result, by inducing effusions round vital organs, or exhaustion of the nervous power from hemorrhages and excessive excretions; and that the danger in these cases is so much the greater, that their symptoms are often obscure and insidious. It has also been shown that when, in consequence of the influence of morbid sympathies, congestive irritation has been excited in several vital organs at the same time, the simultaneous disturbance of their functions, and consequent unequal distribution of the circulating fluids, may give rise to the most formidable symptoms, and prove as certainly fatal as the destruction by inflammation of any vital organ. We have seen, also, that with regard to the treatment of congestive diseases, the practitioner must be on his guard lest the obscure and often insidious character of the symptoms should deceive him respecting the

true nature of the disease; that these affections being all more or less allied to inflammation, generally require an antiphlogistic plan of treatment: that this, however, will sometimes require to be carefully modified, and is likely to prove injurious if carried beyond a certain point, as congestive diseases are often induced and aggravated by a state of general debility.

Morbid Appearances of Inflammation.—

There are few things in the study of pathology more difficult and of greater importance than to define accurately what are the appearances in the dead body by which the different morbid affections of the vascular system, from the state of slightest injection to that of high inflammation, can be distinguished from each other. Accuracy of knowledge on this subject is evidently highly desirable, as our views of the nature of disease can be derived only from the combined evidence afforded by the symptoms observed during life, and the deviations from healthy structure found after death. Before, however, entering upon the consideration of this important part of our subject, it is necessary to premise that a variety of morbid changes of structure sometimes take place, both at the moment of death and at a certain period after, bearing a close analogy to those induced by disease: a knowledge of these changes is of the first importance to prevent their being erroneously attributed to disease.

In speaking of the functions of the minute vessels, we stated that their contractility survived for some time the action of the heart; that in consequence of this they continued to propel the blood into the capillaries and small veins in which it necessarily accumulated, while the larger arteries, not receiving any fresh supply of blood, remained empty. This sufficiently accounts for the circumstance of all delicate vascular textures, the surfaces of mucous and villous membranes; the pulp of the brain, texture of the lungs, &c. often presenting an unusually red and injected appearance in the bodies of persons who die with much blood in their system; these congestions bear a strong resemblance to the passive congestions that are formed during life. They vary according to the manner in which the circulation has been first interrupted, whether in one or both sides of the heart, or in the vessels of one particular organ. The different parts of the body may, however, assume also various degrees of redness and injection after death, which it would be a serious mistake to attribute to the effects of disease. The formation of these congestions can easily be proved by experiment; for if the colour and degree of injection of different organs be noted immediately after death, and the same organs be examined again at different successive periods, parts naturally white will be observed to become red, vessels and patches of ecchymosis become apparent where none could previously be seen. It is possible, indeed, to produce at pleasure a red congested appearance of the lung in any one of its surfaces, by letting the body lie for some time on its back, side, or face, and to bring about a similar result in any portion of the intestines by suffering it to hang in a dependent position. Numerous experiments were made on this subject by Rigot and Trousseau; and the blood sometimes oozes in

such quantity as to accumulate in the cavity in the form of a hemorrhage. These sanguineous congestions are formed not only when the mass of the blood is considerable, but also after protracted diseases.*

These congestions are principally observed on the exterior of the body in the most dependent parts of the skin, such as the back and calves of the legs, which present a uniform livid red colour, disposed in stripes or patches. Red streaks, either parallel or intersecting each other, are also sometimes seen on the arms, thighs, thorax, and abdomen, and not confined to the dependent parts of the body; the vessels of all these parts, especially the veins, are found minutely injected with black blood; the streaks occur in the course of large veins, and seem to be the effect of the transudation of their blood staining the surrounding tissues. During the last moments of life, owing to the weakened action of the heart, there is not so much blood propelled to the surface, and it has a tendency to accumulate in the internal organs; the internal cadaveric congestions present a uniform red tint, disposed also in isolated spots, stripes, or patches; the blood escaping from its vessels forms effusions, and stains the neighbouring tissues; if there exist previously serous effusions, they become tinged with the colouring matter of the blood; there is also extravasation of the serous fluids; and effusions take place into the cavities of serous membranes or in the cellular tissue; the bile likewise transudes through the gall-bladder, and stains the surrounding parts. All these appearances are more particularly found in the membranes of the brain lining the posterior part of the skull, and in the posterior part of the spinal canal; in the lobes of the cerebellum, and posterior lobes of the cerebrum; in the posterior portion of the lung; the most dependent portions of the stomach and intestines, and in the kidneys. These parts present sometimes a uniform deep red colour, resembling the most intense congestion.

At a later period, when putrefaction commences, various gases are disengaged, and particularly sulphuretted hydrogen, which penetrate the coats of the blood-vessels as well as all other tissues, change the colour of the blood, and produce the various tints of brown, livid, and green, that characterize putrefaction. These changes of colour are first noticed on the concave surface of the liver, in consequence of its vicinity to the transverse arch of the colon; they next manifest themselves in the abdominal muscles, and subsequently in the integuments.

Congestions after death are formed, therefore, in three different ways: by the gravitation of the fluids within their vessels; by transudation of the fluids through the parietes of the vessels and imbibition of the neighbouring tissues; and by chemical affinities.

The nature of the first species of cadaveric congestion is sufficiently obvious not to require any explanation. The fact of the transudation of fluids through the membranous parietes of vessels, and of all animal tissues having in a certain degree the property of imbibition even during life, has been clearly established by the experi-

* Andral. *Op. cit.* vol. i. p. 83. This chapter contains a very full and interesting account of the occurrence of congestions and effusions after death.

mental researches of Magendie, Foderé, and Dutrochet: the functions of exhalation and absorption seem to be, partly at least, carried on by transudation and imbibition. The vessels and serous membranes are, however, considerably less permeable to the fluids they contain during life than after death, which is partly attributed by Magendie to the current of circulation constantly conveying away the fluids before they can accumulate in any part; the solids are also endowed by their vital principle with a greater degree of density and power of resistance during life, whilst after death the physical laws acquire their full influence.

The patches and stripes of uniform red are the effect of this property of transudation and imbibition; the tissues appear as if soaked in blood and stained with it. This uniform red tint is frequently observed on the internal coat of the blood-vessels and of the heart; it is of a vermilion red in the arteries, and of a darker red in the veins: the redness penetrates all the coats of the smaller and thinner vessels, and extends sometimes to the adjacent tissues: the vasa vasorum of the large vessels are minutely injected. These appearances in the blood-vessels are almost constantly found at the end of twenty-four hours in the bodies of persons who have died from an obstructed state of the circulation, or from diseases in which the blood is preternaturally fluid. The small quantity of colourless or reddish serous effusion found in almost every body in the arachnoid of the brain and spinal marrow, in the pericardium, pleura, and peritoneum, thirty-six hours after death, is to be attributed also to transudation. Congestions and effusions from transudation occur most frequently in those diseases in which the blood is thin, and retains its fluidity after death, such as scorbutus, purpura hemorrhagica, and all diseases usually called putrid: they are seldom observed in the neighbourhood of large veins and arteries on account of the thickness of their coats; they are greatly facilitated by the rapidity of putrefaction, and therefore materially influenced by the heat and moisture of the atmosphere.

With regard to the effects of chemical affinities, it is important to remark that, when a portion of lung, intestine, or brain, presenting little or no vascularity, has been exposed for a short time to the atmosphere, it assumes a bright scarlet appearance, resulting from the arterialization of its blood, which, being thus more highly coloured, is apparently increased in quantity. We have already stated that the gases evolved by putrefaction give the blood a brown, livid, or green hue; the texture of the part becomes more friable and flaccid, and these appearances have, we apprehend, been sometimes mistaken for gangrene. Further details of the cadaveric appearances will be found in Andral's *Pathological Anatomy*, (vol. i. article 4, p. 70.) and in the works on Medical Jurisprudence by Foderé, Paris, and Beck, [Devergie, Guy, and A. Taylor.]

We have thought it desirable to describe at some length these cadaveric appearances, feeling the great importance of their not being mistaken for the effects of disease, especially with respect to forensic medicine. There is, perhaps, no point in pathological anatomy which has given rise to

greater diversity of opinion, has proved a more fertile source of error, and remains yet more undetermined, than the exact nature of the morbid appearances which separately characterize congestions both active and passive, and inflammation. This is in fact a subject often surrounded with many difficulties, an ignorance of which has led to the erroneous practice of pronouncing hastily and indiscriminately as inflammatory, appearances of redness, injection and turgescence, belonging perhaps only to either active, passive, or cadaveric congestion. We shall therefore point out, as far as we are enabled in the present state of pathological knowledge, the characteristic signs by which we can establish a line of demarcation in the dead body between these various morbid appearances.

1. The existence of various degrees of *redness* in any tissue, depending on minute vascular injection, is not alone sufficient to indicate inflammation, as redness is produced also by several forms of congestion. An increase of volume likewise is not always characteristic of inflammation; it may arise from the distended state of the vessels, or the slight serous effusions that occur in congestions both active and passive. Increase of volume may depend, moreover, on a morbid activity of the functions of nutrition and secretion, causing a diseased growth of texture without the necessity of an inflammatory action. Congested tissues become also more soft and friable in consequence of the greater quantity of fluids they contain. The redness and increased thickness of a membrane and softening of its texture cannot, therefore, be always considered unequivocal marks of inflammation.

The following are the only sure signs of genuine inflammation: considerable increase of vascularity with extravasation of blood or coagulable lymph, and the formation of pus or other morbid products, leading to a decided change in the structure of the part affected. The presence of all these signs at the same time is not, however, required: there are variations in this respect, according to the texture of the part, the intensity and duration of the inflammation. A very minute injection, chiefly of the small arterial branches; a vivid red colour, disposed in dots or striæ occupying the whole thickness of the tissue, and not removable by pressure or ablution; spots of ecchymosis, occasioned by the rupture of some of the small vessels; effusion of blood on the surface, or its infiltration within the texture of the part, are all characteristic of recent inflammation. The exudation of coagulable lymph, the secretion of pus, and the formation of ulcers, indicate a more advanced period of inflammation. This, however, is not constant, as both lymph and pus are sometimes poured out, and ulcers very rapidly formed in certain soft tissues, as, for instance, in mucous membranes. The organization of lymph and conversion into new tissues, the complete organization of abscesses, and the formation of purulent sinuses, point out inflammation of longer standing: the minute vascularity and redness have in this latter case generally disappeared.

2. Injection, redness, and patches of ecchymosis exist also in passive congestion; but the injection then is seated principally in the veins. The

redness is of a dark-brown hue rather than florid; the blood extravasated is thin and fluid, and the red colour is easily removed by ablution: the texture of the solids is soft, flabby, and easily torn, and the condition of the whole body usually indicates a state of cachexia. Active congestions are distinguished from passive by the vascular injection occupying chiefly both the large and small arteries, the net-works formed by their extreme ramifications being so minutely filled with blood as to impart to the tissue an intensely bright red colour; the blood is generally very viscid, and the texture firmer than in passive congestion. This is a condition of parts bordering on active inflammation, although no distinct change of structure has yet taken place. It is often described as inflammation, and the mistake is not perhaps of much practical importance, since they both frequently give rise to the same local and constitutional symptoms, and require the same mode of treatment; the morbid appearances belonging to inflammation and active congestion are, moreover, often united in the same organ; active congestion is most frequently attended with serous effusions or hemorrhage; inflammation, more generally with the effusion of coagulable lymph and pus, or ulceration. It must, however, be acknowledged that the distinction between active and passive congestion is often extremely difficult, if not impossible; and it will be necessary in general to attend to other circumstances besides the morbid appearances; such, for instance, as the mode of death, whether it has been sudden and rapid, or lingering; attended with violent struggles, or tranquil; also the nature of the preceding disease, and the state of the other organs of the body. We may thus ascertain whether the venous system is generally congested or not; and it should be remembered that the parenchymatous and membranous organs are usually found gorged with blood after disease of the heart and asphyxia, in consequence of the mechanical obstruction to the return of blood to the heart.

It is important, however, to remark that the morbid appearances indicating active or passive congestion, such as redness, injection, turgescence, and even slight effusions, which existed during life, sometimes completely disappear after death. There can be no doubt that this may happen, because there are instances in which, although the skin or the eye presented some of these appearances during life, they have been found quite pale after death. When, therefore, there have been well-marked symptoms of congestive disease during life, the absence of the usual morbid appearances after death is not always sufficient to destroy our belief in their existence. We know that nothing may be found in the brain after apoplexy from simple congestion, though such cases are not of frequent occurrence. The changes of structure induced by true inflammation, such as suppuration, ulceration, &c., are free from this source of deception.

3. A little attention will be sufficient to distinguish the cadaveric congestions arising from mere gravitation of the fluids, from those produced by disease; the vascular injection and redness is confined to the most dependent parts of organs, and is found in a number of organs at the same time,

varying of course according to the position of the entire body, or of certain regions only; this should always be a subject of particular inquiry. A considerable degree of injection, therefore, confined to one organ, and especially not occupying its most dependent part, may fairly be attributed to disease. The redness, injection, and sanguineous or serous infiltrations resulting from transudation, occur at a later period after death; the tissues are of a uniform red, as if dyed with blood; the blood can sometimes be washed away by repeated ablution, or by maceration for some hours in water; but this will not be the case four or five days after death. If a considerable degree of sanguineous infiltration is observed in one organ only, some days after death, and if it be accompanied particularly with much injection of both its large and small blood-vessels, there is little doubt but that it is the effect of disease; but if similar appearances exist also in different other parts of the body, it is much more probable that they originate in the cadaveric transudation that attends putrefaction. There is frequently, however, great difficulty in forming a right judgment in such cases, and it is necessary to exercise the utmost caution and discretion on this subject when called upon to give evidence before a court of justice. The various appearances depending on the action of chemical affinities in a more advanced state of putrefaction, are too well characterized to deceive any well-informed observer.

In judging of the morbid appearances, it will be necessary to take into consideration:—1. the period at which the body is examined; 2. the position of the part; 3. whether there existed any mechanical obstruction to the circulation during life; 4. the mode of death; 5. whether there were any symptoms of acute vascular disease during life.

Local Symptoms of Inflammation.—Inflammation has been described both by ancient and modern writers as characterized by four local symptoms. These have been accurately noticed by Celsus: *notæ vero inflammationis sunt quatuor—rubor et tremor cum calore et dolore* (Lib. iii. cap. 10.) These symptoms may not all exist in every case, but the greater number of them are usually present; they may assume also various respective degrees of intensity. In some tissues there is generally very little redness or swelling, but intense pain. The pain may be intense, although the inflammation is moderate, or the pain be slight and the swelling considerable. The heat also varies in the same manner, the inflammation being sometimes attended with little increase of heat, while the swelling is great. These four symptoms exist in a moderate degree in the first stage of the inflammatory process, sometimes described as sub-acute, and which we have distinguished from perfectly developed inflammation by the term *active congestive* or *congestive irritation*. It is only when these symptoms have acquired a certain degree of intensity, leading to morbid changes of structure, that they constitute, according to the view we have adopted, true inflammation.

Redness.—Some tissues are naturally red; their redness, therefore, must be preternaturally increased to become morbid. A quickened circulation may cause a temporary increase of redness,

heat, and even swelling, which soon subsides, and is in this case only physiological; the increase of redness must therefore be permanent to be accounted morbid. The redness is manifestly owing to the increased quantity of blood in the diseased part distending the vessels, and penetrating into the minute vascular ramifications which previously conveyed only colourless blood. Mr. Hunter froze the ear of a rabbit and thawed it again; this occasioned considerable inflammation, an increased heat and thickening of the part: this rabbit was killed when the ear was in the height of inflammation, and the head being injected, the two ears were removed and dried; the uninflamed ear dried clear and transparent, the vessels were distinctly seen ramifying through its substance; but the inflamed ear dried thicker and more opaque, and its arteries were considerably larger. The redness sometimes partly depends also on the formation of new vessels, but this of course can only happen in advanced stages of inflammation. Preternatural redness alone is not sufficient to constitute inflammation; it must be accompanied with a certain degree of pain, heat, and swelling; for we have seen that it is a common attendant of congestions, active, passive, and cadaveric. Its intensity is very variable; some dense fibrous tissues, such as tendons and ligaments, exhibit very little redness when inflamed, having but few vessels; whilst in more vascular textures the redness is bright and florid, constituting one of the most prominent symptoms; as, for example, in some cases of cynanche maligna, in which the pharynx and tonsils are of an intense fiery red with burning heat and pain, in consequence of the extreme injection and distension of the minute vessels; when the blood, however, stagnates, the redness changes to a dark purple, indicating mortification. The same appearances are observed in gangrenous erysipelas. The redness may assume various tints, from a bright scarlet to a dark livid purple, with every intermediate shade. It may also appear in patches, stripes, streaks, or be uniformly diffused; it is generally greatest in one point, decreasing gradually as it extends, until it becomes imperceptible, or sometimes terminating abruptly. It may be made to disappear by pressure, but returns as soon as the pressure is removed.

Swelling.—The swelling is produced in the first stage of inflammation by the greater influx of blood; at a later period it is increased by the effusion of serum, the extravasation of blood, and the deposition of coagulable lymph or pus; the interruption of the absorption may also be noticed as one of its causes. The swelling often remains after the inflammation has disappeared, particularly when it has induced much change of structure. Swelling alone does not constitute inflammation; although one of its symptoms, it may be occasioned by many other causes, such as the displacement of a part, as in hernia, and the dislocation of a bone, by the effusion of blood or water, the accumulation of air, morbid growths, &c. To be inflammatory, it must be conjoined with pain or redness. The degree of swelling depends partly on the violence of the inflammation, and partly on the structure of the parts affected; there sometimes exists very little swelling, as in ophthalmia, and superficial inflammation

of the mucous and serous membranes, and also of the skin; the swelling is then irregularly diffused over a large surface; in other textures it may be considerable and circumscribed. Excessive swelling and redness in a part, without much heat or pain, is very likely to terminate in gangrene.

It is sometimes not easy to ascertain the existence and exact seat of swellings of the internal organs, particularly in the abdomen; and a considerable degree of habit and tact is generally required to avoid mistakes. The swelling may be fixed or movable, pulsatile or not; it may be necessary to make the patient vary his position, or to lessen the fulness of the abdomen by emptying the bowels; the exact seat of the swelling also is to be considered, whether connected with the liver, stomach, bowels or kidneys; situated in the mesentery, or merely in the abdominal parietes. A solid tumour sometimes pulsates in consequence of being in contact with the aorta; this must not be mistaken for aneurism. It is very important to remember accurately the natural relative position of the different organs; the same rule applies to the protrusion of tumours through the parietes of the thorax.

Whilst on the subject of swelling, we must notice the accompanying changes in the consistence or density of the part. Some pathologists have advanced as a general proposition, that inflammation has the effect of hardening soft and softening hard textures, giving as an instance the increased firmness of hepatized lung, and the softening of inflamed bone. We conceive, however, that there is some inaccuracy in this statement, owing to the ideas attached to the terms in which it is expressed not being well defined. Almost all soft parts of the body feel harder to the touch at the commencement of inflammation, in consequence of the distension produced by a greater influx of fluids; but this increased firmness of the part is far from indicating any increase in the force of cohesion of its particles, or a real augmentation of density. A portion of hepatized is much more friable and easily broken down by pressure than sound lung, which, although more yielding to the touch, has a greater degree of elasticity and power of resistance. It is more correct, therefore, to say that recent inflammation has the effect of lessening the force of cohesion of all parts of the body, both hard and soft. This remarkable property of inflammation will be fully considered in the article *Softening*. When soft parts have been exposed to chronic inflammation, they often become hardened in consequence of new concrete products being deposited in their texture, or of its undergoing some change of structure by a slow and vitiated process of nutrition and secretion, as is exemplified in a variety of indurated tumours and morbid growths; in phlegmasia dolens; a peculiar form of hardening of the subcutaneous cellular tissue, and elephantiasis.

Heat.—The application of the hand to an inflamed part is sufficient to prove that its temperature is increased; the air expired, when the nostrils, throat, or bronchial membrane are inflamed, is so heated by passing over the inflamed parts as to feel burning. The sensations of the patient also indicate an increase of heat, although this is generally exaggerated, in consequence of the mor-

bidly increased state of the sensibility; in some nervous affections the patient complains of a sensation of burning heat, whilst the temperature of the part remains natural or is even diminished; there is sometimes a sensation of burning heat in gangrene, when the part is quite cold. The natural temperature of the body varies from 98° to 100° at the heart and on the trunk, but it gradually decreases as we proceed further from the heart, and as the parts become smaller and more exposed to the influence of the surrounding atmosphere; it is thus only 92° at the extremities of the body: this is a fact it will be important to remember in forming any estimate of the increase of heat in inflammation. Mr. Hunter concluded, from experiments he made, that the temperature of inflamed parts is but little augmented; he excited artificially inflammation in the chest, the abdomen, the rectum, and the vagina, without being able to discover any great increase of temperature, the thermometer rising only to 101° ; in one case, however, it was as high as 104° in the abdomen; and in a case of hydrocele the heat of the tunica vaginalis, which was 92° at the time of performing the usual operation, rose to 98° after inflammation had come on. There must, we think, have been some source of error in these experiments, for in numerous experiments made since those of Hunter, the thermometer, when applied to inflamed parts in cases of erysipelas, phlegmonous swellings, &c. has been observed to rise as high even as 107° of Fahrenheit. It is well known also that the general temperature of the body may be very considerably increased in various states of disease, not always inflammatory. When making observations to ascertain the variations of temperature in fever, we have not unfrequently seen a thermometer placed in the axilla, or under the tongue, rise as high as from 105° to 107° : a similar elevation of temperature has been noticed in acute rheumatism, and during the convulsions of tetanus. There is generally a rise of temperature with any great local increased activity of the circulation. Sir E. Home observed the oviduct of a frog, when about to spawn, two degrees higher than the temperature of the heart. Dr. Granville states that, during parturition, he has occasionally found the temperature of the vagina rise to 120° , the elevation appearing to bear a proportion to the degree of action in the organ. (Phil. Trans. for 1825, p. 262.) Every preternatural increase of heat is not therefore to be considered as inflammatory. In cases of fever, and especially of hectic fever, the whole body, or certain regions, such as the cheeks and the extremities, may be of a burning heat for a considerable time, in consequence of a state of active vascular congestion, without any inflammation. There must be a certain degree of intensity and a certain duration of morbid heat, united with other symptoms, to constitute inflammation. Redness and swelling may also exist with very little heat or pain, and pass on to suppuration, as is the case in abscesses by congestion and other forms of chronic inflammation.

We can scarcely expect that any satisfactory explanation of the increase of heat in inflammation will be given as long as there are points in the theory of animal heat that remain involved

in obscurity. As the variations of animal temperature constitute one of the most important morbid phenomena of inflammation, and of many other diseases, the consideration of the various opinions that have prevailed respecting the source of animal heat, and the causes which regulate its variations in disease as well as in health, is a subject of peculiar interest to the pathologist.

The *chemical* theory of animal heat proposed first by Dr. Black, and greatly improved subsequently by Dr. Crawford, (*Experiments and Observations on Animal Heat, &c.* by Adair Crawford, M.D., F.R.S., L. & E., &c.) was long considered to account in a perfectly satisfactory manner for all the varied phenomena of animal temperature, both in health and disease. The accuracy of this theory has, however, been called in question of late years by several able physiologists, who have drawn conclusions from their experiments tending to subvert every one of its main positions. The chemical theory assumed as fundamental facts, 1st, That the generation of heat in animals is the immediate effect of the chemical action of the air upon the blood in the lungs, leading to results strictly analogous to those of ordinary combustion: 2d, That oxygen and arterial blood have much greater capacities for caloric than carbonic acid and venous blood; 3d, That the temperature of the blood is the same on both sides of the heart, and in the large trunks of the pulmonic system; and that the evolution of heat throughout the body is the result of the capacity of the arterial blood for caloric becoming lessened when it is changed into venous, by which a portion of its *latent* caloric is set free.

The important fact of oxygen having a much greater capacity for caloric than carbonic acid has been denied by Delaroche and Berard; and the fact of the capacity for caloric of arterial blood being greater than that of venous has been disputed also by Dr. Davy. The experiments, however, for estimating the capacities of gases and fluids for caloric are of so delicate a nature, and liable to so many sources of error, that the conclusions of these two gentlemen are by no means considered as fully proved. It has been asserted also, as the result of numerous experiments, that the heat of the blood on both sides of the heart is not uniform, but that the arterial blood is warmer than the venous by one or two degrees: it must be acknowledged that this opinion seems to have a great weight of evidence in its favour.

The experiments, however, which would have most completely overthrown the *chemical* theory, if their conclusions had been confirmed, were those of Mr. Brodie; they led to the conclusion, by maintaining artificial respiration in decapitated animals, that the generation of heat has no connection whatever with the changes the air and blood undergo in the lungs, but is entirely dependent on the influence of the brain and nervous system. (Phil. Trans. for 1811, p. 37; also Phil. Trans. for 1812.) Legallois having, however, performed experiments of a similar description, arrived at conclusions directly opposed to those of Mr. Brodie, and tending strongly to confirm the opinion of the evolution of heat always bearing a relation to the consumption of oxygen. (Ann. de Chim. et Phys. tom. iv. p. 5. 113.)

The inaccuracy of Mr. Brodie's conclusions was further clearly established by the investigations of Dr. W. Philip, who pointed out several important sources of error in his experiments. While, however, it is admitted by Dr. W. Philip that the action of the air upon the blood in the lungs is the great source of animal heat, he has been led to conclude by some ingenious experiments, that its extrication from the blood throughout the system depends on the direct action of the nervous influence on the blood, and that the generation of heat may therefore be regarded as a kind of secretion.*

The advocates of the chemical theory have differed with respect to the part of the animal economy in which the combination of the oxygen of the air with the carbon of the blood takes place. Dr. Crawford maintained that the carbonic acid is formed in the lungs; that the heat evolved by its production is absorbed and becomes latent in consequence, as before mentioned, of the great capacity for caloric of arterial blood; and that it is again set free on the blood being changed into venous. Lefrange and Hassenfratz conceived that the air is absorbed by the blood in the lungs, and that the combination of its oxygen with the carbon of the blood takes place in the course of circulation, leading in this way to a gradual evolution of heat. Dr. Edwards has adopted this opinion, and supported it by experiments which appear extremely conclusive. Mitchell and Faust, however, having lately made in America some highly interesting experiments on the *endosmosis* of gases, consider that they have ascertained, beyond all doubt, that the carbonic acid is generated in the lungs. (*American Journal of Med. Sciences*, vol. vii. Philad. Nov. 1830.) If it be true, as stated by some able chemists, that the most delicate analysis can detect no carbonic acid in venous blood, this would at once prove fatal to the opinion of Lefrange.†

On the whole the weight of evidence seems to be still greatly in favour of Dr. Crawford's theory; and although doubts may have been thrown out on the accuracy of some of his fundamental conclusions, none of them have yet been successfully controverted. It appears highly probable that no theory can ever be established without a due reference to the connection which respiration has with the production of animal heat. It must, in the mean time, be admitted that the temperature of a part is not always in proportion to the strength and rapidity of its circulation, and that there are other circumstances, not hitherto well understood, by which the phenomena must to a certain extent be influenced: this is particularly the case with respect to the circumstances that influence the extrication of heat, and regulate the ever-varying changes of temperature in different parts of the

body. In some cases, for instance, of gouty inflammation, the heat of the part feels extremely pungent to another person, although there is not the least symptom of any increased influx of blood; the heat of the surface of the body is very high in some nervous fevers in which the vascular action is only moderately increased. Dr. Hastings states that he has seen several cases of fever in which the circulation was even remarkably slow, the pulse being only 45, when the temperature of the body was 105°; and that the heat has also been 100° in cases of hydrocephalus, with a pulse at 60 or 70. (*Hastings on Inflammation*, p. 110.) There is great reason to believe that the influence of the nervous system over the evolution of heat throughout the body is very considerable, especially in some states of disease; and if this be a well-founded conjecture, it would enable us to explain in a perfectly satisfactory manner several of the phenomena of this interesting process, which cannot so well be accounted for on chemical principles.

There is one circumstance, besides chemical action, which must, we conceive, have a considerable degree of influence in modifying the animal temperature, and which appears to us to have been hitherto too much overlooked. The various materials of which the body is composed are undergoing, during the process of assimilation, disassimilation, and secretion, an incessant change of state; some passing from the gaseous to the fluid, and from the fluid to the solid state, whilst others experience similar changes in an inverse order. These variations of density must necessarily be attended with both a considerable extrication and absorption of caloric, partly, no doubt, under the influence of chemical and electro-galvanic agency. It is, therefore, reasonable to suppose that the diffusion of animal heat throughout the body is in some measure connected with the operations, physical, vital, and chemical, constantly going on in the extreme vessels; and we shall probably never be able to construct any perfect theory of animal heat until we are better acquainted with the functions of these vessels. It is well known that every material disorder of the functions of nutrition and secretion modifies the temperature of the body: when the powers of assimilation exceed those of disassimilation, and the function of nutrition is in great activity, the faculty of producing heat is considerably increased; while, when the waste of the body surpasses its nutrition, the faculty of producing heat is weaker. Thus, in healthy individuals in the prime of life this faculty is greater than in old and sickly people; this is likewise exemplified by the cooling effects of the evaporation of the cutaneous perspiration, and, in dogs, of the pulmonary exhalation. In inflammation there is a great accession of nutritive fluids, which, becoming condensed, necessarily give out heat, whilst absorption and disassimilation are completely suspended; this must inevitably create a considerable preponderance in the extrication of heat over its absorption, and contribute to raise the temperature of the part.

Dr. Edwards has adopted the conclusion, from his beautiful experiments *On the Influence of Physical Agents*, that the production of animal heat is to be referred to a special power possessed

* It has been ascertained by Prevost and Dumas, from some very valuable experiments upon the proportional quantity of globules contained in the blood of different kinds of animals, and of different parts of the sanguiferous system in the same animals, that there exists an exact ratio between these globules and the temperature of the animal, which is highest in those whose blood contains the largest proportion of globules.

† A good account of the various opinions brought forward on the subject of animal heat, and of their respective merits, will be found in Dr. Bostock's valuable *Elementary System of Physiology*, vol. ii. p. 243.

by the living body, a kind of calorific function, which varies according to age, states of health or disease, and climate; that this power of generating heat is intimately connected with the respiratory, circulating, and secreting functions, and that it cannot suddenly undergo any permanent alteration during health. Dr. Edwards' interesting experiments admit of some important applications in pathology. The power of generating heat is distinctly proved to be less in children than in adults by nearly five degrees of Fahrenheit, and their temperature can, therefore, only be maintained at the standard of health by artificial heat, contrary to the commonly received pernicious opinion that children resist cold better than adults: this is fully confirmed by the great tendency observed in children to become cold and pallid, and to be affected with other symptoms of exhaustion, from the incautious use of bleeding and purging. The faculty of producing heat diminishes as the heat from external agents increases, and *vice versa*; so that this faculty is greater in the inhabitants of cold than in those of hot climates. But the power of generating heat is not capable of being either increased or diminished suddenly during health; hence the injury sustained by all sudden changes of the atmospheric temperature. When an inhabitant of the north removes to the south, his faculty of producing heat being too great in relation to the climate, there is an excess of heat in his system, by which he is greatly predisposed to inflammatory affections; and this will continue to be the case until his power of generating heat has been gradually lowered, so as to become adjusted to the climate: a change of this description is found to require in general about two years. Recent experiments, made with great accuracy, prove that animal temperature is not, as was supposed, equalized all over the globe. Dr. John Davy ascertained that the inhabitants of Ceylon have a higher temperature than Europeans by nearly two degrees; this is the effect of the heated atmosphere in which they live, and would be still greater were it not counterbalanced by the circumstance of their generating much less heat than Europeans.*

Dr. Edwards observes, also, that the faculty of producing heat is considerably modified by disease. In all inflammatory diseases it is greatly increased; in chronic and organic diseases, especially of the organs of respiration and circulation, it is often much lowered. Individuals labouring under such diseases are consequently observed to suffer severely from cold, and to be in general benefited by emigration to a warmer climate, where a diminished power of generating heat is more compatible with the enjoyment of good health. [See on all this subject the physiological works of Müller, Carpenter, or Dunglison.]

Pain.—Pain has a highly important influence in inflammation; it varies from the slightest increase of sensibility to the most violent suffering. It may be induced by an irritation of the nervous system without any corresponding increased action in the vascular system; severe spasm causes intense pain, as is seen in cramps. There are ex-

cruciating neuralgic pains of long continuance, as in *tic douloureux*, without any accompanying inflammation. In consequence, however, of the intimate connection between the functions of the nervous and vascular systems, and especially those of the minute vessels, nervous irritation is generally attended with increased vascular action. We have already seen that the first effect of the application of irritants to the living body is the excitement of pain, and that this is soon followed by an accelerated circulation and increased flow of blood to the part. It is not easy to explain why the action of irritants is sometimes confined to the nervous system, unless we can suppose that there is some state of disease affecting exclusively the structure or function of the nerves.

The pain in inflammation is either to be attributed to the direct irritation of the nerves by the exciting cause, or to their compression in consequence of the over-distension of the vessels, or the stretching of the fibres of the part; the pain is often increased with each dilatation of the arteries, constituting what is called *pulsatile pain*. There are great variations in the degree and nature of the pain, depending on the texture of the part, the number of its nerves, the violence of the inflammation, nature of the irritating cause, &c.: it must be acknowledged, however, that until we are better acquainted with the structure of the nerves and nature of the nervous principle, we can scarcely hope to account for all the varieties of their morbid excitement.

It is generally very acute in parts largely provided with nerves, and especially when they are delicate and pulpy; for the degree of pain is rather in proportion to the number of nerves terminating in a part, than to the size of the nerves passing through it. In parts of a dense and unyielding texture the pain is also generally very severe, although they have but few nerves, and are not naturally endowed with much sensibility; this is owing to the great compression of the nerves by the distended vessels. We see this exemplified in bone, tendon, ligament, all fibrous textures, and even the hard cartilaginous surfaces of joints, which become red and extremely painful under inflammation: the same takes place in soft parts whenever surrounded by fibrous bindings. When there is great tension, the pain is often so excruciating as to disturb the whole nervous system and bring on delirium; hence the good effects of relieving the tension by practising incisions even in the early stages of inflammation before the formation of matter: they are often followed by the instantaneous remission of fever and delirium. This is probably the reason of the inflammation of serous membranes, which are generally spread out tightly, being attended with much more violent pain than that of mucous membranes. Mucous membranes are also much less sensitive than the skin, and their inflammation is often not attended with much pain: this is one reason for the inflammatory affections of the mucous membrane of the alimentary canal having been so often overlooked. The degree of pain is not always therefore in proportion to the original sensibility of the part, but depends also on its tense and unyielding character.

The pain is usually pruriginous, pricking, and burning in the skin; acute and shooting in serous

* Some observations having been made recently by one of our medical officers on the coast of Africa on the comparative heat of Negroes and Europeans, it was found that the temperature of the former was several degrees higher than that of the latter.

membranes; dull and throbbing in cellular and parenchymatous organs; lancinating in cancer and malignant tumours; obtuse and heavy in glands and bones. A sense of weight and throbbing generally indicates a tendency to suppuration, and the pain usually subsides on the formation of matter, particularly if it has a free issue. The pain is in some instances continued, in others periodical; the sensibility of some of the organs of sense, such as the nose and mouth, is diminished during inflammation, whilst the eye and the ear, when inflamed, become exquisitely sensible. The pain is sometimes so slight, that it amounts only to a morbid soreness or tenderness on pressure. Besides pain, the sensibility of the part is morbidly increased to all external impressions, so that those which before gave pleasure become painfully exciting. Most of the internal organs perform their functions during health without transmitting any perceptible impression to the sensorium; but when inflamed, we become immediately conscious of their various actions, in consequence of these being attended with uneasiness and pain: we can then distinctly *feel* that we have a stomach, heart, lungs, &c.: these sensations are always sure signs of a state of disease, and intended no doubt as warnings that we may avoid persisting in the use of what might prove injurious.

The pain arising from mere spasm is generally lessened by pressure, as is observed in colic; and this forms a good distinction from inflammatory pain, which pressure aggravates. The pain of inflammation is, however, chiefly increased by sudden and partial pressure; for frequently a gentle pressure of the whole of the inflamed part gradually increased, can be endured without pain, and even mitigates it.* One of the effects of general pressure is to diminish the influx of blood, and lessen in this way the swelling, the heat, and all the other symptoms of inflammation. General and graduated pressure has on this account been recommended, and sometimes successfully applied as a remedy; it has been used to this effect by Dr. Balfour in rheumatism, by Mr. Carmichael in cancer, and Mr. Velpeau in erysipelas. We have witnessed good effects from it in some cases, but have seen it aggravate the symptoms in others.

The sudden disappearance of intense pain in a highly inflamed part often indicates the approach of gangrene. Very severe pain has a great influence in inflammation by the morbid sympathies and constitutional disturbance it excites.

Some caution is frequently required in ascertaining the existence of pain. Under certain states of general nervous irritability, the patient complains of tenderness in whatever part of the body pressure is applied; this tenderness is sometimes greater, or perhaps entirely confined to certain regions, and more particularly to the epigastrium and the hypochondria. There are in some nervous persons at all times a great intolerance of pressure in the epigastrium. We have known a hasty and superficial examination in such cases lead most erroneously to the conclusion of inflam-

mation being present, and to the consequent adoption of active remedies, where there was no actual disease. Mistakes of this kind are by no means of rare occurrence in the present times, since the minds of practitioners have been so exclusively occupied with the idea of the great prevalence of inflammatory diseases over all others, and especially of gastro-enteritis; and persons have in this manner not unfrequently been subjected, without the least occasion, to long courses of bleeding, purging, and mercurial treatment.

The presence of pain or tenderness alone, without any of the concomitant symptoms, is never sufficient to constitute inflammation; by diverting a little the patient's attention, and then gradually repeating the pressure, it will often be found that his first complaints were greatly exaggerated.—There is in general much difficulty in ascertaining the seat of pain in infants, as they merely exhibit general signs of suffering, without being able to describe their sensations. It will be necessary in such cases to watch carefully the expression of the countenance for the ordinary indications of pain, when pressing the different parts of the body: infants are sometimes observed to carry frequently their hands to the part of the body that is affected.

Pain, even of the most intense description, may also become latent in consequence of the sensibility of the sensorium being impaired by disease. This not unfrequently happens in febrile affections when the head is much affected; local inflammations, which at first complicated the fever, may thus be supposed to have subsided, while in reality they are only masked, and are proceeding in their destructive course: it is necessary, in order to guard against this deception, to make daily, in such cases, a minute and careful examination of the condition of the principal viscera. There is another source of delusion with respect to pain: it is sometimes felt at a distance from the seat of the inflammation in a greater degree than in the diseased part. In such cases the pain is generally conveyed by nerves passing through the inflamed part to other remote parts, in which they terminate. We have familiar instances of this peculiarity in the morbus coxarius, in which the only pain complained of is frequently in the knee, and sometimes likewise in sciatica.

There is a particular expression of countenance characteristic of the existence of pain in each of the different viscera; the contraction of the forehead and eye-brows, combined with a wild, staring, or heavy expression of the eyes, are the usual indications of pain in the head. The distension of the *alæ nasi*, contraction upwards of the commissures of the lips and of the cheeks, and protrusion of the eyes united to heaving of the shoulders, point out pain in the thoracic viscera. A falling in of the cheeks, contraction downwards of the angles of the mouth, an elongated and pinched appearance of the features, with sunk eyes and pallidness, indicate abdominal disease. There is an expression of great dejection in all chronic diseases of the urinary organs.

Besides the local symptoms just described, there are others which have reference to the disturbance of the functions of the organs affected. Thus, inflammation of the brain is attended with delirium, vertigo, coma, convulsions, and paralysis; inflam-

* Dr. Elliotson's Lectures on Inflammation, Med. Gaz. Nov. 26, 1831, in which a clear and comprehensive description is given of the local symptoms.

mation of the larynx with a shrill, crowing, hoarse, or feeble voice, and difficulty of breathing; that of the pharynx with difficult deglutition; that of the lungs with dyspnoea, cough, and various kinds of expectoration; hepatitis with pain in the shoulder and larynx, besides pain, heat, and fulness in the right hypochondrium; gastritis with nausea and vomiting, besides fulness, heat, pain, and great tenderness in the epigastric region; nephritis with retraction of the testicle and vomiting; panaris with swelling of the glands of the axilla, &c. When the inflammation affects exhaling and secreting organs, there is a change in the quantity and quality of the secretions; they are at first diminished, or even suspended; they then return altered perhaps in colour, thickness, or smell.

In the inflammation of internal organs these functional and sympathetic symptoms are often of the greatest value, as the more ordinary local symptoms are mostly beyond the reach of our observation. When the inflammation is extensive and severe, the functions of other organs are also disturbed: the whole constitution may become more or less affected; and this affords another class of symptoms called *constitutional*, from which we often derive considerable assistance in our diagnosis. These form the next subject of consideration.

[From the whole consideration of the subject, we are justified in embracing the views of a recent able writer, (Alison, in *Tweedie's Library of Medicine*, 2d edit. vol. i., Philad. 1843; see, also, his *Outlines of Pathology and Practice of Medicine*, Amer. edit., Philad. 1844): "In order," he remarks, "to give the requisite precision to the general notion of inflammation, as a local change of the condition of any part of the body, it seems only necessary to include in it, besides the pain, swelling, heat and redness, the tendency always observed, even when the changes in question are of short duration, to effusion from the blood-vessels of some new products, speedily assuming, in most instances, the form either of coagulable lymph or pus. It is true, that there may be inflammation either of so slight intensity, or short duration, as never to show these, its usual consequences; but we shall escape a great deal of useless verbal discussion and misapprehension if we lay it down as a rule, never to apply the term except in cases where we are satisfied, that the tendency to these effusions exists, and that, if they do not appear, it is only because of the minute scale, or the rapid abatement of the diseased action. A peculiar perversion of nutrition or of secretion, we hold to be essential to the very existence of inflammation; and all descriptions, and all attempts at explanation of the changes to which the term is applied, if they do not include this, their most essential peculiarity, we must regard as necessarily and fundamentally defective."]

Constitutional Symptoms of Inflammation.—It has already been stated in the experimental inquiry into the nature of inflammation, that the action of stimuli on the living body was not always limited to the part to which they were applied, but extended frequently to the whole animal economy, exciting various degrees of disturbance in its several functions. The existence and nature

of this constitutional derangement were demonstrated by several experiments.

Inflammation may extend in several ways beyond its original seat. By continuity:—when it extends along the surface or throughout the substance of the same tissue: thus there is a great tendency to the rapid diffusion of inflammation along the surface of the skin in erysipelas; and the same is observed in the inflammation of mucous, serous, and fibrous membranes. By contiguity:—when it is communicated to adjacent tissues of a different nature: the inflammation often extends in this manner from serous membranes to the organs they invest. The facility with which inflammation spreads by contiguity depends, in a great measure, on the disposition of the connecting cellular membrane: when loose, it transmits the inflammation rapidly from one part to the other; but when dense, it appears to oppose strongly the propagation of the disease. It was a remark of Laennec, that congestions and gangrene had a greater disposition to spread by contiguity, and acute inflammation by continuity.

The local extension of inflammation is, on the other hand, checked by differences in the texture, the vital properties, and in the functions of the various organs and tissues of the body; and we may add, that general tendency in all living matter to resist the destructive effects of disease. One of the means by which this is effected is the effusion of coagulable lymph, and contraction of adhesions around the seat of the inflammation; so that the continuity of the parts is interrupted, and the disease circumscribed.

The communication of inflammation to parts of the body *remote* from its original seat takes place in two different ways, either through the medium of the circulation, or that of the nervous system. It has been satisfactorily proved, by direct experiment, that when deleterious substances are inserted into any part of the body, they are sometimes absorbed into the blood-vessels, and conveyed by the blood to remote parts, where they excite various diseased actions. (Magendie's *Physiology*, p. 347, Milligan's translation.) We have further demonstration of this being the case from numerous pathological facts, as in the morbid effects of various animal and other poisons, which it would be difficult to explain in any other manner than by the absorption of the morbid matter. It is, therefore, very generally admitted that the blood is the vehicle of a great many morbid principles; and that the deterioration of its qualities is to be placed among the most frequent causes of disease. In inflammation it is easy to conceive, when it is either of an unhealthy character or the result of a specific cause, how the morbid products of the local affection, being absorbed into the blood and circulated with it throughout the body, should sometimes excite inflammation in distant organs and disturb the general health. Morbid impressions are, however, transmitted also from one part to another by the nervous system; and nervous sympathy is therefore another great cause of the constitution being so frequently and variously affected by local inflammation. We think it, therefore, desirable to offer here a few observations on the influence of sympathy.

The structure of the human body is very com-

plicated, its elementary materials being so arranged as to constitute an assemblage of tissues and organs having distinct physical and vital properties; these tissues and organs act reciprocally on each other, producing by their combined operations the complex phenomena of life. Every living part of the body has a general sympathy with the whole system, or a particular sympathy with certain parts of it; and the functions of each part are more or less essential to the healthy action of the whole. The influence of these reciprocal sympathies is, therefore, very considerable, especially in disease. It is through the medium of the brain and nerves that sympathies are established between all parts of the system; receiving morbid impressions from diseased parts, the nerves transmit them to the other organs of the body, and in this manner become the source of an infinite variety of both local and constitutional morbid phenomena.*

Inflammation in one part of the body may also disturb the functions of the others by its direct influence on their circulation, independently of any nervous sympathy. The great accumulation of blood in an inflamed part may be the means of depriving another of its usual supply of blood; thus the inflammation of internal organs attracts sometimes the blood from the surface towards the centre of the body, creating coldness and pallidness of the skin; the lower extremities are likewise cold in cases of determination of blood to the head; on the other hand, if the regular return of the blood to the heart be prevented by the inflammation of any of the central organs, such as the lungs, heart, large vessels, &c., this will cause it to accumulate in remote organs, and impede their functions. These unequal distributions of blood from the mere mechanical derangement of the balance of the circulation are of frequent occurrence, and a much greater source of constitutional derangement than has generally been supposed: they may be looked upon as a species of *sanguineous* sympathy.

There exists a strong sympathy also between the different organs engaged in the same function: when the stomach, for instance, is in a state of disease, all the other organs belonging to the digestive function are more particularly predisposed to sympathize with it. One eye has also been known to become inflamed through mere sympathy with inflammation that existed previously in the other. This kind of sympathetic influence has been called *sympathy of function*. It has been advanced by Bichat that similarity of structure chiefly is a great source of sympathy, and that, for example, when a serous or fibrous membrane or a muscular organ was inflamed in one part of the body, there was a strong tendency to inflammation of the same texture in every other part of the body.

The various morbid sympathies and constitutional symptoms to which they give rise, are considerably modified by those peculiarities of constitution which have been termed temperaments and idiosyncrasies. The temperaments are formed by

a preponderance in the development and activity of certain tissues over others in the same body; they may be divided, to suit practical purposes, chiefly into four—the sanguineous, bilious, phlegmatic, and nervous; there are, however, various combinations of these, forming a number of subdivisions. By idiosyncrasies are meant peculiarities of constitution belonging only to one or a few individuals; these are innumerable, often discovered only by accident, and in general difficult to explain. Thus certain alimentary and medicinal substances affect some individuals in a manner totally opposite to their general mode of action. There are also predispositions of the constitution to certain forms of disease, which are called *diatheses*. Having premised these general observations on the different modes of extension of inflammation on sympathies and temperaments, we shall proceed to the important consideration of, 1st, the influence of the constitution on local inflammation; and, 2dly, of the various forms of constitutional derangement induced by inflammation.

Influence of different states of the Constitution on local Inflammation.—We have already had occasion to remark, that every living part seems to be endowed with an inherent faculty of resisting, to a certain extent, the effect of disease. We are unacquainted with the nature of this faculty: it cannot be satisfactorily accounted for by structure, and is to be referred most probably to the immediate influence of the vital principle; it has been designated accordingly by the ancients *vis medicatrix naturæ*. It is in consequence of this faculty of resistance, that whenever a living part has sustained any injury, either from external or internal causes, an increased activity is soon observed to take place in most of its vital actions, and a process *essentially vital* is set up, by which the effects of the injury are often prevented, removed, or repaired.

The faculty of resisting disease is observed to exist in different degrees in different individuals, and in the various parts of the same body. It is generally greater or less in proportion to the strength and soundness, or weakness and unsoundness, of the constitution. In strong and healthy constitutions, there is in general only moderate predisposition to inflammation, even after the severest injuries, which are repaired by a mild though efficient degree of inflammatory action. But in individuals whose constitutions are either originally weak, irritable, or unsound, or have been rendered so by long-continued disease, the tendency to resist inflammation is much weaker, and when excited, it is generally more violent, spreads more rapidly, and is less easily removed. It is also well known that parts of the body having a low vitality, such as tendons, ligaments, bones, &c., resist inflammation much less effectually than those more highly organized. It is highly important, therefore, in a practical point of view, to remember that there are circumstances in which the violence and spreading of inflammation may be greatly increased by a state of general debility.

A disordered state of the constitution operates not only in favouring the increase of inflammation, but opposes also a formidable obstacle to the establishment of those restorative processes by which it is brought to a favourable termination. The

* See Dr. Thomson's account of particular sympathies in his *Lectures on Inflammation*, and also some excellent remarks on the influence of local and general sympathies in the work on inflammation by Mr. James, second edition.

principal sources of disorder in the constitution by which local inflammation is liable to be affected, may be referred to the following: a state of general plethora combined with an over-degree of activity in all the functions of life—an opposite condition of the system arising from deficient nourishment, and attended with general languor and debility—the vitiation of the qualities of the blood and other animal fluids, the effect either of bad food and air, or of the introduction into the animal economy of morbid and other deleterious substances—a disturbed and irritable condition of the nervous system—a disordered state of the digestive function, and that in general of any of the vital functions—organic disease of an important organ—and, lastly, a predisposition to some form of specific disease, such as scrofula, gout, cancer, &c. Innumerable examples of the influence of all these morbid conditions of the constitution upon local inflammation might easily be adduced, were it not incompatible with the limits of this article; but we shall have occasion to enlarge upon this view of our subject when treating of the constitutional effects of inflammation.

There is one highly important practical rule to be deduced from the preceding considerations, namely, that from whatever cause the disorder of the constitution may proceed, the attention of the practitioner must be first directed to the amendment of the general health before he can hope to succeed in removing the local disease; this latter must in fact be treated by constitutional remedies; for if local applications only be relied upon, they will seldom be treated by constitutional remedies; for if local applications only upon, they will seldom be found of much avail. The merit of having called the attention of the profession to this important principle in pathology, is due, as already observed, to the late Mr. Abernethy, who directed more especially his inquiries to the influence of the state of the digestive organs over local diseases: we must refer the reader for fuller details on this important subject to Mr. Abernethy's valuable writings. (On the Constitutional Origin of Local Disease.)

Various Forms of Constitutional Disturbance Induced by Inflammation.—Inflammation of any parts of the body, whenever it is very intense, excites a disturbance in the functions of the heart, brain, and stomach, characterized by a series of morbid phenomena which have received the name of *symptomatic* or *sympathetic fever*. This morbid state of the constitution reacts, however, powerfully in its turn on the local inflammation by which it has been excited, so that there exists the most intimate connection between the local affection and constitutional reaction. This is a circumstance leading to highly important consequences, for the sympathy of the constitution is generally the result of a salutary effort of the powers of life to assist in arresting the progress or removing the effects of the local disease, and the accomplishment of this desirable end depends in great measure on the local and constitutional morbid actions being duly balanced.

Many proofs can be adduced in support of this mutual dependence of the local and constitutional affection upon each other. The reaction of the constitution corresponds generally in degree with

the strength of the local inflammation, the former being aggravated or diminished in the same proportion as the latter increases or lessens. When the reaction is excessive, it tends to aggravate the local disease: when, on the contrary, the reaction is deficient, the local affection may either remain stationary and assume a chronic character, or it may increase rapidly, and affect by sympathy remote parts of the body, as sometimes happens in the unhealthy inflammation excited by morbid effluvia or animal poisons. It is well known that if the constitution becomes much disordered, or if its powers happen to fail during the progress towards restoration of any wound, the inflammation of the wound, which was before perfectly healthy, either assumes immediately an unhealthy character, or entirely disappears, leaving the part even sometimes in a state of mortification. The discharge from a wound, moreover, is generally scanty, and never of a healthy character as long as the symptomatic fever continues high; but as soon as the fever abates and the general secretions are restored, the discharge becomes more copious and healthy. If, on the other hand, an individual reduced to a state of extreme debility from severe local disease, be seized with inflammation of a vital organ, he will sometimes bear with impunity a degree of general depletion which would have been previously sufficient to destroy him. (James on Inflammation, p. 46.) The preceding instances, to which many others could easily be added, will be sufficient to establish the fact of the existence of the closest sympathy between the local and constitutional morbid actions.

The constitutional reaction not only varies as already stated, in degree, but also in its nature; and the correspondence is likewise maintained in this respect between the local and constitutional affection. The character or type of the symptomatic fever is influenced chiefly by the following circumstances in the temperament and previous state of health of the individual,—the seat and extent of the local affection, and the nature of the exciting cause. In individuals of a sanguineous temperament there is generally a strong reaction of the vascular system, and the type of the fever is essentially *inflammatory*, and seldom attended with much danger. In those of a nervous and irritable temperament, or whose constitutions have been weakened by disease, the fever is chiefly characterized by considerable disturbance of the *nervous system*, and by a variety of anomalous and untoward symptoms; there is frequently in this form of fever a degree of over-excitement followed by rapid collapse. The character of the reaction, however, may be entirely derived from the seat and extent of the inflammation, or the nature of the exciting cause: thus the inflammation of fibrous tissues, that consequent upon extensive injuries, or poisoned wounds, &c., generally induces very great disturbance of the nervous system, and the most dangerous forms of sympathetic fever, even in robust and healthy subjects. It is worthy of remark in these cases, that whenever we can change the character of the local disease by substituting healthy for unhealthy inflammation, the character of the constitutional affection becomes also immediately impaired.

There is another important form of constitu-

tional affection that differs widely from the preceding; it is characterized by the total absence of all reaction, and by a state of direct prostration and rapid sinking of the powers of life; this dangerous affection may also depend either on the temperament and previous state of health, the seat and extent of the local affection, or nature of the exciting cause.

The constitutional symptoms present other variations with respect to their character or the order of their appearance; they may be remittent or intermittent; precede the appearance of the local symptoms, occur simultaneously, and sometimes only after them. The character of the fever may be modified by the inflammatory and nervous types being combined in an almost infinite variety of degrees. It would be impossible, however, to describe every shade of difference; and we think it sufficient therefore for practical purposes, to adopt the division of the constitutional affections into, 1st, *inflammatory reaction*; 2d, *nervous reaction*; and 3d, *the state of direct prostration and rapid sinking without reaction*. We must be understood not to use the terms inflammatory and nervous in an exclusive sense, but as only implying that such is in each case the predominant nature of the reaction.

1. The appearance of the constitutional as well as of the local symptoms does not always immediately follow the introduction of a morbid agent into the system; a period of variable duration often intervenes, which may be considered as one of *incubation*. This important period is sometimes characterized by a certain degree of constitutional derangement; the symptoms of this derangement being, however, obscure, have not hitherto obtained the attention they perhaps deserve, and are often unnoticed both by the patient and the practitioner. There may be a feeling of general uneasiness and lassitude; pains in the limbs, disturbed sleep, sometimes headach, depression of spirits, slight alternations of chill and heat, a decrease of appetite, a bitter taste, clammy and furred tongue, a tendency to constipation, and turbid urine: other symptoms, besides the preceding, might no doubt be sometimes detected by close observation; they all indicate the latent influence of some morbid cause, acting on the entire system, and depressing more especially the functions of the circulation and innervation.

After the period of incubation has lasted a variable interval of time, the local symptoms of inflammation generally make their appearance; and these are followed sooner or later by a more marked degree of constitutional disturbance. The patient is seized with rigor, nausea, or vomiting; the face is pale, the skin cold and rough, the pulse small and frequent: to this depression succeeds a general reaction, characterized by a dry burning heat of the skin, headach, flushing of the face, pain in the loins, restlessness, great general anxiety, soreness of the whole body, and sometimes delirium. The pulse is full, hard, and frequent; the breathing hurried; the secretions become diminished and altered; the tongue is furred, dry, and red, especially at the edges and point; there is loss of appetite and great thirst; the bowels are confined; the urine is scanty and high-coloured,

but it remains clear and emits a strong animal smell. The blood drawn from the veins is buffed and cupped, a state of the blood which has already been fully described. These symptoms vary in severity and duration according to the seat and intensity of the inflammation.

In all inflammatory affections there are also daily variations in the acuteness of the symptoms, constituting paroxysms of exacerbation and remission. The exacerbations generally occur towards night, when there is an increase of the pain, heat, and swelling, and an exasperation of all the febrile symptoms. As the morning approaches, the symptoms lessen in severity, and there is either a partial or complete remission of fever, characterized by an abatement of the pain, and frequency of the pulse, and by the breaking out of moisture on the skin.

Besides these daily variations, the course of inflammatory affections may be divided into three periods—one of invasion, one of increase, and one of decline. The febrile symptoms already described persist, varying only in intensity, until the inflammation has reached its height. During the period of decline they are variously modified according to the mode of termination of the local disease: if by resolution, there is a gradual abatement of the fever, attended usually with a restoration of the diminished secretions and critical evacuations from some of the excretory organs. Thus, as the local symptoms decrease, the frequency of pulse and heat of the skin gradually subside; the tongue becomes moist and clean; the thirst, restlessness, general pains, and delirium disappear; there is a variety of critical evacuations, by profuse sweat or a copious flow of urine; by diarrhoea, expectoration, ptyalism; or by spontaneous hemorrhage from the nose, stomach, bowels, kidneys, or uterus. These critical discharges occur either singly or are variously combined; they are frequently preceded by a severe general rigor and exacerbation of all the constitutional symptoms, *exacerbatio critica*, which is sometimes mistaken for an aggravation of disease, but is soon followed by profuse sweat and other evacuations, which lead to a complete remission of the fever. The variations in the state of the urine deserve particular attention; a full account of them will be found under the section *Resolution*. The ancients attributed these critical evacuations to the expulsion of the morbid matter, by which blood and humours were deprived of their inflammatory and other deleterious properties; and they considered them as being strictly analogous to the suppuration of phlegmon.

When, however, the inflammation terminates in suppuration, there is during the period of decline an imperfect remission only of the constitutional symptoms; the fever returns after a deceitful suspension or partial abatement of its symptoms for a few days. It assumes a more decidedly remittent character; slight paroxysms of rigor are experienced towards evening or after the meals, followed by flushes of heat, particularly in the cheeks, hands, and feet; also thirst, restlessness, and frequency of pulse; the exacerbation increases until towards morning, when it is relieved by profuse perspiration, and there is a well-marked remission of fever during the

forenoon; this constitutes *hectic* fever, which has been fully described in the article *FEVER*.

The sudden cessation of violent pain attended with prostration of strength, increased rapidity, weakness and irregularity of the pulse, cold clammy sweat and delirium, denote the fatal termination by gangrene.

It is important to observe, that when the period of increase of the inflammation has been attended with high general excitement, that of decline is sometimes marked by a great and dangerous collapse of the powers of life, particularly in old people and young children. The probability of such an occurrence should be carefully kept in view, in prescribing active remedies during the violence of the disease in such subjects; for otherwise a state of fatal sinking or dropsical effusion may be brought on by too active a treatment, although it may perhaps have appeared justified at the time by the immediate relief it afforded. If old people were formerly stimulated to death under the mistaken notion that they are not subject to inflammation, we suspect that some in the present day may have sunk under the indirect effects of excessive bleeding, owing to a disregard of the practical precept just alluded to.

The series of constitutional symptoms we have just described are those of the simplest form of inflammatory fever. This fever is generally induced by the development of common acute inflammation from either accidental or constitutional causes; it affects most commonly robust healthy individuals, of a sanguine temperament, in whom there is a redundancy of rich blood—a condition of the system which has received the name of inflammatory diathesis. The simple inflammatory fever may be considered as a salutary effort, by which the general powers of the constitution are brought into action, in order to assist in relieving some part of the body from a state of disease, by which the harmony of the functions, essential to health, is more or less disturbed. The fever may itself become a source of danger, when too violent, by aggravating the primary disease, or by exciting inflammation in other parts of the body; or when, from deficiency of the powers of life, the fever of reaction is too weak, the local disease is sometimes only partially removed, and passes into a chronic state: a deficient reaction is thus frequently the cause of inflammation being followed by changes of structure, such as indurations and effusions.

2. There is a form of constitution directly opposed to the sanguineous: it is chiefly characterized by weakness and irritability of the nervous system, and called the nervous temperament. This condition of the system is very obnoxious to inflammation, which, when developed, runs a much more irregular and unpropitious course than in the sanguine temperament. The constitutional symptoms of inflammation in this temperament are, as already stated, rather characterized by disturbance in the nervous system than by strongly increased vascular action, and the fever generally assumes a nervous, typhoid, or ataxic type. Another peculiarity of constitution which often accompanies the former, is a vitiated state of the blood, whose qualities have become altered, in consequence, probably, of some disorder in the functions of nutrition or sanguification. The combination of

these two conditions of the system gives origin to the very worst forms of symptomatic fevers, called *adynamic* or *putrid*, in which to the most formidable nervous symptoms are united an extremely vitiated state of the secretions, and a great tendency of the blood and other fluids to rapid decomposition. There is sometimes a combination of the inflammatory and typhoid or *adynamic* forms of fever, exhibiting symptoms of high vascular excitement with great deficiency of nervous power; this is a complication of disease attended with extreme danger, and requiring considerable tact and caution in its treatment.

The essential character of the irritability of temperament which predisposes to the preceding forms of constitutional derangement, is over-activity of the nervous system, combined with deficiency of the power of resistance. Irritability may be induced by deficiency as well as by excess of stimulus: a certain degree of stimulus is necessary to preserve the healthy tone of every living part: thus, if the retina be deprived of its natural stimulus by the long-continued exclusion of light, it becomes weak and irritable, and intolerant to that degree of light which was previously endured without inconvenience. An excess of stimulus, as in inflammation, produces exactly the same result. The stomach in the same way becomes weak and irritable by long abstinence from the use of meat and wine, and can only be brought back by slow degrees to tolerate even moderate quantities of stimulating food, as we see exemplified in convalescence after protracted acute diseases, and in all cases of long-continued starvation. When the privation of stimulus is carried beyond certain limits, instead of increased irritability, the sensibility becomes gradually weakened, until it is at last completely extinguished, and a state of torpor succeeds; the effect of long-continued over-stimulus is likewise to induce torpor, both extremes thus leading to exactly the same result. These illustrations of the opposite causes which may give rise to irritability, are susceptible of some important practical applications in the pathology of inflammatory diseases. There is no state of the constitution attended with so many complicated, obscure, and varied morbid phenomena, and so difficult to manage, as that which is characterized by either local or general irritability.

The irritability may be confined to one organ or to one function; it may be justly said that there is in every constitution some weak part more predisposed to disease than others; and this may be the result of original structure, or have been acquired by habits of life or previous disease.

In consequence of the great excitability of the nervous system in irritable habits, and want of power to sustain action, the sympathetic fever of inflammation is frequently characterized by a state of great over-excitement, followed by collapse. For example, the first effects of any serious injury or of the spontaneous development of inflammation in an irritable constitution may be a momentary state of depression, languor, or stupor. This, however, is, after a variable interval of time, succeeded by one or several paroxysms of rigor, sometimes very severe, which usher in the variable train of symptoms: nausea, vomiting, and great irritability of the stomach; a dry brown tongue, parch-

ing thirst, obstinate constipation, scanty and high-coloured urine; præcordial anxiety and great restlessness; rapid pulse, either bounding or small, contracted, and irregular; burning dry heat of the skin; oppressed hurried breathing with frequent sighing; flushed countenance; severe headach; contracted pupils and wild expression of the eyes; incoherence, amounting sometimes to fierce maniacal delirium, requiring restraint; convulsive paroxysm, with great distortion of the features, not unlike epilepsy. This state is followed by one of considerable exhaustion, characterized by somnolency; sunk, haggard, and livid aspect of the countenance; profuse chilly and clammy sweats; small, irregular, fluttering pulse, rapid sometimes beyond reckoning; panting respiration; passive convulsions; hiccup and subsultus; coma and stertor, terminating in death.

The symptoms do not, however, always present this extreme degree of violence, nor lead so rapidly to a fatal result; they frequently assume the form of mild typhous or adynamic fever, characterized at one period by restlessness, anxiety, some headach, occasional low muttering delirium, moderate heat of skin, and frequency of pulse; the skin is covered with petechiæ, the tongue black and dry, the alvine evacuations vitiated and fetid; whilst at another period there are stupor, chilliness, slight convulsions and subsultus, and the usual symptoms of collapse. These various forms of constitutional derangement are especially distinguished by a rapid alternation of symptoms denoting contrary states of the system, and they derive their essential character, as before observed, from a state of excitement not supported by sufficient vital power to maintain and carry it through.

In this general state of morbid irritability, very slight causes of irritation give rise sometimes to the most violent constitutional disturbance, so that the general symptoms are not always proportionate to the extent of the local inflammation, nor a sure criterion of the degree of danger; the pulse may rise to 160, the heat of the skin be very high, and all the other symptoms usually indicating dangerous inflammation of some important organ, may be occasioned by only a trifling wound or furuncle, slight inflammation of the tonsils, or rheumatism of a joint. It is necessary, therefore, in forming a prognosis, not to be guided entirely by the general symptoms, but to take also into account the seat and extent of the inflammation. At other times, however, the local affection takes upon itself the impress, as it were, of the constitution; the inflammation is either exasperated and spreads rapidly, or it is partially suspended, or there is a complete cessation of vital action in the inflamed part, which becomes cold, livid, flabby, and sometimes gangrenous: these unfavourable changes have been frequently observed in extensive wounds after injuries or operations; in which cases no restoring process can be established so long as this disturbed state of the nervous function continues.

When, in the course of the salutary fever induced by common inflammation, any circumstance occurs to create severe disordered action of the nervous system, the regular course of the fever is immediately arrested and completely changed, and a new train of symptoms, chiefly nervous, and of

a more dangerous and destructive character, make their appearance. This circumstance has led some pathologists to consider constitutional nervous irritation as a morbid condition of the system, totally distinct from that which has received the name of fever. There appears, however, to be no good foundation for such a distinction, for the fever has merely assumed a new character, which corresponds exactly with that of the nervous, irritative, or typhoid fevers, that have been frequently described by nosological writers.

The description of fevers under consideration attend some of the worst forms of inflammation, such as confluent small-pox, the malignant varieties of scarlatina and rubeola, several species of gangrenous inflammation, and especially hospital gangrene: this combination of local inflammation with constitutional typhoid symptoms is often extremely perplexing, presenting to the practitioner at the same moment the most opposite and contradictory therapeutic indications.

We have already stated that the nervous and irritative class of fevers are to be attributed either to constitutional causes, or to the seat, extent, and nature of the local inflammation. The following are some of the principal constitutional causes, which are extremely numerous:—great mental depression, arising from anxiety, grief, or the apprehension of death; exhaustion from over-exertion of mind, and particularly from excessive study and loss of sleep; or that consequent upon large evacuations, either by spontaneous hemorrhage, or copious bleeding and purging: an impure atmosphere; certain natural states of the body, such as that of pregnancy and lactation; the long continuance of organic disease, especially in the uterus, testicle, stomach, urinary bladder, or any of the large joints. One of the most common and active causes, however, is the abuse of spirituous liquors; the constitution of those who indulge to excess in the use of malt liquors, (as, for instance, brewers' servants,) is distinguished by a state of extreme plethora, combined with nervous debility; and although apparently robust, they bear very ill the loss of blood, being soon affected with low delirium, partial convulsions, coma, and other symptoms of prostration. In habitual gin-drinkers the nervous system is so weakened by constant over-excitement, that they sink rapidly under a similar train of symptoms, from even slight inflammatory attacks. Over-activity and weakness of the nervous and vascular systems are predominant features of the constitution of infants and young children, and inflammatory symptoms rapidly attain in them a high degree of intensity which is soon followed by an opposite state of collapse and sinking.

Individuals endowed with great nervous irritability, and particularly puerperal women, are sometimes subject to sudden attacks of acute pain in the head, chest, or abdomen, accompanied with considerable constitutional disturbance, bearing so strong a resemblance in several of its symptoms to active inflammation, that the affection has often been mistaken for either arachnitis, pleurisy, or peritonitis; it is a form of disease depending, however, entirely on nervous irritation, combined at times with some degree of active congestion. The disease sets in with rigor, generally more

severe and lasting than in cases of inflammation; the reaction is proportionally violent, and characterized by considerable nervous disorder and great irregularity in the course of the symptoms; there are frequent alternations from one extreme to another, differing in this respect from inflammatory reaction, which pursues its course more steadily. The general symptoms correspond with the description already given of the nervous and irritative forms of sympathetic fever, but it may be useful to offer a few observations on the local symptoms, for the purpose of defining more accurately the diagnosis of this affection from true inflammation, as it is sometimes rather obscure.

The affection of the head is characterized by acute general pain, great intolerance of light and sound, contraction of the pupils, vertigo, wakefulness, and delirium, sometimes even maniacal. This differs from arachnitis by the disease coming on more suddenly without any premonitory symptoms, and acquiring at once an extreme degree of violence; besides, in the latter the symptoms are less acute, and increase only gradually.

When the chest is affected, there is acute pain in some part, so severe as to check a deep inspiration; but the pain shifts its situation, shooting from one side to another, or towards the back; and if the patient be made to repeat the inspiration several times, the increase of pain becomes less and less; there is no cough or crepitus in making a deep inspiration, and the absence of all the signs of inflammation usually detected by the stethoscope will afford every information that can be desired for a correct diagnosis. There are, sometimes, severe attacks of palpitation and violent throbbing of the carotids, abdominal aorta, and all the large arteries.

The affection of the abdomen is denoted by acute pain and great tenderness on pressure, either confined to one part, or more or less diffused. There is as great an intolerance of pressure in some cases as exists in peritonitis, the more local pain resembling that of gall-stones. The distinction, however, from inflammation is established, by the suddenness of the attack, the violence and irregularity of the general symptoms, and the severe sympathetic affection of the head, which very seldom occurs in peritonitis or enteritis.

The effects of the treatment will afford additional sources of diagnosis. The loss of blood is not well tolerated in this form of disease, depletion to a few ounces causing syncope; whilst, in the inflammatory affections alluded to, the patient can bear the abstraction of forty or fifty ounces of blood before fainting is induced. Bleeding may sometimes appear to afford complete relief at the moment in cases of nervous irritation; but the paroxysm of pain soon recurs with equal if not greater violence; and it has persisted in some instances with unabated or increasing urgency, notwithstanding an enormous loss of blood. The symptoms on the other hand gradually yield to the use of purgatives and opiates, and of a light nutritive diet. In patients who have died of this affection no traces of inflammation have been discovered in any part of the body, and no other morbid appearance than at times a slight vascular injection of some of the organs.

This important form of disease had not been

hitherto well understood; the profession is indebted for a good account of it to Dr. Gooch, and more especially to Dr. M. Hall.* It is attributed by the latter gentleman to intestinal irritation. This, no doubt, is very frequently the case, but we have traced it also to uterine irritation; and it may in some instances be referred to primary irritation of the brain, particularly in persons reduced to a state of great nervous exhaustion by any of the causes already mentioned. When excessive loss of blood by hemorrhage or blood-letting does not prove fatal through immediate sinking, it is sometimes followed by an excessive reaction resembling that we have just been considering, excepting only that the principal local affection is confined to the head, and there is a more marked tendency to subsequent exhaustion. We must refer for an excellent account of this latter affection to the article BLOODLETTING.

When inflammation occurs in constitutions in which an artificial plethora has been created by indulgence in the pleasures of the table, so that the functions of the different organs are oppressed by excessive repletion, the constitutional reaction is sometimes very feeble, the secretions are generally unhealthy, and the fever may assume a typhoid or adynamic character in consequence of this state of *indirect* debility. It is highly important to discriminate between a fever thus induced, and one of exactly the same character originating in *direct* weakness and nervous irritability. In the former case the debility being *indirect*, and the effect only of the oppression of the powers of life, the fever would be aggravated by the stimulating plan of treatment which in the latter case it may sometimes require; while, by disregarding the apparent debility, and having recourse to depletion and other active remedies, all the untoward symptoms are speedily removed, the character of the fever is transformed from typhoid to inflammatory, and both the local and constitutional affection pursues a more favourable course. It is in such cases that the pulse is found to acquire a greater degree of fulness, firmness, and regularity, under the repeated use of the lancet and the free exhibition of purgatives.

It was stated that the character of the constitutional symptoms was sometimes influenced by the *seat*, *extent*, and *form* of the local disease, independent of any predisposition of the constitution. Thus, with regard to *texture*, injuries of parts of little sensibility and low organization frequently induce a higher and more alarming degree of nervous irritation, than that of parts more largely endowed with nerves and blood-vessels; inflammation of the dense unyielding texture of tendons, ligaments, fasciæ, and fibrous membranes, especially of the periosteum, has already been mentioned as exciting an intense degree of local pain and tension. This generally gives rise to considerable disorder in the functions of the nervous system, while the constitutional excitement induced by the inflammation of mucous and serous membranes, or even of vital organs, more generally assumes the form of simple inflammatory fever.

* Commentaries on the Diseases of Females, by Marshall Hall, M. D., &c.; and Morbid and Curative Effects of Bloodletting, by the same author.

The lesions of muscular and fibrous tissue, especially when the irritation is kept up by the presence of any extraneous body, are attended with a most severe degree of general irritation frequently ending in tetanus. Injuries or erysipelatous inflammation of the integuments of the head, chest, and abdomen, are followed by greater constitutional disturbance than those of other regions of the body, in consequence probably of contiguous sympathy. The inflammation of veins, which bear some analogy in their structure to fibrous membranes, is particularly characterized by symptoms of nervous and typhoid fever, and spreads rapidly along those vessels to a considerable distance. The injuries of nerves bring on most alarming symptoms of general irritation, being a frequent cause of convulsions and tetanus: this is chiefly owing to the propagation of morbid impressions along their branches, as they are rarely found inflamed. The ganglia of the great sympathetic form perhaps an exception, having been found by Mr. Swan intensely injected in cases in which the system had been strongly impregnated with mercury. (Travers, Inquiry concerning Constitutional Irritation.)

With regard to the *form* of the local injury, narrow and punctured are followed by more constitutional disorder than broad and open wounds; this frequently happens after the injury of some fibrous membrane or the puncture of a nervous filament, the complete division of which would have been of no importance. When the inflammation extends beneath a fibrous membrane, and suppuration takes place, the form of the wound not admitting of the discharge of the accumulated fluids, a considerable degree of tension and pain is the inevitable result. There may be for a time no local symptoms of the existence of the disease beyond a slight degree of tension and tenderness. When matter, however, is formed, an uniform diffused oedematous swelling, with erysipelatous inflammation of the skin, is observed round the margin of the wound, but without any distinct fluctuation; and this is accompanied with very violent constitutional disturbance, which can only be relieved by large and free incisions. The symptoms arising from the puncture of a nerve are more developed in the course of the nerve, and in the constitution generally, than in the wound itself.

Contused and lacerated wounds, especially when of considerable magnitude, and attended with great destruction of parts, are necessarily followed by most serious and alarming derangement of the constitution. This is the case with gun-shot wounds, especially when important organs are injured and foreign substances remain within the wound; from the exposure also of muscles by the tearing away large flaps of skin; the denuding of an extensive surface of the cutis by burns and scalds; the extensive laceration, exposure, and crushing or comminution of the larger joints; the displacement and protrusion of the ends of fractured bones, with partial or complete divisions of great muscles and blood-vessels. There is considerable danger in these cases of the powers of the constitution sinking rapidly under the shock they have received, as will be mentioned hereafter: but a fatal termination may likewise take place

from the violence of the nervous irritation leading to convulsions and tetanus; or from the gradual exhaustion induced by the erysipelatous, gangrenous, and sloughing inflammation, which usually precede the reparatory process in all such extensive injuries.

The constitutional symptoms are also frequently characterized by great nervous irritability and depression, low delirium, and convulsions, after severe operations, either for recent injuries or the removal of chronic diseases. Hence the great importance, whenever practicable, of attending carefully to the state of the patient's constitution previous to the performance of any serious operation.

Besides the seat, extent, and form of the injury, the *nature* of the exciting cause has also a powerful influence over the character of the general symptoms. This is particularly evident in the case of poisoned wounds, whether received in dissection, or from the bites of venomous animals. We have, in this class of cases, very striking and instructive examples of the most dangerous forms of constitutional affection from local disease.

The constitutional symptoms correspond with the description already given of the irritative and typhoid forms of fever, varying only in different individuals as to the relative degrees of reaction and collapse, to the combinations of severe nervous symptoms, with weak or strong vascular action, and to the more or less vitiated state of the secretions. In a case described by Dr. Duncan, there was profuse dark-coloured clammy sweat of intolerable fetid and disagreeable smell, so abundant as to wet the bed-clothes and stain them of a dark colour. This diaphoresis was critical, and it scarcely ever occurs but in cases that recover.

There are considerable differences, however, with respect to the local affection. In some cases the poisoned wound is exempt from external inflammation, the patient sinking exclusively from the action of the morbid matter on the constitution; sometimes there is the formation of a vesicle or pustule on the wound, followed by pain and inflammation of the cellular membrane of the arm, axilla, and thorax of the same side; or without any reaction in the wound, there may be severe pain and diffused swelling in the axilla and breast on the wounded side, followed by patches of a red diffused swelling and excruciating pain in distant parts of the body. In other cases there is violent reaction in the wound, leading to suppuration and gangrene in the tendinous sheaths of the finger or hand, accompanied with painful diffused erysipelatous swelling of the arm, axilla, and integuments covering that side of the body. Sometimes numerous vesicles, some of a considerable size, have formed on the inflamed parts, containing either a transparent serum or a dark-coloured fluid, the erysipelas round these vesicles assuming a dusky hue; and, lastly, the diffused inflammation of the cellular membrane on the arm or trunk has, in some instances, terminated in extensive suppuration and sloughing. The remarkable disposition shown by the inflammation in all these cases to rapid extension, arises, no doubt, from its affecting tissues in which inflammation generally spreads by continuity, such as the ab-

sorbents, veins, subcutaneous cellular membranes of tendons, and fasciæ of muscles. (See Travers, Inquiry concerning Constitutional Irritation.) This is also owing in some measure to the erysipelatous character of the inflammation, which induced Dr. Good to give it in his nosology the name of *erythema anatomicum*.

The constitutional symptoms are chiefly to be ascribed to the introduction of the poison into the mass of the blood, whose qualities it vitiates and renders deleterious, and to the morbid action of this deteriorated blood on every part of the animal economy, and more especially on the vital organs; poisons have also been conceived to affect the nervous system in a more direct manner by the transmission of morbid impressions along the nerves. We have already stated that there are strong arguments and facts in support of each of these opinions, and that it is probable that the influence of both causes must to a certain extent be admitted.

It has been remarked that the constitutional affection is often as severe, and proves as rapidly fatal, in cases attended with scarcely any local affection, as in those in which whole regions of the body are engaged in inflammation. Extensive local disease is not therefore always so serious an aggravation as might at first be supposed; the danger is in proportion to the degree in which the poison has been mixed with the blood and has deteriorated its qualities, and to its paralyzing influence on the nervous power. It is generally considered that whenever the action of the poison can be confined either to the wounded or to any of the other inflamed parts of the body, by exciting in them inflammation of a healthy character, its pernicious influence on the constitution is considerably lessened, if not altogether prevented. Mr. Travers very justly observes, "Inflammation is not necessary to the most virulent and fatal action of the poison, and in general I should be disposed to say of these cases, that the symptoms of local inflammation and constitutional irritation exist in an inverse ratio of severity."

A great many interesting cases illustrating the different forms of local and constitutional affection produced by poisoned wounds, are to be found in Mr. Travers' Inquiry concerning Constitutional Irritation—a work the most complete and valuable without exception yet published on the highly important subject of which it treats, and reflecting the greatest credit on the author's talent and observation.

The form of the disease most analogous to the preceding, is that arising from the bite of the more venomous serpents, and especially of the rattle-snake (*crotalus horridus*, Lin.), and of the cobra di capello (*coluber naja*, Lin.); it only destroys life in a shorter time. The local and constitutional symptoms take place nearly simultaneously; the bitten limb swells instantaneously, and the inflammation shoots with great speed up its entire length to the axilla and shoulder; and if life continue long enough, it darts down the side over the pectoral muscle, and produces there the same kind of erythema as in the cases already described. The vital principle, however, is from the first suddenly exhausted, as if by a stroke of lightning; the blood ceases to flow in the smaller ves-

sels of the swollen part, which feels deadly cold; the action of the heart is so weak that the pulse is scarcely perceptible; the stomach so irritable that nothing can be retained in it; dejection and horror overpower the mind, and the patient sinks with a low muttering delirium. Very powerful stimulants applied instantly may check the deadly influence of the poison, and sometimes produce a cure; but if life be sustained until the venom has exhausted its malignity, the debility is so extreme, and the sphacelus so extensive, that the unhappy sufferer often falls a victim to the local mischief. Dr. Mason Good, from whose Nosology the foregoing description is taken, gives an interesting account of the case of a man who died in St. George's Hospital, from the bite of a rattle-snake exhibited in London; he remarks that all other serpents have an immunity against each other's bite; but the rattle-snake not only kills every other, and even its own kind, but being so far irritated as to inflict a personal wound, has been found to kill itself.

The frightful assemblage of symptoms that characterize hydrophobia afford an example of the highest conceivable degree of over-excitement, and fatal disorder of the whole animal economy. One very remarkable circumstance connected with the action of the rabid virus, is the great length of time during which it has in some cases remained dormant in the constitution before taking effect; it is difficult to account for this long period of incubation of a virus that proves so rapidly destructive after it begins to operate. The invasion of the constitutional symptoms is sometimes accompanied with slight pain and inflammation of the wounded part; but the local affection is never severe, and in some cases completely wanting.

In all the preceding cases there have been very few traces of disease found after death, beyond those resulting from the local inflammation; the only morbid appearances ever observed have been partial vascular injections in some of the internal organs, and this only in a small proportion of cases. A high degree of injection of the medulla oblongata and pharynx is stated to have been found in some cases of hydrophobia.

3. The third modification of the constitutional derangement induced by local irritation or inflammation in the irritable temperament, is that of sinking without reaction. The symptoms of this state of sinking are not unlike those of a prolonged fit of syncope, only more severe. The patient first experiences a degree of vertigo followed more or less quickly by gradual loss of consciousness. This, however, is sometimes only partial, there being rather a tendency to drowsiness, from which the patient can be momentarily roused by any strong and sudden impression; he is also affected with a sensation of shuddering, considerable degree of universal pallor, contraction and coldness of the surface, and particularly of the countenance; the pupils are dilated; the breathing is short, at one time almost imperceptible and only carried on by the diaphragm, or at another interrupted by short irregular sighing; the pulse is slow, feeble, or indistinct; the tongue and fauces are dry, the stomach is irritable, and vomiting sometimes procures relief by creating a general reaction. When, however, this is not the case,

other more formidable symptoms make their appearance; the pallidness, collapse of the countenance, and coldness of the surface, increase; the breathing becomes more oppressed, and is attended with a peculiar crepitating noise; there is restlessness, agitation, and delirium, followed by coma, convulsions, relaxation of the sphincters, and stertorous breathing, ending soon in death.

The symptoms offer, however, many variations; in some cases the patient falls so gradually into a state of apparently quiet sleep, as not to excite any suspicion of danger; but this is succeeded by stupor, and he dies without any struggle. In other cases, he is affected with delirium, restlessness, and frightful convulsions. Convulsions, however, may appear without delirium or coma, the latter being of most frequent occurrence in infants. When sinking does not terminate in death, it is followed by either partial, excessive, or healthy reaction. In slight and temporary syncope, returning animation is indicated by the gradual restoration of warmth on the surface, with occasionally a gentle moisture of the skin; the breathing becomes more full and free; there is deep sighing and sometimes hysterical sobbing; the pulse recovers its fulness and strength; and consciousness gradually returns as if the patient were awaking from sleep.

In the state of more severe sinking, reaction is generally ushered in by rigor: a state of great depression of the nervous energy has the effect of lowering the action of the heart, and causing a gradual accumulation of blood in the central parts of the body, while the circulation is diminished in the capillaries of the surface and extremities. This unequal distribution of the circulating fluid impedes the action of the two most important vital organs, until the constitution, unable to bear any longer the irksome oppression, is roused to a convulsive effort, in order to remove the obstacles opposed to the circulation and respiration. The commencement of this effort at reaction is indicated by rigor, and sometimes also by vomiting and hiccup; the action of the heart is immediately increased, and the reaction becoming general, leads to a restoration of the circulation and heat of the surface, to a relief of the embarrassed breathing, and to a revival of the depressed energies of the brain and nervous system. If these changes take place without violence and are sustained for some time, a permanent healthy reaction is established; they may, however, be only momentary, in consequence of the insufficiency of the nervous power to keep up reaction, and the patient sinks again into collapse. Rigor of long continuance without any return of heat, or frequently recurring, indicates likewise a want of power in the system. At other times the reaction may be too strong, and lead to a condition of the system opposite to sinking,—that of over-excitement. The shudder which accompanies the shock differs from rigor: it is a cerebral affection of short duration, produced by a painful impression of the mind, and it is not necessarily connected with any change in the temperature of the body. (Inquiry concerning Constitutional Irritation, by B. Travers, Esq. p. 138.)

It is of great practical importance that the distinction between these opposite morbid conditions

of the system should be well understood, and the changes from the one state to the other require to be watched with the utmost vigilance; for the treatment which may be the means of restoring life during the period of sinking, might prove destructive during that of reaction. The rule laid down by Mr. Travers, of maintaining action without forcing action, should be constantly borne in mind; the effect produced by stimulants must also be carefully observed, in order that they may be laid aside as soon as reaction has taken place, and opposite measures should then be adopted if required.

The state of sinking is brought on by all causes tending to depress considerably the nervous power. Nervous weakness being the chief characteristic of an irritable constitution, it is strongly predisposed to this form of disease. The effect of sudden and painful emotions on weak and irritable persons in causing syncope and convulsions is well known, and has even proved fatal in individuals much exhausted by disease. The breathing of putrid and pestilential effluvia has sometimes caused such a degree of faintness and sinking that life has been extinguished before reaction could take place. Individuals have died in the cold stage of the algide fever from a similar cause. Several powerful narcotics, by completely paralyzing the action of the brain and nerves, and probably also that of the heart, prevent all reaction, and destroy life with amazing rapidity. Patients who have been much exhausted by long and painful inflammatory affections, sometimes sink unexpectedly at the moment they were considered convalescent. Some of the cases of sudden and unexpected death that take place without any known cause during attacks of severe illness, may reasonably be accounted for in this manner. Profuse hemorrhage is a frequent cause of sinking, especially in puerperal women, whose vital powers have been much lowered by the sufferings of tedious and painful labour: the sinking in these cases is often attended with frightful convulsions. Among the frequent causes of sinking is to be reckoned the sudden shock the constitution receives from severe injuries, which operate in this way either in consequence of their extent or of the tissues that are affected; as, for instance, when many textures are implicated in a wound, and extensive portions of skin detached, or when joints and tendinous structures are lacerated, and large bones comminuted.

The effect of extensive burns in causing direct prostration is very remarkable; the great sensibility of the skin as the organ of tangible impressions, the importance of its functions as a secreting surface, and its numerous sympathies with all the vital organs, will sufficiently account for the system receiving a severe shock when it is extensively injured. The danger is greater when the burn is seated on the integuments of the trunk than on those of other parts, in consequence, probably, of contiguous sympathy. The tendency to sinking may continue for the first three days after the accident; but at the end of this period, reaction is generally established. The situation of the patient is very analogous to that of a person stunned by a fall; he is in a state of apathy bordering on stupor, without actual loss of consciousness; there

is an absence of all pain, as if the sensibility had shrunk below the point of pain. The complaint of pain is, therefore, rather a favourable sign: continued shivering is completely the reverse.

The shock which the brain receives in concussion brings on symptoms of sinking; the stupor resulting from other casualties is the effect only of functional disorder, while that arising from injuries of the head is generally connected with physical derangement of the organ: in the latter case, when reaction takes place, there is much greater reason to apprehend and guard against cerebral inflammation than in the former.* Children are sometimes affected with sinking after excessive evacuations; this is chiefly indicated by a tendency to stupor and coma, which has often been mistaken for hydrocephalus. Full details respecting the diagnosis and treatment of this important affection will be found in the article *HYDROCEPHALUS*. The shock inflicted by the pain of a severe operation often brings on sinking, especially if the vital powers have been previously depressed by recent injury or painful chronic disease, or else if the patient has been under great dread of the operation, or much alarmed at the prospect of death.

Severe and intense pain is of itself destructive. Puerperal women have sunk after difficult and protracted labour, from the mere paralyzing effect of intense and long-continued pain; ruptures of the stomach, gall, and urinary bladders are sometimes productive of such sudden and excruciating pain as to bring on rapid and fatal syncope. The effects of severe pain are variable: the sudden infliction of intense pain may be instantly followed by such a degree of direct general torpor that the individual appears as if completely stunned, and little or no pain is afterwards experienced. When intense pain is long endured, it absorbs every other feeling, and induces a remarkable degree of insensibility to all surrounding impressions. Severe pain at other times brings on delirium, convulsions, vomiting, suspension of the secretion of urine, and other symptoms of over-excitement; but this is of short duration, and is soon succeeded by a state of exhaustion and torpor. Long-continued pain impairs all the operations of life, and gradually exhausts the vital principle itself; so that pain has been justly called the greatest sedative in nature. The sudden remission of intense pain has sometimes been followed by syncope and death.

Very intense pain of an unimportant part is sometimes well tolerated; while slight pain of a vital organ or highly sensitive part, such, for instance, as the urethra, may be sufficient to cause syncope. The constitution in some cases becomes accustomed to the impression of moderate pain, when frequently repeated or long-continued; the susceptibility to all impressions, whether pleasurable or painful, being lessened by habit. When the pain of inflammation is so intense as to constitute its most prominent symptom, and has not yielded to full depletion, the inflammation is sometimes kept up by the continuance solely of the pain. It is of great importance in such cases to subdue the pain at once by means of large opiates; we have seen attacks of peritonitis attended with

violent pain yield immediately to this plan of treatment.

We shall conclude this short account of the various acute forms of constitutional derangement that are induced by inflammation, with the following concise and at the same time comprehensive remarks of the great Hunter:—"Nature requires to feel the injury; for where, after a considerable operation, there is rather a weak, quiet pulse, often with a nervous oppression, with a seeming difficulty of breathing, and loathing of food, the patient is in a dangerous way. Fever shows power of resistance; the other symptoms show weakness sinking under injury." (*Treatise on the Blood and Inflammation*, ch. iv. s. 6.)

Local inflammation may go through its different stages without any interruption, except a certain degree of exacerbation and remission in its symptoms at different periods of the twenty-four hours. But inflammation is also sometimes intermittent, and even periodical, and the constitutional symptoms in these cases follow the order of the local symptoms. There is a greater tendency to periodicity and intermission whenever the nervous system is much affected.

The order in which the constitutional symptoms occur with respect to the local symptoms is variable. In some instances they precede the local, as in the whole class of exanthematous diseases, and often also in erysipelas. In most inflammatory affections arising from external injury, the febrile symptoms succeed to the local at a longer or shorter interval of time, according to the seat and severity of the injury, and the susceptibility of the constitution. In some very severe injuries, as for instance in extensive burns, the local and constitutional symptoms appear almost simultaneously; the same is often observed in severe inflammation of the pleura and peritoneum.

There are also differences between the local and constitutional symptoms with respect to their relative degree of violence. The febrile symptoms, as before observed, run sometimes so high that they completely conceal the local affection; and they may assume so formidable an appearance, either from their violence or malignity, as to constitute the chief source of danger. Inflammation is sometimes excited in distant organs by sympathy with the organ first affected, and the secondary inflammation becomes stronger than the primary, so as to completely supersede it; in which case a new disease is established. If, however, inflammation proceeds in two organs at the same time, the additional disease, although even slight, increases considerably the danger, particularly if the constitution has been much impaired by the first inflammation.

The organs the most subject to be affected with sympathetic inflammation are the brain, the lungs, the alimentary canal, and sometimes the skin. There are often more severe sympathetic pains in other organs than in the inflamed one, these pains being chiefly of a nervous character: this is particularly the case in inflammations of the mucous membrane of the alimentary canal and urinary bladder, and also in nephritis. Gastro-enteritis is frequently attended with severe pain in the head and loins, or violent cramps and pains in the lower extremities, while very little pain is felt in

* For a full account of the phenomena of shock, &c., see Travers, *Op. cit.*

the stomach and bowels: this accounts for the original disease in these cases being so frequently overlooked. Severe pain in the stomach is one of the common symptoms of nephritis. There is a markable tendency in some varieties of inflammation to change frequently their position through the influence of sympathies; this peculiarity is frequently observed in erysipelas and rheumatism, and in the inflammation of the parotids called *mumps*, which is often superseded by inflammation of another organ, as the brain, the testis, or mamma. This erratic tendency of inflammation will be more fully considered when treating of metastasis.

Idiopathic, or essential, and symptomatic fever have been considered by some pathologists as differing materially in their nature. There does not, however, appear to be any reasonable ground for this distinction. Inflammation is frequently the exciting cause of fever; but on the other hand, inflammation often occurs in the course or towards the decline of fever, as one of its consequences. The primary morbid phenomena essential to the existence of fever—a disturbance in the functions of the heart, the brain, and the stomach—are always the same, whether arising from a deteriorated state of the blood, from external morbid impressions acting on the brain and nervous system, or from sympathy with a diseased organ. These exciting causes may possess different degrees of activity, create a greater disturbance in one order of functions than in the others, and be single or combined in the same case; and hence the variations observed in the character, severity, and course of the symptoms by which the different types of fever are distinguished. When an inflamed organ is the exciting cause, the fever subsides as soon as the inflammation is subdued. When a vitiated state of the blood is the cause, the fever likewise subsides as soon as the blood has recovered its healthy qualities. When both these causes are combined in the same case, although the local inflammation may be quickly removed, the fever pursues its course until the blood also is restored to its healthy condition. We have in each of these cases the same primary morbid phenomena, differing only in degree, and in being variously combined according to the nature, activity, and combinations of the exciting causes.

Before concluding our remarks on the different forms of symptomatic fever, we have to notice some peculiarities in the state of the pulse and in several of the other symptoms, deserving of attention. The character of the pulse varies not only with the intensity of the inflammation and type of the fever, but also according to the particular organ or structure affected. The pulse of common acute inflammation is generally characterized by fullness, hardness, and moderately increased frequency. In the inflammation, however, of some of the abdominal viscera, such as the stomach and intestines, the pulse is small, contracted, wiry, and rapid; there is also a remarkable degree of sinking and general prostration of strength, the consequence probably, of the extensive sympathies of these organs with the brain and spinal marrow, through the medium of the ganglionic nerves. These two peculiarities in the symptoms might possibly mislead, if not well understood, with re-

spect to the true nature of the complaint, and prevent the adoption of those active measures by which alone the patient can be saved; the usual effect of free depletion in these cases is to increase the fullness and strength of the pulse; this variety of the pulse has been called *abdominal*, as it is seldom observed in inflammation of the organs of other cavities; it does not either attend the inflammatory affections of all the abdominal viscera, but more particularly the inflammations of the digestive tube, especially when seated in the peritoneal coat and various prolongations of that membrane.

The character of the pulse is likewise influenced by the particular structure affected. In the inflammation of serous and fibrous membranes, and in most cases of inflammation attended with intense pain, the pulse is in general contracted, hard, wiry, and very frequent; whilst in inflammations of the cellular tissue, of mucous membranes, and of parenchymatous and glandular organs, the pulse is usually fuller, softer, and less rapid; in diarrhoea the pulse, as is well known, is sometimes intermittent. The frequency of the pulse, instead of being increased, may be reduced below the standard of health, notwithstanding the existence of severe and dangerous inflammation; this arises generally from some affection of the brain, lessening the general susceptibility of the system, and preventing the free development of the constitutional symptoms. In the inflammation of muscular and fibrous tissues, there is a very high degree of heat, and great frequency of pulse, followed by profuse and long-continued perspirations; the degree of danger, therefore, as before stated, is not always in proportion to the severity of the general symptoms.

We have hitherto been considering the various forms of constitutional affection arising from *acute* inflammation. We have next to describe the constitutional derangement that attends *chronic* inflammatory diseases, and which differ from the preceding in several points of considerable importance.

Constitutional Symptoms of Chronic Inflammation.—The term chronic inflammation implies the absence of acuteness and activity, and a tendency to long continuance. Inflammation may be of a mild and obscure character from the beginning, or else it may have been acute at first, and have subsequently assumed a mild and *chronic* form. If after acute inflammation has reached its height, it is not brought to a speedy termination, or is only partially removed, it has a great tendency to become chronic. Both the local and general symptoms of chronic inflammation differ in several respects from those of acute, and require also some important modifications in the mode of treatment. We shall first briefly consider the principal differences observed in the local symptoms, as they will assist in explaining the modifications of the constitutional symptoms.

The local symptoms are never so strongly marked, and are sometimes, indeed, so obscure as to be perceptible only to the scrutinizing eye of an experienced observer; there is but a very slight degree of pain, seldom much heat or redness, and sometimes but little swelling. The functions of the inflamed organ are more or less disturbed; in some cases the functional derangement is remark-

ably slight, notwithstanding the existence of extensive organic disease: the secretion of bile has often continued healthy in livers considerably enlarged and thickly studded with tubercles; the respiratory function has not been very sensibly affected, although a vast abscess has been found in one of the lungs. When the progress of the inflammation has been very slow and circumscribed, so that the remaining portions of the organ have preserved their healthy condition, and the constitution has been able to adapt itself gradually to its diminished activity, the local affection is not aggravated by any strong general reaction.

Mild cases of chronic inflammation excite very little general disturbance; this is sometimes limited to a slight loss of flesh and decrease of the general strength, and is also characterized in some cases by a change in the colour of the skin, which becomes either pale or sallow. The severer cases are attended with various degrees of febrile excitement, never amounting to the regular continued fever of acute inflammation, but occurring in paroxysms with variable intervals of more or less complete remission. During the latter part of the day, or first hour of the night, the patient experiences a sensation of general uneasiness, languor, and sometimes chilliness, followed by headach, frequency of pulse, heat of skin, dryness of the mouth, and thirst; these symptoms continue until morning, when they subside either with or without perspiration. There are frequently conjoined with the preceding, a variety of nervous symptoms, especially in chronic inflammation of the liver and uterus; and the local affection not being detected, the disease has been often treated as purely nervous. When the disease lasts for any considerable time, the general health becomes materially impaired; the patient is affected with progressive emaciation, or sometimes partial dropsy, and dies in a state of marasmus. If the inflammation leads to suppuration, symptoms of regular hectic fever make their appearance.

The progress of chronic inflammation is generally marked by many variations, the symptoms being at one time slow and obscure, or to all appearance so completely removed as to excite hopes of recovery, and increasing suddenly at another time without apparent cause. Chronic inflammation is prolonged in some cases by a frequent repetition of the exciting causes, such as irregularities of diet, exposure to cold, &c., or its continuance may depend on the weak and irritable state of the constitution. One circumstance important to be remembered is the strong tendency of chronic inflammation to assume an acute form, from the influence of even very slight causes. This passage of chronic into acute inflammation is generally attended with considerable danger; for an organ of which the structure has been previously weakened or perhaps materially altered, is little able to resist the effects of acute disease. Sometimes, however, the supervention of acute inflammation has been the means of removing chronic disease of long standing, as is often the case with chronic sores and swellings.

Chronic inflammation has, in some cases, been quickly removed on the sudden appearance of some other more general affection, such as a cutaneous eruption, rheumatism, gout, &c.; it seldom termi-

nates in gangrene, but most frequently in the thickening and induration of textures, the formation of false membranes; or in adhesions, ulceration, sero-purulent effusions, ossification, or the formation of new tissues. When acute inflammation is on the decline, the danger of rousing anew excessive action by the premature exhibition of stimulating diet or medicines is generally understood; there is, however, another risk at this period, which is not unfrequently overlooked. When the strength of the patient has been reduced beyond a certain point, by too long a perseverance in the use of active remedies and of low diet, there may not be sufficient power for the establishment of the restorative process, and the inflammation may assume from this cause a chronic and unhealthy character; this is particularly liable to occur in old or weakened subjects. The study of this class of inflammations is of considerable importance, and a great deal of valuable information on the subject will be found in the works of Puzos and Broussais. (*Histoire des Phlegmasies Chroniques.*)

Progress and Duration of Inflammation.

—The progress of inflammation, with respect to its more or less favourable course, is influenced by the structure, situation, and state of the part affected, by temperament, hereditary disposition, diathesis, age, sex, habits of life, quality of the air, climate, &c. We shall offer a few remarks on the influence of each of these circumstances.

It is observed, with respect to *structure*, that in highly organized and vascular parts, in those in which the circulation is vigorous from their vicinity to the heart, and endowed with a strong nervous energy, inflammation is generally more disposed to run a speedy and favourable course, than in parts of an opposite structure, or more remote from the centre of the circulation. Hence inflammation of the skin, cellular tissue, and muscles goes more rapidly through its different stages, whatever be its termination, than the same affection in bones, tendons, fasciæ, and ligaments; when parts possessing a low vitality are preternaturally excited, they frequently mortify, not having sufficient power to resist the disturbance of the inflammatory action. The lower parts of the body are, for the above reasons, more prone to inflammation, and when inflamed recover more slowly than the superior parts; a depending position retards also the curative process by impeding the return of the blood through the veins. The inflammation of vital organs, although they are very vascular, often takes an unfavourable course, on account of their extensive sympathies giving rise to severe constitutional reaction.

One of the remarkable and important laws of healthy inflammation is that of its being always most actively developed on the side of the part affected which is nearest to the external surface, or to some outlet; this is beautifully exemplified in the pointing of abscesses; if seated under the skin, or in the muscles, the walls of the abscess become thinned by absorption on the side nearest the skin, and the pus tends to make its way to the surface; or if seated near the intestines, the pointing takes place towards the cavity of the bowel. It is thus that foreign substances are sometimes cast off, after remaining even for years lodged in some parts

of the body,—a passage being gradually made by the spontaneous development of inflammation on that side of the substance only which is nearest the surface.

With regard to the *state* of the part, whenever it has been previously weakened by inflammation, it is more predisposed to a return of disease, and each attack lessens the chance of a complete and permanent recovery; thus persons who have suffered from severe injuries of the head are sometimes rendered delirious by stimulating food, or taking the smallest quantity of any spirituous liquor. When the circulation of a part has become languid, in consequence of the ossification of its vessels or of paralysis, there is not sufficient power for the perfect development of the inflammatory process, and it often terminates in mortification. All new-formed parts, such as encysted or sarcomatous tumours, excrescences, granulations, cicatrices, false membranes, callus, &c. having only a low degree of vitality, cannot long resist inflammatory action, and are soon destroyed either by ulceration or sloughing.

We have already adverted to the influence of *temperament* over the constitutional symptoms; the local character of inflammation is also considerably modified by diversities of temperament: thus the sanguine temperament is predisposed to acute inflammation of highly vascular organs; the bilious temperament to erysipelas, &c.

Inflammation is greatly modified also by the *diatheses*, or morbid predispositions, and in many cases these morbid states of the constitution give the inflammation a specific character: thus the scrofulous, rheumatic and gouty diatheses, whether natural or acquired, give origin to as many corresponding varieties of inflammation, as will be more particularly specified hereafter. Many peculiarities of constitution are transmitted from parents to their progeny; these hereditary morbid tendencies are likely to be brought into action, if the individuals be placed in circumstances favourable to the development of the diseases which they induce; otherwise they may long remain dormant in the constitution, and sometimes even, after passing over one or two generations without manifesting themselves, may break out in the third.

The progress of inflammation is materially affected by *age*, in consequence of the changes in the activity of the circulation and distribution of blood, and in the energy of the nervous system observed at the different periods of life. In *childhood*, the circulation being very active, the inflammatory process is always rapid and mostly healthful; but the great determination of blood to the head, peculiar to that age, occasions a more than ordinary tendency to inflammatory affections of the brain and other parts about the head, such as hydrocephalus, ophthalmia, otitis; to mumps, and other glandular swellings of the neck; to cynanche, cutaneous eruptions of the scalp, &c. The inflammatory affections of children are frequently attended with convulsions, owing to the great susceptibility of their nervous system. Another peculiarity by which these affections are distinguished is their remarkable disposition to assume either a remittent or intermittent form; this may perhaps be also attributed to the irritability and weakness of the nervous system in childhood. In *youth*,

the progress of inflammation is still more vigorous and healthful, but the tendency to affections of the head diminishes, and the thoracic viscera become more prone to inflammation; accordingly pneumonia, pleurisy, and phlegmonous inflammation, are observed to prevail at that age. In the *adult* period of life, inflammatory action appears more particularly directed towards the abdominal viscera, giving rise to attacks of gastritis, enteritis, hepatitis, nephritis, cystitis, &c. In *old age*, as the powers of life decline, the energy of the vascular system becomes weakened, and its organization is frequently impaired; the inflammatory action is therefore much more languid, and less disposed to terminate favourably; this unpropitious tendency is often increased by the pre-existence of visceral disease. This period of life is also characterized by weakness and irritability of the nervous system. The most common inflammatory affections of old people are chronic catarrh, peripneumonia-notha, chronic cutaneous eruptions, gangrenous erysipelas, &c.

The influence of *sex* is to be considered. The greater delicacy of fibre and higher degree of nervous susceptibility of females, predisposes them more to inflammation than men; although this is in some measure counterbalanced by males being more exposed to the influence of the exciting causes from the nature of their pursuits and their irregular habits of life. The course of inflammation in women is more rapid and less steady than in men, being complicated with many nervous symptoms: their inflammatory affections are also greatly modified by the influence of the uterine functions.

The *habits and condition of life* are likewise deserving of some consideration. In persons of sedentary habits, or who indulge in food and liquor to excess, inflammation is generally severe, and often assumes an unhealthy character, in consequence of the repletion of the system and vitiated condition of the fluids. When the body has been much debilitated by a deficiency or the bad quality of the food, previous disease, or any other cause of weakness, the inflammation is languid, and there is not sufficient power to establish any reparatory process; hence the great difficulty often experienced in such cases in obtaining the reunion of fractured bones, the healing of ulcers, or resolution of tumours, &c. There are also peculiar forms of inflammation induced by particular employments; as, for instance, the chimney-sweepers' cancer, the bakers' and grocers' itch, the barrel-grinders' cough &c., an excellent account of which will be found in the article *ARTISANS, DISEASES OF*.

The effects of *air* on the progress of inflammation are very remarkable, and entitled to particular attention. They are to be attributed chiefly to the important influence of the air over the qualities of the blood and vigour of the circulation. A pure air imparts to the blood rich and nutritive properties, and acts as a stimulus to the circulation, so that wholesome materials are supplied, by which the inflammatory processes are carried on with activity to a favourable termination; in an impure and foul air, the blood is impoverished or vitiated, the circulation feeble or irregular, and all the morbid actions necessarily partake of this defi-

ciency of power. The air exerts moreover a powerful and direct influence over the nervous system, and through it on all the functions of life, especially those of the digestive organs, and of the skin. These reasons sufficiently account for the slow progress of inflammation, and the unhealthy character it so frequently assumes in close ill-ventilated apartments, low situations, cold and damp seasons, or during the prevalence of certain winds; and likewise for the remarkable improvement observed after the removal of patients to a more airy situation, by transferring them even from a lower to an upper floor in the same building, and after favourable changes of weather. It has been justly remarked by Mr. James, (James on Inflammation, p. 80) that there is no poison more injurious than foul air, and no restorative more effectual than pure air; indeed it exercises in this respect a greater influence than even food. The effects of the damp and foul air of ill-ventilated wards in causing the diseases called hospital gangrene, have been frequently noticed by practical writers.

Besides these general effects of air, there are certain regular and periodical changes produced in the human constitution by the different seasons, which considerably modify the character and course of inflammation; these changes seem to depend partly on the circumstance of each season causing a greater determination of blood towards certain organs than others. We thus see inflammatory diseases most prevalent during winter and spring: pneumonia, inflammatory catarrh, and acute rheumatism are principally diseases of winter: pleurisies, cerebral inflammation, the febrile exanthemata, and other acute diseases of the skin, are the general concomitant affections of spring. In summer and autumn there appears to be less predisposition to very acute inflammation, and the predominant diseases of these seasons are congestions and subacute inflammations of the liver and mucous membranes of the alimentary canal, such as bilious fever, gastro-enteritis, dysentery, diarrhoea, and cholera morbus. During the prevalence also of epidemic diseases, all local inflammations are observed to partake more or less of the type of these diseases. If it be inflammatory, the local diseases are very acute; if typhoid, the local inflammation is of a low type. Some epidemics create a remarkable tendency to erysipelatous inflammation, and when the epidemic has either a remittent or intermittent type, the most common inflammations show a remarkable tendency to assume the same character. This influence of epidemic constitutions over local diseases has been well described by some of the ancients, and especially by Sydenham and Stoll.

The duration of inflammation varies according to its intensity, the texture of the part affected, nature of the exciting cause, and state of the constitution. Violent inflammation is seldom of long duration; it may exist for only a few hours, and has sometimes proved fatal in the course of a day; it passes through its different stages with great rapidity in infants, who require on that account to be visited frequently when labouring under inflammatory affections, as considerable changes may take place in the course of even a few hours; it may also prove rapidly fatal when affecting vital organs, such as the heart and brain, particularly

if attended with excruciating pain. When inflammation is not violent, it may last for months, and even years: this difference in duration forms the ground of one of the divisions of inflammation that will be presently examined. Inflammation, when of long continuance, frequently induces changes of structure. One of the effects of long-continued inflammation is to leave the vessels so much weakened that they remain preternaturally dilated, and the part preserves a certain degree of redness and thickening which may not disappear for years; this happens particularly in the cicatrices and scars consequent upon burns and old ulcers.

Varieties and Divisions of Inflammation.

—The variety of forms assumed by inflammation are extremely numerous, and have been arranged under some classification or other by most practical writers. But in the present state of pathological knowledge we are too imperfectly acquainted with the exact nature of proximate causes, and with many other important circumstances relating to the history and theory of diseases, to be able to frame any truly scientific nosological arrangement, and all the classifications of inflammation are on that account more or less defective. They are deserving, however, of some notice, as tending to give a systematic view of the most important peculiarities of inflammation, and as affording some assistance in the study of this multifarious class of diseases, and in laying down general rules of practice.

Inflammation has been divided into *acute* and *chronic*: it is important that these terms should be understood as expressing only different *degrees* and not different *kinds* of inflammation. The term *acute* is generally used to denote that the inflammatory process is both active and of short duration: it may be considered sufficiently accurate in the former sense, but will often prove incorrect in the latter; for inflammation is susceptible of being maintained in a state of great activity for a considerable length of time, especially if the exciting cause continues in operation, or its application be frequently renewed. *Chronic* inflammation implies the absence of acuteness or activity, and a tendency to long duration. When acute inflammation is only imperfectly relieved, it often continues for a considerable time in a state of lessened activity, and is then chronic in every acceptance of the term; but inflammation may be of an obscure and mild character from the very beginning, and it cannot therefore be correctly called chronic from the mere absence of acuteness. An intermediate degree of inflammation between the acute and chronic has been termed *subacute*; this frequently consists of the state we have described by the name of congestive irritation.

Inflammation has also been divided into *active* and *passive*: these terms designate merely the degree of intensity of the inflammatory action, and are not exactly synonymous with acute and chronic; for passive inflammation may be of short duration, whilst active inflammation may, as already stated, be more prolonged. When the pain, redness, and heat are only slight, while the swelling is considerable and attended with an abundant secretion, the inflammation is said to be

passive: this form of affection ought rather to be considered as a species of congestion; and the term passive can scarcely be applied with strict propriety to any species of true inflammation. Inflammation is sometimes distinguished into *tonic* and *atonic*; these terms refer more to the powers of the constitution than to the intensity of the local disease. When the constitution is strong, the inflammation is called tonic. If the constitution be in a state of debility, there may be very violent inflammation in a part; but in consequence of the want of sufficient power in the system to maintain this local action, it soon subsides; and the inflammation either disappears, as is seen in atonic gout, or perhaps mortification takes place. This is called atonic inflammation. The terms *sthenic* and *asthenic* have also been applied to inflammation; they are derived from Dr. Brown's well-known division of diseases into two great classes, and refer, like the terms tonic and atonic, to the powers of the constitution; *sthenic* being used to express a high degree of power, and *asthenic* a deficiency of power.

In order to avoid the ambiguous and ill-defined notions generally conveyed by the terms active and passive, acute and chronic, &c., as applied to inflammation, Andral has adopted a new and very simple division. He classes all inflammations and congestions under one head, termed *hyperæmia*, or excessive presence of blood in the part. When the accumulation of blood is due to increased action, this constitutes *active hyperæmia*, including all forms of active congestion and inflammation. When, on the contrary, the accumulation of blood arises from debility or obstruction, &c., it is called *passive hyperæmia*, which comprehends passive congestions. Andral's division has still, however, the disadvantage of applying the same name to diseases very dissimilar in their characters, such as, for instance, every variety of active congestion and inflammation; besides, moreover, the great inconvenience always attached to the introduction of any new nomenclature in science. It appears, therefore, more desirable to adhere to the old terms, endeavouring only to give them a more precise meaning.

Inflammation may be *continued*, *remittent*, or *intermittent*. Acute inflammation in healthy constitutions endowed with sufficient power to maintain vigorous action, assumes most generally the continued form. We have already stated, in speaking of the influence of age, that the inflammatory affections of children exhibit a great tendency to remittance or intermittence; and that the same peculiarity is sometimes observed in persons of an irritable temperament or advanced in life. We have instances of intermittent inflammation in ophthalmia, which sometimes returns very violently every evening, or every other evening, at a certain hour. Otitis is frequently intermittent; and catarrh has also occasionally assumed a periodical character. (Elliotson's Lectures on Inflammation, Med. Gaz. Dec. 1831.)

Next to the duration and different degrees of intensity of inflammation, its causes have also been adopted as the basis of several divisions. Inflammation, considered in this point of view, has been distinguished into *accidental*, *spontaneous*, and *symptomatic* or *secondary*.

Accidental inflammations are those arising from *mechanical* causes, such as pressure, friction, cutting, and lacerating instruments, &c., or *chemical* causes, including all irritating, acrid, and corroding substances, high degrees of temperature, and great cold: all these causes excite inflammation in the part to which they are applied; but the inflammation arising from cold often manifests itself at a distance from the part on which the cold has acted. In accidental inflammations the local symptoms generally precede the constitutional, and the latter follow, with respect to their increase or decline, the course of the former.

Spontaneous or Idiopathic Inflammations are those which cannot be distinctly traced to the action of any external agent, and appear to derive their origin from various morbid conditions of the constitution, such as a state of general or local plethora, the over-excitement or deficient action of certain organs, &c. Spontaneous inflammations are susceptible of being influenced to a certain extent by peculiarities in the state of the atmosphere, the exact nature and mode of operation of which we are unable to explain. That such, however, is the fact is clearly proved by the circumstance of this class of inflammations assuming sometimes an epidemic form, which constitutes a good line of distinction from the preceding class.

Symptomatic or Secondary Inflammation.—It has already been observed, when describing the constitutional symptoms, that whilst inflammation was frequently a primary cause of great general disturbance in the animal economy, it was also on many occasions only symptomatic of a previously disordered state of the constitution; the inflammation appears then as a symptom only of another more general disease. Among the causes of symptomatic inflammations, one of the most frequent is the introduction into the system of poisons, such as those of variola, rubeola, scarlatina, &c. The patches of erysipelatous and gangrenous inflammation which appear in different and remote parts of the body after poisoned wounds, are merely symptomatic of the typhoid and malignant fever which is the primary and more immediate effect of the poison. The various cutaneous affections attending the febrile exanthemata are merely symptoms of a general disease, and do not constitute its essential features, as they are often very slight and sometimes even altogether wanting; the latter case constitutes a variety of disease described by nosologists as *variola sine variolis*, *morbilli sine morbillis*. The buboes of the plague afford another instance of symptomatic inflammation, and the various swellings and critical abscesses subsequent to continued fevers are of the same description. The paroxysms of some intermittent fevers have been attended with regular attacks of ophthalmia, diarrhoea, or dysentery. Erysipelas and anthrax are in numerous instances to be traced to a state of general repletion, combined with a vitiated condition of the blood and of all the secretions, and are accompanied by typhoid fever.

Symptomatic inflammation is of frequent occurrence also after the healing of large and long-established ulcers; after the removal of a limb, in a state of profuse suppuration in consequence of compound fracture; and particularly in cases of

phlebitis, which are so often attended with the formation of abscesses in parts remote from the original inflammation. Symptomatic inflammation is attributed in general either to nervous sympathy or to a vitiated state of the blood. The absorption of pus and its combination with the blood is considered by some pathologists as the principal cause of the secondary inflammation and suppuration. It has been ascertained beyond doubt that pus is sometimes absorbed both by the veins and lymphatics, and circulated with the blood; it may be either the produce of the inflammation of the vessels themselves, as in cases of phlebitis, or be taken up by them from inflamed and suppurating parts. Pus has been found in the veins and lymphatics in the neighbourhood of diseased joints, of unhealthy stumps, of old ulcers, and of inflamed organs, such as the uterus, intestines, liver, and brain. Collections of matter have also been found, however, in these cases, in parts of the body remote from the inflamed organ; as, for instance, in the lungs, spleen, joints, serous cavities, and even in some of the muscles; and this has occasionally taken place without the least trace of any concomitant inflammation being discovered in these parts. M. Dance states, in his work on this interesting subject, that he has observed pus in the veins of the arm, on bleeding women affected with uterine inflammation and phlegmasia dolens. We have seen purulent deposits in several parts of the spleen of a man who died of fever soon after the healing of a large chronic abscess between the muscles of the thigh; the texture of the spleen was in every other respect perfectly healthy. Small collections of pus have been observed by Andral and Velpeau in the centre of the coagula of blood found in the heart and large vessels. (*Andral, Pathol. Anat. transl. vol. i. p. 97.*) It appears reasonable to conceive that the mixture of pus with the blood should become a source of irritation, as well as any other heterogeneous principle, and this may, therefore, be admitted as an occasional cause of symptomatic inflammation; it can scarcely, however, be considered as the only cause, since we have seen that these accumulations of pus sometimes take place as the effect of an ordinary process of secretion, and without any accompanying inflammation.

The absorption of pus was for a long time erroneously considered to be the primary cause of hectic fever. That this is a mistake is clearly proved by the fact that hectic fever is often induced by the long-continued irritation of vital organs, with very little or even the total absence of suppuration; while very extensive collections of matter may exist for a long time in parts of less importance without any hectic.

Symptomatic inflammation differs in most cases from spontaneous inflammation by following a fixed and regular course, and having always the same mode of termination, as is exemplified in the febrile exanthemata. Among the secondary inflammations may be included that of the pleura consequent upon the opening of a tubercle or abscess into its cavities, or that of the peritoneum from the perforation of the intestines, bursting of an hepatic abscess, or rupture of the uterus.

The division of healthy inflammation adopted

by Mr. Hunter was the adhesive, suppurative, and ulcerative. He observed that in the cellular membrane, and all circumscribed cavities, the adhesive inflammation takes place more readily; whilst in internal canals, and all cavities having a communication with the exterior and which are lined with mucous membranes, the suppurative and ulcerative inflammation come on most readily, and the adhesive very seldom. Adhesions would in general prove hurtful in these membranes; and they only take place from very violent and long-continued inflammation.

Mr. James, in his work on inflammation, takes, as the basis of his division of inflammations, their disposition either to be *limited* by the effusion of organizable coagulable lymph, or to *spread*. This distinction appears founded in nature: for the common inflammation of the cellular membrane, and of parenchymatous and glandular organs, which is termed phlegmon, is generally circumscribed by the effusion of coagulable lymph; whilst in certain textures, such as the fibrous, inflammation shows a remarkable tendency to spread, assuming the character of erysipelas; and the same tendency seems also to be induced in all other parts of the body by a deficiency in the powers of the constitution; a certain degree of vital action being required for the production of coagulable lymph. The orders in Mr. James's division are established on the principle of the degree of connection of the organ with the vital functions of the animal; and the genera are founded on the original disposition of inflammation to have particular modes of termination, as, for instance, in boil and whitlow to suppurate, in carbuncle to slough, and in mumps to resolve; and this disposition, he justly observes, is so strong as to render it extremely difficult to procure any other termination.

One of the most usual divisions of inflammations with reference to their nature has been into *common* and *specific*. Common or healthy inflammation is that which usually follows the action of mechanical or chemical causes, of which phlegmon may be taken as the general type.

Specific inflammation is distinguished by certain peculiarities in its symptoms and progress, which are to be attributed either to a special morbid diathesis or to the specific nature of the exciting cause. Thus inflammation of the urethra from a mechanical cause is common inflammation; the inflammation from gonorrhœa is a specific inflammation. The principal varieties of specific inflammation are the *scrofulous*, *syphilitic*, *rheumatic*, *gouty*, *erysipelatous*, the *gangrenous inflammation*, produced by morbid poisons, or else by constitutional causes; the *unhealthy inflammation* that characterizes cancer and all new growths of a malignant description.

Scrofulous and syphilitic inflammation affect a variety of tissues at the same time; the peculiarities by which they are distinguished will be fully described in the articles SCROFULA and SYPHILIS.

Gouty, rheumatic, and erysipelatous inflammation will be described when treating of the modifications of inflammation by texture.

The peculiarities of the inflammation arising from animal poisons have been sufficiently detailed under the head *Constitutional Symptoms*;

and those belonging to cancer and other new growths of a malignant nature will be considered in a separate article.

Latent Inflammation.—It was observed, in the account of the constitutional symptoms of inflammation, that in some cases no inflammation exists, although many of its symptoms are present. It is a fact equally well established, that inflammation sometimes occurs, even to a considerable extent, without any indication of its existence from either local or general symptoms; or it very often happens that the more important are absent, and those which are recognised are insufficient to indicate the disease. Hoffmann was the first writer who noticed the latency of inflammation, and affirmed that he had found most intense abdominal inflammation without pain or sense of heat; and his observations were confirmed by subsequent writers. Baglivi states, "*Pleuritides frequenter sunt occultæ, quia indolentes, unde gravissimi errores in praxi succedunt.*" (Prax. Med., lib. i.) Stoll has also given an interesting account of an epidemic fever, the chief character of which was a latent peripneumony; and in his *Ratio Medendi* a description is given of other forms of latent inflammations.*

Modern pathologists have confirmed the frequency of latent inflammatory diseases, the detection of which is now rendered more easy from the various improvements which have been recently made in diagnosis, more especially in the physical signs of diseases.

It is very difficult to account for the occurrence of inflammation without its characteristic signs; for not only is this latency observed in structures in which the sensibility is dull, but in those in which, under inflammation, it is most exquisite, as in pleurisy and peritonitis. It has been remarked by many practical writers that the condition of the nervous system has a material influence in obscuring local inflammations; this is more especially the case in continued fevers, in which the various local inflammations are rendered latent in proportion to the degree of affection of the nervous system. This, however, is not the sole cause, for cases of latent inflammation constantly occur where the nervous system is comparatively little if at all affected; it is important, however, in fever with moderate or severe cerebral affection, that the state of the various organs should be carefully examined, in order to discover the existence of organic inflammation.

It is also well known that some tissues, such as mucous membranes, may undergo inflammation, and even changes of structure consequent thereon, without pain or other local indication of disease, although the constitution sympathizes powerfully with the inflamed organ. We have an instance of this in the equivocal nature of the symptoms of inflammation of the mucous membrane of the intestines, and in the latent symptomatic bronchitis of fever. Again, the progress of chronic inflammation is sometimes so slow and gradual that both the organ affected and the constitution become accustomed to it by insensible degrees, and even accommodate themselves to the impedi-

ment of function the lesion induces. Even the brain, which is the organ from which sensibility is derived, affords an illustration of this pathological fact, as local or partial inflammation of this organ may exist, and be proceeding to disorganization of its structure without urgent symptoms. In such cases not only are the more prominent signs, such as pain in the head, sense of weight, or vertigo, absent, but the mental powers are often scarcely affected, or only to a very slight degree, and the attention of the patient and his physician is perhaps for the first time awakened to the danger of the disease by some sudden seizure which rapidly destroys life.

Latent inflammation of the lungs has been alluded to as of frequent occurrence in continued fever, and would be frequently entirely overlooked, were the practitioner to trust entirely to the absence of the ordinary symptoms. In these cases auscultation seldom fails to detect the existence, nature, and extent of the pulmonary disease, which is often the chief source of danger. It is a well-ascertained fact also that partial or circumscribed pneumonia, catarrh, or congestion of the lungs, may exist for a considerable time without any perceptible change in the general health. If these partial chronic affections of the pulmonary organs be neglected, they often lay the foundation of more extended and dangerous disease; in such cases the value of auscultation must be admitted by the most sceptical.

Equally uncertain are the symptoms of several intestinal lesions, gastro-enteritis, and hypertrophy, and ulceration of the mucous follicles; so fallacious indeed have the symptoms of these lesions proved, that pathologists despair of fixing on their peculiar pathognomonic signs.

Chronic inflammation and even suppuration of the glandular organs of secretion, the liver and kidneys, chronic diseases of the heart, pericardium, and large vessels, originating primarily in inflammation, are among the latent affections discovered only after death.

Latent inflammation of the lungs or liver sometimes succeeds to capital operations, such as lithotomy or amputation, and to severe injuries of the head. We have already alluded to the non-inflammatory purulent deposits observed in organs after severe surgical diseases or operations.

These facts, connected with the occurrence of latent inflammation, show the necessity of careful investigation into the history of each case in which there is the slightest suspicion of latent disease going on in any organ essential to life. In the absence of external or evident symptoms, physiological examination may often assist the practitioner in its detection, more especially in those organs which cannot be brought under ocular or manual inspection. For example, chronic diseases of the brain may often be discovered by imperfection in the performance of its several important functions. In pulmonary inflammation, the state of the respiration as to the frequency and regularity, the nature and intensity of the sounds elicited by auscultation, and the character of the expectoration, afford important guides. In intestinal inflammation, inquiry as to the presence or absence of pain, the condition of the tongue, the frequency and character of the alvine evacua-

* A good account of both latent and symptomatic inflammations is given in the article *Inflammation* in the *Dictionnaire de Médecine*.

tions, and the other modes of exploration of the abdomen, are never to be omitted.

It must, however, be admitted, that even with the most minute and careful investigation, latent inflammations elude observation, and tend much to impress on the reflecting mind the diffidence with which we should pronounce the existence or non-existence of organic lesions during life, unless they are accompanied with such manifest signs as to render their existence and nature perfectly unequivocal.

Varieties of inflammation according to texture.—While the study of the healthy structure of the separate textures of the body has materially contributed to the improvement of physiological science, the great attention paid of late years to the diseased structure of the different animal tissues has led perhaps more than any other circumstance to a similar rapid advance in our knowledge of pathology. The merit of having first pointed out the advantages that might be obtained from investigating the modifications induced by disease in the structure of the part affected, and of making the animal tissues the basis of a new nosological arrangement, is attributed on the continent to the celebrated Pinel. We have before observed, however, that the writings of William Hunter, Cullen, and John Hunter contain many allusions to the striking differences several tissues present in their diseased structure; and that Dr. Carmichael Smith published an admirable paper in 1788, in which this learned physician took a comprehensive view of the peculiarities of inflammation as they are observed in the different sorts of organic substance found in the animal body.

We proceed to give an account of the changes of structure induced by inflammation in the principal tissues, and acknowledge the valuable information we have received on this important subject from the excellent work of Gendrin. We have consulted also, with much advantage, the works of Laennec and of Andral, and the valuable *Elements of General and Pathological Anatomy* of Dr. Craigie.

1. *Cellular tissue.*—The two most obvious properties of the cellular tissue in health are its expansibility and elasticity. When examined after the full development of active inflammation and before suppuration has taken place, it is found inextensible, hard, and easily broken down; its areolæ are filled with a red homogeneous, opaque, gelatinous-like matter, with which it is so firmly incorporated that it cannot be removed by ablation. The density and infiltration decrease from the centre of the inflammation; the redness also gradually lessens in intensity, but the vessels are enlarged, very minutely injected, and distended with blood. Where the redness disappears, the tissue has preserved its elasticity, but is filled with a yellowish serous fluid forming a greater or less degree of œdema, according to the laxity of the tissue and depending position of the part. When the inflammation has been violent, there are found in the central portion, besides the sanguineous infiltration, small cavities filled with black extravasated blood, mixed sometimes with serosity, or broken-down fatty and cellular substance, or a puriform fluid. When these cavities are numerous, or when large and attended with

extensive disorganization, there is a great risk of mortification.

If the part affected contains much of the vesicular adipose tissue, it will be variously affected according to the degree of the inflammation; when moderate, the fat is mostly resorbed; but if intense, it is broken down, mixed with the blood, and converted into a yellowish and pultaceous matter. The preceding morbid alterations constitute what is termed by Gendrin the *red infiltration*. As the inflammation proceeds towards suppuration, the redness gradually decreases, and is only very slight after the secretion of pus has commenced. The cellular tissue then becomes softer and spongy; the sanguineous infiltration is succeeded by that of a yellow puriform fluid; and this constitutes the *yellow infiltration*.

When the suppuration is completed, the pus collects into one or several cavities; the walls of these cavities are lined by a condensed layer of red and vascular cellular substance; the swelling becomes more defined and circumscribed; the surrounding œdema diminishes, and a common abscess is thus formed.

The variety of inflammation just described is that belonging to common *phlegmon*, and is always circumscribed; it may take place in any part of the body, but some are much more disposed to it than others; it often occurs, for instance, under the jaw, in the axillæ, near the rectum or urethra, &c. Phlegmonous abscesses frequently appear after febrile diseases, particularly the exanthemata, and are generally considered critical.

There is another form of acute inflammation of the cellular membrane, differing chiefly from the preceding in not being circumscribed, but spreading by continuity without any regular limits, and which has received the name of *diffused inflammation*. This is a constant attendant of the erysipelas phlegmonodes, and is occasioned also by the inflammation of veins, by sprains and external violence, by the inflammation of deep-seated fibrous textures, and that of poisoned wounds. Although frequently combined with erysipelatous inflammation, it may exist without it, and generally terminates in diffused suppuration of several portions of the inflamed cellular tissue, and sometimes in sloughing. The first account of diffused inflammation of the cellular membrane as a separate disease was given by Dr. Duncan.

In *chronic inflammation*, the cellular tissue loses its elasticity, and becomes condensed and thickened by the uniform infiltration of a coagulated, albumino-gelatinous fluid, which fills its areolæ. It is difficult to divide with the knife, and not so easily broken down as in acute inflammation; in some cases the infiltration is of a greyish white, in others it has a red marbled appearance. The inflammation may either be circumscribed and terminate abruptly, or become diffused and surrounded with œdema. That peculiar affection of infancy called the *skin-bound disease*, originates in chronic inflammation of the cellular membrane. The whole surface of the body is swelled and hard, and the skin is cold and tight-bound. A similar disease has been sometimes observed in the upper and lower extremities of adults, especially in young women of a phlegmatic temperament, and is extremely difficult to remove.

Chronic inflammation of the cellular membrane may end in suppuration or ulceration. It never supplies perfect pus, but rather a sero-purulent viscid yellowish fluid, sometimes slightly tinged with blood; it shows no tendency to cicatrization, forming rather cold abscesses, fistulous canals, and chronic ulcers. The walls of the abscess are sometimes permanently organized, so as to be converted into a cyst.

Gangrene may be the effect of the intensity of the cellular inflammation. There is also a form which tends to destroy the vitality of the part from its commencement. This is either the effect of morbid poisons, or of an irritable and depraved habit of body; it is of frequent occurrence after poisoned wounds, and in some varieties of erysipelas, and constitutes the formidable disease termed *hospital gangrene*. The inflamed tissue becomes flabby, of a livid or black colour, intolerably fetid; and it finally separates from the living parts in the form of eschars. The moment the part has become gangrenous, all circulation, both in the blood-vessels and absorbents, ceases, and the vessels are obliterated: the truth of this, which was always taken for granted, has been fully demonstrated by a number of experiments performed by Gendrin.

Serous Membranes.—It is a well-established fact that a serous membrane and the organ it invests, may each be affected with inflammation separately, although in perhaps the majority of cases the inflammatory action extends more or less from the one to the other. The serous membranes are connected with the textures which they either line or invest by a cellular tissue of different degrees of density, and it is not always easy to ascertain the exact line of separation between the serous membrane and the subjacent cellular tissue, in consequence of the great similarity of their texture. This is an important consideration in deciding upon the thickness of serous membranes; for where the sub-serous tissue is loose and abundant, a considerable portion of it may be raised with the membrane, and add apparently to its thickness. Gendrin has given the best explanation of the causes of thickening in serous membranes. Some pathologists have denied that they are ever really thickened; but this is a mistaken assertion, as is rendered particularly evident by the changes induced by chronic inflammation.

The sub-serous cellular tissue always participates in the inflammation of serous membranes, and traces of the inflammation are observed in this tissue, before the substance and free surface of the membrane are at all affected. The first changes induced by inflammation are a red injection and serous infiltration of the connecting cellular tissue, which loses its elasticity and is easily torn; sometimes globules of air have appeared, forming a slight degree of emphysema. When the inflammation has lasted some time, this serous infiltration penetrates between the laminae of the serous membrane, causes a real increase of thickness, and renders it opaque. These changes are greater where the membrane is connected to the adjacent part by an abundance of loose cellular tissue, as is the case with the portion of arachnoid covering the brain, than where this tissue is very close and firm, as in the portion of the arachnoid lining the dura mater. The degree of facility

with which inflammation is propagated from serous membranes to the adjacent parts, and *vice versa*, depends also, in a great measure, on the density of the sub-serous cellular tissue, and on its penetrating more or less into the texture of the subjacent organs.

The inflammation of serous membranes exhibits, therefore, in the beginning, patches of a uniform bright red, confined to their adherent surface, and to the subjacent cellular tissue, which is infiltrated with serum. As the disease advances, the free surface of the membrane becomes dotted with small red points, and overrun with minute red streaks; the vessels, which before conveyed only a colourless fluid, beginning to admit red blood. The red patches gradually spread and unite together, and the number of red dots increases, resembling very small petechiae; in some cases they are much larger and stellated, constituting patches of ecchymosis. The membrane in the intervals is white and opaque, and there is a sensible increase of its general thickness, arising from the infiltration of serum between its laminae.

Some serous membranes are but very slowly injected in inflammation, and sometimes even not at all, as for instance the arachnoid; but as soon as the subjacent cellular tissue becomes red and filled with serosity, the membrane loses its transparency, assumes a milky-white appearance, and is increased in thickness.

In cases of simple congestion, all the vessels of the sub-serous cellular tissue are very minutely injected, and sometimes a few of the vessels of the membrane itself; and the great vascular injection seen through the transparent membrane has occasionally been mistaken for inflammation. The redness, however, can easily be removed by pressure and ablution; there are no permanent red dots or patches of ecchymosis; the membrane is neither thickened nor opaque; there is either no sub-serous effusion, or, if any, it is very slight, and the fluid not coagulated. It is necessary to remark that, when the redness of inflammation is only slight and of recent date, it often disappears partially after death.

One of the effects of commencing inflammation in a serous membrane is an increase of secretion, and the effusion of a serous fluid, at first limpid, and of a citron or reddish colour. This fluid contains a small proportion of albumen, which increases when the inflammation is severe, and it bears a strong resemblance to the serum of the blood. When the inflammation is only moderate or partial, the fluid may be absorbed almost as fast as it is effused, so that there is little or no accumulation. The surface of the inflamed membrane has been sometimes found unusually dry, although highly inflamed. This has occurred in cases of arachnitis, pleurisy, and pericarditis, in which the inflammation was very intense and proved rapidly fatal.

As the inflammation increases, and particularly if intense, all secretion is suspended, or it consists only of a very small quantity of bloody serum or of pure blood, as is seen occasionally in the arachnoid, pleura, and peritoneum: the effusion of blood has been sometimes very copious in pleurisy and peritonitis, and described as hemorrhagic inflammation. It is the constant effect of violent

inflammation to stop both exhalation and absorption. We have stated already, when treating of congestions, that large effusions, not purulent, are more frequently the produce of congestive irritation than that of active inflammation. When the inflammation abates, if, instead of ending in resolution, it is disposed to pass into the chronic state, the effusion then increases considerably, and, losing its limpidity, consists of a mixture of pus and serum: the pus is yellow or greenish, and sinks to the bottom. It is important, therefore, to remember that the period of decline of the inflammation of serous membranes is always attended with the danger of increased effusion. There is sometimes exuded, chiefly on the surface of the arachnoid, a layer of thick green pure pus, without any serous fluid or plastic coagulable lymph, and adhering but slightly to the surface of the membrane: this has been also observed, though more rarely, in the peritoneum and pericardium. Pus is effused also in the sub-serous cellular tissue; and this is the most usual form of suppuration in the arachnoid, as pus is but seldom poured out from its free surface. In the other serous membranes, on the contrary, pus is more frequently exuded by their free than by their adhering surface. The greater looseness and vascularity of the sub-serous cellular tissue in the arachnoid may account for this difference. The serous fluid effused beneath the arachnoid, and in the pia mater, has a gelatinous appearance, and consists of coagulated albumen, combined with various proportions of serum according to the intensity of the inflammation; in some cases, one part of the effusion having been absorbed, the remainder becomes circumscribed in cavities formed by false membranes.

The surface of an inflamed serous membrane soon becomes covered, wherever the inflammation extends, with a very thin layer of an apparently albumino-gelatinous substance; when this is removed, the membrane is found to have lost its smooth polish, and appears rough. This deposit gradually becomes thicker and more adherent, and forms the rudiment of a false membrane: it is almost always accompanied with a serous or sero-purulent effusion; but in some rare cases the effusion has been wanting. This organizable matter has been found by the experiments of Dowler and Lassaigue to consist of two parts; one concretescible and adhesive, formed of fibrine; the other fluid, and contained in the cells of the former, consisting of albumen; it constitutes what is generally known as coagulable lymph, and by undergoing certain modifications is converted into pus. When adventitious membranes do not become organized, Laennec says they are generally softened down into pus. There is a greater disposition to the formation of false membranes in the serous than in any other tissue of the body. The coagulable lymph is variously disposed; when exuded in considerable quantity, portions of it are generally separated from the surface of the membrane, and float in the shape of flocculi in the sero-purulent effusion, giving it a turbid whitish appearance, especially in the abdomen; from which circumstance arose the old opinion, that the effusion of this fluid in puerperal women was owing to the metastasis of the milk.

The lymph is sometimes deposited in the shape

of small globules studding the membrane; at others it forms papillæ symmetrically arranged, or assumes a granular or a reticulated appearance; this is generally the case in the pericardium. The organizable matter itself is porous and cellular, containing a fluid that may be expressed by pressure. The soft portions of coagulable lymph that adhere to the opposite surfaces of the serous membrane, following the movements of these surfaces in the cavities of the thorax and abdomen, are drawn out into filaments, lamellæ, or cords, which, becoming organized, constitute cellular adhesions; their organization takes place in the following manner: the false membrane gradually becomes denser and more adherent, in consequence of the absorption of its thinner portion, and at last exhibits traces of commencing organization by becoming injected with blood. How to account for the presence of the blood is an interesting subject of inquiry, which has excited much discussion: it must either be brought by the vessels of the serous membrane which shoot into it, or else be spontaneously formed in the original lymph. Gendrin relates some interesting microscopic observations in support of the former opinion, for which we must refer the reader to his valuable work, not having space to quote them. (*Histoire Anatomique des Inflammations*, vol. ii. p. 551.) Laennec and some other pathologists, have adduced, however, facts that seem to prove beyond all doubt that coagulable lymph possesses an independent vital property, in virtue of which it becomes organized. Laennec has shown that portions of exuded fibrine perform the functions of secretion, absorption, and nutrition, before the slightest trace of any vessels can be discovered in them; for in some cases of peritonitis and pleurisy he found that the exhalation and absorption of serous fluids took place to a considerable extent between the layers of coagulable lymph, before they were organized; and that one layer of lymph is moreover capable of secreting another, as proved by a case he published in the *Journal de Boyer* for the year 1801. The fluids, therefore, under the influence of some vital impulse, must make channels for themselves in all directions between the fibres and laminae of the lymph; this process is justly compared by Andral to the life of some zoophytes composed of an amorphous mass of gelatine, who absorb, digest, excrete, and are nourished, although they do not present any vestige of regular organization. Serous fluids and collections of well-formed pus and of calcareous matter have been found in the centre of masses of coagulated fibrine, by Andral, Velpeau, and several others, showing that it was susceptible also of morbid irritation. The development of various new morbid growths may, no doubt, be accounted for on the same principle.

The first traces of organization in the coagulable lymph are the appearance of a few red dots, resembling small collections of blood, and analogous to the *punctum saliens* in the vitellary membrane of the chick, the fibrine being endowed with a similar property of secreting red blood. Sometimes there are red lines or furrows running in various directions and anastomosing, so as to form meshes and net-works; and at a later period we find distinct blood-vessels, through which the blood regu-

larly circulates. The globules of the blood probably move about in various directions, tracing passages for themselves through the lymph, until regular vessels are thus formed; or else the small trains of coagulated blood become converted into vascular tubes. Laennec states, that on examining these trains of blood, he has found them to contain small white cylindrical filaments of fibrine, permeable in the centre and containing blood, and which he considers to be the rudiments of vessels. Some of the branches of this independent circulating system finally inosculate with the vessels of the adjoining tissues. The vessels formed in a clot of blood have been successfully injected by John Hunter and Sir E. Home, as may be seen in some beautiful preparations in the museum of the London College of Surgeons. It is in the inflammation of blood-vessels that the various transformations the fibrine undergoes can be the most accurately traced.

As soon as a regular circulation of blood has been established in the mass of coagulated lymph, it begins to lose its homogeneous nature, and may assume a laminous, cellular, mucous, or fibrous texture, analogous to the structure of the tissue by which it has been supplied; the nervous and muscular tissues form the only exception. In serous membranes the filaments and lamellæ of soft lymph, after being highly injected, gradually shrink into thin transparent laminæ, until their redness and vascularity entirely disappear, and they assume the exact appearance of a portion of cellular or serous tissue; these new textures are found to be provided with blood-vessels, lymphatics, and nerves; and this affords a striking proof of the independent vitality existing in each particle of living matter. The preceding is the mode of formation of all cellular adhesions. As soon as the false membrane begins to be organized, it may become the seat of inflammation, exude on its surface soft organizable lymph, similar to that from which it has derived its origin, and undergo various transformations exactly in the same manner as any other tissue. It is evident, from what has been just stated, that the two opinions respecting the formation of false membranes may both be admitted; that there are first currents of blood traversing the coagulated lymph without vessels; that there are vessels formed independent of any communication with adjoining parts; and that some of these vessels finally anastomose with the vessels of the surrounding parts, so as to connect the circulation of the new tissue with that of the system. The period at which false membranes become vascular varies; numerous vessels have been seen on their surface twelve hours after their formation, and in other cases they have remained several months without presenting any trace of organization.

The alterations of structure produced by *chronic* inflammation in serous membranes differ from those of acute inflammation rather in degree than in kind; the transition, indeed, from the one stage of inflammation to the other is in general very gradual, and there are often intermediate and mixed cases, which it would be difficult to refer exclusively to either.

The redness is generally less, and inclines to a dark brown; the principal difference consists in

the increase of thickness and density of the membrane; the sub-serous cellular tissue, which is completely filled with albuminous fluid, has become so identified with the membrane on the one side, and portions of false membrane are often so firmly connected with its free surface, that when the membrane is raised, its thickness and density appear considerably augmented. We have preserved portions of arachnoid membrane, which had been long exposed to chronic inflammation, fully as thick as common parchment. There are sometimes patches of a pearly white, perfectly opaque, and of a greater thickness and firmness than the rest of the membrane.

One of the alterations peculiar to the chronic inflammation of serous membranes is a rough granulated appearance of their surface, well described by Gendrin; these granulations are but slightly raised, white, irregularly dispersed, imbedded in the substance of the membrane, and are sometimes intermixed with a number of brown dots: the granulated bodies are firm, and never soften down or suppurate. The surface of serous membranes is sometimes also studded with masses of tubercular matter, which may acquire a considerable size; these tubercles are developed either in the substance or on the surface of the membrane, but generally in connection with adventitious membranes, and sometimes become softened. Tubercles are much more common in peritonitis than in pleurisy.

The effused fluid is mostly of a yellowish or milky white, and has a peculiar and sometimes fetid smell; it may contain portions of a flaky albuminous substance, mixed with pus, or be altogether puriform, or, as in the majority of cases, consist of a clear serum. It has been sometimes found entirely gelatinous, resembling a solution of isinglass. The quantity of effusion is usually so considerable as to distend the cavity in which it is contained, and compress the adjoining organs, as is seen in empyema and chronic peritonitis.

There are generally found false membranes, always completely organized, and in some cases very thick, and of a firm, fibrous, cartilaginous, or even osseous texture; these adventitious membranes are sometimes disposed in layers of different textures and degrees of density; they give the serous membrane an appearance of great thickening, which has not unfrequently been a source of deception; but on closer inspection the membrane will be found, beneath the adventitious tissues, not very materially altered. In some cases numerous adhesions are found, with an infiltration of pus between them; and when this occurs in the thorax, its cavity may become contracted, especially if, as occasionally happens, the pus makes its way by a fistulous opening to the surface. The cavity lined by the serous membrane may also be completely obliterated by a mass of adventitious tissue of a dense, indurated, fibrous nature, or else spongy, cellular, and filled with an albumino-gelatinous matter: this adventitious tissue is sometimes separated from the serous membrane by a thin stratum of soft lymph, especially when death has been occasioned by an attack of acute inflammation.

These firm and completely organized adventitious textures always indicate the pre-existence of acute inflammation. When an acute attack has

supervened on chronic inflammation, the false membranes are found, as well as the serous membrane, of a vivid red, and covered with newly effused coagulable lymph or fresh pus, which are the products of the recent inflammatory action; Gendrin states that it is sometimes possible to ascertain when there has been more than one attack of acute inflammation, by the different degrees of organization of the newly-formed tissues. The fatal termination of chronic inflammation is to be attributed in the great majority of cases to the superintention of acute inflammation.

The serous membrane is sometimes found perfectly black, in consequence of the extravasation and infiltration of blood; this is the effect of an hemorrhagic congestion occurring in the course of chronic inflammation; besides the large spots of ecchymosis on the surface of the membrane, there is generally an effusion of blood into its cavity, which is mixed with the pus or serous fluid it already contained; these appearances could scarcely be mistaken for gangrene. Hemorrhage is not an unfrequent accompaniment of pleurisy, both acute and chronic; it is supposed to be occasionally the result of the rupture of some of the delicate vessels of the false membranes; the effusion is in general considerable, and causes the inflammation to become chronic. Laennec conceives that this mixture of blood and coagulable lymph favours the formation of fibrous and cartilaginous adventitious tissues, and states that he has observed in such cases a layer of dense membrane lining the costal and pulmonic pleura, and united by a third layer of a soft, gelatinous, semi-transparent substance.

Chronic inflammation has sometimes subsided, leaving the effusion behind it. This is rather a rare occurrence, as the effusion general disappears with the inflammation. There are, however, some instances of ascites and hydrothorax subsequent to peritonitis and pleurisy, and other cases, perhaps more numerous, of hydrocephalus succeeding chronic arachnitis in children. When the effusion has remained a considerable time, all traces of inflammation in the solids may have been removed. It should, however, be kept in mind that simple effusions are more generally the effect of active congestion than of acute inflammation. Chronic inflammation of serous membranes is often attended with swelling, induration, and suppuration of the neighbouring lymphatic ganglions.

There are no cases on record of the specific *gangrenous* inflammation of serous membranes. When affected with gangrene, it is always the consequence either of the violence of the inflammation of the membrane itself, or of the gangrene of adjacent tissues, such as, for instance, the bursting into the cavity of the pleura of a gangrenous abscess of the lung, and does not therefore require any separate description. The same may be said with respect to ulceration.

The Skin.—The two organic textures of the skin, the dermis and rete vasculosum, may be separately affected with inflammation. The rete vasculosum (or corpus mucosum) is sometimes the chief seat of the inflammation, as is exemplified in erysipelas, the exanthemata or eruptive fevers, and the scaly, vesicular, and papular cutaneous

eruptions. This will be described under the generic name of *erythemoid or diffuse inflammation*. The rete vasculosum and external surface of the dermis may be jointly inflamed, and an eruption of pustules or tubercles, often followed by ulceration, take place, as in variola, vaccinia, and other pustular and tubercular cutaneous diseases. This will constitute the division of *pustular inflammation*. Or the substance of the dermis itself may be the chief seat of the inflammation, which often extends in this case to the subcutaneous cellular tissue, of which furunculus, anthrax, &c., are examples. This will form a third division into *inflammation of the dermis*. We have followed in this respect the classification of Gendrin.

The inflammation, however, in each of these divisions is by no means always limited to the one texture, but, if very acute or of long duration, extends to the others, as might naturally be expected, considering the intimate connection existing between the different parts of the skin. Cutaneous affections often undergo in this manner great modifications in their appearances, one form of disease assuming in succession the characters of several others, or there being mixed cases; this will account for the great difficulty often experienced in assigning with accuracy every case to its proper class in the nosological arrangements of cutaneous affections.

Acute erythemoid inflammation comprehends the inflammation arising from blisters, burns, erysipelas, scarlatina, rubeola, &c.; it is almost always more or less diffused, and characterized in its commencement by a bright uniform fiery redness of the surface of the skin, called *rubefaction*; the exhalation being suspended, there is a dry burning heat, and also a very slight degree of tumefaction, perceptible only to the touch. If the inflammation increase, the epidermis becomes detached and raised, either in large bullæ and phlyctenæ, or small vesicles, by the effusion of a limpid yellowish serosity. When the epidermis is removed, the inflamed surface appears of a rosy tint, slightly yellow: it is covered with red streaks, is rather tense, and exquisitely painful; small drops of limpid serum are constantly exuding. If the inflammation subsides at this period, the redness, pain, and serous secretion diminish, and the surface becomes covered with a pellicle of soft plastic lymph, which is gradually converted into a new cuticle. When the inflammation has been violent and the epidermis detached, a thick layer of a white concrete viscid lymph is sometimes found under it, as is seen in burns and blisters.

When the inflammation ends in resolution, without phlyctenæ or vesicles, the epidermis often falls off in small furfuraceous scales, under which a layer of new epidermis of a shining bright or violet red has been formed, and which does not assume its natural colour until after some time, as is exemplified in rubeola and scarlatina.

If the inflammation, however, is intense and prolonged, there is poured out a reddish serum, which gradually becomes turbid, sero-purulent, and at last completely purulent. When suppuration is fully established, the inflamed surface is of a bright red, has a rugous or villous appearance, and portions of lymph are sometimes exuded

along with the pus. As the inflammation and suppuration diminish, the small granulations, which resemble those of common wounds, gradually become lined with a thin pellicle constituting the new epidermis.

Intense inflammation of the rete vasculosum extends frequently to the dermis and subjacent cellular tissue, as is seen in the erysipelas phlegmonodes and in severe burns; the skin is then tumefied and tense, and its redness does not disappear on pressure. The dermis and subjacent cellular tissue are injected with a red gelatinous fluid, and there are sometimes spots of ecchymosis or of extravasated blood on the surface. The inter-areolar adipose substance is absorbed: the texture of the dermis has lost its elasticity, is easily lacerated, and appears as if carnified. There is sometimes extensive suppuration and sloughing of the cellular tissue. These are the various appearances presented by the skin in erythemoid inflammation, from the slightest to the most intense erysipelas.

If the skin has been slightly inflamed just before death, every trace of inflammation disappears in a few hours after death. At a later period, however, Gendrin states that the portion of skin which was inflamed is found in a state of passive congestion, and the epidermis becomes sooner detached by putrefaction than in other places. But when the cutaneous inflammation has been at all severe, the rete vasculosum always continues much injected after death, and there is sometimes also a certain degree of sub-cutaneous œdema. A few days after death the injection and œdema are considerably increased by cadaveric congestion, which might lead to the belief that the inflammation had been much greater than it really was; this arises from acute inflammation increasing the tendency of the solids to putrefy, by lessening their force of cohesion.

The inflammation which gives origin to pustules (*pustular inflammation*), is of a phlegmonous character, each pustule bearing a considerable resemblance to a small phlegmon. They make their appearance first by small red dots, which increase gradually to round spots of a bright red, a little raised in the centre, giving a feeling of roughness or rugosity to the skin; the swelling of these spots goes on increasing until they form small, round, firm, red tumours, imbedded more or less deeply in the dermis, each tumour being surrounded by a red areola. The progress in the development of these pustules is very variable, being in some diseases fixed and regular. They differ also in their form, structure, and mode of termination. Some, as variola, are flattened, have several cells, and are depressed in the centre, the depressed part being attached to the dermis by one or several small white fibrous connections.

An eruption of acute pustules is also occasioned by the application of a variety of irritating substances, and particularly of tartar-emetic ointment and mercurial plasters: they are small, depressed in the centre, and have only one cell containing a little pus. Pustules may be either disposed in groups or irregularly scattered over the body: some varieties are acuminate instead of being depressed at their apex. Pustular diseases of a chronic character will be considered

under the head of *chronic pustular inflammation*.

Inflammation of the *dermis, corion, or cutis vera*, includes chiefly two varieties of disease—*furunculus* and *anthrax*: the dermis is undoubtedly the principal seat of the inflammation in these affections, although it extends in general more or less to the subjacent cellular tissue.

Furuncle commences with a pimple in the skin, which gradually increases until it forms a small tumour of a conical shape, with a pustule on its apex, and generally very hard; it is of a bright or dark red, accompanied with burning heat, and excessively painful. The vascular and cellular processes that fill the areolæ of the dermis appear to be the primary seats of this inflammation, which afterwards spreads to the surrounding parts; it terminates in suppuration, and in the expulsion of a small body called *core*, after which the little abscess heals in the usual manner.

Cores have generally been considered as portions of cellular tissue which have mortified, in consequence either of the violence or unhealthy character of the inflammation; and this appears the more probable, that a fetid and unhealthy pus is discharged from the abscess with them. Gendrin, however, is of opinion that cores are not sloughs, but a morbid secretion or pseudo-membrane, the product of the inflammation of the inter-areolar cellular processes. As they become enlarged, they distend the fibrous sides of the areolæ, creating great tension and a certain degree of strangulation; they act as foreign bodies in exciting considerable inflammation in the sides of the areolæ; these are at first in a state of red infiltration, and adhere firmly to the cores; but as suppuration advances, the latter are gradually loosened and finally expelled. Gendrin states that cores consist of a viscid semi-transparent homogeneous yellowish white substance, and that he has never been able to discover in them any vessels or the least appearance of organization. The opinion of so accurate a pathologist is entitled to considerable weight, and should not be rejected without further careful investigation of the subject.

There is considerable analogy between the anatomical characters of *anthrax* and *furuncle*; the former is, however, a much more extensive and severe disease; it occurs generally at a more advanced age, is connected with a vitiated state of the constitution, and sometimes with the existence of a morbid poison in the system, as, for example, in pestilential fevers. Gendrin considers anthrax to differ only from *furunculus* in the circumstance of a number of the areolæ of the skin being affected with inflammation instead of one, and he states that he has seen the portion of affected skin pierced in this manner with a great many holes. There is evidently, however, mortification of several portions of skin and cellular tissue, besides a new inflammatory deposit.

Anthrax commences, like furuncles, with a small pimple, which extends rapidly both in breadth and depth until it forms a large flat tumour, only a little raised above the surface of the skin, and extending under it into the cellular tissue; it is nearly immovable, very hard and painful, of an intensely burning heat, and of a deep but rather dark red; it feels like brawn, is dis-

tingly circumscribed, and its surface is covered with livid pustules or vesicles; as the disease advances, the skin mortifies in the centre and ulcerates at the circumference; a fetid unhealthy pus is discharged, and after a considerable time and much suffering a large slough is separated, consisting apparently of the union of several sores, and completely sodden with pus. When the slough is removed, there remains a large ulcer, which heals by a slow suppurative process.

There are three varieties of anthrax: one benign and mild; another malignant, having a greater disposition to mortification, of which the anthrax of the plague is a good instance; and one variety of a chronic character, similar to chronic furunculus. The lymphatic glands in scrofulous subjects sometimes undergo a sloughing inflammation called glandular anthrax.

We have examples of *chronic erythemoid inflammation* in chronic erysipelas, old blisters, and many of the scaly, papular, and vesicular cutaneous diseases, such as lepra, psoriasis, ichthyosis, lichen, prurigo, pemphigus, rupia, herpes, scabies, miliaria, and eczema. In those cases in which the epidermis is not raised into vesicles or bullæ, the surface of the skin is injected, of a dark red colour, not removed by pressure, dry, hard, rather thickened, and covered with a number of small red elevations like enlarged papillæ, which give it a rugous appearance; the epidermis falls off in scales which are frequently renewed, or it forms scabs, from which there sometimes oozes a viscid puriform fluid having a disagreeable smell. When these scales drop or are removed, they are generally succeeded by others.

The epidermis is raised in other cases into vesicles, phlyctenæ, or bullæ, containing a yellowish serum. The fluid of the vesicles may be resorbed, so that the detached epidermis forms a thin scale which falls off, as soon as a new epidermis has been formed; or the fluid concretes into a scab, which is also removed after the formation of a new epidermis. There is frequently a succession of new vesicles and scabs on the same part. The denuded skin under the phlyctenæ and vesicles is injected, red, and sometimes supplies a series of scabs without healing. When blisters have been long kept open, or when the chronic inflammation has been severe, as in psoriasis inveterata, the texture of the dermis is much altered; it is thickened and injected with a gelatinous fluid of a yellow red, has lost its elasticity and density, being easily torn, and entirely deprived of adipose substance; the subjacent cellular tissue is also more or less thickened and œdematous. When the surface has been long denuded and suppurating, it is covered with soft, flabby, bleeding granulations of a yellowish red colour, and sometimes with layers of whitish concrete lymph, which is removed with the dressings. In ichthyosis the epidermis is enormously thickened, and acquires the hardness of horn; and in the common elephantiasis the dermis and subjacent cellular tissue are sometimes converted by the infiltration of an albumino-gelatinous matter into a new texture, thick, dense, homogeneous, and very like brawn.

Chronic pustular inflammation includes the various forms of impetigo, porrigo, ecthyma, acne, and mentagra, to which we may add the different

kinds of tubercles into which the pustules frequently degenerate.

The pustules of these chronic cutaneous affections differ in their form, size, and situation; they are either large, acuminated, and with a hard and inflamed base, resembling in some cases small furunculi, as in ecthyma, impetigo, and acne; or they are small, round, granulated, and covered with thick scabs, as in porrigo; they may be dispersed over every region of the body, as in ecthyma and the impetigo sparsa, or be confined more particularly to certain parts, as in impetigo figurata, acne, and porrigo. Their first appearance is usually indicated by minute, red, itching spots, which are soon raised into small round tumours; they are at first hard, either red, or of the colour of the skin, imbedded in the rete vasculosum and generally also in the dermis; the rete vasculosum around them is deeply injected, and of a yellow red, and the injection extends in severe cases to the entire thickness of the dermis, and even to the subjacent cellular tissue.

The pustules quickly suppurate and then contain an opaque and viscid fluid, or thick pus of a peculiar and disagreeable smell, similar in porrigo to that arising from mice. The suppuration is followed by desiccation and the formation of scabs; these are either thick, prominent, conical, and of a green or brown colour, as in impetigo figurata; or yellow, concave, and cupped, as in the porrigo favosa; or disposed in flat, irregular, lamellated masses, as in porrigo larvalis and lupinosa. When the part is thickly studded with small pustules, as in porrigo, the whole of the intervening skin is inflamed, tumefied, red, and excoriated, secreting a thick, purulent matter, which, uniting with the crusts of the pustules, forms large masses of thick scabs; there are often intermediate fissures in the scabs, through which matter is constantly discharged. The inflammation is attended also sometimes with abscesses of the scalp. The sebaceous follicles are considered by some to be the principal seat of the inflammation in acne and mentagra, and the bulbs of the hair, in porrigo. Syphilitic pustules are characterized chiefly by their copper violet colour and great disposition to ulcerate; they are also sometimes depressed in the centre or flat, especially in children. A detailed account of pustular affections of the skin will be found in the separate articles on cutaneous diseases.

Tubercles are larger and less inflamed on their first appearance than pustules. Some never suppurate, remain indurated and have but little vascularity, such as the verrucæ and moluscæ. Others, after acquiring a certain size, become inflamed, suppurate, are covered with thick scabs, and finally degenerate into unhealthy ulcers, which is the course of syphilitic tubercles. There are also a variety of fleshy excrescences and vegetations of the skin which may be considered as modifications of tubercular inflammation; they occur frequently after syphilis, and sometimes in scrofulous subjects; but occasionally also as a mere local affection.

Phagedenic inflammation of the skin is of a peculiarly malignant character; it leads to the formation of unhealthy ulcers, which spread more or less rapidly, destroying, by a process of suppu-

ration and sloughing, the parts which they invade. It may affect almost every tissue of the body, but the skin is more subject to it than any other; it may supervene on other forms of inflammation, and sores of every description may assume a phagedenic character; this is more particularly the case with syphilitic and scrofulous ulcers, in which acute phagedenic inflammation is not unfrequently excited by the irritation of mercury. Phagedenic inflammation is sometimes idiopathic, especially in constitutions which have inherited either a scrofulous or syphilitic taint, or both.

There are two varieties of phagedenic ulcers, the *acute* and the *chronic*. In the *acute* the edges are swelled, inverted, jagged, and intensely red. The surface of the ulcer is of a fiery red, and discharges blood, accompanied with burning heat and extreme pain; it secretes a thin, sanious, acrid fluid. The acute phagedenic ulcer often spreads very rapidly, destroying the parts in some measure by a sloughing process. This form of phagedenic inflammation frequently occurs in scrofulous and syphilitic ulcers.

The *chronic* phagedenic inflammation of the skin commences generally by the development of small pustules, which soon degenerate into tubercles, the summits of which ulcerate; the edges of the ulcers are raised, indurated, of a violet red colour, less painful, and more circumscribed than in acute phagedena; the texture of the skin and subjacent cellular tissue is converted into a hard homogeneous substance resembling brawn; the bottom of the ulcer is of a dirty white, and covered with flabby granulations; the discharge is sero-purulent, fetid, and sometimes sanious. The secretion frequently concretes, forming thick hard scabs, under which the ulcer continues to extend; this form of phagedena spreads more slowly, but destroys with the same certainty as the acute; it enlarges chiefly at the circumference, while syphilitic ulcers have a greater tendency to extend in depth; it sometimes heals in the centre while spreading at the edges, and large soft vegetations arise occasionally from its surface; it varies in activity, being at one time indolent and at another more inflamed; the surrounding skin is often of a violet red, studded with hard tubercles or pustules of impetigo, and greatly predisposed to be affected with erysipelatous inflammation. After healing, these ulcers leave thick, red, and deeply furrowed cicatrices similar to those of burns.

The preceding form of phagedenic inflammation is principally observed in the formidable disease called lupus, and in the elephantiasis Græcorum.* There is a variety of phagedenic ulcer of the skin more superficial than the preceding, appearing in the form of tortuous lines or furrows, and called sometimes herpes serpens or exudens.

The skin is extremely liable to be affected with cancerous inflammation, cancer frequently having its origin in the skin, and spreading afterwards to the subjacent tissues; it commences by small pimples or pustules, which, after remaining for a greater or less interval of time hard and indolent,

assume the form of tubercles, become more inflamed, are affected with lancinating pains, and finally ulcerate; the ulcers are deep, have hard, jagged, indurated, inverted edges, with a pale red, sanious, soft, and fungous surface; they gradually extend in depth and circumference; the surrounding tissues are converted into a new homogeneous substance, intersected with white fibrous or fibro-cartilaginous bands, and presenting often small cells, containing a sanguineous or cerebriform softened matter. Cancer of the skin occurs most frequently on the nose, lips, cheeks, prepuce, scrotum, and at the margin of the anus. We must refer the reader for a more detailed account of the various forms of cancer to the article SCIRRHUS.

The skin is more subject to idiopathic gangrenous inflammation than any other part, because it is most exposed to the direct action of deleterious agents, and it is also the principal seat of critical and symptomatic inflammations.

One of the frequent causes of gangrenous inflammation of the skin is poisoned wounds. The first effect that follows the introduction of any venomous matter into the skin, is the appearance of a small vesicle, attended with much itching; the skin under the vesicle is hard, and of a livid red around it; the hard tubercle in the centre, which is mostly insensible, soon assumes a black colour; the red areola spreads, the skin becomes tumefied, more livid, and covered with small phlyctenæ; the black gangrenous eschar extends rapidly from the centre to the circumference; the swelling of the skin and cellular tissue increases with considerable œdema and sometimes emphysema; the gangrene extends also in depth to the subjacent cellular tissue, and reaches frequently the tendons and bones, causing extensive sloughing. The constitution soon begins to suffer, and gangrenous erysipelas appears in several other parts of the body. We have already seen, however, when describing the constitutional symptoms, that the patient sometimes sinks from the destructive influence of the poison on the system, without any local affection.

In some very unhealthy constitutions, erysipelas occasionally assumes a gangrenous character from its first appearance; the inflammation is deficient in activity, and attended with considerable œdema the skin is of a livid or dark red, covered with a number of phlyctenæ, beneath which are observed black livid spots; the portions of skin thus affected soon mortify, and the gangrene spreads with rapidity, creating large sloughs both of the skin and cellular tissue. In some cases small ulcers appear on the surface, or collections of matter are formed in the cellular tissue, destructive suppuration being thus added to the gangrene.

The skin may also be affected with gangrene in consequence of the intensity of the inflammation, or from the direct action of irritants, such as intense heat, chemical agents, &c.: or finally from the benumbing effects of excessive cold.

A. C.

Inflammation of Mucous Membranes.—Previous to entering upon the description of the inflammatory affection of mucous membranes, we think it necessary to describe the healthy structure of these tissues.

* An interesting account of two cases of the true elephantiasis that occurred in this country is given in the Medico-Chirurgical Transactions for 1815, by Mr. Lawrence and Dr. Southey.

In the greatest part of its extent, mucous membrane consists of a spongy tissue, more or less soft, and varying very much in thickness: this is the mucous corion, on the surface of which the ultimate vascular ramifications of it are found. An epidermis or epithelium is very distinctly seen on this corion in some situations, that is, at the orifices of mucous cavities. It diminishes in thickness as we trace it from the origin of the mucous membranes, till in the more internal parts it eludes our observation; in fact the existence of the epithelium in the internal mucous membranes cannot be demonstrated.

Mucous membrane is especially remarkable for a series of mucous crypts or follicles, which are uniformly to be met with, varying, however, in number and arrangement in the different situations. An examination of the foramen cæcum at the base of the tongue and of the tonsillitic follicles will clearly expose their structure. In the gastro-intestinal mucous membranes they are found in great numbers, and under two different modes of arrangement: in the one case they are isolated and distinct from each other, (*glandulæ solitariae*), under which form they are chiefly met with in the large intestine; in the other they are deposited in clusters, (*glandulæ aggregatae*), and are to be seen chiefly in the small intestine, in the duodenum, and the colic extremity of the ileum.

Two varieties of eminences are found upon the free surfaces of mucous membranes; of these the most voluminous are called *papillæ*, of which the best-marked examples are on the tongue, glans penis, and clitoris. In parts provided with *papillæ*, the mucous membrane is furnished with a distinct epithelium.

The second class of eminences are the *villi* or *villosities*, which are found most prominent on the gastro-intestinal membrane. They are highly vascular, and the recent observations of Leuret, Lassaigue, and others, leave no doubt that in them the capillary extremities of the lacteals commence. They appear, therefore, from this fact, as well as from other considerations, to be materially connected with the absorbing function. The pathologist should bear in mind that these minute bodies may be injected with equal facility either from the arteries or mesenteric veins, which latter, being destitute of valves, permit the injected fluid to pass in a retrograde direction.

The healthy colour of those portions of the mucous system which are near to the orifices, is so obvious to the most superficial observer as to render any remarks upon it unnecessary. The natural colour of the more deep-seated portion varies in infancy, adolescence, and old age. At the former, it is transparent or of a rosy white colour; at the latter age, it is of a dull white, but retains a slight rosy hue; in old age, it becomes ash-coloured. The process of digestion increases the rosy colour of the membrane, and sometimes, especially with young subjects, induces a cherry red colour, obviously by increasing the flow of blood to it. Gendrin has found that fasting for any length of time also has the effect of heightening the colour of the membrane, which may be removed by nourishing the animal.

That the kind of death, moreover, has considerable influence upon the colour of the membrane

is obvious, as in cases of death from chronic disease, from anæmia, and from asphyxia. Lastly, Gendrin found the mucous membrane increased in colour during the traumatic fever succeeding to a severe wound inflicted on an animal.

1. *Acute Erythemoid or Diffuse Inflammation.*

—A change of colour is the most prominent mark of inflamed mucous membrane, occasioned by an increased vascular injection of those portions of the membrane to which irritation has been applied. This change of colour varies in extent and intensity, the membrane exhibiting either slight and superficial arborescent networks of an arterial red colour, or uniform spots, either red, brown, or black, and occupying the whole substance of the membrane.

The many varieties of vascular injection which mucous membrane in general, but that of the alimentary canal especially, presents, render it a matter of moment to determine, with as much precision as possible, those signs which characterize the vascularity of inflammation. Pressure diminishes the natural redness, or that of congestion, but does not produce that effect on the colour of an inflamed part. If the inflammation have existed for even a short time, maceration does not cause the redness totally to disappear, and those who are in the habit of making morbid preparations know how well the inflamed membrane exhibits its vascularity when dried and varnished, as if the inflammation had excited a greater degree of cohesion between the blood and the coats of its containing vessels.

In the highest degree of inflammatory action, we not unfrequently find spots of extravasation, the submucous tissue being injected with blood, which either has escaped from the rupture of a minute capillary, or transuded through the parietes of the vessels. In those membranes which present numerous villi on their surfaces, inflammation begins by red points or dots, which appear to occupy the extremities of the villi, giving them a tumid erectile appearance. This condition of the membrane may be clearly demonstrated by examining it under water, or with the aid of a lens, or even by viewing its surface in an oblique direction. As the inflammation advances, the number of points increase, appear to coalesce, and give an aspect of diffused redness to the surface of the membrane. When the colour of the mucous tissue is naturally red, the increased colour is uniform, nor is there an obvious appearance of arborescent or capilliform injection.

The surface of inflamed mucous membrane loses much of its natural softness; it is rugous, and if it be covered with *papillæ*, these bodies are rendered more prominent and swollen than natural; if with villi, a similar effect is produced; if crypts abound on the surface, the orifices of these secretory organs are less apparent, from the swollen condition of their margins.

Increase of the thickness of the membrane is a constant attendant on inflammation, as is well seen in coryza and laryngeal inflammation; it is in general immediately consequent on the redness, and in proportion to the degree of vascularity. At an early period of the attack, the density of the membrane appears to be also increased, but as the inflammation advances, the membrane becomes

softened. The condition of the submucous tissue is deserving of attention; it is frequently infiltrated with a serous, or occasionally a bloody fluid, by which the thickness of the membrane is increased: this is more conspicuous when there are folds, such as the *valvulae conniventes*.

A particular affection to which some mucous membranes are more especially liable may be here alluded to; it is, as Gendrin has well observed, intermediate between inflammation and œdema, and is distinguished by the term *œdematous*, on account of its principal characteristic being extreme infiltration of the substance of the mucous membrane, as well as of its submucous tissue, with serum. Of this, œdema of the glottis, and the œdematous condition so often seen in the velum and uvula, present familiar examples. The adhesion of the mucous membrane to the surfaces which they line is diminished considerably by inflammation, so that they are detached from them with facility—a facility, however, which varies according to the natural thickness of the membrane, and the structure of the connecting cellular tissue.

At the first invasion of the inflammation, the secretion of the membrane is somewhat increased in quantity and less viscid than natural; when the inflammation is at its height, the secretion is almost suppressed, and the membrane consequently dry; but as this period is always of short duration, the secretion is soon re-established, and often discharged in considerable quantity, assuming at times a greenish colour, and being occasionally tinged with blood. The orifices of the follicles are generally enlarged and open. Towards its decline, the secretion sometimes assumes a puriform character, and is in general very copious; this has been long known in the schools as exemplifying purulent secretion without solution of continuity.

Acute inflammation of mucous membrane sometimes terminates rapidly in gangrene, giving rise to the formation of large sloughs, which, when thrown off, leaves a considerable solution of continuity. Such is the case in certain inflammations of the throat, (*cynanche maligna*), and in some severe forms of dysentery; in which disease the mucous coat of the large intestine often presents several patches of this kind.

The action of some acrid poisons excites in mucous membrane a high degree of inflammatory action, of which, universal tumefaction of the membrane, and sometimes black or livid spots, produced by the infiltration of the subjacent tissue with dark blood, are the unequivocal signs.

Such are the appearances which characterize erythemoid inflammation of mucous membranes: all are of great value, in deciding the question as to the existence of inflammatory action, a point in the determination of which great caution should ever be observed.

The anatomical characters of chronic inflammation of mucous membranes differ in some essential particulars from the acute, the appearances varying according to the stage and duration of the inflammation. It occurs in patches or stripes, the intervening portion of the membrane preserving its natural pale colour. In the more recent cases, the colour is of a dusky red, inclining to a ma-

hogany tint: the substance of the membrane is thickened and increased in density, the mucous follicles are slightly enlarged, and the secretions are copious, viscid, ropy, or puriform, as in chronic ophthalmia, bronchitis, gonorrhœa, or catarrh of the bladder. When the inflammation has been of longer duration, the dusky redness of the former stage passes into an ash-grey colour, interspersed with black spots or streaks, which gives the membrane a dark mottled appearance. The thickening also not only disappears, but the membrane becomes even thinner than natural, and sometimes considerably softened; this softness, when combined with serous infiltration of the submucous cellular tissue, is the cause of the mucous being so easily detached from the muscular coat, and gives the internal surface of the membrane an œdematous appearance. In cases of inflammation of the mucous membrane of long standing, this tissue is sometimes still more altered in structure; it becomes hypertrophied and indurated; its colour changes to a grey white; its surface appears rugous and granular; and, finally, effusion of an albuminous matter, between all the coats of the intestine at the points of disease, obliterates the structure so entirely, as scarcely to leave any traces of its original configuration. Vegetations resembling warts are also in those latter instances not unfrequently found on the mucous surface. These appearances, which affect exclusively villous membranes, may be often observed in cases of chronic dysentery.

2. *Pseudo-membranous Inflammation*.—Mucous as well as villous membranes, when acutely inflamed, effuse a concrete fluid, which, neither in appearance nor in chemical properties, can be distinguished from that which is formed by serous membranes.

It has been affirmed by Bichat and others that mucous membranes do not effuse lymph or contract adhesions. On this subject Dr. Craigie observes that the question of adhesion depends not so much upon the fact of albuminous exudation as upon the anatomical disposition of the cavity or canal, whether it be sufficiently small to favour the approximation of opposite and corresponding surfaces. Thus in the gastro-intestinal mucous membrane, which is in general capacious and distended either incessantly or frequently with foreign bodies, mutual approximation is too imperfect to admit of adhesion. Yet by some observers this is asserted to have happened. In situations, on the contrary, in which mucous surfaces line narrow tubes, as the lachrymal duct, the Eustachian tube, the urethra, and perhaps the Fallopian tubes, obliteration of the canal by adhesion of its sides is more frequent.

It is certain that the surgeon has not unfrequently occasion to observe corresponding points of narrow canal, as the urethra, adhering apparently by concretion of its sides. Dr. Craigie concludes from these facts that the assertion of Bichat, of the inaptitude of mucous surfaces to adhere, requires some limitation; and from other facts, he is disposed to infer that one of the conditions necessary to the albuminous exudation and the subsequent concretion of mutual surfaces, consists in the destruction of the mucous epidermis by abrasion or ulceration.

These false membranes adhere in some instances to the mucous surface by which they are effused, and often form an exact mould of the cavity or canal in which they occur: they are of a much softer texture than the false membranes which exude on inflamed serous surfaces, and have no trace of organization. When this membraniform exudation succeeds to acute inflammation of the mucous membrane of the mouth and pharynx, it constitutes that disease which Bretonneau describes under the name *Diphtheritis*, which first appears in the form of small points or streaks of redness of the mucous membrane, but without much swelling; this is succeeded by the exudation of isolated white spots, chiefly on the follicles at first, which gradually increase in number, and cohere in patches, occupying a more or less considerable portion of the surface of the uvula, tonsils, and posterior pharynx. These membranous formations, when detached, vary in thickness, but are generally white and transparent; when they are of an ash-grey colour, this arises from their being tinged with blood. This colour, and their being often accompanied with fetor, render them liable to be mistaken for gangrenous sloughing of the mucous membrane of the throat. They may be confined to the mouth and pharynx, or they may extend and dip into the larynx, œsophagus, nasal fossæ, or Eustachian tube, and when they are thrown off, are in some cases renewed several times. Andral met with a case of inflammation of the pharynx with membranous exudation on the palate and tonsils. The inflammation spread to the larynx, and destroyed the individual. On opening the body, false membranes were found not only in the larynx, trachea, and bronchial tubes, but on the inner surface of the nostrils and around the ethmoid cells. The inflammation in this case had thus spread from the pharynx to the vocal and respiratory organs, and into the cavity of the nose. (Arch. Med. 1825.)

The air-passages are more frequently covered with false membranes than any other mucous surface; and it may be observed that children are more subject to affections of the mucous membrane of the air-passages—the formation of false membranes is consequently more common at this than at other periods of life. When they form in the air-passages, they vary in thickness and consistence; some are transparent, and of extreme delicacy; others are several lines in thickness, and so consistent, that they can not only be removed entire, but afterwards preserve their moulded form. A viscid fluid is interposed between the inflamed surface and the false membrane, by which their adhesion is prevented: in some instances minute filaments have been observed in these exudations, by which it has become united to the surface on which it has formed.

We have already mentioned that the membrane which is formed in diphtheritis sometimes dips into the upper part of the larynx. Inflammation of the mucous membrane of the larynx is, however, seldom followed by membranous exudation, but generally, when intense, the inflamed membrane is covered with thick viscid or semi-puriform fluid, which is most abundant in the sacculi of the larynx. Minute portions of fibrine may be occasionally effused, and give a greater degree of con-

sistence to the exudation. The pathology of these cases is, however, very different from that of laryngitis, in which the inflammation is seated in the submucous cellular tissue by which the mucous membrane is united to the cartilages of the larynx.

In tracheitis, or croup, the inflammation is followed by the rapid exudation of a tenacious membranous substance, which is moulded to the form of the trachea. This false membrane is generally limited to the trachea and of a tough consistence; when it extends to the bronchia it is much softer, and in the smaller bronchial tubes it becomes quite fluid. The impediment to the respiration in croup is to be attributed in a great measure to the presence of these false membranes, but also to the swelling of the tracheal membrane, and to the bronchitis which very often accompanies the disease. The spasmodic affection of the muscles of the larynx, which occasionally accompanies croup, adds much to the sufferings and danger of the patient: when the disease proves fatal, the death is owing to the mechanical obstruction of the air in the trachea and bronchial tubes by the false membranes.

The formation of false membranes is also a consequence of inflammation of the gastro-intestinal mucous membrane; and, as noticed by Andral, it occurs more frequently in its supra-diaphragmatic than its infra-diaphragmatic portion. In children, the mouth, pharynx, and œsophagus are occasionally lined with a membraniform exudation, which terminates abruptly before it reaches the stomach. After puberty, these formations are equally uncommon, either on the internal surface of the stomach or intestines, Andral having never seen any either in the stomach or small intestines, and in only two instances had he observed false membrane lining the large intestine. Cases, however, of this kind have been observed in adults. We lately attended a female who frequently voided a considerable quantity of false membranes from the bowels. They appeared, from their size and form, to have been effused on the mucous surface of the small intestines, and evidently, from the history of symptoms, were the result of chronic gastro-enteritis. The disease disappeared after repeated local detractions of blood from the surface of the abdomen, counter-irritation, and a bland diet.

Andral mentions a remarkable case of a young girl of twelve years of age, in whom all the air-passages were lined with false membranes; they were found also in the pharynx, œsophagus, and stomach, where they existed in the form of large bands, extending from the cardiac to the pyloric orifice, beyond which point they did not reach. The mucous membrane was much more red beneath than in their intervals.

Pathological writers allude to the discharge of portions of the mucous coat of the bladder. There can be little question, we presume, that these morbid products are false membranes which have formed on the internal membrane of the bladder, and after being detached, have been expelled with the urine. The urethral mucous membrane appears to assume the puriform secretion rather than exudation of lymph. The inflammation frequently extends to the submucous cellular tissue, and by

infiltration and thickening of this structure, contraction or stricture is induced.

False membranes occasionally form in the cavity of the uterus, in consequence of an irritated or inflamed state of the uterine mucous membrane. These membranes are sometimes thrown off in detached shreds after painful menstruation, or at irregular periods, when the internal surface of the uterus is inflamed. In some instances they bear the exact mould of the cavity of the uterus, and have such a degree of consistence as to admit of manual examination and even preservation in alcohol. Sterility is a common effect of these false membranes of the uterus.

3. *Pustular Inflammation* has its seat chiefly, if not entirely, in the mucous crypts or follicles. We not unfrequently meet with a simple enlargement of these glandular organs (glandular so far as they are connected with a secreting function), in certain forms of fever, as well as in other anomalous affections. When acute inflammation attacks one of these follicles, it becomes enlarged, swollen, and vascular. The mucous membrane and subjacent tissue soon exhibit marks of the inflammatory action; and when the membrane is villous, the villi are red and increased in size. A pustule is formed, round and prominent, more or less acuminate; and if a set of aggregated follicles become inflamed, the pustule is more flattened, and has a larger circumference. Frequently we find on the apex of these bodies a minute orifice, indicated by a dark spot, through which by pressure we soon squeeze out a mucous or puriform fluid, whilst in others we cannot observe any trace of an orifice.

The pustules of mucous membranes which we have most frequently an opportunity of examining, are those more especially seen in the membrane of the mouth and pharynx. They are usually known under the name of aphthæ, and are essentially the same in their mode of origin, as those which are developed on the deeper-seated membranes.

The pustules on the inner surface of the intestinal tube often appear in a form nearly resembling that of the variolous pustule. The occurrence of these intestinal pustules in connection with fever has been minutely noticed by Ræderer and Wagler in their history of the Gottingen epidemic, and afterwards by Petit, Pinel, and others. They have been supposed to coexist frequently with the cutaneous eruption of small-pox; and we may add, that although this is not a very frequent occurrence, yet a sufficient number of cases are on record to establish the fact.

We may, however, state that the possibility of the existence of pustules on a membrane devoid of an epithelion has been called in question. But if it be considered how numerous are the mucous crypts, and that in general, if not always, the pustule (so called) is found to occupy one or more of these, we can have no difficulty in accounting for its formation. In some instances, the apex of the pustule presenting a minute opening, in others that opening being closed by adventitious membrane, the follicular pustules of mucous membranes may be said to correspond in every respect with the pustules of the follicles and sebaceous glands of the skin, as exemplified in acne, mentagra,

porrigo, and some varieties of impetigo. The analogy between the pustules that occur on membranes provided with epithelion and those of the skin is sufficiently obvious.

It may be mentioned that the most constant and frequent locality of pustular inflammation in the intestinal canal is about the cæcal half of the ileum. This is the form of disease described by Bretonneau under the appellation *Dothineria*. (See FEVER.)

4. *Ulcerative Inflammation*. After a pustule is fully formed, its centre soon becomes depressed, and it loses its conical form. In some cases, this depression is owing to an enlargement of the orifice of the follicle, but more frequently it is produced by an incipient ulcer. The increase of this depression, and the gradual disappearance of the pustule, indicate the progress of the ulcerative process; finally, a circular ulcer, or when several follicular ulcers cohere, a patch of ulceration occupies the site of the original pustule. This is the most frequent commencement of ulcers of mucous membranes: their numerous variations of form, extent, and depth, are dependent on the intensity of the inflammation, and the extent to which the neighbouring tissues are involved. Ulceration of a mucous surface does not always originate in the follicles: it is sometimes the result of acute inflammation of both mucous and villous tissue; or of small sloughs, or even of an inflamed or diseased condition of a subjacent tissue; as, for instance, when a tubercular deposit in that tissue acts as a source of irritation to the mucous membrane.

Andral reduces the forms of those ulcers which are met with in the intestinal canal, to the following:—1. The circular form, remarkable for their great regularity. 2. The oval form, particularly noticed in the ulcerations of Peyer's glands. 3. The linear form, the ulcer appearing as a groove or fissure. 4. The irregular form, the margin being jagged. This latter form occurs most frequently.

Ulcers of mucous membranes, when considered as to their depth, or as to the nature of their surface, present many varieties, from simple erosion to the complete destruction of the mucous tissue. Thus, in some there is merely so much of the surface of the membrane eroded as to prove the existence of a solution of continuity: if the membrane be covered with epithelion, it is also removed by the ulcerative process: if it be a villous membrane, the villi are likewise destroyed. This form is the result of an inflammation of slight extent. It is more frequent in its occurrence than is generally thought, as from its superficial nature it is very apt to be overlooked. The floor of the ulcer may be formed by the mucous corion as above described; but when the ulceration is deeper, so as to destroy the corion, the submucous tissue is the foundation of the ulcer, which varies in colour, consistence, or thickness. Sometimes the muscular tissue forms the bottom of the ulcer: this state is met with in fever and in some severe forms of dysentery; not only is the superincumbent tissue removed in these cases, but that which passed in between the fibres of the muscles is, as it were, dissected out. The muscular tissue being destroyed, the bottom of the ulcer is formed by the

serous coat of the intestine. These cases often terminate in perforation of the intestine, whether by rupture of the delicate serous membrane, or by an extension of the destructive process to it. The probability of the occurrence of perforation depends, not on the extent or long duration of the ulcer, but on the rapidity with which it burrows.

The possibility of the cicatrization of ulcers of mucous membranes has been disputed: recent observations have, however, fully attested the fact of their cicatrizing. The case of the late Professor Beclard, so well known by reason of the celebrity of the distinguished individual who was the subject of it, would alone prove the fact. This able anatomist, at one period of his life, laboured under marked symptoms of gastric inflammation, which yielded to an active treatment and rigid regimen. Some years after, upon the occurrence of his death from a totally different affection, a distinct cicatrix was found in the small curvature of the stomach. Besides this well-authenticated case, the testimony of Troillet, Louis, and other pathologists, leaves no longer any doubt on this subject.

The gastro-intestinal mucous membrane is by far the most frequent seat of ulceration. Next in point of frequency are the bucco-pharyngeal and laryngeal membranes; while the bronchial and urino-genital portions rarely exhibit ulceration.

Nervous Tissue. Acute inflammation of the brain is comparatively rare as an idiopathic disease, but is often the result of external violence, in which case it is generally partial or circumscribed. Examples of general cerebritis are not uncommon as one of the complications of fever; on examination the brain presents general vascularity, but the congestion is greater in the arteries than in the veins; when the blood is accumulated chiefly in the veins and sinuses, it indicates that the lesion partakes more of the character of venous congestion than of inflammation.

On cutting into a portion of inflamed brain, numerous red spots appear, the blood oozing from small vessels, which in the healthy state convey only the colourless part of the blood. The cerebral pulp is at the same time infiltrated with minute effusions, or spots of blood, which give it a striated, or when the spots are numerous, a marbled appearance; and when in still greater numbers, they form small coagula. These bloody effusions, which may occupy a considerable part of one hemisphere, or only a small portion of the brain, extend more or less in breadth, and give rise to the various shades of redness observed in the section of a portion of inflamed brain, the grey or cortical substance assuming, when inflamed, a dark red or brownish colour, and the medullary a light rose tint.

The highest degree of inflammation which is compatible with the organization of the cerebral tissue is never general, but confined to portions of the brain of various extent, around which the tissue presents the characters of inflammation in a more moderate degree. These inflamed portions, which acquire a certain degree of firmness and elasticity, are not exactly circumscribed, but are continued and blended with the surrounding tissue, the traces of inflammation being gradually lost in the healthy structure. In subacute or

chronic inflammation of the brain, the anatomical appearances are much the same as in the acute, but its duration gives rise to important modifications. The redness soon changes to a crimson, purple, or light brown tint; this change of colour is followed by a diminution in the consistence of the inflamed structure, varying according to the duration of the inflammation, from slight though evident softness of the cerebral tissue to pulpiness, or even semi-fluidity. At the utmost limits of moderate inflammation, a slight though evident softness (*ramollissement*) may be remarked, and only recognised by comparing the softened with the healthy portions of the brain. This incipient stage of softening, which we have repeatedly observed in continued fever, is ascribed by some writers to the infiltration of the inflamed tissue with serous fluid, a supposition rendered extremely probable from the circumstance of the portion of the pia mater which invests the softened pulp being at the same time infiltrated with serum. When the inflammatory action has been still more intense, the structure of the brain is not only softened, but disorganized and infiltrated either with blood or pus. When blood is diffused in the disorganized pulp, it constitutes the *red* softening, in contradistinction to that form in which globules of pus are mixed with the broken-down cerebral mass, which, from the colour it acquires, is termed *yellow* softening of the brain.

The red and yellow softening are sometimes combined in the same morbid mass; blood, pus, and brain being thus blended together, and giving the cerebral tissue a dirty grey appearance, the shade varying according to the proportion in which they are mixed.

There is another kind of softening which, though analogous, differs in many respects from either of the preceding—the *white* softening, in which the cerebral pulp is disorganized and infiltrated with serous fluid. It occurs chiefly in isolated parts of the medullary substance, very often in the corpus callosum, fornix, and septum lucidum. The diseased portions are usually of a pure white colour; but when the cortical substance is affected, it inclines more to a yellow or grey tint. This form of softening is often observed in elderly subjects, and is generally accompanied with serous effusion in other parts of the brain: it is also believed by some pathologists to form one variety of hydrocephalic disease.

Softening of the brain occurs more frequently in the cineritious than in the medullary part, the cineritious substance being from its great vascularity predisposed to inflammation: of the central parts of the brain, it is found more frequently in the septum lucidum, corpora striata, optic thalami, central part of the hemispheres, cerebellum and crura cerebri, and, according to Dr. Craigie, in the order now enumerated.

There is another alteration of the brain consequent on inflammation—infiltration of the cerebral tissues with pus, which is in some instances diffused in drops through its substance; in others the purulent fluid is confined in distinct cavities of various sizes, the boundary being formed either by the substance of the brain itself, (*undefined cerebral abscess*), or by an organized cyst (*encysted cerebral abscess*).

Though suppuration may take place in any part of the brain, purulent collections are more frequently met with in the hemispheres. They are occasionally the result of acute, but more generally of chronic cerebral inflammation; their progress is slow, and the symptoms, which are always very obscure, vary according to their extent and situation.

Abscesses have been found in the cerebellum by various pathologists, the pus being generally confined in an organized cyst.

Induration has been mentioned as an effect of cerebritis, though some authors deny that it is the result of inflammation or of capillary injection. The fact, however, of its being accompanied with injection of the capillaries, and that the symptoms during life were those observed in chronic inflammation of the brain, are strong presumptive evidence of its inflammatory origin. The induration, which may be general or circumscribed, varies from the consistence of wax to that of cartilage.

Ulceration has been stated to be one of the terminations of inflammation of the brain, and without asserting that this lesion never occurs in the brain, we are inclined to think that some of the older authors have described *softening* as ulceration of this organ. In the cases which bear the greatest analogy to erosion, the ulcerative process appears to have commenced at the convolutions, and to have been connected with circumscribed inflammation of the pia mater.

Gangrene of the brain is very uncommon. It is described by Baillie (*Morbid Anatomy*), who states that portions of the brain occasionally become gangrenous after violent injuries of the head, but that it is extremely rare when the inflammation arises from any other cause. He mentions one case which had fallen under his observation, in which the mortified part of the brain was of a very dark brown colour, and as soft as the most rotten pear. A similar case, succeeding to injury of the head, is given by Saure, (*Mem. de l'Acad. de Chir.* tome i.), in which the substance of the brain was black and gangrenous to the depth of three fingers' breadth.

The spinal marrow being similar in structure to the brain, is consequently liable to the same morbid changes; our knowledge of its lesions, however, is more incomplete, less attention having hitherto been paid to their investigation. The various morbid changes which have been described by pathologists originate in inflammation either of the membrane or substance of the cord; indeed, though the spinal marrow is enveloped with the same coverings as the brain, inflammation is seldom confined to either the membranes or the substance of the cord, but appears to affect both the one and the other at the same time. Those cases, which have been detailed as examples of meningitis of the cord by Abercrombie and other writers, confirm this observation.

In inflammation of the spinal marrow, the membranes and substance of the cord are much injected. The inflammatory action is soon followed by softening of the spinal marrow for a greater or less extent; sometimes the softening is limited to a very small portion: in other cases it extends throughout the greater part of the cord. Blood is sometimes mixed with these softened

portions, constituting red softening; and when pus is intermixed, it gives rise to yellow softening. In some instances, the spinal canal contains a quantity of serous fluid, or a layer of puriform fluid is occasionally spread on the membranes, the pus being occasionally mixed with blood, but without apparent softening of the cord. These cases constitute undefined suppuration or abscess of the cord.

The tissue of nervous cords and their minute filaments becomes occasionally inflamed, and gives rise to a variety of acutely painful sensations. This affection may have a spontaneous origin, but it is more frequently produced by punctured, lacerated, or contused wounds, or by the application of a ligature, as in the common accident of including a nervous twig in tying a blood-vessel for the suppression of hemorrhage or the cure of aneurism. In these cases it is supposed that inflammation is produced in the neurilemma or covering of the nerve, which becomes vascular, indurated, and painful. We have an example of spontaneous neuralgia or nerve-ach in sciatica, in tic douloureux, and neuralgia of the median nerve in the arm, and posterior tibial nerve in the leg. These neuralgic affections may also arise from external violence applied in the vicinity of their origin, and of those parts in which they ramify.

Inflammation of nervous tissue may terminate in resolution, in effusion of lymph around the nerve, in ulceration, and in enlargement of the nerve from deposition of new matter. This latter state sometimes succeeds to amputation; the extremities of the nerves become inflamed, and finally much enlarged and indurated—the consequences of chronic inflammation of their neurilemma.

Vascular System. Notwithstanding the important share the blood-vessels have in the pathology of inflammation, they are not themselves very often the subject of this action. There is still much difference of opinion among pathologists as to the precise anatomical appearances which should be considered as indicating inflammation of blood-vessels, some attaching no importance to changes in colour and consistence, which others deem important lesions and the cause of many serious diseases.

The following are, however, the characters of acute inflammation of a large blood-vessel: redness, rugosity, thickening and softening of its internal membrane, the coagulated blood adhering to it either immediately, or through the intervention of a layer of effused lymph: the middle and outer coats are also injected, thickened, and lacerable, and the consistence of the vessel is so much diminished that it is very easily torn.

1. *Inflammation of Arteries.* Though arteritis was considered by Laennec a very rare disease, subsequent investigations have proved that it is not altogether so uncommon as this celebrated pathologist was inclined to believe. The larger arterial trunks have been found more frequently inflamed than the smaller branches; indeed, from the silence of authors on the subject of inflammation in the smaller arteries, it may be concluded that it very seldom occurs.

Arteritis may be either acute or chronic. In acute arteritis the internal membrane is of a bright

red colour, and evidently swollen. It is sometimes difficult to determine, whether the redness in the internal membrane of the heart and the larger arteries arises from inflammation, or is the effect of imbibition or staining. When the redness is not accompanied with vascular injection, tumefaction, and alteration of tissue, more particularly when it is circumscribed and terminates abruptly, or appears in patches, it is to be ascribed to imbibition from contact with the blood contained in the artery. When the redness arises from inflammation, the membrane loses its polished and glistening appearance, has a villous aspect, and is easily detached from the other coats. The vasa vasorum also become more numerous and injected, and although it is often difficult to recognise these vessels in the centre of an inflamed membrane, they become clearly developed at its limits. The redness of inflammation differs also from that of imbibition in presenting various tints in the different coats, whereas inflammatory redness preserves the same colour in all. It is, therefore, now agreed that redness of the internal membrane of the heart and arteries, unaccompanied by any other anatomical characters of inflammation, cannot be deemed evidence of arteritis. In inflammation of arteries the redness is accompanied with thickening and swelling of the inner membrane, effusion of lymph either on its free or adherent surface, and increased vascularity with softening of the middle coat, so that the internal and middle tunics present all the ordinary characters of adhesive inflammation. In genuine arteritis, too, the coats are easily detached from each other, and some writers have observed, in intense cases of arterial inflammation, purulent effusion or infiltration between the coats, but more frequently purulent exhalation from the surface of the internal membrane.

Chronic arteritis is also chiefly confined to the larger arteries, being seldom if ever met with in the smaller arterial tubes. The chief feature of chronic inflammation of the inner membrane of the heart and arteries is redness, but even in recent cases it is more deep than in acute arteritis. When the disease is of long standing, the membrane becomes of a dusky red or brown shade, rugous, and generally softened. These appearances are more remarkable in the vicinity of calcareous, bony, and other morbid deposits, from which circumstance many pathologists have concluded that chronic inflammation is the original source of these organic lesions in arteries. Without attempting to deny the possibility of this origin of these deposits in inflammation, we may remark that their primary formation is not in the inner membrane, but either in the middle coat or in the delicate cellular tissue, which connects the middle to the inner tunic, and that this coat can often be detached from these deposits. Besides, in endeavouring to come to a correct conclusion on this subject, it is to be kept in mind that these various morbid alterations in the arterial coats, whether steatomatous, cartilaginous, calcareous, or bony, form in detached points remote from each other, and without any appearances which indicate the previous existence of inflammatory action. Laennec states that though we know not the nature of the derangement of the economy that produces an ossification or a cancer, it is certainly not the same

as that which produces pus. Other writers have endeavoured to clear up the difficulty by supposing that all these morbid changes, which are not the usual products of common inflammation, are the effect of *specific* inflammation; the calcareous deposits, for example, requiring the gouty diathesis for their elaboration; so that, according to this view, every variety of disposition must be the result of a different specific inflammatory action. (See ARTERITIS.) In whatever way these morbid productions are originally formed, the irritation they induce in the arterial coats is evidently a source of chronic arteritis, which may terminate in ulceration.

2. *Inflammation of Veins.* This is a more frequent and fatal disease than that of arteries. Though frequent allusions were made to this lesion, the first distinct account was given by the late John Hunter, in a paper in the Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, in which many of the most important facts connected with inflammation of veins are clearly pointed out. Since the time of Hunter, many valuable contributions have been made to this department of pathology by Meckel, Breschet, Bouillaud, Velpeau, Dance, Ribes, Hodgson, Davis, Travers, Arnot, and Lee.

The anatomical characters of an inflamed vein are, uniform redness, more or less deep, with swelling and pulpiness of the inner coat, which is easily detached from the middle tunic. The redness and swelling soon extend to the middle and outer coats, so that the vein feels hard and contracted, resembling a deep red cord, imbedded in its cellular sheath, which is generally infiltrated with bloody serum.

The canal of the inflamed vein is filled with coagula of blood often mixed with pus, or a false membrane adheres to the inner membrane, filling its cavity completely, and rendering the vessel an impervious cord.

When a vein becomes inflamed after a wound or puncture, the inflammation sometimes extends along its inner or lining membrane to the principal venous trunks, and occasionally to the membrane which lines the cavities of the heart. From the facts adduced by Mr. Arnot, it appears that there are considerable differences in the extent of vein occupied by inflammation in phlebitis. In some instances the inflammation is limited to the vessel in which it originally appeared; in others it is found to have spread into several or most of the veins of a limb, from that primarily affected. These circumstances, as well as the fact that death has resulted from phlebitis limited to a few inches only, lead to the conclusion that the danger from this disease bears no ratio to the extent of the inflammation of the vein.

The anatomical appearances of an inflamed vein are uniform deep redness of the inner membrane extending over a limited or more extended portion of the vessel. The coats of the vein are generally swollen and indurated, and more easily separated than in the healthy state. The dense cellular substance in which the vessel is imbedded, is at the same time injected and infiltrated with bloody serum. The cavity of the vein is filled with coagula, with which purulent matter is occasionally blended, and its diameter contracted or

often obliterated by false membranes which adhere to the surface of the inner coat, and thus render the vessel a hard impervious cord. In fourteen cases out of nineteen, Mr. Arnot found pus, or pus mixed with lymph, in the cavity of the vein; in two the contents are described as consisting of "adhesive matter," and in another the vena cava contained "flakes of lymph." In one case, described by Mr. Hodgson, in which the inflammation occurred in a vein previously diseased, neither pus nor lymph was found in the vessel.

The characters of chronic inflammation of veins differ little from the acute. The redness is of a more deep brown or violet tint, and the coats more thick, so that when the vein is cut across, it preserves its cylindrical form like an artery. The contents of the vein are similar to those described in acute inflammation.

Ulceration occurs more frequently in the larger arterial trunks than in the veins. We have already noticed ulceration of the internal membrane of the heart as an occasional consequence of inflammation. In arteries, the ulceration may be confined to the internal tunic alone, or it may extend to and destroy the muscular coat, so that the blood escapes through the erosion, and, distending the external coat, gives rise to the aneurismal dilatation so minutely described by Scarpa, and which indeed, in the opinion of this pathologist, constitutes the true anatomical character of aneurism. In process of time, however, or from violence, the external coat may be lacerated; the blood then escapes into the cellular sheath in which the artery is enveloped, and thus a true aneurismal tumour is formed.

When ulceration of the larger veins has been observed, it has apparently commenced in the internal lining membrane, and gradually extending to the other coats. The vein has sometimes formed an attachment to some adjoining hollow viscus, the tissue of which becomes also destroyed by ulcerative absorption, and the blood thus escapes into its cavity.

Blood-vessels may be said to be insusceptible of gangrenous inflammation, as they escape the general destruction of the tissues in mortification and sphacelus. It is extremely doubtful if the tissue of the heart be ever affected with gangrene, the cases mentioned by Senac, Portal, and Corvisart, in which gangrenous spots were seen on the surface of the heart, being too vaguely described to be admitted as examples of this lesion.

The tissue of arteries seems to have great power in resisting mortification. Dr. Thomson relates that he has seen instances of phlegmonous erysipelas, in which several inches of the femoral artery were laid completely bare by the gangrene, ulceration, and sphacelus of the parts covering it, without its giving way before death. The arteries had the appearance of raw flesh, and were obviously thicker and more vascular than natural, the blood circulating through them, and assisting in supplying with nourishment the parts on which they were distributed. When gangrenous inflammation has been so severe that it extends to the blood-vessels, it has been observed that hemorrhage does not take place, either when the vessel is divided, as in amputation of the limb, or when the limb has dropped off. The blood is prevented

from escaping in those cases partly by the extension of adhesive inflammation, which occurs in the line of separation between the dead and the living parts, to the blood-vessels of the limbs, so that their surfaces are pressed together, and adhere more or less completely, and partly also by the coagulation of blood in the extremity of the vessels. This filling up of an artery by coagulated blood happens, Dr. Thomson conceives, by the closure, by adhesive inflammation, of the small branches going off from the trunk, and by the disposition which is given to the blood to coagulate, in consequence of the secretion of coagulable lymph on the inner surface of the inflamed vessel.

Inflammation of the Lymphatic Vessels.—This system of vessels is not unfrequently inflamed; and, according to Bichat, inflammation occurs more frequently in the absorbents than in the veins. This assertion is corroborated, when we reflect that the absorbents are constantly exposed to irritation from wounds, punctures, and the introduction of morbid poisons into the system through the external surfaces. Though inflammation of the absorbents is by no means a rare disease, it seldom proves fatal, the inflammation generally terminating in resolution. In those cases in which an opportunity has been afforded of examining an inflamed absorbent, its coats have been found swollen and indurated, and a layer of plastic lymph adhering to its inner membrane. The cellular tissue surrounding the inflamed vessel is involved in the inflammatory action, denoted during life by a red line, which is exquisitely painful, and after death by induration and serous infiltration.

Andral has examined the thoracic duct and lymphatic vessels in upwards of six hundred subjects, and found but in a very few instances any appreciable alteration of the thoracic duct. In three cases only its parietes appeared red and injected; and in one of these the interior of the duct was filled with pus, and its coats were thickened and friable. In the case of a woman, who died at La Charité, with cancer of the uterus, the thoracic duct, which was considerably enlarged, and of a dead white colour, was filled with a puriform fluid, and its internal surface studded with an infinite number of round white bodies about the size of peas; in the intervals between which the parietes of the duct were thickened, and of a dead white colour, traversed here and there by reddish lines, and in other points they were reduced to a soft pulp of a dirty reddish white. The left subclavian vein, into which the duct opened freely, was distended by a number of dense firm clots of blood firmly adhering to the coats of the vein, the inner surface of which was wrinkled, and of a deep brown colour. This affection of the thoracic duct and subclavian vein evidently originated in inflammation. Andral has occasionally met with the same morbid changes in the lymphatic vessels.

Inflammation of the lymphatic ganglions is more common than that of the lymphatic vessels. Those ganglions are composed of two distinct tissues,—lymphatic vessels variously convoluted, and cellular tissue, by which these convolutions or ganglions are united. These distinct structures may be demonstrated in the human subject by anatomical injection and nice dissection, and the

various diseases to which these ganglions are liable originate in one or other of those two anatomical elements. Inflammation of the lymphatic ganglions, which may be propagated from the lymphatic vessels, or arise primarily in the ganglions, is characterized by redness and swelling. The inflammation may be confined to one ganglion, or it may extend to several. The enlargement apparently arises from tumefaction of the cellular tissue, which unites the convolutions of the lymphatics, or from thickening of their coats, as a mercurial injection passes freely through all the convolutions of an inflamed lymphatic ganglion, proving that their cavity is still pervious.

When an inflamed ganglion is cut into, a number of small brownish red points are seen on the divided surfaces; these are exudations from the divided blood-vessels, which have become diffused in the red substance of the inflamed ganglion. When the inflammation is more intense, the consistency of the ganglion becomes of a dark violet colour, spongy and soft, and often mixed with blood.

When the inflammation terminates in suppuration, the pus may be infiltrated in cellular tissue connecting the convolutions, or in the structure of the ganglion, giving it a dirty grey or ash colour. In other cases an abscess forms, so that all traces of its parenchymatous structure are lost, the cellular envelope of the ganglion alone remaining and forming a cyst to the abscess.

When lymphatic ganglions are affected with chronic inflammation, the swelling and hardness are greater than when the inflammation is more acute. The cellular tissue, in which they are enveloped, becomes also inflamed, and forms a dense capsule around the ganglion. Lymphatic ganglions may enlarge in groups, as when the mesenteric glands become enlarged from follicular ulceration, or in chronic non-suppurating buboes of the axilla or groin. When an incision is made into a ganglion affected with chronic inflammation, it presents a dense homogeneous structure of a brown red colour, the vessels with which it is traversed being increased in number, tortuous and dilated, ramifying in all directions, and interspersed with white cellular filaments.

Chronic inflammation of lymphatic ganglions seldom terminates in suppuration unless acute inflammation supervene. The pus in these cases is infiltrated in the cellular tissue covering the inflamed ganglion.

Inflammation of Muscular Tissue.—From the comparatively few opportunities of examining inflamed muscular tissue in the human subject, it has been necessary to institute experiments on the lower animals, with the view of ascertaining the appearances this tissue presents when inflamed. The muscular tissue itself does not seem to assume readily inflammatory action; at least inflammation does not leave any well-marked traces of its existence. The principal alteration appears to take place in the intermuscular cellular tissue, which becomes red from increase in the number and size of its blood-vessels; the muscular fibres are at the same time somewhat increased in density, while the contractility, and consequently the power of motion, are more or less impaired, according to the degree and duration of the inflammation.

Gendrin states that if a portion of the centre of a long muscle be once inflamed, its extremities alone retain the contractile power, the middle or inflamed part remaining quite motionless, although the nerve which supplies the muscle is irritated, or even when it is subjected to the influence of galvanism. As the inflammation advances in duration or intensity, the cellular tissue which enters into the composition of the muscle, as well as that which connects it to the surrounding parts, becomes swollen and infiltrated with serosity, with which a portion of coagulable lymph is generally mixed, whereby its density is not only increased, but the muscular tissue so firmly bound and interwoven, that it is difficult to separate the two tissues, and when this is effected by dissection, the muscular tissue appears sensibly swollen, and of a more or less deep red colour. When the inflammation is intense, the cellular as well as the muscular tissue assumes a deep red or violet colour, and traces of commencing disorganization are perceptible, the muscle and its connecting cellular membrane becoming softened and infiltrated with blood. Suppuration finally takes place, the pus being diffused both in the cellular tissue which surrounds, and in that which enters into the composition of the muscle. The muscular substance becomes finally completely disorganized, and often sloughs extensively; or it is converted into a grey indurated mass, in which irregular cavities form, containing a dirty serosity or ill-conditioned pus.

It appears too from repeated experiments, that when the muscular tissue is destroyed, it is never regenerated; the lesion being repaired by the formation of a cellular or fibrous web which fills up the vacant space. There are several instances of chronic suppurative inflammation in muscle on record, the best example of which is inflammation of the *psoas* muscle, of which Schoenmezel (*De musculis psoa et iliaco suppuratis*, Heidelberg, 1776,) has given a case in which the whole of the *psoas magnus* and *iliacus* of the right side was destroyed and converted into purulent matter, forming a sac which extended from the last lumbar vertebra along the surface of the ileum to the small trochanter.

Inflammation of the muscular tissue of the heart is acknowledged to be a very rare affection, and according to the testimony of Baillie and Laennec, when it does happen, it is never a primary disease, but the consequence of extension or inflammation of the pericardium to the muscular structure of the heart. Though cases of genuine carditis are confessedly rare, the probability of its occurrence is placed beyond doubt by the instances which have been recorded; the most satisfactory we have met with is that related by Mr. Stanley, (*Med. Chir. Trans.* vol. 7,) in which the inflammation was general throughout the tissue of the heart.

The most unequivocal proof, however, of true carditis is when the inflammation terminates in suppuration. In these cases the inflammation is partial, and confined to those portions of the cardiac tissue in which the pus is deposited. The abscess is uncircumscribed, the purulent matter being infiltrated in the cellular membrane which connects its muscular fibres.

Ulcers of the heart have been found both on its external and internal surface, though this lesion also has been very rarely observed. The only case Laennec ever met with occurred on the internal surface of the left ventricle; it was an inch long, and half an inch wide, and more than four lines deep in the centre. This ventricle, which was at the same time in a state of hypertrophy, ultimately ruptured. The patient survived only two days.

Inflammation of the tongue (*glossitis*) is a very formidable disease, whether we regard its effects on respiration or deglutition. The organ, when inflamed, becomes swollen, of a vivid red colour, and very painful; as the inflammation proceeds, the swelling increases often to such a degree, that the tongue is thrust out of the mouth, and by its pressure on the larynx impedes both respiration and deglutition. The inflammation may terminate in resolution, suppuration, or even gangrene. The first is the more frequent result, which the practice of making deep incisions into the inflamed tongue tends greatly to promote. When suppuration takes place, the abscess is sometimes superficial, so that it points, and may be opened by an incision. In other instances it is deep-seated, and from the increased swelling there is so great hazard of suffocation, that, if deep incisions made into the tongue do not reach the abscess, it may become necessary to open the windpipe to save the patient's life—an operation which has been repeatedly performed with success in such cases. Gangrene is a rare termination of glossitis, and is indicated by the dark livid colour of the tongue, and the gangrenous odour from the mouth. (See *Glossitis*.)

The uterus being a muscular organ, is liable to the effects of inflammation of this tissue. Uterine inflammation is generally partial, occupying particularly the fundus and posterior part of the organ, and is almost invariably accompanied with inflammation of that portion of the peritoneum which covers its fundus. Its vessels are at the same time gorged with blood; the internal membrane of the organ is of a violet red colour, the injection of the muscular substance giving it a vermilion red or livid hue, according to the duration of the disease; and when blood is extravasated, the portion of the tissue in which this takes place appears marbled, and of a soft spongy consistence. In the more advanced stage of uterine inflammation, pus is infiltrated through its substance, and is generally found at the same time in the uterine veins.

Ulceration is another effect of inflammation of muscular tissue. This is sometimes observed in deep ulcers of the extremities, which corrode in succession the skin, cellular membrane, fascia, and ultimately the muscular tissue. It is also observed in the tongue in idiopathic inflammation of this organ, or when it arises from the use of mercury. We have already seen that ulceration occasionally takes place in the heart, and chronic ulceration of the cervix of the uterus is familiar to every pathologist.

Gangrenous inflammation of muscular tissue occurs in the external muscles, as well as in internal organs which have a muscular formation. This lesion is recognised by the black or green colour of the muscular fibres, which are very soft and easily torn, and by the peculiar gangrenous

odour of the sphacelated part. When gangrene occurs in an external muscle, the sphacelated portion may slough off, and the patient ultimately recover. If the sphacelus be extensive, it generally destroys life. Gangrene of an internal organ is almost invariably fatal.

Fibrous Tissue.—Bichat included under this term, *tendon, ligament, fascia, aponeurosis, and periosteum*, in which arrangement he has been followed by succeeding anatomists. This general arrangement, however, has been disputed by Dr. Craigie, who regards the anatomical structure of those several tissues, as well as the chemical composition of some of them, so essentially distinct as to preclude this general classification. For example, the structure of tendon differs from that of ligament and periosteum in being united in regular parallel fibres, and having greater tenacity—the fibres in the latter crossing in all directions, and consequently being with difficulty separated. Inflammation of fibrous tissue is attended with the ordinary effects of inflammation, but it rarely if ever terminates in suppuration or ulceration. We shall examine the effects of inflammation in individual fibrous tissues.

In inflammation of tendon, the natural polished glistening appearance is lost, and is succeeded by faint redness; when it is more violent, this injection is accompanied by softness or pulpiness of its texture, and as the inflammation proceeds, the redness gradually passes into a leaden grey colour; the tissue of the tendon becomes subsequently much thickened, and of a doughy consistence, indicating that its vitality is lost. These changes in inflamed tendon are frequently observed in common whitlow, and in severe injuries of the extremities accompanied with laceration, but particularly in gun-shot wounds.

The structure of ligament, periosteum, and fascia, especially that of the two first, is exceedingly similar. The minute filaments of which it consists are so interwoven in various directions, as to form one of the strongest and most compact tissues of the body. It is very sparingly supplied with blood-vessels, nerves, and absorbents. Inflammation of the capsular ligaments of the larger joints, or of the funicular ligaments, as, for example, the lateral ligaments of the elbow, wrist, knee, or ankle-joints, may arise spontaneously, from external injury, or from extension of inflammation of the synovial membrane or articular cartilages to the ligaments. When the inflammation is spontaneous, it is generally of a more chronic kind than when it arises from other causes. Inflammation of ligamentous tissue is speedily followed by thickening of its structure; the inflammatory action is seldom limited, but spreads to the synovial membrane and surrounding cellular tissue, giving rise to effusion into the cavity of the joint, and swelling of its external tissue, which not unfrequently terminates in the formation of superficial abscesses.

Ligamentous inflammation may terminate in resolution or in ulceration, of which latter we have an example in strumous disease of the hip-joint, in which not only a portion of the capsular ligament, but the round ligament which connects the femur to the acetabulum, is destroyed by the ulcerative process.

Inflammation of the periosteum (periostitis) differs little in anatomical characters from that of ligament. It is never confined to this tissue, but extends to the cellular tissue, by which it is connected to the skin and subjacent bone, and from which it is easily separated. A perceptible tumour is thus formed, which is hot and painful, and when examined, is found to consist of injected cellular and periosteal tissue, infiltrated with serum or lymph.

Periosteal inflammation may be limited, or it may spread over a considerable extent. When it is limited to a small spot, it constitutes the swelling termed *node*, which forms more readily in some situations than in others, more particularly on the tibia, radius, ulna, clavicle, and sternum. Nodes are sometimes converted into bony swellings (*exostosis*), the lymph which is effused being mixed with calcareous matter. Periostitis sometimes terminates in suppuration and abscess, in which case the skin and cellular membrane over the diseased periosteum become red, swollen, and very painful; fluctuation is perceptible, and when the abscess is punctured, or bursts spontaneously, the corresponding portion of the bone is generally destroyed by caries. Some cases of periostitis are merely symptomatic of primary inflammation or other disease of the bone, the inflammation having spread from the bone to the periosteum.

Fascia, from its extent and importance in the construction of the body, as well as its being evidently the seat of rheumatism, requires special notice. Dr. Craigie has ably combated the idea that inflammation of the muscular tissue is a cause of rheumatism.

"Independent of the fact that the rheumatic pains occur often round joints in which there are no muscles, the theory is at best only an ingenious assumption, and is not supported by any strong facts or arguments.

"Though rheumatic pain is often referred to muscular parts, it is less frequently so than to joints and parts covered by aponeurotic sheaths and fasciæ. Of 520 cases, Haygarth observed in 388 the rheumatic action to be seated in joints, in 118 in muscular parts, and in 14 wandering, general, or migrating through the limbs. Of 170 cases, in 154 one or more joints were inflamed; in 33 cases both joints and muscles were simultaneously affected; and in some cases only were the muscles affected without the joints.

"Though from these facts Dr. Haygarth infers that acute rheumatism is seated chiefly in the joints, he does not attempt to ascertain the particular texture, in the affection of which the disease consists. It is further manifest that while it is impossible to exclude affection of the muscles entirely, it results that this affection is only secondary. The proof adduced by Dr. Scudamore from pressure of the whole course of a muscle, and grasping its substance during severe rheumatism, to show that the fleshy part is not the seat of complaint, is entitled to attention. Combined with those already mentioned, and with other considerations to be adduced immediately, it results that the rheumatic action is seated in a texture, which, confined neither to the site of the joints nor to that of the muscles exclusively, is common to both, and which, from its extensive

distribution and complicated arrangement, accords best with the phenomena, progress, and effects of the disease. It is unnecessary to repeat the considerations above adduced from the anatomical relations and characters of fascia and its various divisions. That they are the chief seat of acute rheumatism, may be inferred from the following circumstances:

"1. When the rheumatic action is seated in muscular parts, instead of being confined to the muscular fibres, it may always be referred to the aponeurotic membrane which covers or penetrates them. 2. The peculiar pains of rheumatism are always most distinct in those situations in which several folds of aponeurotic membranes meet; and their migrations may be traced from one extremity to another of aponeurotic membrane, and along the course of its principal divisions. 3. The kind of pain which attends rheumatism resembles that of the fibrous tissues in general when inflamed, in undergoing aggravation under the influence of external heat, and during the night. 4. This view of the seat of rheumatic disorder affords the most probable explanation of the effusion which takes place in the tendinous sheaths (*bursæ mucosæ*); for since each sheath is partly enveloped in aponeurotic membrane, the inflammatory process which takes place in the latter soon gives rise, as in analogous cases, to effusion, critical or non-critical, from the contiguous synovial membrane. 5. This view also affords the most rational explanation of the fact remarked by all authors, that rheumatism almost never terminates in suppuration. To suppose that muscle does not suppurate is, perhaps, erroneous, from what has been above adduced. That fascia and fibrous tissue in general is little disposed to suppurate, unless when mechanically injured, is manifest from a number of circumstances; and this may, perhaps, be regarded as the true explanation of the fact now noticed. 6. It must further be remarked that inflammation in this tissue renders it thick, hard, and rigid; and occasionally causes between its fibres effusion of lymph, which increases this thickening, induration, and rigidity. On these changes depend the immobility of rheumatic parts, and the loss of power which follows long and obstinate or neglected and repeated attacks of the disease.

"The question whether there be any thing peculiar in the nature of rheumatic inflammation, is not undeserving attention. This, however, is not the place for discussing it; and if the views now advanced be well-founded, it may be inferred that its peculiarities consist in the anatomical and physical qualities of the texture in which I have attempted to show it is seated.

"Though in acute rheumatism the inflammation affects a large proportion, if not the whole, of the fascial system, local forms of the disease may occur, in which it is confined, with more or less accuracy, to one or two fasciæ. Thus inflammation of the fascia of the temporal and masseter muscles produces rheumatism of the temple and rheumatic locked-jaw; that of the occipito-frontal fascia, rheumatism of the head; that of the cervical fascia, crick in the neck; that of the pectoral fascia and the intersections of the intercostal muscles, spurious pleurisy (*pleurodyne*);

that of the abdominal fascia, a rheumatic belly-ach; that of the lumbar fascia, *lumbago*; and that of the aponeurotic parts of the gluteal muscles, genuine *sciatica* or hip-gout. (Op. cit. p. 515.)

Inflammation of cartilage, which is generally of a chronic character, may take place as a primary disease; but it more generally succeeds to synovial inflammation. It is characterized by redness, spongy swelling, softness, and finally ulceration or erosion of its structure. Erosion, which in cartilage is analogous to caries in bone, consists first in minute perforations, which extend in number and depth, and, by their coalescence, form patches of an irregular size and shape. When the erosion extends in depth, the epiphysis of the bone is exposed, excavations form, and sometimes the cartilage is entirely removed. The joint is thus destroyed, unless, as in some cases, *ankylosis* take place.

We have another instance of inflammation and ulceration of cartilage in the larynx, in which the inflammation may either take place primarily, or it may spread from the mucous membrane of the throat to the perichondrium or investing membrane. The disease in these cases is generally chronic, even at its commencement; and, though it may arise from cold, it is more generally to be traced to the effect of a specific poison—the syphilitic or the mercurial. It often succeeds to the development and subsequent disorganization of tubercular formations in the structure of the larynx, giving rise to the disease termed *phthisis laryngea*. Both these differ essentially from the more acute and rapidly fatal forms of laryngitis, which consist in acute inflammation and infiltration of the submucous cellular tissue of the glottis.

Fibro-cartilaginous tissue is regarded as intermediate between the fibrous and cartilaginous, possessing the flexibility and elasticity of the former, with the toughness and resistance of the latter. The intervertebral substance of the vertebræ, the semilunar cartilages of the knee-joints, and the cartilages which unite the pelvic bones, are composed of this tissue. These parts are liable to inflammation, which may either originate in their own substance, but more generally in the surrounding structure, or in the synovial membrane with which they are in most instances invested. The inflammation in fibro-cartilaginous tissue produces swelling and softening, which frequently terminates in erosion, as we occasionally observe after inflammation of the semilunar cartilages of the knee-joint and of intervertebral substance.

Mortification may take place in fibrous tissue. When this occurs, its glistening appearance is lost, and changed to an ash-grey colour, while its texture becomes softened and easily torn. It may even become completely dead or sphacelated, as in sloughing of the cornea, or when large portions of the soft parts, or even an entire limb has been removed by idiopathic gangrene: in these cases the fibrous tissue sloughs with the other structures of the mortified limb.

Bone.—The structure of bone undergoes the process of inflammation, which is the origin of many of those diseases to which the osseous system is liable. It may arise spontaneously, or from various kinds of injuries. The process by which

the extremities of fractured bones are united, and the erosion which takes place when the epiphyses become separated, are examples of the adhesive inflammation of bone. The bony union by which these injuries are repaired is effected by the blood which oozes from the periosteal and medullary arteries, and the subsequent elaboration of coagulable lymph into which new vessels penetrate, so that the lymph becomes an organized substance similar to granulation, and is termed *callus*. Upon this new substance points of bone are deposited by a peculiar and hitherto unexplained action of the nutrient vessels; these points of bone become gradually more numerous, and finally coalesce into larger masses, until the fractured extremities are at length united by solid bone.

Idiopathic inflammation of bone may arise either in the periosteal covering, or in the cancelli, or medullary structure. We have already explained the effects of inflammation of the periosteum in producing those swellings called nodes: when the periosteal inflammation is very acute, it produces not only thickening of the membrane and deposition into the subjacent cellular tissue, but inflammation of the portion of bone with which it is in contact. If the inflammation be not promptly arrested, suppurative inflammation of the periosteum, followed by caries or ulceration of the bone, succeeds, which often penetrates the substance of the bone to a considerable depth.

Another form of osseous inflammation is that arising in the filamentous medullary structure of long bones, producing swelling and effusion into the cancelli, which may terminate either in permanent induration and enlargement of the bone, or in suppuration. When suppurative inflammation thus takes place, the matter is sometimes deposited in the cavity of the bone, and generally proves a source of great constitutional disturbance. In other cases the vitality of the bone is gradually destroyed from within outwards, constituting the disease termed *necrosis* by surgical writers. This may affect either a part or the whole of the shaft of the bone; so that the epiphyses and periosteum, which are seldom affected, only remain. In the progress of the disease the dead portions are enclosed in a case of newly-formed bone, and covered with thickened periosteum.

The two diseases termed *caries* and *necrosis* afford an illustration of ulceration and gangrene of bone. In *necrosis*, however, reparation is effected by the formation of a new envelopment around the mortified or dead bone. In superficial gangrene of the long bones, such reparation is not observed; these latter cases, therefore, have a greater affinity to gangrene of soft parts.

Inflammation of the medullary texture of the epiphyses, and of the short or cuboid bones, such as the vertebral, tarsal, carpal, and digital, is the cause of the disease described by surgical writers under the term *spina ventosa*.

Dr. Craigie states that the cancellated arrangement of the osseous matter and of its medullary web in these bones, explains the progress and phenomena of the disorder. That this is the seat of its action is to be inferred, first, from the phenomena of the disease; and, secondly, from its effects as seen in diseased bones. *Spina ventosa*

never occurs in a bone with distinct medullary canal, unless at the epiphyses, where the structure is cancellated. When it takes place in these situations, it first induces an enlargement of the epiphyses, with extreme deep-seated pain in the bone. Soon after the periosteum becomes thick and swelled; and in no long time sanious matter is found beneath it issuing from the cancelli, which are then softened, partially destroyed, and excavated. If in this state such a bone be examined, the broken cancelli are filled with a reddish, soft, spongy, vascular mass, producing flabby granulations *passim*, and secreting bloody sanious fluid. The compact shell is partly destroyed by irregular ulceration, and partly extruded by the distending force of the swelled medullary web. The diseased epiphysis then presents a large irregular anfractuous cavern, filled with soft spongy substance, which is either the web itself, or the new products which its inflammation has generated. In this manner it is frequent in the upper end of the tibia or the lower end of the femur, or in the extremities of the radius or ulna. (*Op. cit.*)

The effects of inflammation in the different tissues having been briefly considered, it is necessary to show the changes induced by inflammation in organs which are composed of several tissues (*complex tissues*). The structure of the lungs is, of all the organs in the body, the most complex: it consists of arteries, veins, absorbents, nerves, and the ramifications of the bronchial tubes, lined with mucous membrane, and terminating in very small round cells; all these component parts being firmly united by cellular tissue. It is necessary to be able to distinguish congestion from inflammation of the pulmonary substance, as there is certainly no organ in the body so frequently the seat of congestion. We find very generally, on examining the lungs, even when the person dies in an exhausted state, as in continued fever for example, that the most depending portions are in a state of congestion. This is owing to the blood gravitating from the position of the body after death. This appearance, though often mistaken for the effect of inflammation, is a pseudo-morbid appearance. It is frequently found in cases where there has been a severe and protracted struggle previous to dissolution, or where there has been a mechanical obstruction to the circulation produced by some organic disease of the heart.

The anatomical characters of inflammation of the substance of the lungs (*pneumonia*) differ according to its stage or degree. Laennec has described three stages, which he considers may be easily recognised; these he has distinguished by the terms *obstruction* (*engouement*), *hepatization*, and *purulent infiltration*, all of which present different anatomical characters.

In the first degree (*engouement*, or *obstruction*) the portion of inflamed lung is externally of a livid or violet colour, which is not removed by immersion in water, or even injecting water into the pulmonary vessels, and more heavy and dense than natural. When pressed between the fingers it is still crepitous, though less so than in its sound state, retaining the impression of the finger like an cedematous limb. It is necessary, however, to bear in mind that lungs which possess naturally

a considerable degree of density have proportionally less crepitation. This density of the pulmonary tissue is more remarkable in children. When cut into, the structure is of a dark red colour, the tissue being filled with a serous fluid, more or less tinged with blood; but though evidently injected, the natural soft spongy texture is unaltered, and still permeable to air.

In a more advanced stage of pulmonary inflammation, the smaller bronchia, air-cells, and connecting cellular membrane, become swollen, so that the quantity of air in the inflamed portion of lung is diminished and supplied by blood. This constitutes the second degree of pneumonia (*hepatization*). It is characterized by a deep red colour of the inflamed portion of the lung, varying in different points from that of violet grey to blood red, and by the greater density and consistence of the granulated texture exhibited in its section, giving it somewhat the appearance of liver, from which the term hepatization has been derived. The hepatized portion of lung has lost its crepitous feel, is impermeable to the air, and sinks in water; and when divided, no air escapes, but a small quantity of bloody serum, mixed with a thick opaque fluid, may be expressed. When the minute structure is examined closely, the natural pulmonary texture has lost its cellular appearance, and appears to be composed of a number of small red grains, oblong and flattened, which, according to Laennec, are the air-cells transformed into solid grains, by the thickening of their parietes, and the obliteration of their cavities by a concrete fluid. Andral, however, states that this granular appearance is often altogether wanting, so that its surface, when cut into, appears smooth and compact. He supposes the granular appearance to depend on the degree of tumefaction which the air-cells undergo; for when the tumefaction passes a certain limit, its effect is to approximate the cells so closely that they become confounded together, and the granular appearance vanishes entirely.

The extent of pulmonary substance occupied by these two degrees of inflammation is various. Sometimes the inflammation extends over an entire lobe, (*pneumonia lobaris*): in other instances it is confined to one or more lobules (*pneumonia lobularis*): in some cases it affects only the air-cells (*pneumonia vesicularis*): some writers indeed consider that in pneumonia the inflammation commences in the air-cells, from which it is propagated to the parenchymatous tissue.

When pulmonary inflammation has advanced to the formation of pus, this fluid is found either in the form of purulent infiltration, or collected into an abscess. Purulent infiltration is by far the more common appearance; this succeeds to the most intense degree of pulmonary inflammation, and often takes place with great rapidity. According to Andral it has formed within four days after the first symptoms of pneumonia had made their appearance. The portion of lung in which the purulent infiltration has taken place presents an ash-grey colour, from which it has been termed *grey hepatization*, to distinguish it from the second stage of pneumonia, the *red hepatization*. If the pus be squeezed from the pulmonary texture, it assumes the colour of the red

hepatization, but it is much softened and consequently easily lacerated. The grey colour is evidently owing to the admixture of pus with the red tissue of the inflamed lung.

These three stages of pulmonary inflammation may be often seen in different portions of the same lung; sometimes an entire lung is infiltrated with pus, while the other presents different stages of pneumonia; some portions being in a state of red, others of grey hepatization, the one stage passing by insensible degrees into the other.

With regard to the portion of lung most frequently affected with pneumonia, it appears from the statements of Laennec, Andral, and others, that it occurs most generally in the lower portions, though it is not uncommon to meet with a circumscribed portion of the centre of the lung inflamed, the surrounding parenchyma being quite sound.

It is a singular circumstance, also, that the left lung should be much more frequently the seat of pneumonia, and, indeed, of almost every lesion, than the right. Of two hundred and four cases of evident pneumonia, the right lung was affected in one hundred and twenty-one instances, the left lung in fifty-eight, and both lungs in twenty-five. (*Andral, Clin. Méd. tom. ii.*)

Abscess of the lung has been very rarely met with, though cases succeeding to pneumonia are recorded by several writers. In these instances the boundary of the excavation in the lung, which is filled with pus, is formed by the pulmonary tissue.

Another and perhaps more frequent form of pulmonary abscess is that in which pus is deposited in the lung, not as the consequence of inflammation, but from this fluid, formed in some other part, being conveyed through the medium of the circulation, and deposited in the lung. There are many striking instances of these purulent deposits succeeding to important operations, and to purulent collections in other organs of the body, which, after an attentive examination, Andral proposes to range in two classes. In one, it appears that the pus is formed in the torrent of the circulation, or is introduced into it from some organ in a state of suppuration, and in its passage through the tissue of the lung is separated as through a filter, and either collected into an abscess, or infiltrates the pulmonary tissue. It is probably by a similar process that mercury injected into the crural vein of a dog traverses the whole circulating system until it arrives at the lung, where it abandons the circulating fluid. In the other class of cases, some cause with which we are unacquainted alters the blood, coagulates it in the pulmonary vessels, and transforms it into purulent matter in the smaller branches of these vessels. (*Anat. Patholog. tom. ii.*)

The termination of inflammation of the lungs in gangrene is exceedingly rare, and when it is met with, it is not always to be regarded as an indication of the intensity of the pneumonia, as it has been found in cases when the symptoms, as well as the appearances of inflammation, were very slight and equivocal. Laennec regards it as very similar to idiopathic gangrene, such as anthrax, pestilential bubo, and malignant pustule. Andral, on the other hand, asserts that gangrene

of the lung, as well as of other parts of the body, may succeed to every species of hyperæmia, whether mechanical or vital, provided it be so considerable as to impede or prevent the afflux of arterial blood to the part.

Gangrene of the lung occurs under two forms—the *circumscribed*, and the *uncircumscribed*; the one differing from the other only in extent.

Circumscribed pulmonary gangrene occurs in a small portion of the lungs only; the mortified part is separated by a suppurative process which is established around it, and the eschar or slough is expelled with the expectoration through perforation of one or more of the bronchial tubes. An ulcerous excavation discharging a dirty fluid remains, which, by mixing with the expectoration, gives it a most offensive odour. When the gangrene occurs near the surface of the lung, it produces erosion of the pleura, which is succeeded by pleurisy and pneumothorax.

Uncircumscribed pulmonary gangrene is much less common than the circumscribed. Laennec had only seen two cases of it during twenty-four years, and he had only known of five or six cases of it in the hospitals at Paris during the same period. He gives the following characters of this lesion, which may occupy a great portion of one lobe, or occasionally the greatest part of one lung. The pulmonary tissue, more humid and less cohesive than in the sound state, has the same degree of density as in the first state of peripneumony, œdema of the lungs, or the serous engorgement occurring after death; its colour varies from a dirty white or slightly greenish hue, to a deep green, approaching to black, with a mixture, occasionally of brown, or of earthy or yellowish brown. In some places the pulmonary substance, altogether or nearly sound, blends insensibly with the gangrenous part; in other instances, these are separated by a portion of lung inflamed in the first degree, and in still rarer instances by pulmonary hepatization.

Spleen.—The spleen consists of few anatomical elements—first, a fibrous investing membrane, constituting its proper capsule of the organ; secondly, an internal cellular arrangement into which the blood is poured; thirdly, blood-vessels, lymphatics, and nerves. As the parenchyma of this organ, therefore, consists of two component ingredients only, fibrous tissue and blood, its diseases must be referable to one or other of these. Andral thinks its diseases ought to be the same as those of the veins, for it is evidently a vast venous network, in which the cellular is substituted for the vascular form. He therefore considers the lesions of the spleen to be of two kinds; those of the first, which are rare and unimportant, have their seat in the capsule, or in its fibrous prolongations, which constitute the walls of the splenic cells: those of the second, of much greater frequency and importance, originate in some of the elements of the blood.

The capsule of the spleen is liable to the diseases of fibrous tissue, and consequently to inflammation, though such instances are rare. Abercrombie has seen the spleen completely enveloped in a thick dense covering of false membrane, in connection with peritonitis, but without any disease of its substance. In such cases,

however, the lymph was probably effused from the inflamed peritoneum, and not by the capsule of the spleen. This membrane has also been found adherent to the contiguous viscera in cases of purulent infiltration, when the pus is making its way towards the surface of the spleen, and if the organ to which it becomes attached be hollow, (as the stomach or alimentary canal,) the matter is discharged into it. The capsule of the spleen has been found in many of those instances soft, pulpy, and lacerable.

Cases of purulent formations in the spleen are not very common, more especially those in which pus is found in no other organ. It is improbable that such instances originate in inflammation of its parenchyma, since we have seen that its structure is such that it may be said to be almost insusceptible of inflammatory action, unless the blood be presumed to be susceptible of inflammation. Whence, therefore, originates the pus? This is a question of rather difficult solution, though Andral thinks from some experiments it would seem probable that the blood in the spleen may be converted into pus; and that the disturbance in the system which has been observed to accompany this lesion, is to be regarded as the result of the conversion of the blood into purulent matter.

A more frequent form of purulent formation in the spleen is when this organ becomes infiltrated with pus, at the same time that similar purulent deposits take place in other organs. In these cases it is supposed that the pus is formed in some distant organ, and after being carried in the blood, is deposited in the spleen and other organs at the same time. In such examples, the primary disease has sometimes occurred in connection with diseases of the uterus, or of the uterine veins; as in a case recorded in the *Transactions of the College of Physicians*, (Vol. v. p. 204,) and in another alluded to by Andral, (*Anat. Path.*): in other instances, the purulent depositions have succeeded to external injuries and severe surgical operations. The pus may be collected in drops, or in cavities of greater or less extent; it is sometimes confined in a cyst of false membrane, but more frequently the wall of the abscess is formed by the structure of the spleen, in which case the abscess is often of very considerable extent.

The termination of such cases is various: the abscess may, by adhesive inflammation and the subsequent process of ulcerative absorption, burst into the cavity of the chest, belly, stomach, or intestines, or it may be discharged through the kidneys by the urine. Splenic abscesses have been known also to open externally through the walls of the abdomen, the back, or the loins. (*Andral.*)

Though the thyroid gland is occasionally inflamed, it seems to be as little susceptible of inflammation as any gland in the body. When inflamed, its vessels are numerous and injected, so that its tissue is red and swollen, and feels much firmer than in its natural state; these changes being produced partly by serous infiltration, or when the inflammation is more intense, by the effusion of coagulable lymph or blood into its structure.

From the rare occurrence of inflammation of this gland, its pathological appearances consequent to inflammation have been scarcely noticed in the writings of pathologists.

Inflammation of Glandular Organs of Secretion.—Without entering into the disputes of anatomists, as to the form and texture which are necessary to constitute glandular structure, we shall merely state, that the most perfect glands are the lachrymal, salivary, submaxillary, sublingual, mammary, and prostate—the pancreas and testicle (*colourless glands*), and the liver and kidneys (*coloured glands*). Their external form is generally round or ovoid, and most of them consist of small lobules, connected by cellular tissue. For their size they are the most vascular parts of the body, a large supply of blood being necessary for the purpose of elaborating the various fluids secreted by glands.

When a glandular organ is inflamed, it increases in size, and its excretory ducts become enlarged and distended: the tissue of the colourless glands is of a slight rose tint: in the coloured, the natural redness becomes deeper, the injection extending throughout the interlobular cellular membrane. The excretory ducts are filled with fluid which is generally limpid, unless the inflammation be intense, when it becomes red, and even bloody. These anatomical appearances, however, pass off very rapidly after death.

Inflammation of a gland generally terminates in resolution; but if, from its intensity or improper treatment, it proceed to suppuration, the purulent matter forms in the cellular tissue of which the gland is partly composed, the proper substance of glands being not very susceptible of the suppurative process. When, however, the inflammatory action is very intense, it undergoes a species of suppuration; it loses its consistence, and to the softening succeeds infiltration with a thin kind of pus, the sensible qualities of which depend very much on the state of health and particular constitution of the individual.

When suppuration takes place in glands which have large secreting ducts, as the liver and kidneys, the mucous membrane with which these canals are lined sometimes assumes the suppurative action; hence, when pus is mixed with the fluid which the gland secretes, (the bile or urine for example,) it may be secreted either by the inflamed mucous lining of the duct, or there may be a communication between an abscess in the organ and the duct through which the matter is discharged.

These general observations being sufficient to give an idea of the effects of inflammation in glandular organs, we shall, without noticing specially the external glands, make a few remarks on inflammation of the internal organs of secretion—the *pancreas*, *liver*, and *kidney*.

1. The *pancreas* appears to be seldom the subject of inflammation and its consequences; in those cases which have been reported as instances of inflammation of this organ, the symptoms during life were not only very obscure, but the anatomical characters of the lesion not well defined.

In the cases which are reported, redness, more or less deep, and loss of consistence of the substance of this organ, with injection and infiltration of the interlobular cellular membrane, are the morbid

appearances described. The inflammation does not appear to have extended through the whole structure of the gland, but limited to one portion of it.

When inflammation of the pancreas has terminated in suppuration, the small lobules of which the pancreas is composed assume a grey-red colour, and become soft, and finally so completely disorganized, as to lose all trace of their original structure. The purulent matter is in some cases diffused through the cellular substance; in other instances the pus is confined in a distinct cavity or cyst, the abscess sometimes forming a tumour of considerable size adhering to the surrounding viscera. Sometimes, again, the pancreas has been found hard and shrivelled in the centre of the purulent deposit. These pancreatic abscesses have been known to make their way across the cellular tissue of the mesocolon, and, by perforating this membrane, the purulent matter has escaped into the cavity of the abdomen.

2. Congestion of blood may take place in the parenchyma of the liver, from causes originating in the organ itself, or as the effect of sympathetic disturbance in some other part. Again, when there is any obstacle to the free return of blood to the right side of the heart, the blood accumulates in the liver, and thus passive hepatic obstruction or congestion is induced. When this takes place, the liver is of an uniform red colour, a little increased in bulk, and evidently changed in density or consistence. Under the pressure of congestion the blood-vessels sometimes give way, and the blood is diffused through its parenchyma, constituting what the French writers term *hepatic apoplexy*. This lesion may be the result of rupture of one or two of the larger hepatic vessels, or of exudation from the capillaries.

Inflammation of the liver is more common in warm than in temperate climates; and notwithstanding the frequency of its occurrence, its anatomical characters are not very distinctly laid down, which may arise from hepatitis being very rarely fatal in the inflammatory stage, so that few opportunities of ascertaining the morbid appearances occur. The appearances in inflammation of the liver differ according to its intensity, duration and extent. Though inflammation may occur either in the serous covering, or in its parenchyma, it appears to be much more frequent in the latter. Indeed, from the history of hepatitis, given by writers who have had extensive opportunities of observing the disease in hot climates, we are informed that inflammation of the capsule of the liver is of comparatively rare occurrence.

In the milder forms of hepatic inflammation the organ is slightly increased in size and density, and of a dark red colour, from accumulation of blood, which flows freely where an incision is made. These changes are more evident when the inflammation is circumscribed or partial, as the morbid may be then contrasted with the healthy structure. In the more advanced stage, or when the inflammation has been from the beginning more intense, the parenchyma is more or less softened, and very vascular, the vena portæ, mesenteric vessels, and mucous membrane of the duodenum, being gorged with blood.

The degree to which this hepatic softening occurs depends on the degree and duration of the inflammation. In the more intense cases, the tissue of the liver occupied by the inflammation is reduced to a soft lacerable pulp of a deep violet or brown colour.

When hepatic inflammation terminates in suppuration, the pus may be diffused through the parenchyma of the liver, so as to give it a green-yellow colour, the tissue in which it is infiltrated, and for some extent around, being softened and disorganized. In other instances the pus is confined in abscesses, varying in size, sometimes distinct from each other, but occasionally communicating by perforations. These abscesses may be bounded by the parenchyma of the liver only, or by a more or less completely organized cyst; they often acquire a very large size, in some instances containing several pints of pus.

The termination of abscess of the liver is various;—1, it may be discharged through an opening in the hypochondrium, or some other situation: 2, when adhesion between the hepatic abscess and some portion of the alimentary canal or kidney takes place, the pus may be discharged by the stomach, bowels, or kidney: 3, the abscess may burst into the cavity of the abdomen: 4, it may perforate the diaphragm and be discharged into the cavity of the chest or pericardium; or if an adhesion form between the hepatic abscess and the lung, the pus may be discharged through a perforation in the bronchial tubes by expectoration. Andral alludes to a case of hepatic abscess situated near the gall-bladder, emptying itself into it, and passing from thence into the biliary duct; and also to a case in which abscess of the liver communicated with the vena cava.

Gangrene of the liver, if it do really occur, must be regarded as an extremely rare termination of hepatitis, as no unequivocal instance of this lesion has been recorded. Mr. Annesley, whose extensive opportunities of observation entitle him to be regarded as an authority, states that he never observed it as a termination of hepatitis of warm climates.

3. Inflammation of the kidneys is characterized by obscure redness of the tubular, and bright-red colour of the cortical substance, the tissue of the former acquiring a degree of firmness, the latter becoming softened, and easily torn.

The emulgent vessels are generally turgid, and the inner membrane of the pelvis and infundibula red and injected, the redness often extending along the membrane of the ureters.

In more intense renal inflammation the tissue of the kidney becomes of a deep red or chocolate colour, and remarkably softened.

Inflammation of the kidney may terminate in resolution, softening, and induration of its parenchyma, or in the formation of pus. Purulent formations in the kidney may take place in three different modes. 1. The inflammation may commence in and be confined to the tubular or secreting portion, and pass into suppuration, in which case the uriniferous tubes, infundibula, and pelvis of the kidney, secrete purulent matter, which is discharged with the urine. In these cases the kidney is not enlarged in size, and the signs of inflammation are confined to the secreting part of the organ. 2. The pus may be infiltrated through

the tissue of the kidney, accompanied with deep-red colour and softening of its substance; a number of white spots, frequently mixed with blood, are seen, from which pus may be squeezed; they are often mistaken for masses of tubercle. This form may be the result of inflammation, or of general purulent diathesis, when pus is found in other organs. 3. The purulent matter may be collected in distinct abscesses. These may be of small extent, the surrounding parenchyma being scarcely altered; or the whole tissue of the organ may be transformed into a purulent sac, which, according to Andral, is generally multilocular, the septa consisting of hard lardaceous tissue. They may exceed in bulk the kidney itself, and thus produce a tumour distinguishable through the abdominal parietes.

The inflammation in some cases commences in the renal capsule, to which it may be limited, or it may extend to the adjacent portion of the kidney. In these cases suppuration generally follows, but the abscess is exterior to, and unconnected with the substance of the kidney, the structure of which is unaltered, though often, from the pressure of the abscess, diminished in bulk. Abscesses sometimes form in the abundant loose cellular tissue which lies beneath the peritoneum, and surrounds the kidney and its proper capsule. Morgagni gives a case of this kind, which contained four pounds of purulent matter.

Renal abscesses may be discharged in various ways:—1, the pus may pass off with urine; 2, it may burst into the abdominal cavity and produce peritonitis, which is speedily mortal; 3, the abscess may form an adhesion and open into the colon; 4, it may be discharged externally by a perforation in the loins.

Gendrin has quoted a case from Ledran, in which a renal abscess opened at the loins, and the matter having forced its way in the sub-peritoneal cellular tissue down under Poupart's ligament and around the crural vessels, was also discharged at the inner part of the thigh. He alludes also to that case related by De Haen, in which an abscess in the left kidney, after destroying the substance of the organ, formed an adhesion to the diaphragm, which it perforated, and destroyed the inferior lobe of the left lung, the kidney and lung thus forming one large sac.

Causes of Inflammation.—There are few circumstances connected with pathology more obscure and unsatisfactory than the etiology of diseases. This is fully exemplified in the obscurity in which the origin of almost every form of inflammatory disorder is involved. Many, indeed, arise without evident cause, constituting what has been denominated by practical writers spontaneous inflammation—a term which simply denotes that the causes are so obscure as to elude observation.

It would appear, however, that certain circumstances predispose the system or render it more liable to inflammation; this predisposition may exist either in the system in general, or it may be confined to a particular region, organ, or tissue.

The *predisposing* causes may be arranged in two classes, the first depending on general sanguineous plethora; the second are connected with local determination of blood. Practical writers have usually mentioned the sanguine temperament

among the individual causes which predispose to inflammation. Persons who possess this temperament are generally supposed to have a superabundant quantity of blood, whereby the vessels, more especially the capillaries, are kept in a state of undue distension, the blood having at the same time great consistency or richness. It is also asserted that adults, especially male adults, and those possessing what is called a strong constitution, are more predisposed to inflammatory diseases. It has always appeared to us, however, that these views are not supported by facts and observation, and in our own experience, we have generally found that weak and delicate persons are much more frequently attacked with inflammation than the more robust and vigorous. Not less unsupported by evidence is the notion entertained by Van Swieten, that serous evacuations, such as profuse sweating, salivation, or copious flow of urine, predispose the body to inflammation, in consequence of the blood acquiring greater consistence from the abstraction of its watery principles. A predisposition to inflammation, or tendency to particular local determinations of blood, is observed at certain periods of life. We accordingly find that there is a greater tendency to cerebral fulness in infancy and childhood than at other ages; towards puberty, we observe fulness of the pulmonary system, which accounts for the frequency of nasal and pulmonary hemorrhage at this period. In adults, on the other hand, diseases of the abdominal viscera connected with vascular fulness are more common, though it should be kept in mind that congestions or irregular distributions of blood are more common than organic inflammation. It is often of great consequence to discover those circumstances which give a predisposition to inflammation in particular organs and tissues. These may often be traced to a state of partial or local plethora, connected with causes which are inherent in the part itself, though a predisposition to local inflammation is frequently acquired. Thus the undue exercise of an organ frequently predisposes it to inflammation, an illustration of which is the tendency to ophthalmia or retinitis induced by long-continued use of the eye, or straining this organ in examining very minute objects; in the effect of long-continued application to study in producing slow, insidious, cerebral fulness; in the effect of long-continued exposure to cold in laying the foundation of pulmonary diseases; and in the tendency to hepatic inflammation engendered by residence in a warm climate.

It is also a well-known fact that a predisposition to inflammation is given by previous attacks. This is so much a matter of experience and observation that it is scarcely necessary to adduce examples in illustration.

Whatever circumstance or combination of circumstances breaks up the general powers predisposes the body to inflammatory diseases, by rendering it unable to contend against the exciting causes. It is in this way that undue bodily or mental exertion, the depressing passions, long-continued watching, impure air, improper or scanty supply of food, or insufficient clothing, may be regarded as predisposing causes of inflammation.

It is worthy of remark that the predisposing

causes have a considerable influence in determining the type of the subsequent inflammation, as well as the nature and extent of the curative measures. Those inflammatory diseases which arise suddenly, are generally connected with a full habit, and require active treatment; while those which come on more slowly, or in exhausted constitutions, are of the asthenic character, requiring greater circumspection in the nature and extent of antiphlogistic remedies. In such cases we are often obliged to support the general powers, when the local symptoms render the topical and even the general abstraction of blood, among other antiphlogistic measures, expedient.

The *exciting* causes of inflammation are no less obscure than the predisposing. Many pathologists have expressed their doubts as to the possibility of inflammation ever arising spontaneously. There can be no doubt that in many instances organic inflammation appears without our being able to discover its cause. Thus, inflammation is often set up in the brain, chest, or abdomen, without any evident cause. The inflammation is then termed spontaneous, in contradistinction to accidental inflammations, which are so called from their originating in causes applied immediately to the part affected. It would be unreasonable to say that in such cases the inflammation arose without some cause, though it may not be possible to detect it.

There has been too great disposition, on the part of systematic writers, to take for granted the ordinary list of exciting causes of inflammation. A little reflection will soon convince the patient observer of nature, that the causes of diseases are more mysterious than we are led to suppose from perusing systematic treatises. If the etiology of diseases were studied at the bedside, the obscurity of this department of medicine would be apparent; and it has been constantly observed that most idiopathic inflammations are developed by causes which elude our observation.

The effect of atmospheric causes on diseases in general has attracted the notice of physicians from very early ages. Inflammatory disorders are certainly more common in cold, variable, moist weather, and more especially when the wind blows from the north; hence, in the winter and spring, we observe the various types of inflammatory diseases. The mucous membranes seem to suffer more particularly in cold moist weather, and the serous membranes and parenchyma of organs in cold dry weather; while in summer cutaneous inflammations (idiopathic or secondary) are observed to be most frequent.

Inflammation may arise from injuries of various kinds, such as wounds, whether punctured, incised, lacerated or contused; from the irritation of foreign bodies, such as renal, biliary, gouty, and salivary concretions; and from pressure, as in the instance of a bandage or ligature applied to the extremity; or in the example of pressure produced on an internal part by aneurismal or other kinds of tumours, whether solid or fluid, the pressure of which causes inflammation in the parts to which it is applied.

Another exciting cause of inflammation is the direct application of heat. This is exemplified in the effect of exposure to the rays of the sun in

producing inflammation of the brain or external integuments of the head and face, and in the effect of heat in producing scalds and burns.

The effects of cold, as an exciting cause of inflammation, more especially if combined with moisture, are well known. We observe inflammation occur in parts to which the external air has free access—the eye—the ear—the tonsils—the larynx or trachea, and the mucous membrane of the lungs, after exposure to cold. These are instances of the effects of the direct application of cold. At other times the application of cold is followed by inflammation of a distant organ, an indirect effect being sometimes thus produced on an internal part, by the local application of cold and moisture. Thus a person who gets the feet thoroughly wet may afterwards have inflammation of the throat, of the lungs, or intestines, according to some local but still unexplained predisposition. We have another exemplification of the effect of cold in producing inflammation in frost-bite, in which very often rapid destructive inflammation is set up from the application of intense cold.

Undue exercise of the functions of an organ may become not only a predisposing, but an exciting cause of inflammation. In this way undue exercise of the mental powers is a frequent cause of inflammation of the brain. In like manner, also, inflammation may be produced in the eye, as is frequently observed in persons who are obliged to use this organ unduly in their daily avocations. Inflammation of the vocal organs is a common consequence of long-continued loud speaking; hence noisy maniacs frequently become hoarse from the constant vociferation in which they indulge.

Some substances, when taken into the stomach as remedies in disease, produce inflammation of particular parts. We have an example of this in the inflammation of the salivary glands, and sometimes of the skin, produced by the exhibition of mercury, or in the gastro-intestinal inflammation which is the result of the employment of arsenic as a remedy in some diseases, but more especially when it is taken in such quantity as to act as a poison. To the same head of causes of inflammation, we may refer the various examples of local irritation and its consequences arising from irritant poisons. According to Dr. Christison, these effects of local irritation vary from the slightest redness to ulceration and even gangrene.

Thus externally, alcohol reddens the skin; cantharides irritates the surface of the true skin, and causes vesication; tartar-emetic causes deep-seated inflammation of the true skin and a pustular eruption; the juice of manchineel, spreading inflammation of the subcutaneous cellular tissue; arsenic has all of these effects, as also death of the part and subsequent sloughing. Internally, alcohol reddens the stomach as it does the skin, but more permanently; while other substances, such as the diluted mineral acids, nitre, arsenic, cantharides, euphorbium, and the like, may cause all the phenomena of inflammation in the stomach and intestines, namely, extravasation of blood, effusion of lymph, ulcers, and gangrene. (Christison on Poisons, second edit.)

There are other substances belonging to the class of irritants—the acro-narcotic poisons—

which have a compound action, the one local and irritating, the other remote, producing an impression on the nervous system. To this class belong the *atropa belladonna* (deadly nightshade,) the *datura stramonium* (thorn-apple), and the *nicotiana tabacum* (tobacco).

The morbid animal poisons, as exciting causes of inflammation, belong also to this head. Some of these have a local action only, as the poison of itch or syphilis; more generally, however, the poison, though introduced locally, affects the general system, as in the instance of small-pox and cow-pox, and the poison of hydrophobia. It would appear, moreover, that some animal poisons operate through the medium of the blood. It is probably in this way that measles, scarlet fever, plague, the natural or uninoculated small-pox, and some other acute disorders, are produced. Many of these diseases, as is well known, give rise in their progress to various local inflammations, the danger to life depending in a great measure on the severity of these local lesions.

Terminations or Effects of Inflammation.

—The mode in which inflammation terminates depends on several circumstances, more especially the nature of the exciting cause, the intensity and duration of the symptoms, the peculiar constitution of the individual, the curative measures adopted, and the stage of the disease at which they have been employed.

1. *Resolution*.—Inflammation may gradually subside by the unassisted efforts of the system, constituting spontaneous resolution; or its progress may be arrested by the employment of remedies before it has effected any change of structure in the part. Resolution is not only the most favourable, but the most common termination of inflammation; it is indicated by the progressive abatement of the local as well as general symptoms, and especially by the restoration of the natural functions of the part. When resolution takes place suddenly, the French writers apply the term *delitescence* (from the verb *delitescere*), implying sudden disappearance; this is exemplified when a primary inflammation suddenly disappears and attacks another organ. This sudden decline of the inflammatory action is less frequently observed, however, than the more slow and gradual process of resolution.

The resolution of inflammation is often preceded or accompanied by *metastasis*, or translation of the disease from one part to another. We have an instance of this in the common occurrence of inflammation suddenly leaving one tonsil and seizing on the other, in the sudden recession of the glandular inflammation in mumps, and the subsequent inflammation of the testicle in the male, or the mamma in the female. In gouty and rheumatic inflammation, such sudden translation is frequently observed. The articular inflammation in gout sometimes recedes from the foot, and appears in the hand or knee, and occasionally attacks some internal organ, the stomach or brain. The sudden recession of rheumatism from joint to joint is a still more common occurrence, and is the cause of the generally protracted nature of this disease. A still more dangerous effect of the recession of rheumatic inflammation is, when it leaves the joints and fixes on the mem-

branes of the brain or the serous covering of the heart.

Physicians, from observing the complete cessation of inflammation, when a secondary disease is produced, have endeavoured to imitate nature, and by means of derivation or counter-irritation applied in the vicinity of an inflamed organ, to establish an internal disease, in the hope of withdrawing the inflammation from an internal to the external and less important part: these measures now form an important part of the local treatment of inflammation. (See COUNTER-IRRITATION and DERIVATION.)

When inflammation is about to terminate in resolution, various changes take place according to the stage and intensity of the inflammatory action, and the structure of the inflamed part. In the slighter grades of the disease, the frequency of the circulation diminishes, the blood-vessels contract in their diameter, so that those which, during inflammation, were so much dilated as to admit the red particles of the blood, again receive only a colourless fluid. When the inflammatory action has been more severe, the resolution is accompanied, if not effected, by an increase of the natural secretion of the part. If the inflammation occur in a serous membrane, the exhalants secrete an undue quantity of serum, or even coagulable lymph, which goes on so long as the inflammatory action continues; but whenever resolution takes place, the further progress of effusion is not only arrested, but the fluid already thrown out is gradually removed by absorption. When inflammation occurs in a mucous membrane, the natural secretion, though at first diminished, is afterwards increased, and more or less altered in its quality, more particularly if the inflammation have passed into the chronic stage.

Thus we find in bronchitis and muco-enteritis, that though in the primary stage of inflammation of these membranes the natural secretion is suppressed, as the diseased action proceeds, the natural secretion is first restored, and afterwards increased in quantity, and finally altered in quality. The error of attempting to check the secretion from an inflamed mucous membrane, especially in the early stage of the disease, the increased discharge being the natural solution of the diseased action, is, therefore, obvious. Besides these local circumstances which are observed when inflammation terminates in resolution, we find occasionally other changes take place, which, from their supposed influence in effecting this desirable solution, have been considered critical. There is sometimes an increase of the perspiration, or moderate diarrhoea, but more generally the urine exhibits marked alteration in its physical and chemical characters. While the inflammatory action is proceeding, the urine, though high-coloured, is clear, and does not, on cooling, deposit a sediment; but when the inflammation is disappearing, it deposits, on cooling, a red sediment. The following ingenious explanation of this appearance of the urine is given on the authority of Dr. Prout.

In healthy urine there is lithate of ammonia, which is pale and white, as also a yellow colouring matter, the nature of which is unknown, but which is thought to be, perhaps, a modification

of lithic acid. If to lithate of ammonia out of the body what are called the *purpurates* be added, a pink substance is immediately produced, such as is observed in hectic fever; and if the urine have its usual yellow colouring matter, a mixture of that with the pink appearance produced by the purpurates and the lithate of ammonia gives a red colour, pink and yellow mixed together, forming a red colour. In this diseased state we are informed by chemists that nitric acid in excess is formed in the urine, which acts on the lithic acid, and converts some of it into a new acid called the *purpuric*, which, uniting with the salts of the urine, forms the purpurates; and these purpurates, mixing with the lithate of ammonia, which is always in the urine, produce a pink deposit, which, united with the yellow colouring matter, becomes red. The lithate of ammonia and soda are formed in some degree of excess in the urine under inflammation, and nitric acid is produced; which, as has been stated, acting on the lithic acid, produces purpuric acid; and thus the formation of the purpurates is explained. Those mixing with lithate of ammonia produce a pink substance; and when this unites with the yellow colouring matter, the colour is changed to red. The cause of the urine being high-coloured or red, without sediment, till the inflammation declines, is this, that the same substances are in the urine, but held in solution by the activity of the complaint; but when it declines, an excess of lithic acid is formed, producing *super-lithates*, which are very insoluble; and, therefore, a great portion of them falls down in the form of a precipitate: hence the red sediment. (Elliotson's Lectures on Inflammation.)

The resolution of inflammation is sometimes accompanied by hemorrhage, with which inflammatory action is often intimately connected. Critical hemorrhages may take place either immediately from the inflamed part or from some neighbouring organ. We have an instance of the one, in the hemorrhage which succeeds to inflammation of mucous membranes, and of the other, of epistaxis in apoplectic or inflammatory states of the brain. These spontaneous hemorrhages are always followed by most marked relief of the local and general symptoms.

When inflammation does terminate in resolution, it effects other morbid changes in the inflamed tissue. The terminations, or, more properly speaking, the effects to which we allude, are *Effusion*, *Suppuration*, *Mortification*, *Ulceration*, *Induration*, *Softening*, and *Hemorrhage*.

2. *Effusion*. The exemplification of effusion as a consequence of inflammation is best illustrated in the serous membranes. After the violence of the inflammatory action has subsided, and the natural secretion of the membrane, which, during the primary stage of inflammation, had been suspended, is restored, an increased effusion of serosity takes place. The fluid which in these cases is secreted, and which happens only when the inflammation is moderate, bears so strong an analogy, both in its physical and chemical characters, to the serum of the blood, as to have received the appellation of serosity or serous fluid. It is generally of a pale straw colour and transparent, though occasionally, when the inflammation is a little

more intense, it contains a small proportion of albumen, which renders it slightly turbid. When the inflammatory action has been more violent, the fibrinous principle of the blood is separated; the admixture of which with albumen and serum constitutes coagulable lymph. It is this product which, when mixed with serous fluids, renders them turgid; the flakes of coagulable lymph, from their greater specific gravity, generally falling to the bottom of the cavity in which the effusion takes place, lining at the same time the surface of the inflamed membrane, and constituting that product termed *false membrane*.

When an intense inflammation has lasted several days, the fluid acquires a yellow colour from admixture of purulent matter: when this is considerable, the effusion very nearly resembles in appearance well-formed pus; but it still contains a large proportion of coagulable lymph and serous fluid.

In the commencement of the formation of false membranes, the exudation is soft and without consistence; but from the thinner parts being gradually absorbed, they become more dense, and adhere to the inflamed membrane, forming webs of various figures, which extend from one point to another of the surface on which they arise. When subjected to pressure, they give out a large proportion of fluid consisting of serum mixed with albumen; the solid substance appearing globular when viewed with the microscope, and, according to the analysis of Davy, consisting chiefly of fibrine.

False membranes often become completely organized, and of a distinctly cellular structure, capable of being injected; and when the inflammatory action ceases, they are converted into cellular tissue covered with a serous membrane, and afterwards liable, like serous tissues, to inflammation.

Fibrine is also sometimes effused from inflamed mucous membranes, and gives rise to the formation of false membranes, such as that which is effused in the larynx and trachea, or from the mucous surface of the intestines or uterus. The false membranes formed in mucous cavities, however, are less consistent than those which are effused on serous surfaces, probably owing to their containing less of the fibrinous principle. When an inflamed mucous membrane is about to terminate in the exudation of a false membrane, an unusual quantity of viscid mucus is secreted, which gradually becomes more consistent from the admixture of fibrine which is effused in the subsequent stage of the inflammatory action. These pseudo-membranes, as was stated before, generally bear the mould of the cavities in which they form.

[When the effusion of liquor sanguinis is examined by the microscope at the commencement of its becoming organized, a number of exudation corpuscles, formed as the fibrin coagulates, is seen in it. These have the appearance of regular cells, arranged in layers, and adhering together by an unorganized substance. Some hours later a fibrous character presents itself, which is supposed to be owing to the adhesion of the cells together in lines. Between the cellular fibres a considerable amount of cystoblastema yet remains, and they may be readily separated or torn in any direction. A vascular network next appears, which forms a

communication with the vessels of the subjacent surface. (Gerber, *General Anatomy*, by Gulliver, Lond. 1842.)

According to M. Andral, (*Hématologie Pathologique*, Paris, 1843, or Amer. edit. Philad. 1844,) two matters—the one globular, the other reticular—characterize, in the solid, the morbid process which we term inflammation. The reticular matter is nothing more than fibrin, perfectly similar to that which exists in the blood;—the globular matter, he thinks it probable, is also fibrin, but altered in its nature, and arrested in its coagulation. These two matters have very different destinations. The one—the reticular—is susceptible of passing into the organized state: vessels may be seen ramifying in it, and it may become a tissue. It is this which forms adhesions, and under the name of 'coagulable lymph' is interposed between the lips of wounds, and becomes the medium of their reunion. In place of being injurious by its presence, it is, consequently, an instrument of reparation for the tissues, and ultimately becomes completely identified with them. The other, on the contrary—whether it have a common origin or not with the reticular—can never remain in the textures without disturbing more or less the whole economy. It is incapable of organization; exhibits no trace of vitality, and is rejected by the organism. If not eliminated, disease results, and the elimination itself is frequently not accomplished without the supervention of unpleasant symptoms.]

The organization of coagulable lymph gives rise also to the process of *adhesion*—an operation of nature by which surfaces of parts which have been recently divided become re-united, the lymph becoming a living intermedium whereby the continuity of the part is ultimately restored. A knowledge of the fact that parts which have been divided may be again united by adhesive inflammation, has laid the foundation of many of the most important improvements in surgery.

The mode in which divided parts are united, and injuries repaired, termed union by the first intention, is similar to that which takes place in the formation of false membranes. If a surface which has been divided, an incised wound, for example, be examined a few hours after the solution of continuity has taken place, it will be found covered with a layer of coagulable lymph. Dr. Thomson made some experiments upon animals with the object of ascertaining the earliest period at which coagulable lymph is effused from the surface of a wound; he observed a distinct layer of lymph covering wounds he had made within less than four hours after they had been inflicted; though he thinks a longer period may be required in the human subject, in different persons, in different textures of the same individual, and in the different states of health and disease. The exudation of the lymph is speedily followed by the formation of blood-vessels, which often become, in the course of a few hours, so large as to be capable of being injected. This is the state of re-union termed by Mr. Hunter *adhesive inflammation*.

In many instances the reparation of an injury or divided surface is effected by a different process—that of *granulation*, termed by the older writers

union by the second intention. The process of granulation takes place, when from various circumstances wounds do not unite by adhesive inflammation, or when there has been a considerable loss of substance in a part, as in abscesses, ulceration, and gangrene. In these cases a layer of coagulable lymph is effused on the surface of the wound, which, as in the process of adhesion, becomes penetrated with blood-vessels, and thus a living intermedium is formed. Soon afterwards the surface is covered with purulent matter thrown out by a peculiar action of the vessels of the part, in which circumstance, besides the non-union of the divided tissue, the granulating differs from the adhesive process. Granulations assume the appearance of small red points and eminences, and according to Dr. Thomson, the mode in which nature effects their formation may be seen by injecting and carefully examining the internal surfaces of abscesses, or the granulating surfaces of healthy sores or ulcers. From numerous observations made in this way, it appears the exudation of a layer of coagulable lymph may be regarded as the first step in the process of granulation. The second consists in the penetration of this lymph with blood-vessels, nerves, and absorbents; the third, in the inosculation, or union by open extremities, of the vessels in these granulations; and in the last step, if it may be called so, of their formation, the granulations are covered over with cuticular substance by which the further secretion of pus is prevented, and the process of healing by granulation completed. (Lectures on Inflammation.) In this way the process of cicatrization is explained.

The subject of adhesive inflammation was minutely investigated by John Hunter, and in the chapter of his work on inflammation, entitled "On the Use of Adhesive Inflammation," he has pointed out this admirable contrivance of nature in preventing the extension of diseased action, and in repairing its effects in different structures. Mr. Hunter has also given a description, which has never been excelled in modern times, of the various processes by which this reparation is effected. The first step of the process by which solutions of continuity, whether simple incised wounds or loss of substance in any organ or part of the body are united or regenerated, is adhesive inflammation, which varies in intensity according as the reparation is to be accomplished by the first intention (adhesion), or by the process of suppuration. In the first mode, the inflammatory action never reaches the stage of suppuration; in the latter the inflammation should be moderate in order to insure cicatrization. It is well known to surgeons, that if a wound be irritated during the process of union by the first intention, the adhesive readily passes into the suppurative inflammation, so that the union by the first intention is frustrated; if, on the other hand, the surface of a suppurating wound be irritated during the healing by granulation, cicatrization is retarded and often entirely prevented.

The necessity, therefore, of moderating inflammation in the treatment of wounds, that this action, which is indispensable for the accomplishment of union by adhesion and cicatrization, may never exceed proper limits, or of occasionally

stimulating the surface of a sore when the healing process is languid, is thus explained.

[It has been maintained, however, by Dr. Macartney, of Dublin, after a comparative survey of the operations of reparation and inflammation, as performed in the different classes of animals, (*Treatise on Inflammation*, Dublin, 1838,) that the powers of reparation and reproduction are in proportion to the indisposition or incapacity for inflammation;—that inflammation is so far from being necessary to the reparation of parts, that in proportion as it exists, the latter is impeded, retarded or prevented,—that when inflammation does not exist, the reparative power is equal to the original tendency to produce and maintain organic form and structure,—and that it then becomes a natural function, like the growth of the individual, or the reproduction of the species.]

In every tissue, adhesion is effected, as before explained, by the effusion and subsequent organization of lymph, which in the course of time is transformed into a new substance, similar to cellular or fibro-cellular tissue, which adheres to the lips of an incised wound, and constitutes the medium or bond of union by the first intention; or it is deposited in the cavity of suppurating wounds, and upon which granulations are subsequently deposited, so as to fill up the vacuity which has been occasioned by the solution of continuity.

[If examined with a microscope at the commencement of the process of organization, it is seen to contain a large number of exudation corpuscles. In a short time, these corpuscles present the appearance of regular cells, disposed in layers, and adhering together by an intermediate unorganized substance, bearing a strong resemblance to the cells of tessellated epithelium. Some hours later, the mass exhibits an evidently fibrous character, owing to the adhesion of the cells together in lines, their form being prolonged in the same direction. A vascular rete next makes its appearance and forms connections with the vessels of the subjacent surface: the first appearance of this network is in the form of transparent arborescent streaks, which push out extensions on all sides; these encounter one another, and form a complete series of capillary reticulations, the distribution of which very nearly resembles that which has been seen in the villi of the intestines. Before the vascular rete appears, pale-coloured cytoblasts are produced, which, after the completion of the rete, pass over into the nearest capillary veins, being pushed on by the blood, which is brought from the nearest arteries; and in this manner the circulation is established. (Carpenter, *Principles of Human Physiology*, § 600.)]

In the reparation of cellular tissue, the first stage is the effusion of lymph, which becomes gradually organized, and transformed into a texture so similar to the primary tissue, that it is impossible to distinguish the one from the other except by its greater degree of density or hardness, and that its cells do not communicate so freely, for in œdema the cicatrices of wounds or abscesses do not fill with fluid.

Serous membranes become united by adhesive inflammation, either by union of the two serous surfaces, as we observe in pleuritic adhesions, or when there is a solution of continuity of this

membrane, as in wounds of the lungs or intestines. Dr. Thomson states, that in some experiments in which he removed a portion of the pleura pulmonalis, it appeared to be regenerated, as he was unable to distinguish easily the cicatrix from the surrounding parts. Gendrin also found the peritoneum thickened at one point in which ulceration of the intestine had commenced in the peritoneal tunic.

In solutions of continuity of the skin, when union by the first intention takes place, adhesion is effected by fibro-cellular tissue, which nearly resembles in formation the cutaneous structure. It differs, however, in some respects, chiefly in the non-regeneration of areolæ, indentations, or fatty matter. In extensive losses of the cutaneous tissue, the reparation is effected by suppuration, granulation, and the ulterior stage of cicatrization; but although the newly-formed substance is covered with an epidermis so as to resemble the original skin, it never acquires the perfect organization of cutaneous texture; it is less yielding, movable, and elastic, and without indentations by which sound skin admits of distension. Its vitality is also less active, for, as is well known to surgeons, when an old sore breaks out, the cicatrix is gradually destroyed.

A similar process to that just described appears to take place when portions of mucous membrane are destroyed by ulceration, viz. the effusion and organization of lymph, and the formation of an organized cellular membrane. The newly-formed tissue, however, has none of the properties of a mucous membrane, and never performs the function of secretion. The cicatrix is generally white, contracted, and is neither endowed with villousities nor follicles. We have examples of the healing or cicatrization of mucous membrane in ulceration of the throat, bronchia, and urethra; and in the follicular ulceration which accompanies some forms of fever, and also in ulceration of the mucous membrane of the stomach, or of the colon in dysentery.

The adhesive inflammation of blood-vessels is exemplified in wounds, or when a ligature is applied to an artery or vein. Effusion of lymph takes place both within the canal and on the surface of the vessel: this fluid becomes organized and finally transformed into a firm fibro-cellular web, which becomes closely connected with the internal and external tunics, and thus obliterates its canal. The fibrine of which the plug is composed is also organized, and may be even injected, showing the distinction between this substance and a clot of blood.

A similar process takes place in inflammation of veins, which we have shown to be more susceptible of adhesive inflammation than arteries; and that adhesive inflammation of this system of vessels frequently occurs, and gives rise to important and often dangerous diseases.

In nervous tissue, adhesive inflammation is observed in the reparation of various lesions of the brain and nerves, though pathologists are generally agreed that regeneration of the cerebral and nervous pulp never takes place. The process of adhesive inflammation of the cerebral tissue is exemplified in the obliteration of apoplectic or hemorrhagic cysts, in which, according to Rochoux,

the appearance of the effused blood differs according to the duration of its effusion. When death ensues quickly, at the end of three or four days for example, it is in the form of soft blackish clots: after a month or six weeks it becomes firmer, assumes a deep brown colour, and resembles the blood of aneurismal tumours. At a more remote period it becomes still more compact, and of a pale red colour, bordering on ochreous matter; and lastly, it is entirely absorbed. Around the coagulum a layer of lymph is effused, which becomes organized and transformed into a cellulofibrous cyst, which separates the clot from the cerebral substance. When the coagulum becomes completely absorbed, the cyst gradually contracts, till its walls approximate, and finally adhere by thin bands of cellulofibrous tissue, which in some cases cross the cyst in various directions, so as to connect its opposite sides at these intersecting points. In many instances, however, the cyst remains open and is filled with a turbid fluid.

In wounds or laceration of nerves, the divided extremities of the cord are united by lymph, which is gradually transformed into firm fibro-cellular tissue. From experiments which have been made with the view of ascertaining whether the true nervous pulp be regenerated, it is now generally admitted that such reproduction does not take place, the substance of the cicatrix not being capable of transmitting nervous impressions.

When muscular tissue is divided or destroyed, the reparation is not effected by the regeneration of muscular substance, but by very firm fibro-cellular tissue. This newly-formed substance becomes more firm according to the extent to which the extremities of the muscle are separated. When this is considerable, the intervening substance becomes almost ligamentous, but never acquires either the appearance or properties of muscular fibre.

When solution of continuity or loss of substance of fibro-cartilaginous tissue (cartilage or ligament) takes place, the structure becomes swollen, inflamed, and softened; to which succeed effusion and organization of lymph, which is in process of time converted into dense fibro-cellular tissue; but it is in many respects dissimilar to the primary or original tissue.

The adhesive inflammation of bone is effected first by the effusion of lymph from the periosteal and medullary arteries, softening and swelling of fractured extremities of the bone, the subsequent organization of their lymph, and its successive transformation, first into fibro-cellular tissue, then into a semi-cartilaginous substance, on the surface of which there are subsequently deposited a number of points of osseous substance. These points of ossification cohere, and form a thick irregular soft bony callus. The thinner parts of this callus are gradually absorbed, the solid bony substance alone remaining; and by the further absorption of the softer osseous particles, the medullary and cancellated structure of the bone becomes ultimately formed.

[It has been generally supposed, that the processes of granulation and suppuration, which are attended with much local inflammation, and constitutional disturbance, when the surface is large, are the only means by which an open wound can

be filled up. Occasional instances, have, however, occurred, in which large wounds have closed under the clot of blood by which they were at first covered, without any suppuration or other symptom of inflammation; and in these it has been found, that the new surface much more nearly resembles the ordinary one, than the cicatrix does, which follows granulation. Dr. Macartney (*op. cit.*) terms this the *modelling process*, and regards it to be precisely analogous to that which is concerned in the ordinary process of growth, and in the reproduction of whole parts, which takes place in the lower animals without inflammation. The most effectual means of promoting this kind of reparative process, and of preventing the interference of inflammation, vary according to the nature of the injury. The exclusion of air from the surface, and the regulation of the temperature, would appear to be the points of most importance. Dr. Macartney insists also on the constant application of water dressings. (Carpenter, *op. cit.*, §§ 602 and 603.)]

3. *Suppuration*.—Inflammation may also terminate in suppuration or the formation of a fluid termed pus. Various opinions have been entertained as to the mode in which this fluid is produced.

The older writers ascribed it to the breaking down of the solids, and the changes subsequently induced in extravasated blood; some regarded it as the effect of putrefaction of the serum or of the chyle, while others imputed its formation to the wasting or melting down of the fat. In modern times the generally received opinion is, that pus is separated from the blood by a peculiar action of the blood-vessels of an inflamed part, analogous to that of secretion; but in what way this fluid is elaborated is as little understood as the mode by which the various secretions are formed from the parent streams. It would appear, from experiments made on this subject, that pus is formed by a gradual conversion of the coagulable lymph into this fluid. For a detailed account, however, of this process, the physical and chemical character of pus, as well as its mode of formation in different tissues and organs, we beg to refer to the articles *ABSCESS* and *SUPPURATION*, and to the section of this article, *Theory of Inflammation*.

4. *Mortification*.—Mortification, or the complete death of a portion of the body, although produced by various causes, is not an unfrequent termination of inflammation, though it is a more frequent consequence of acute than of chronic inflammation. The terms *gangrene*, *mortification*, and *sphacelus*, have been used synonymously by many writers. Dr. Thomson has proposed to employ the term *gangrene* to express that stage of mortification which precedes the death of the part; and *sphacelus*, to denote its complete death or mortification, the circulation and sensibility being completely destroyed.

When gangrene occurs as the effect of inflammation or other causes, or arises spontaneously, it is announced by a change of colour, sensibility, and temperature in the inflamed part. The bright red colour of inflammation is replaced by a deep purple, livid, or blue appearance, which soon passes into a dark brown or black; the affected part

becomes insensible to the action of stimuli, while at the same time its temperature is diminished. It loses also the dense elastic feel which it had acquired during the inflammatory state, and becomes soft and flaccid; and if the mortification occur in the skin, the cuticle is raised in vesicles (phlyctenæ) which are filled with a yellow or bloody serum. A putrid odour begins soon after to be exhaled, which increases with the severity of the other symptoms, the progress of which is sometimes rapid, at other times more slow.

The complete death of the part is announced by a great decrease of temperature, a total loss of sensibility, and consequently cessation of pain, and a crepitous sensation produced by the pressure of air as a consequence of putrefaction. It is also known to anatomists, that the structure of a sphacelated part is so completely changed that an injection cannot pass into the vessels.

When mortification occurs in external parts, recovery frequently takes place even under the most unpromising circumstances. In internal organs it is almost invariably a fatal lesion. The symptoms which denote mortification in parts of the body important to life are, sudden cessation of pain, remarkable depression of the powers of the system, with symptoms referable more to the typhoid than the inflammatory character; there is great restlessness and uneasiness, but not arising from pain; the countenance becomes anxious, the features shrunk, and the aspect wild and cadaverous; the pulse small, rapid, and irregular; hiccup, followed by delirium and cold sweats, precedes the fatal issue.

We have already stated that mortification is more frequently induced by acute than by chronic inflammation. It is, however, important to bear in mind, that the death of parts is not always to be explained either by the degree or duration of inflammation. In certain epidemics, and in some conditions of the system, a state of local vascular excitement, amounting to little more than congestion, is followed by sphacelus of the affected parts. This is seen in the throat during the prevalence of malignant scarlatina, and in some forms of erysipelas: in malignant, eruptive, and typhoid fevers too, the inflammation produced in those parts of the body subjected to pressure or friction frequently terminates in gangrene.

There are few parts of the body which are not subject to gangrenous inflammation. Inflammation of the brain, though subject to all the changes consequent to inflammation, rarely if ever terminates in gangrene, though its membranes have been found in a mortified state after external injuries. There are certain tissues, however, in which inflammation is more apt to terminate in gangrene than in others. Nature seems also to have endowed the vascular system with a remarkable power of resisting mortification. Surgeons have frequent opportunities of witnessing large blood-vessels exposed, and apparently in a sound state, when the surrounding structures are completely destroyed by gangrene or ulceration. It is well known that in gangrenous parts no hemorrhage follows the division of the sphacelated parts, or even an incision made several inches above the boundary between the dead and living parts. This is owing to the arteries being filled with a coagu-

lum of blood, which adheres to the inner surface of the vessels so firmly as to resist the impulse of the blood when they are divided. In one instance, related by Mr. O'Hallason, no bleeding followed the removal of a limb, though the incisions were made four inches above the seat of gangrene: and Dr. Thomson saw, in a case of mortification of the thigh, a coagulum of blood in the external iliac artery, extending as high as the origin of this vessel from the aorta.

On the other hand, we observe that inflammation more readily passes into gangrene in some tissues and organs than in others. It is observed more frequently, as a consequence of inflammation, in the skin and cellular membrane, in the organs of digestion and respiration, than in other parts of the body. Mortification takes place also more rarely, and makes slow progress in muscular, ligamentous, and tendinous structures.

Besides the occurrence of mortification from inflammation and other external causes, it may arise, without previous inflammation, from the introduction of acrid poisons, from lightning, or the near approach of cannon-balls, or from animal poisons, such as that of the viper, cobra di capello, or the rattle-snake.

Mortification takes place not only as an effect of inflammation, and from the other circumstances just enumerated, but as an idiopathic disease. This form differs in some respects from that arising from the causes alluded to, and has been distinguished by the term *dry gangrene*, from the dry appearance of the mortified part, the skin, cellular tissue, muscles, tendons, and ligaments, being hard and dry, and showing no tendency to putrefaction. It generally occurs in the lower extremities; and from the arterial trunks being almost invariably ossified, it has been supposed that this form of gangrene arises from this state of the blood-vessels.

It is a remarkable but well-ascertained fact, however, that dry gangrene may be also produced by eating unsound rye. The rye-plant or rye-corn (*secale cereale* of Linnæus) is used in some countries, particularly in the north of Europe, as an article of food, and also affords, by distillation, an ardent spirit. Bread made from rye is less nutritive but more aperient than any other kind. This grain is liable to a morbid growth, more particularly when great heat succeeds to heavy rains. It is a black curved excrescence, not unlike the spur of a fowl, which grows on the spike, and is sometimes found in such quantities as to form nearly one fourth of the produce of the rye. It is called *secale cornutum*, or the cockspur in rye. In France it is known by the name of the ergot (*siège ergoté*). This diseased growth is attributed to the destructive operation of an insect which perforates the rye-corn and destroys its parenchyma.

Unsound rye has a singular effect on the human body: viz. lassitude, weakness of the extremities, intoxication, and periodic convulsive movements. This state, which has been called raphania, or convulsiones cerealiæ, continues from a few days to several months.

It is stated by Dodard and other writers, that persons who used rye-bread containing a considerable quantity of the diseased grain were liable to a

gangrenous affection of the extremities, attended with little fever, inflammation, or pain, though the affected limb became dead, and separated from the body. The limb became at first cold and insensible, and in the progress of the disease dry, hard, and withered. For a full account of this curious subject, the reader is referred to Dr. Thomson's work on inflammation.

Mortification may, when it is slight, terminate, 1. by resolution; 2. by adhesion; 3. by ulceration; 4. by sphacelus, or the death of the part, the last being by far the most frequent termination. (See MORTIFICATION.)

5. *Ulceration*.—When a solution of continuity follows as an immediate consequence of inflammation, the morbid process by which it is effected is called *ulceration*.

Previous to the time of Hunter, ulceration was supposed to be produced by the corrosive power of the fluids of the part in which the diseased action occurred. This celebrated pathologist, however, demonstrated satisfactorily that the solution of continuity was not affected by the acrimonious quality of the fluids, but by the action of the absorbents, the removal of parts or tissues by these vessels constituting the ulcerative process. He designated the formation of an ulcer by simple loss of substance, *ulcerative absorption*; and when the solid parts covering abscesses, aneurisms, and deep-seated tumours, in their progress towards the surface, were gradually removed by ulceration, he applied the term *progressive absorption*.

Dr. Thomson has proposed to distinguish the separation of dead or mortified parts by the term *disjunctive absorption*; but this appears to be an unnecessary refinement of medical terminology. Ulceration may occur as a consequence of every degree or kind of inflammation, not only in soft parts, such as skin, mucous membrane, brain, lung, liver, &c., but also in the texture of bone, in which structure the ulcerative process is termed *caries*. Indeed, we find that all textures of the body are susceptible of ulceration. "We see this exemplified," Mr. Lawrence observes, "when mortification has attacked an entire limb, and when the separation takes place by a natural process. Suppose, for instance, that the foot and lower part of the leg were mortified, and that the mortification stop in the middle of the leg, we find that the skin, the cellular membrane, the fascia, the muscles and tendons, blood-vessels, nerves, and even the bone itself, are all penetrated by the process of ulceration." (Lectures on Inflammation.)

Another familiar illustration of the progress of ulceration is observed in the progressive absorption which takes place in an internal aneurismal tumour, in which we find the sac of the aneurismal adhering to the parts with which it comes in contact, but after forming an intimate bond of union, the mass is gradually though slowly removed by the process of absorption; even the bone which intervenes between the external surface and the aneurism being finally absorbed.

It is this removal, Dr. Thomson remarks, of one texture after another, first the sac of the aneurism, then the pleura costalis, then muscles, bones, cellular substance, and cutis, layer after layer, that Mr. Hunter wishes to express by the term *progressive absorption*—a term sufficiently expressive

of the general phenomena which it exhibits, and of the gradual and successive disappearance of the parts which cover abscesses, aneurisms, and tumours, in their constant and uniform progress to the skin. In this process the adhesive inflammation precedes the outward progress of the aneurism, and limits, as in phlegmon, the extent of the swelling, and, as it were, directs it to the surface of the body. (Lectures on Inflammation.)

The occurrence of ulceration is much more frequent in some textures than in others, depending on the degree of vascularity of the part which it affects. It is observed also to be a more frequent effect of chronic than of acute inflammation. The skin appears, of all other tissues, to be most susceptible of ulceration. Mucous membranes, cellular tissue, bones, and articular cartilages, come next in order. Fascia, ligamentous structure, and tendons, are the least liable to ulceration. Hence, as Dr. Thomson states, when abscesses form under ligamentous or fibrous fasciæ, we find that they are long in getting to the surface, and that they seldom arrive at this by the shortest and most direct road, but usually by passing through some texture or organ that is more susceptible of being absorbed.

It is important to remark, however, that inflammation of the same tissue, apparently the same in kind, degree, and duration, will terminate at one time in ulceration, and at another pass off without producing solution of continuity. The importance, therefore, of ascertaining those circumstances which influence the termination of inflammation in ulceration must be obvious.

6. *Induration*.—This effect of inflammation is frequently observed. When it follows acute inflammation, it depends on the presence of fluids effused into the tissue of the inflamed part; when it takes place as an effect of chronic inflammation, it is more frequently produced by the presence of various solid products to which this process gives rise. Induration is most generally observed in soft spongy cellular organs, as the brain, cellular membrane, lungs, &c., but more frequently in the two latter tissues, in which the induration subsequent to inflammation is often very considerable, and produces remarkable alteration in their structure.

7. *Softening*.—An opposite state, that of softening, is not an uncommon effect of acute inflammation. Although it is observed to take place in all tissues, it most frequently occurs in the substance of the brain, mucous membranes, and cellular tissue. As this subject is one of great practical importance, and has of late been very fully investigated, it will be fully considered under the article *SOFTENING*.

8. *Hæmorrhage*.—Inflammation is often followed by hæmorrhage. The effusion of blood may take place from almost every tissue and organ in the body, but more frequently from those parts which are covered with mucous membranes. The various circumstances under which hæmorrhagic effusions, as a consequence of inflammation, take place, will be found under the article *HÆMORRHAGE*.

Treatment.—From the serious and often fatal effects of inflammation, it is of the greatest importance to endeavour to subdue the symptoms

on their first appearance, that those terminations or effects we have been considering, some of which have a dangerous and often fatal tendency, may be prevented. The necessity for the adoption of prompt measures is more especially necessary, when the inflammation is seated in an organ essential to life, in which the changes of structure frequently go on with great rapidity, so as either permanently to injure the function of the part, or to destroy life. Thus, when inflammation attacks the brain, lungs, heart, or intestines, or when it occurs in parts the organization of which is so delicate that the inflammatory action speedily destroys the structure and functions, as, for example, the retina or iris, the ear, or the larynx, the most energetic treatment should be adopted on its very first appearance. Another reason for the immediate employment of suitable measures in inflammation even in parts which are less essential to life, is, that when the blood-vessels become unduly distended for any length of time, they contract with difficulty, and thus give a greater susceptibility to recurrence of the inflammatory action, or, in other words, a predisposition to relapse.

Before commencing the treatment of inflammation, if any obvious exciting cause exist, it is proper to endeavour to remove it, and also to avoid every circumstance which can tend to keep up local or general excitement.

The object to be kept in view in the treatment of inflammation, is to effect resolution. This is, in some instances, the natural and spontaneous solution of the disease, though in the majority of instances it is induced by measures which tend to subdue the local and constitutional excitement. It is necessary, in estimating the probability of accomplishing such a desirable termination, to consider the duration of the inflammation, since we can only hope to bring about resolution in the more early stages. Even although the measures employed prove inadequate to this end from the duration of the symptoms before their application, still the severity or extent of the termination which may have ensued may be materially lessened by the judicious employment of means calculated to subdue inflammatory action.

The remedies by which the symptoms of inflammation are removed, have been termed antiphlogistic treatment, that is, remedies against inflammation. We have seen that the capillaries or vessels, which in the natural state admit only the colourless part of the blood, become so enlarged during inflammation as to admit red blood, and from their being thus surcharged, are inadequate to carry on the circulation. We have also seen that with this local congestion the vascular system throughout the body sympathizes, giving rise to symptomatic fever, during which the blood, being impelled with unnatural force, increases the distension and obstruction in the capillary circulation. These circumstances at once show the necessity of bloodletting, as the principal means of removing inflammatory diseases.

In all cases of active inflammation, but more especially when the constitutional symptoms are severe, general bleeding is to be employed, with the object of diminishing the quantity of blood, and, at the same time, of abating the force and frequency of the action of the heart and arteries.

The abstraction of blood from the system is more especially necessary in inflammation of important organs, as of the brain, pulmonary and abdominal viscera, in which diseases it forms the principal means of cure.

It is generally found that inflammation of serous membranes requires larger losses of blood than when the parenchyma or substance of an organ is inflamed, and that, on the other hand, inflammation of mucous surfaces is less under the control of general bleeding; in such cases the local is preferable to the general abstraction of blood.

The propriety or necessity for general bloodletting being determined, the question as to quantity requires consideration. For this there cannot obviously be any fixed or determinate rule, as it must depend on the importance of the organ inflamed, the intensity of the inflammation, its duration, and the peculiar circumstances which each case presents. When an organ important to life is inflamed, and if there be no special circumstances to forbid copious bloodletting, the effect produced on the symptoms is a matter of greater moment than the quantity of blood abstracted.

The too common practice of prescribing a certain number of ounces of blood to be drawn from a vein in an acute disorder is most reprehensible. The disease may yield to the abstraction of a few ounces of blood, or a much larger quantity than was at first anticipated may be necessary. Hence the obvious advantage of the physician superintending the bloodletting he prescribes, in all cases of emergency. Every practitioner must have seen cases in which, though he had imagined a moderate bleeding (sixteen to twenty ounces) would have cut short the disease, a very considerable quantity of blood has been lost before an impression was made on the symptoms. In one case of pericarditis which lately fell under our observation, in which, after the disease had been nearly subdued, a recurrence of the symptoms took place with redoubled violence, according to usual custom twenty ounces of blood were ordered to be drawn from the arm. From the urgency of the symptoms, however, we superintended the operation. No relief of the pain was obtained after twenty, thirty, forty, and fifty ounces were abstracted. When sixty had been taken away, the patient exclaimed, "I now feel relieved." This large bleeding was necessary as a means of relief from most acute suffering. Besides the quantity abstracted, the rapidity with which the blood flows has an important influence on the symptoms. The blood should be drawn from a large orifice, that a decided impression may be at once made on the disease; for which purpose, in cases of inflammation of a vital organ, a vein in both arms may be opened, and the blood allowed to flow till there is an approach to syncope, which may be favoured by placing the patient in the erect posture, whereby the flow of blood to the heart and upper parts of the body is retarded. It is incredible the quantity of blood which some patients have lost before inflammation of an internal organ has been subdued. The late Dr. Gregory used to relate in his lectures the case of a young woman who lost two hundred and thirty ounces of blood in the space of a few days, before an attack of pleurisy was

overcome. Such large bleedings, however, are seldom necessary.

The effect of bloodletting, more especially if carried to approaching syncope, in lessening inflammation, may be observed by comparing the state of the conjunctiva in acute ophthalmia, before and after the patient has been freely bled. The distended and tortuous vessels are no longer visible, and for some time after the conjunctiva often remains as pale as in its natural state. The same effect is produced on internal organs, and those structures which are not visible.

It is seldom that a single bleeding is sufficient to subdue active inflammation, even when carried to a sufficient extent. The disease may for a time appear subdued, but when the system rallies, when reaction succeeds to the depression consequent on a profuse bleeding, the symptoms reappear sometimes with the same intensity as at first, but more generally in a mitigated form, and require a repetition of the bleeding. We have sometimes seen the abstraction of a few ounces of blood, when the pulse was beginning to rise, indicating the period of reaction, give a final blow to the disease. Hence, in active inflammation, we are disposed to recommend, an hour or two after the first bleeding, the bandage to be re-applied, and a small quantity of blood (eight or ten ounces) to flow from the orifice. Even with this precaution the symptoms in many cases return, and therefore it is necessary to consider those circumstances which indicate the necessity of the further abstraction of blood, and the extent to which it should be carried.

1. There are some particular symptoms from which an indication as to the further loss of blood may be taken. We have observed that the effect of inflammation in an organ is to disturb seriously its functions; hence, when the natural function of an inflamed organ is restored, it is a true criterion of the cessation of the inflammation. When, however, the function of the part is only partially restored, or if, after being completely recovered, it again become disturbed, it is a sure proof that the inflammatory action is still lurking, and may, on the application of a trivial exciting cause, be again called into its former activity. Under such circumstances the further abstraction of blood will be necessary.

2. Another symptom requiring consideration as to the propriety of repeated bloodletting, is pain. In the early stage of inflammation it is more or less acute, but generally mitigated or removed by venesection; and when a moderate bleeding produces partial or complete cessation of pain, it proves that the inflammation has not made great progress. In other cases the relief from pain is less instantaneous or considerable, but takes place gradually with corresponding abatement of the other symptoms, and is often completely removed by local bleeding and counter-irritation. If, however, the pain be only partially mitigated, or its removal be of short duration, or after having been completely removed, it recur, announcing the renewal of inflammation, there can be no hesitation about the necessity of further depletion.

Again, we find that when acute passes into chronic inflammation, the pain abates, and ultimately entirely ceases, which may lead to the impression that the inflammation has been extin-

guished. Acute pain not unfrequently supervenes in such cases, and announces the conversion of chronic into acute inflammation, requiring a repetition of bloodletting and other measures for its reduction.

It is necessary, however, to remark that young practitioners are too often deceived in the expectation of acute pain in inflammatory diseases. We have already seen that when inflammation is allowed to proceed and to assume the chronic form, the pain abates, and at length finally ceases.

In many of the phlegmasiæ there is no pain, even when intense inflammation is going on. This is more especially the case in inflammation of the parenchyma of organs; in the brain, for example, in which most active diseases may be proceeding even to a fatal termination without any indication of pain. If, however, the symptoms be analyzed, abundant proofs will be given of the existence of serious inflammatory disease. Again, in pneumonia or inflammation of the pulmonary tissue, there is often no pain, the disease being indicated by cough or embarrassed respiration, and the crepitating sound of the breathing; or in cases of latent pneumonia, by the stethoscopic phenomena alone. Even in the advanced or chronic stage of inflammation of serous membranes, the pain abates or entirely subsides, while slow and insidious inflammation is going on. Were the practitioner to overlook such symptoms, and to imagine that in the absence of local pain inflammation did not exist, the life of his patient might be sacrificed.

3. The pulse has from the remotest antiquity furnished an indication of the propriety of bloodletting, and of the necessity for its repetition in acute diseases. In the phlegmasiæ the pulse is increased in frequency, and in volume or strength; and in inflammation of serous membranes it acquires more or less hardness, wiriness, or tension. The object of bloodletting is to reduce these states of the pulse, more especially the hardness, and in proportion as this is accomplished, the operation is beneficial; so that when we fail in removing this hardness of the pulse by profuse bleedings, the issue of the case is seldom doubtful. It is necessary, however, to bear in mind that in cases in which large losses of blood have been sustained, the reaction is often accompanied with a hemorrhagic throb or jerking of the pulse. We have often seen bloodletting prescribed for this state of the pulse, and observed that it invariably increased by the depletion; the crassamentum of the blood, at the same time, becoming progressively smaller at each bleeding. In these cases there is exhaustion with excessive reaction—a condition of the circulation which tends to impel the blood in inflamed parts, so that bloodletting proves indirectly a stimulating rather than an antiphlogistic measure when employed under such circumstances.

The state of the pulse alone, however, without reference to the general symptoms, is not always a safe criterion of the necessity for bloodletting. We find in many inflammatory diseases that the pulse does not exceed the average frequency or strength observed in health, so that were the practitioner to withhold his lancet solely because the pulse deviated little if at all from its natural state,

a serious or often fatal error would be committed. In such cases the degree of pain or other local symptoms of inflammation must regulate the practice. We very lately found it necessary to abstract once and again a considerable quantity of blood from a patient with abdominal inflammation, whose pulse did not reach the ordinary average frequency. In this case it was discovered afterwards that the ordinary quickness of pulse did not exceed sixty. Again, in the early stages of inflammation of the brain, the pulse seldom exceeds the natural standard, or is often even slower than usual, though it is generally observed to rise after bloodletting. The state of the local symptoms, therefore, is always a more safe criterion of the propriety of adopting active measures in inflammatory diseases than either the pulse or the general symptoms.

4. The appearance of the blood, when drawn, will frequently, in conjunction with other symptoms, afford assistance as to the propriety of further abstraction. We do not think that the buffy coat, which has been regarded as a test of the presence of inflammation, should much influence the decision, as we find it occasionally wanting in inflammatory diseases. When, however, the blood on cooling exhibits the buffy coat, more especially when it is tenacious, the crassamentum firm, the pulse wiry or corded, and the pain unsubdued, it may be confidently predicted that the inflammation is not subdued, and therefore more blood may be safely and advantageously taken. In the advanced stages of inflammation in persons whose powers are feeble, or when blood has been repeatedly abstracted, though the blood still exhibits the buffy coat, it is soft, and the coagulum loose. It appears, indeed, from the experiments of Prevost and Dumas, that when blood has been repeatedly abstracted, the red particles are diminished in number; and were we to judge from the gradual diminution of the fibrine, it would seem that this principle is also lessened. This appearance of the blood shows that inflammation still exists, but that no advantage will be derived from further bloodletting.

5. A most important circumstance, which it is necessary to consider in the treatment of inflammation by bloodletting, is the period or duration of the disease. If the symptoms have been allowed to go on without any effort being made to subdue them, it is vain to expect the same results from the vigorous use of the lancet, as in the more early stage. Profuse bleeding has less influence on the local disease than on the general powers; so that when inflammatory disease has slowly but steadily increased in an enfeebled habit, while at the same time the insidious approach of the symptoms has been overlooked, the patient has a better chance from the judicious employment of modified antiphlogistic measures, of which a moderate bleeding may often form part.

6. It is almost unnecessary to state that the quantity of blood extracted in inflammation must, with other circumstances, have reference to the age of the individual. The diseases of infancy are generally of the inflammatory kind; but it is very difficult to open a vein in infants. In such cases one or two leeches may be applied to the back of the hand or foot, and the bleeding after-

wards encouraged by warm fomentations, or immersing the limb in tepid water. In the older infant, the number of leeches must be increased according to age. In some instances the leeches may be applied to the neighbourhood of the inflamed organ; as by this mode of abstracting blood the local symptoms are not only more speedily arrested, but the general symptoms, with which every form of acute infantile disorder is almost invariably accompanied, are reduced.

In childhood, greater advantage is often derived from venesection than in infancy; indeed the active forms of disease at this period of life are too often overlooked, the practitioner being satisfied with the local detraction of blood, while the bolder measure of venesection is required. It is true that blood is less easily drawn from the veins of the arm in children, but there is ample resource in the jugular, from which any quantity may be taken by a little adroitness on the part of the surgeon.

The period of life when bloodletting is most required, and produces the most decided effects, is from manhood to middle age, when the powers are vigorous. After the middle age the powers decline, and the system is less able to contend with active disease, and the remedies necessary for its removal. While at the one period bloodletting may be carried fearlessly to the required extent, the practitioner must be more cautious when he is contending with acute disease at an advanced age.

7. Physicians often derive useful information from observing the prevailing type of diseases. In idiopathic fevers more especially, this knowledge is almost indispensable for the safe conduct of the case. The same observation is applicable to the treatment of inflammation, in which there is often a material difference in the intensity of activity of local and constitutional symptoms, as well as of the power of the system to bear large losses of blood. The most palpable illustration of this is the different types of fever which accompany puerperal or child-bed fever, which is well known to require different treatment according to the prevailing character of the epidemic.

7. Much has been said about the influence of temperament in determining the treatment of inflammatory diseases. The diseases of the sanguine temperament have been supposed to be of a more acute character, and to require a more active mode of treatment, than the melancholic or nervous. Greater weight, we apprehend, has been given to this notion than experience has warranted. Were the acute disorders of those of the melancholic temperament to be treated on this idea, serious errors would undoubtedly be often committed. The fact seems to be that persons of the sanguine temperament are more predisposed in general to acute or inflammatory diseases, and consequently are more frequently the subjects of them than those of the melancholic, bilious, or nervous; but when inflammation has once taken place, there is less difference as to its intensity, from the constitution or temperament of the individual, than has been usually imagined.

[Recent researches into the constitution of the blood in various diseases have led M. Andral to infer, (*Hématologie Pathologique*, p. 123, Paris, 1843, or Amer. edit. by Drs. J. F. Meigs and A. Stillé, Philad. 1844,) that when once the blood

has commenced producing an excess of fibrin, a certain time is required before this disposition is exhausted; or in other words, the process, he thinks, is self-limited. Still, he is of opinion, that at the earliest period, when the solid is merely congested, and the fibrin of the blood is scarcely above its healthy proportion, the advancement of the disease may be arrested by bloodletting, and in certain cases it may be cut short.

The arrest of the blood in the veins of the extremities, *hæmostasis*, has been employed by Professor Nathan R. Smith, and by Dr. T. H. Buckler of Baltimore, (*Maryland Medical and Surgical Journal*, March, 1843,) as a sedative agent to relieve inflammatory engorgement in parenchymatous organs, or inflammations of membranous tissues; to remove hyperæmia, and to restore the balance of the circulation; as well as to prevent hemorrhage resulting from either rupture of vessels, transudation of blood, or from wounds inflicted upon blood-vessels. If a bandage be applied around a limb sufficiently tight to arrest the venous circulation completely, and at the same time allow the arteries to pulsate, the blood within the distended veins is cut off, as it were, from the general circulation; a depletory effect is, in this manner, induced; and if the arrest of the venous circulation be practised on all the extremities at once, the skin becomes relaxed; the force of the action of the heart and arteries is weakened; and if the ligatures be applied when the heart and arteries have been deprived of a portion of the ordinary amount of blood, owing either to anæmia or to bleeding, so that the vessels are partially empty, it is found, according to Dr. Buckler, that the exhalants of the skin pour out the most copious perspiration; that the patient complains of a light feeling about the head, of weakness, and sickness of stomach; and if the carotids be pressed upon, they are discovered to be scarcely pulsating, and all the phenomena of syncope are found to take place.

Possessed of such powers, *hæmostasis* may be found a valuable agent in the treatment of the phlegmasiæ more especially; and it has been urged upon the notice of the profession by Dr. Buckler. "*Hæmostasis*," he thus forcibly expresses himself, "accomplishes what no other known remedy is capable of doing. It puts syncope under our control, both as to duration and degree. It is capable of exerting, under given conditions, a more powerful control over the circulation than the lancet, antimony, or digitalis; and controls the heart's action without exhausting the vital forces, or giving rise to the ill consequences which the protracted use of most of the sedative agents is likely to do. And, finally, *hæmostasis*, in the hands of judicious practitioners, must prove the means of saving an incalculable amount of blood,—to say nothing of the incredible benefits which would be derived from its adoption by those Sangrados of our art, who bleed empirically in all conditions, and who, in many cases, like the fabled vampire, suck the living current until the vital powers are spent."]

We have been considering hitherto those cases of inflammation in the treatment of which general bloodletting is required. It is not, however, always necessary to take blood from the system, the topical abstraction being often sufficient to ac-

complish the cure. Cases also frequently occur in which the loss of even a small quantity of blood from the system is followed by considerable inconvenience and exhaustion, though the same amount of blood abstracted locally is followed by excellent effects.

This mode of bloodletting may, therefore, be employed 1, when the amount of inflammation is trivial; 2, when the powers of the patient are too weak to admit of general bloodletting; 3, when the active stage of inflammation has been allowed to pass over, and is therefore little under the control of general bloodletting; 4, as an auxiliary to general bloodletting, when further loss of blood from the system is deemed unnecessary. Moreover the local abstraction of blood may be often so managed as to secure the advantage of a general bleeding. Thus, when blood is taken from the temporal artery or from the jugular vein in diseases of the brain, the quantity may be so regulated as to obtain this double advantage: hence the preference given to this mode of bloodletting in acute diseases of the brain.

With regard to the mode of abstracting blood locally, cupping is preferable to leeching in all cases in which it can be employed.

The blood is more rapidly abstracted, and the quantity more nicely regulated. There are regions of the body, however, to which cupping-glasses cannot be applied; under such circumstances recourse must be had to leeches in suitable numbers.

Another powerful antiphlogistic measure in the treatment of inflammation is the exhibition of purgative medicines, which not only remove accumulated secretions, but, according to the class of purgatives employed, produce, by their action on the intestinal exhalants, a powerful derivation from the circulating system. Hence great advantage is derived from a combination of cathartics, which may be administered in suitable doses and at longer or shorter intervals, according to the indication to be fulfilled.

By active purging the general powers may be very much lowered; so much so, indeed, that mild cases of inflammation often yield to the exhibition of purgatives alone, though the more sure and efficacious practice is to employ at the same time other antiphlogistic measures, more especially bloodletting, general or local, according to circumstances.

There is another principle on which the beneficial operation of cathartics may be explained, viz. that of revulsion. When a powerful medicine of this class is exhibited, a copious secretion from the surface of the alimentary canal takes place: the sudden removal of so much fluid from every part of the system not only lessens the quantity of liquids in the diseased as well as the healthy parts of the body, but in the general determination to the bowels, the irritation has been supposed to be diverted from the local inflammation to the intestines. We apprehend, however, that the benefit derived from free purging in inflammation is more owing to the abstraction of fluid, than to the revulsion which may be induced.

The employment of purgatives is more applicable to some forms of inflammation than to others. The circulation in the brain is readily affected by purgatives, as is evident from the paleness of the countenance, and the syncope induced

by active cathartics. Hence in all cases of cerebral congestion and inflammation, purging ought never (unless under special circumstances) to be omitted. In threatenings of relapse, the exhibition of purgatives often supersedes the necessity for local or general bloodletting; and from the intimate sympathy which exists between the intestines and brain, the necessity of attending to the proper regulation of the bowels in the stage of convalescence from acute diseases of this organ must be apparent.

In thoracic inflammation, purgatives form part of the antiphlogistic treatment. Experience, however, shows us that they are less efficacious in this than in some other forms of inflammatory disease; and, therefore, when there is evidence of pulmonary inflammation, more reliance is to be placed on the general and topical abstraction of blood than on the exhibition of purgatives; and when there is gastro-intestinal complication, they are to be rigidly withheld.

Since the morbid states of the alimentary canal have been so thoroughly investigated, practitioners are more guarded in the exhibition of purgatives in the treatment of abdominal inflammation. It is necessary to sweep out the bowels once or twice by some active aperient in the commencement, except when the mucous membrane is the seat of inflammation. It is a great source of anxiety with many practitioners to procure the free action of the bowels in peritonitis, which led the late Dr. Saunders to remark, in his lectures on peritonitis, that the best mode of opening the bowels is by the lancet; a practical precept in which we perfectly agree, as there can be no question of the mischievous effects arising from irritating the bowels by cathartics at a time when it is most important that every source of disturbance be averted.

When the peritoneal inflammation is subdued, the bowels are readily opened by comparatively mild aperients: indeed, this soluble state of the bowels is a tolerably sure criterion of the subsidence of the peritonitis. Much harm is also often done by injudiciously irritating the bowels after the inflammatory symptoms have disappeared; and we have many times traced the recurrence of enteritis to the constant irritation of the bowels by purgatives administered with the object of simply effecting their evacuation, which may be at all times ensured by emollient glysters, or a small quantity of castor-oil.

If it be necessary to be cautious in the employment of purgatives in peritonitis, it is more particularly so in inflammation of the mucous membrane of the intestines, which is not only a very common primary disease, especially in children, but a frequent complication of other acute disorders. It is unnecessary, however, to do more than to allude to this subject in this place, as it has been already fully and ably discussed. (See ENTERITIS and GASTRO-ENTERITIS.)

Mercury is a remedy of considerable power in arresting inflammation, either in conjunction with bloodletting, or in cases in which the loss of blood is deemed inexpedient. The beneficial effect of this medicine is best exemplified in the treatment of iritis, in which disease its power of controlling inflammation and in preventing the effusion of lymph, or, when effused, of effecting its absorp-

tion, are quite perceptible. Another illustration of the powers of mercury in checking the progress of inflammation is observed in inflammation of the larynx and trachea, in which organs, from their delicacy of structure, serious consequences often arise when the inflammation is not speedily arrested.

There can be little question that it exerts a similar influence over inflammation of internal parts, and appears to have a peculiar power in arresting or controlling the action of the capillaries, and of preventing those changes from taking place which are so destructive to the organization of inflamed tissues. In other instances, when the inflammation has assumed a chronic form, and consequently is little if at all under the influence of any form of bloodletting, mercury may be employed with the most decided advantage. The quantity in which it is administered must depend on the violence of the inflammation and the organ that is affected. It is in some cases necessary to bring the system more rapidly under its influence than in others; for instance, in inflammation of the iris, the larynx, or of the trachea. Therefore, after general or local bleeding, two grains of calomel, or five of the hydrargyrum cum creta may be given every alternate hour till there be some decided amendment in the symptoms. In diseases of less urgency, the same quantity may be given at more distant intervals, every four, six, or eight hours, according to circumstances. When the mercury produces purging, it must be combined with opium; or, if opium be improper, some of the ordinary astringents—catechu, kino, or chalk may be employed. Some physicians recommend much larger doses of mercury—ten, fifteen, or even twenty grains of calomel at once, and do not hesitate to repeat these enormous doses at short intervals. We confess we have never seen any case of inflammation which, if curable at all, resisted the more moderate doses we have advised. In the inflammatory diseases of hot climates, which run their course with frightful speed, the rapid introduction of mercury after venesection seems to be the only chance of saving life. In the acute diseases of temperate climates, however, most practitioners prefer the smaller doses, repeated at longer or shorter intervals according to circumstances.

Though mercury is capable of arresting the progress of inflammation when exhibited alone, it is often more successful when combined with opium. This is more especially necessary when there is much suffering from pain.

As a general principle, opium is inadmissible in inflammation, until the excitement has been reduced. That it is a stimulant has been proved by most carefully-conducted experiments on the lower animals, as well as by observation of its effects on the human body both in health and disease.

We have just adverted to the exhibition of calomel and opium in the treatment of inflammation. The notice of the profession was, many years ago (1783), first directed to the efficacy of this combination in the treatment of inflammatory diseases by Dr. Robert Hamilton, of Lyme Regis. He acknowledged that the practice was first suggested from the favourable accounts he had received from a navy surgeon of the treatment of

hepatitis by mercury. He adopted the hint, and found the practice successful in the hepatic inflammation which frequently accompanies the bilious, intermittent, and remittent fevers of this country. He soon, however, found it necessary to add opium to relieve pain, which happily most effectually answered that purpose. The success of this mode of treating hepatitis induced Dr. Hamilton to conclude, that it would prove equally so in every form of internal inflammation. He first prescribed calomel and opium in peripneumony, and was successful in a large proportion of cases, and under a variety of circumstances. The cases of pleuritis, enteritis, and child-bed fever, in which it was employed, also speedily vanished.

The efficacy of this combination in arresting internal inflammation led to its employment in acute rheumatism and in gout; and Dr. Hamilton had the satisfaction of seeing these diseases also give way most readily under its use. The following is a summary of Dr. Hamilton's mode of prescribing it. After bleeding and evacuating the bowels, a pill containing from five to one grain of calomel and from one to a quarter of a grain of opium according to the age and powers of the patient, was directed to be administered every six, eight, or twelve hours, according as the intensity of the inflammation and aspect of the disease required,—plentiful dilution with barley-water or any weak tepid beverage being at the same time enjoined. When there was much fever, with dry parched skin, tartar-emetic and sometimes camphor were added; this combination had the effect of determining powerfully to the skin, and promoting the action of the kidneys and bowels. After three or four pills taken in the course of twenty-four hours, the symptoms were evidently relieved; in other twenty-four, the disease gave way and soon terminated. If, however, there was no abatement of the inflammatory symptoms in the first twenty-four hours, more blood was abstracted, the calomel and opium given more frequently, and continued till the force of the disease was subdued.

It was remarked that when the mercury induced much sweating and purging, the salivary glands did not become soon affected; but it was not uncommon to observe the patient greatly relieved, though the mercury did not affect the mouth, or produce any visible evacuation, except a slight increase of urine or insensible perspiration.

The mercurial plan was almost invariably successful when employed early in the disease; but when adopted in the later stages, its efficacy was more uncertain, though when the mercurial action could be induced on the salivary organs, the recovery was more sure. Counter-irritation was at the same time adopted when necessary.

With regard to the allegation that, as the calomel had been combined with other powerful medicines, the beneficial effects might with greater probability be ascribed to them than to the mercury, Dr. Hamilton states, that though he always regarded the opium as of the most essential service in relieving pain, and that the tartar-emetic and camphor have sometimes contributed to the cure, he had often seen cases in which tartar-emetic, camphor, and opium had been for some days em-

ployed without affording the smallest relief; but on the addition of calomel, the symptoms gave way in a very short time; the amendment seemed in many cases, indeed, to take place as the salivary glands became affected. (Duncan's Medical Commentaries, vol. ix.) Subsequent experience has amply confirmed the practical deductions of Dr. Hamilton as to the efficacy of calomel and opium in the treatment of inflammatory diseases. This combination forms an admirable auxiliary to the use of the lancet in internal inflammation; and when the period for bloodletting has passed over, gives the patient the best chance of recovery.

Neither this nor any other remedy, however, must be permitted to interfere with bloodletting in active inflammation. Mercury may assist in controlling inflammation and render less bleeding necessary, but is in itself inadequate to subdue it. It is, in the first place, necessary to break the force of the disease by venesection, and afterwards to exhibit mercury, care being taken not to push this remedy too far, as it has been observed that its specific effects take place very readily when large quantities of blood have been abstracted.

When the inflammation has passed into the chronic stage, which precedes alteration of structure, mercury is the best, often the only mode of removing it.

Many physicians consider that in active inflammation the administration of opium alone, after a full bleeding, is followed by the most happy effects, especially in irritable habits. We have often in our practice, as well as in that of others, witnessed its efficacy. After bleeding the patient to approaching syncope, having regard to the effect rather than to the quantity abstracted, the reaction which generally follows a large bleeding may often be prevented by two grains of solid opium, or a draught containing one grain of pure acetate or muriate of morphia, administered when the faintness is disappearing. The heart's action is thus controlled, while the nervous system is tranquillized; so that the patient enjoys an interval of refreshing sleep, from which he often awakes with a soft skin and freedom from pain. In many cases this practice, with a moderate cathartic, is sufficient to arrest the inflammatory disease. If, however, after an interval of three or four hours, the symptoms return, with hot skin and wiry pulse, the bloodletting must be repeated, and two grains of opium with three or four of calomel given as before. It may in these instances be advisable to administer afterwards a few doses of this combination in smaller quantities—two grains of calomel with half a grain of opium at intervals of three or four hours.

This practice has been strongly recommended by the late Dr. Armstrong who emphatically said of Dr. Hamilton's treatment, that "it deserves to be written in letters of gold, on account of its great practical utility." In a paper written by this physician in the Transactions of the Associated Apothecaries, entitled "On the Utility of Opium in certain Inflammatory Disorders," he recommends the more early and free use of opium, evidently considering that the great advantage arises from the administration of the opium alone. He advises, after bleeding to approaching syncope, three grains at least of good opium, to be given

in the form of a soft pill; and that strict quietude be enjoined, in order if possible to procure sleep. In some instances, Dr. Armstrong found a smaller quantity of solid opium sufficient; but the dose was made equal by a portion of laudanum, which in highly irritable habits is preferable, because the sedative influence of the opium is thus more speedily procured. On some occasions, where a great quantity of blood has been lost in irritable persons, a large dose has been given after venesection, never however beyond five grains of solid opium, nor a drachm of the tincture at once.

The effects of opium thus administered, according to Dr. Armstrong, are to prevent a subsequent increase in the force or frequency of the heart's action, and a recurrence of pain, while it induces a tendency to quiet sleep and copious general perspiration.

Dr. Stokes has recently brought this subject before the profession in an excellent practical paper* in the first volume of the Dublin Medical Journal, written chiefly with the view of pointing out the advantage to be derived from the administration of opium in peritonitis, occurring under circumstances where bloodletting cannot be employed. The cases alluded to are—1. peritonitis arising from the escape of fecal matters into the peritoneal cavity, through a perforating ulcer of the intestine; 2. peritonitis arising from the bursting of an abscess into the serous cavity, or from rupture of the intestine, induced by external violence; 3. peritonitis occurring after the operation of paracentesis in delicate subjects; 4. low typhoid peritonitis occurring after delivery.

In these cases of peritonitis, the rapid sinking of the vital powers renders bloodletting and the usual treatment in common peritonitis inadmissible; the indications are to support the strength of the patient as far as circumstances permit, and afterwards to endeavour to prevent the further effusion in the peritoneal cavity, by inducing organization and adhesions of the effused lymph. For this latter purpose, Dr. Stokes thinks opium in large doses pre-eminently calculated. This practice was first suggested from the successful treatment, by liberal doses of opium, of two cases of peritonitis after tapping, and of another from the effusion of purulent matter into the cavity of the belly. Dr. Stokes gives several cases in illustration of this plan of treatment. In the first he was unsuccessful, which he ascribes to the exhibition of purgatives, from his mind being warped by an early and unfounded prejudice as to the necessity of evacuations from the bowels. In another, after a moderate leeching, a grain of solid opium was given every hour without inducing the slightest affection of the brain, though the patient took, in the course of eight days, one hundred and five grains of opium, exclusive of opiate injections, administered with the object of checking a severe diarrhoea which set in for three or four days.

Dr. Stokes has subsequently treated cases of common peritonitis with opium, where bleeding was inadmissible, and has had no reason to change

his high opinion of its powers; and further proposes it as a remedy in cases of rupture of the bladder and uterus, in peritonitis after paracentesis, or succeeding to the operation for strangulated hernia, and in pneumo-thorax from pulmonary fistula.

The favourable results of the treatment of inflammation of the serous membranes by opium, has led Dr. Stokes to employ it in the same condition of the mucous membrane, and under similar depressing circumstances. In a very interesting case of severe gastric fever, in which the abdominal symptoms ultimately became alarming, from the supervention of severe diarrhoea, which every day threatened death from exhaustion, a grain of opium was ordered every hour, when the patient seemed in articulo mortis: this was continued for the first twelve hours without inconvenience, but with the effect of procuring refreshing sleep. Next day the remedy was repeated in the same dose every second hour; and from this time the improvement was rapid, and ended in final recovery.

Liberal doses of opium seem also to have had an excellent effect in a case of phagedenic ulceration of the throat. We have seen the most astonishing results from large doses of opium in sloughing phagedenic ulceration, occurring in connection with syphilitic symptoms in broken-up constitutions, such as is frequently observed in the lowest order of prostitutes.

Dr. Stokes has drawn the following conclusions on this subject:—1. that in cases of recent inflammation of serous and mucous membranes, where depletion by bloodletting or other antiphlogistic measures is inadmissible, and the system in a state of collapse, the exhibition of opium has a powerful effect in controlling the disease; 2. that under these circumstances the remedy may be given in very large doses, with great benefit and safety; 3. that its effect, then, is to raise the powers of life and remove the local disease; 4. that the poisonous effects of opium are rarely observed in these cases; the collapse and debility of the patient appearing to cause a *tolerance* of the remedy.

Acute pain may sometimes render the exhibition of opium necessary, even in the acute stage of inflammation. When the pain is so excessively violent as to constitute the most prominent symptom of the disease, and has resisted full depletion and other active remedies, its continuance tends greatly to aggravate the inflammatory action, and may even induce a fatal prostration of the vital powers. Under these circumstances, the subjugation of the pain becomes the most pressing indication, and this is to be effectually accomplished by the administration of opium in doses of from one to two and even three grains. This plan of treatment has proved eminently beneficial in severe cases of peritonitis, of sciatica and acute rheumatism affecting the heart. In those cases attended with extreme pain, two grains of opium may be given at first, and one grain every hour until the pain has subsided. It is necessary that the dose should be increased in proportion to the violence of the pain, and that the remedy be cautiously continued, until it has made a decided impression upon the nervous system, in order to procure the

* Clinical Observations on the Exhibition of Opium in large doses in certain cases of disease, by William Stokes, M. D. one of the Physicians to the Meath Hospital.

relief intended. It is well known that very large doses of opium are well tolerated when the nervous system is much excited; but to guard against any injurious effect of this remedy on the brain, a cold lotion may be applied to the forehead, or if necessary to the whole scalp.

There is another condition of the system in which opium is extremely beneficial, viz. in exhaustion from loss of blood. There are some individuals who do not bear bloodletting well even when it is necessary; in other cases, blood may be abstracted under mistaken views of the nature of the disease, or it may happen that more blood has been taken away than the symptoms either warranted or required.

In those cases of exhaustion arising from the effects of loss of blood, opium, with nourishment and cordials, is the best plan of restoring the patient.

There are some inflammatory diseases in which opium cannot with advantage be prescribed. In inflammation of the brain, it is a doubtful remedy even after the more active symptoms have been reduced. Indeed, in all acute diseases in which the brain is primarily or secondarily affected, the exhibition of opium requires great circumspection. It not unfrequently happens that when the more urgent symptoms of cerebritis have been overcome, the patient continues restless and wakeful, with a cool skin, soft clean tongue, and rapid soft pulse. These symptoms are often decidedly ameliorated by a full dose of opium. In inflammation of the mucous membranes, which generally terminates by an increased secretion, opium, from its tendency to check this salutary process, should be withheld, unless special circumstances arise to render its exhibition imperative.

Of the other remedies of this class, our individual experience does not warrant us to say much in terms of praise.

Digitalis, which was formerly so much extolled for its anti-inflammatory powers, is now rapidly falling into disuse. Though it certainly exerts a peculiar effect on the heart's action, its uncertainty and the length of time which elapses before it produces any decided impression, have tended much to impair the confidence which was at one time reposed in its efficacy in controlling inflammation. We have seen it given in very large doses (ten drops every half hour), and though it lowered the frequency of the circulation, it seemed in many instances to exert scarcely any control over the local disease. From what we have personally observed, therefore, we should not feel inclined to recommend the employment of *digitalis* as an anti-inflammatory remedy.

Colchicum is certainly efficacious in checking gouty and rheumatic inflammation. Some years ago this remedy was much used as a counter-stimulant in visceral inflammation, and was by some imagined to be little inferior in power to bloodletting. These sanguine expectations, however, have not been realized, and at present the administration of *colchicum* is almost entirely confined to the specific inflammation of gout and rheumatism, in which cases, we have prescribed a pill containing the acetic extract of *colchicum* (gr. i.) and extract of *hyoscyamus* (gr. iii.) every eight hours, with excellent effects.

Among the remedies resorted to with the view of resolving inflammation, antimony has always been held in high estimation. Since its first introduction by Paracelsus, antimony has enjoyed more varied reputation in the treatment of acute diseases than any medicine in the *Materia Medica*. After it had been declared a most valuable remedy in many formidable disorders, it was denounced as a poisonous medicine, and interdicted under very severe penalties by the French Parliament in 1566. In later times, however, it has been again brought into use, and within the last century has been prescribed as a most powerful antidote to almost every form of febrile disease. Various forms and preparations of this mineral have been from time to time introduced, but after repeated trials of their efficacy only two have been retained. These are the antimonial powder, *pulvis antimonialis* of the London Pharmacopœia, and the tartrate of antimony and potassa. The virtue of the antimonial powder is not only doubtful, but according to the experience of some physicians it appears to be positively inert, 130 grains having been given by Dr. Elliotson three times a-day without producing even nausea. Dr. Thomson has satisfied himself from experimental investigations that the composition of the antimonial powder, and that of James's powder, which the former was intended to imitate, are totally dissimilar. This excellent pharmaceutical chemist states as the reason, that the antimony in James's powder is in the form of a soluble *protoxide*, while that in the *pulvis antimonialis* of the Pharmacopœia is in the state of an insoluble *peroxide*; and from the ascertained fact that the more soluble the salts of antimony are, the more certain and powerful is their effect on the living body, the cause of the inertness of the one, and the more certain efficiency of the other, is thus explained.

Sometimes the skin becomes moistened, or the bowels gently purged by small doses (two or three grains) of James's powder given every four or six hours. More generally, however, it does not produce any sensible evacuation, the pulse becoming softer, and the skin more cool under its use. It is more efficacious when combined with calomel or blue pill, or occasionally with opium, when there is pain. Thus, after general or local bleeding, a pill containing two grains of calomel or blue pill, the same quantity of James's powder, and a quarter or half a grain of opium, may be given every three or four hours with decidedly good effects, every alternate pill being followed by a saline aperient, should the state of the bowels require it.

The tartrate of antimony and potassa (*tartar-emetic*) is the preparation in most general use. It is seldom exhibited as an emetic, as the action of vomiting in inflammatory diseases is deemed prejudicial, at all events until the general excitement is reduced by bloodletting.

Stohl, however, recommended emetics in pneumonia. We are also told by Laennec, that Riviere vomited his patients in pneumonia with *tartar-emetic* daily, or every second day; and that Dumangin, physician to La Charité, followed this plan, and though he seldom combined bloodletting with it, that his practice was quite as successful as that of Corvisart, who bled much in that dis-

ease. Laennec concludes, that in these cases, the good effects of the tartar-emetic are to be ascribed to the derivation exerted on the intestinal canal.

This mode of treatment still prevails in many parts of the continent, especially in France, as appears from memoirs which have recently emanated from the French press.*

From the well known effects of continued nausea in depressing the heart's action, nauseating doses of tartar-emetic are frequently administered in inflammation, in conjunction with other antiphlogistic measures. For this purpose, a quarter of a grain of tartar emetic may be given in solution every two or three hours. The first two or three doses generally produce vomiting, but afterwards constant sickness is the only effect observed. By this mode of administration, the sub-acute forms of inflammation are often resolved, and in feeble habits, when the disease is little under the control of general or local bleeding, this mode of administering antimony is often followed by the most beneficial effects. The more slow or insidious forms of pulmonary inflammation, or the progress of tubercular disease may also often be checked by administering antimony in nauseating doses.

In still more minute quantities, (one-sixth or one-eighth of a grain every three hours,) tartar-emetic acts as a diaphoretic. This mode of administering antimony in inflammatory diseases was extolled by Cullen, and his example was followed by his pupils. It is seldom, however, prescribed alone, but in combination with other remedies of this class, more generally the saline diaphoretics.

Antimony has been at times exhibited in very large doses as an anti-inflammatory remedy, more particularly in Italy; indeed the large doses in which it has been administered by some continental physicians so astonished British physicians, that the accounts inserted in the foreign journals were at first discredited by many, while others supposed that there was a material difference in the chemical composition of the tartar-emetic. It has, however, been proved by chemical analysis that there is no essential difference between the Italian and British preparations, besides that the formula given in the respective pharmacopœias is nearly alike.

The practice of giving large doses of tartar-emetic was revived in Italy by Rasori, who, after embracing and widely disseminating the doctrines of Brown, had an opportunity of witnessing their fallacy in the treatment of an epidemic fever, which broke out at Genoa in the years 1799 and 1800. The application of the Brunonian principles to the management of this epidemic was attended with such fatal results, as to induce Rasori to change entirely his mode of treatment, and to substitute antiphlogistic measures. The practice of *contro-stimulus* which was pursued consisted in bloodletting, followed by large doses of tartar-emetic, four, six, eight, or more grains being given in the course of the day in any agreeable vehicle. The success of this treatment was as great as the previous plan had been fatal, and had an important influence in subverting the untenable theories

of Brown in the north of Italy. It also induced Rasori to employ the tartar-emetic in other acute diseases, more particularly in peripneumony. From the memoir which he published on this subject, (the translation of which afterwards appeared in the Archives Gén. de Méd. for 1824,) it appears that after one or more bleedings, or without this evacuation, according to circumstances, he prescribed twelve grains of tartar-emetic at intervals daily, which was repeated during the night. If the disease had made considerable progress, he began with twenty or thirty grains, increasing the dose daily till one or even several drachms were taken in the course of twenty-four hours. The result of this practice in the hands of Rasori was encouraging. Of eight hundred and thirty-two cases of pneumonia treated by the tartar-emetic, one hundred and seventy-three only died. It was subsequently prescribed by most of the Italian physicians, some of whom published the results, from which it appears to have been even more successful in their hands.

Laennec was induced from these flattering accounts to make a trial of it, but at first restricted it to cases of apoplexy. Having occasion some time afterwards, however, to attend two cases of peripneumony in which he thought it inexpedient to resort to venesection, he determined to make trial of the tartar-emetic; both patients rapidly and unexpectedly recovered, so that he was encouraged to give it in other cases. Laennec did not prescribe it in the large doses recommended by Rasori; indeed his mode of administration is so judicious that it has been generally adopted. The following is a summary of the manner in which Laennec employed the tartar-emetic in the treatment of pneumonia. As soon as the existence of the disease was recognised, and the patient was able to bear venesection, blood was first taken from the arm, unless in cachectic or debilitated subjects, in which it was deemed advisable to dispense with this evacuation. Immediately after bleeding, one grain of tartar-emetic dissolved in infusion of orange-leaf was directed to be taken and repeated every second hour for six times, after which the patient was allowed to remain quiet for seven or eight hours, if the symptoms were not urgent, or the patient disposed to sleep. If the inflammation had already made considerable progress, the same dose was continued uninterruptedly until there was decided amendment.

It was seldom necessary to give a large quantity of the tartar-emetic, though in extreme cases as much as a grain and a half, two grains, or two grains and a half, were prescribed at the same intervals. Many patients were found to bear these doses of the tartar-emetic without either vomiting or purging being induced: more generally, however, it excited vomiting or purging for the first day, but this effect soon passed off, and the *tolerance* (power of bearing the remedy) became established often within twenty-four hours from the time of its first administration. It was even occasionally necessary afterwards to prescribe gentle aperients to keep the bowels open. It was observed also that the tartar-emetic was most efficacious when it did not produce any sensible evacuation; and that, although severe vomiting and purging are by no means desirable, the cure of the

* Mémoire sur les fluxions de poitrine, par Louis Valentin, M. D. Clinique Méd. de l'Hôtel Dieu de Rouen.

inflammation was often very satisfactory, when the stomach and bowels were much irritated by the remedy. This may often be checked by combining with the tartar-emetic a small quantity of opium. Laennec recommends the addition of one or two ounces of syrup of poppy to the six doses to be taken in twenty-four hours. We have found the irritation very much allayed by adding the dose of the tartar-emetic to the common effervescent mixture, to which a few drops of laudanum may, if necessary, be added.

At the end of a few hours, seldom beyond twenty-four, such a decided improvement in the symptoms takes place, that both the patient and the practitioner are encouraged to persevere with the medicine till resolution of the inflammation be effected, when the medicine should be withdrawn gradually by giving it at more distant intervals. It is singular how patients become accustomed to tartar-emetic, when restored to convalescence. Laennec states that when they are taking their usual allowance of food, nine, twelve, or even eighteen grains of the emetic tartar may be taken daily without their being at all aware of any medicine being given. This is in opposition to the opinion of Rasori, who considers the *tolerance* to be owing to the excess of stimulus which exists in the system and produces the disease; consequently, whenever this is destroyed by the contro-stimulant effect of the tartar-emetic, the tolerance, were this theory correct, should cease, which is certainly in direct opposition to our own experience. We have observed in some cases of pneumonia treated by tartar-emetic, that when the patient could bear a grain every second hour, twenty drops of the antimonial solution produced copious vomiting, showing that this medicine is less emetic in large than in small doses.

Laennec has detailed shortly the several diseases in which the emetic tartar has been found successful in his hands. These were, 1. pulmonary inflammation; 2. inflammation of serous membranes, though he did not appear to place great value on its powers in this class of diseases; 3. hydrocephalus; 4. phlebitis; 5. acute chorea; 6. articular rheumatism; 7. severe ophthalmia; 8. apoplexy; 9. acute dropsy.

No satisfactory explanation has been offered of the mode in which tartar-emetic affects the resolution of inflammation. It appears not only to check the progress of inflammation, but to cause the absorption of inflammatory effusions. Laennec affirmed that he had observed, in a case of articular rheumatism, well marked fluctuation of the knee-joint disappear in the course of six hours by the use of this medicine.

The value of large doses of tartar-emetic, as a powerful anti-inflammatory remedy, is now established by the united experience of some of the most distinguished British and continental practitioners. In our hands, we have seen the most surprising effects produced by it when administered according to the mode proposed by Laennec. We have never found it necessary to exceed twenty grains in twenty-four hours, and when the remedy is at all likely to be beneficial, this quantity need not be exceeded. There are few cases of inflammatory disease in the early stage, which do not yield to prompt bleeding, followed by a few doses

of tartar-emetic; and in cases which have been so long neglected that the period of bloodletting has been allowed to pass over, it affords the best chance of grappling successfully with the disease.

These are the general measures on which our chief reliance should be placed for the removal of inflammation. There are other points of minor importance to be attended to; for example, the thirst is to be allayed by cooling sub-acid drinks, containing lemon-juice, cream of tartar, or a solution of the pulp of tamarinds. It is also sometimes expedient to endeavour to diminish feverish heat by the free admission of cool air, by light bed-clothes, and by administering refrigerants, such as citrate of potash, acetate of ammonia, or nitre. These measures, however, are not to divert the attention from the more active remedies.

The propriety also of removing every source of irritation is obvious; not only is the exciting cause to be ascertained, and, if practicable, removed, but excitement of every kind must be withdrawn; hence in visceral inflammation the greatest quietude of body and mind is indispensable. When, therefore, the inflammation is seated in an external part, all use of the organ must be avoided, and such position adopted, as will be least likely to favour the circulation of the blood towards the inflamed part.

Every kind of food which has a tendency to excite the circulation must be avoided; the very mildest farinaceous aliment being best adapted, and even this should be given in small quantities at stated intervals.

We shall next shortly allude to the local treatment of inflammation.

In all diseases attended with excitement, the free application of cold is decidedly beneficial. In inflammation of the brain, after depletion, the application of cold evaporating lotions, or bladders filled with pounded ice, not only reduces the morbid heat of the scalp, but diminishes the vascular action in the brain. The most powerful mode of applying cold to the head is the *cold dash*, which we regard as little inferior to bloodletting itself; and when the general powers are too weak to render the abstraction of blood to an adequate extent expedient, it is the most effectual mode of arresting the inflammatory action.

In the subacute or chronic form of inflammation of the lung, more particularly in that slow insidious form which attends the formation or progress of tubercles, the local application of cold tends materially to check the progress of tubercular disease. For this purpose the chest is to be sponged daily with vinegar and water, (at first tepid, and afterwards cooled down to the natural temperature,) and after being rapidly dried, the skin should be well rubbed with a coarse towel or flannel. This mode of applying cold has also the advantage of removing or diminishing the susceptibility to cold, which renders the consumptive invalid so liable to returns of the inflammation. In inflammation of the abdomen, cold applications have been recommended by some practitioners. Some years ago Dr. Sutton strongly advocated this practice in peritoneal inflammation, and detailed several interesting cases in which the local application of cold was decidedly beneficial. From Dr. Sutton's observations, this practice appears to

be peculiarly adapted to the chronic stage of peritonitis, when the symptoms are not such as to require bloodletting. (Tracts on Delirium Tremens, on Peritonitis, &c. by Thomas Sutton, M. D. 1813.)

In external inflammation, the application of cold lotions forms an essential part of the antiphlogistic measures. For this purpose a solution of acetate of lead, or a lotion consisting of equal parts of the acetate of ammonia, alcohol, and water, may be employed. These may be used cold or tepid, according to the feelings of the patient.

Warm applications are often very beneficial in inflammation. The warm bath, by producing a powerful determination of blood to the external parts, is often employed with great advantage, more especially in inflammation of the abdominal cavity. For this purpose the temperature of the water should not be too high, (not exceeding 98°,) a greater degree of heat proving a stimulus, and thus increasing the inflammatory action.

The partial application of heat in the form of fomentations is often a powerful mode of reducing inflammatory action, and at the same time of relieving pain. We have an illustration of this in the beneficial effects of the vapour arising from warm water, or the decoction of poppy or hyoscyamus in ophthalmia, and in various forms of external inflammation. Warm fomentations properly applied often prove valuable applications also in internal inflammation. We have often observed excellent effects from them in pulmonary inflammation after general or topical bleeding, and in abdominal inflammation this practice is so beneficial that it is seldom if ever omitted.

The different forms of counter-irritation are employed in certain stages of inflammation with great advantage, after the activity of the symptoms has been subdued. When this has been accomplished, should there be pain, the application of a sinapism or blister to the neighbourhood of the inflamed organ will frequently remove it, and when the inflammation has passed into the chronic form, the repeated application of blisters is decidedly beneficial. Great care, however, should be taken that local stimulants be not applied until the active stage of the disease has been overcome. The principles on which the application of counter-irritants should be employed have been so fully discussed in the articles COUNTER-IRRITATION and DERIVATION, that it is unnecessary in this place to go more into detail. We may, however, just advert to the practice of applying blisters when inflammation has receded from a part it had just occupied, and fixed on another organ, as happens now and then in gout and rheumatism. It has been recommended to apply a blister near the seat of the former disease with the view of recalling the inflammation, but we agree with Mr. Lawrence, that it is better to attack the inflammation vigorously in its new quarters, than to attempt to entice it back to its old seat.

It is scarcely necessary to state, that in determining the measures which may be necessary for the treatment of inflammation, we must bear in view the particular circumstances with which it is accompanied, or which may arise in its progress. For example, we are to consider not only its

duration, and degree or amount, but the age and constitutional powers of the individual, and the effect of such measures as may have been adopted. When inflammation occurs in a feeble or exhausted habit, (and the local symptoms may in such cases be intense,) the treatment must be less active. Perhaps a small bleeding may be hazarded, but in general it will be more safe to trust to local bloodletting, with mercury and opium. It is often necessary in such cases to adopt local antiphlogistic treatment, and at the same time to give general support by animal nourishment. Even wine may be occasionally required.

There is another point of great practical importance connected with the treatment of inflammation. We frequently observe, after the employment of active measures, that the symptoms, though much modified, continue; the general symptoms may even be entirely removed, but the local disease is still perceptible; a degree of passive inflammation or local congestion remains, which a further extension of bleeding or purging infallibly aggravates. This is often observed in ophthalmia, and did not escape the observation of Hunter. In other instances the measures adopted produce exhaustion accompanied with morbid irritability, which it is often exceedingly difficult to distinguish from inflammation. Both the local and general symptoms will, however, afford some assistance. The pulse, though quick, will be found soft and compressible, the skin cool, and there is little if any thirst. The local symptoms are slight; there is often very little pain, and when there is, it is transient. What is to be done under these circumstances? Stimuli may reproduce the inflammation; bleeding and other depleting measures will aggravate the symptoms. It is most prudent in these cases to try cautiously fluid nourishment, with a little wine in sago or arrow-root; and if the state of the local symptoms admit of local detraction of blood, a few leeches may be from time to time applied. In short, a combination of treatment answers best.

In the treatment of congestions of blood—a subject of great importance, though involved in obscurity—we agree with the precepts laid down by Dr. Barlow. If the congestion arise in a plethoric habit, it is evident that general antiphlogistic measures, more especially bleeding, purging, and abstemious diet must be resorted to. This plan, however, must not be carried too far; it is sufficient to take off the pressure from the circulation in order to overcome the plethora. Overbleeding, from the reaction which follows, and the weakness it induces, brings on this very state.

When the local congestion is unaccompanied with general fullness, or when it is the result of irritation, local depletion is to be adopted in preference to the general measures, which are indispensable when plethora exists: indeed, as Dr. Barlow has well remarked, general depletion is not only unnecessary but injurious, enfeebling the system, and weakening those efforts by which the congestion would be naturally relieved. (See CONGESTION OF BLOOD.)

The other measures which in congestive affections may be employed in conjunction with bloodletting, or alone when this evacuation may be

dispensed with, are mild purgatives, diaphoretics, warm bathing, counter-irritation, and low diet. These several measures must be varied, and repeated more or less frequently according to circumstances.

Congestive affections, both of an acute and chronic character, are not unfrequently combined with general debility; and there are cases in which a mixed plan of treatment is often indicated, and the management of which requires generally much tact and caution. The general debility is sometimes the *primary* cause of the acuteness and persistence of the congestion; and if such active antiphlogistic remedies be used as increase the general debility, they will inevitably have the effect of aggravating the local complaint. While, therefore, it may be advisable, in such cases, to keep the local congestion in check by small topical bleedings, counter-irritation, fomentations, poultices, &c. it is often necessary to strengthen the constitution by the use of tonics, generous diet, and change of air.

In many cases of chronic congestions in which the blood-vessels are relaxed, the resolution of the congestion is often greatly favoured by the exhibition of tonics and stimulants. We may mention, for instance, the good effects of various tonics in chronic catarrhal affections, and in some other chronic pulmonary diseases.

In cases of habitual determination of blood, and of a tendency to attacks of congestion of one particular organ, such as the brain, lungs, &c. bleeding by revulsion (or at a remote distance from the organ affected) occasionally repeated, together with great attention to the regulation of diet, and the general management of the system, is found more effectual than depletion in the neighbourhood of the organ, which often induces an increased disposition to an undue influx of blood, although it may procure momentary relief.

Chronic inflammation differs from acute only in degree. The duration of the disease is of little consequence compared with its intensity. It should also be kept in mind that inflammation which has been for some time in a dormant or chronic state, sometimes becomes suddenly acute, and may require vigorous measures for its removal.

In the treatment of chronic inflammation, there being no constitutional excitement, general bloodletting is seldom necessary, local bleeding by cupping or the application of leeches being generally sufficient, unless there be a degree of feverishness, or the inflammation be seated in an organ over which local bloodletting exerts little control, when the abstraction of a few ounces of blood from the arm is preferable. The bowels are to be thoroughly cleansed by purgatives, and afterwards a general action should be kept up by alterative doses of mercurials with the milder kinds of aperients, such as rhubarb with manna and Rochelle salt.

Counter-irritation is especially necessary in chronic inflammation. Blisters are less effective than the more severe kinds of counter-irritants, such as tartar-emetic ointment, or a plaster made of equal parts of Burgundy pitch and yellow wax, to which a scruple or a half-drachm of tartar-emetic (according to the size) is to be added. Either the tartar-emetic ointment or plaster brings out

a copious eruption of pustules, which greatly relieves the chronic forms of inflammation. Sometimes a seton, caustic, issue, or the moxa, is employed with great advantage.

In all cases of inflammation, whether acute or chronic, the regulation of the diet is of essential importance. In acute inflammation the mildest food only is admissible; in the chronic, nourishment may be more freely allowed. Indeed it is often necessary to allow moderate support while local bleeding and other measures are employed. Pure air is of most essential consequence in all acute diseases, and often exerts a most decided influence in the treatment of low kinds of inflammation, which it is often difficult to remove in certain localities.

The general principles by which the treatment of inflammation is to be regulated having been considered, we proceed to state what is necessary to be done when any of its effects or terminations have taken place.

It is necessary, however, to bear in mind, that although the inflammation may have produced either of the morbid changes alluded to, the inflammatory action may be still going on, so that it is necessary to watch the primary disease, as well as its effects. For example, in pleurisy and peritonitis, the liquid effusion in the pleural or abdominal cavity does not necessarily imply that the inflammation of the pleura or peritoneum has ceased: on the contrary, we almost invariably find it necessary in such instances to combat the inflammation on which the effusion depends, at the same time that we attempt the removal of the effused fluid. It is not uncommon to observe, that as the local inflammation is reduced, the effusion disappears simultaneously, or very soon after: in such cases the effusion does not depend, as has been too generally supposed, on diminished action of the absorbents, but on the increased quantity of fluid which is effused from the inflamed surface.

The sudden relief which often follows from bloodletting judiciously employed in cases of acute dropsy is thus explained; and also, how venesection frequently removes dropsical effusion when diuretics in every form and combination have failed. When effusion follows inflammation of a more chronic character, more especially when the powers of the individual are low, it becomes a point for consideration how far any form of bloodletting may be advantageously adopted. In such cases the local abstraction of blood, or other local antiphlogistic measures, may be advantageously combined with such remedies as are calculated to effect the removal of the effused fluid. The various means which are to be employed, as well as the circumstances which are to regulate their administration, have been already considered in the article *Dropsy*, to which we refer.

The effusion which takes place as a consequence of inflammation of any of the three cavities may proceed to such an extent as to embarrass seriously the functions of the contained organs, and even ultimately to destroy life. This has led to an attempt to evacuate the effused fluid by an opening. Such an operation, however, is not always practicable, as, for instance, in the effusion which is the effect of acute hydrocephalic inflam-

mation. A few practitioners of more than ordinary boldness have, however, ventured on tapping the cranium in *chronic hydrocephalus*; but though in some recent examples this operation has been successfully performed, we fear the small average proportion of cases in which it has succeeded will scarcely give general encouragement to hazard it.

When effusion to a considerable amount takes place in the pleural cavity, there is little hope of deriving any permanent advantage from the employment of internal remedies administered with the view of promoting the absorption of the effused fluid. In such cases the chest has been tapped, and with such favourable results that this operation can no longer be viewed as a hazardous attempt, but the only means of saving the sufferer from indescribable suffering and ultimate death. (See *ΕΜΠΥΕΜΑ*.)

When peritonitis terminates in effusion, the effect of evacuating the fluid is doubtful: in many instances the fluctuation is not perceptible during life; and even were the fluid detected, more benefit is derived from occasional leeching, counter-irritation of the abdomen, mercury, and diuretics. By a steady perseverance in these measures, abdominal effusion succeeding to peritonitis has been frequently removed under most unpromising circumstances.

When inflammation has terminated in suppuration, similar principles must regulate the treatment, the extent of purulent formations being often materially diminished by a continuance of measures calculated to abate the inflammatory action. The kind and extent of these measures must depend on the active or passive nature of the local as well as constitutional symptoms, the object in every case being if possible to arrest, or if this be impracticable, to diminish the extent of the purulent formation, and afterwards to promote either the absorption or evacuation of the matter. If the suppurative process be accompanied by local or general symptoms, as in *phlegmonous abscess*, it is evident that a persistence in antiphlogistic measures, including general or local bloodletting if necessary, may be required till the excitement is subdued. It is well known also, that a removal of the inflammatory action frequently takes place in an organ after matter has formed, just as acute may supervene on chronic inflammation, or as the inflammatory process may be suddenly renewed in a part recently inflamed. The necessity, therefore, of watching the progress of inflammation in organs in which purulent formations have occurred, is apparent, though the attention of practitioners, it must be confessed, is too often almost exclusively directed by the local measures which are best calculated to assist the evacuation of the purulent matter.

On the other hand, when suppuration takes place in feeble habits, general antiphlogistic measures must be employed with great caution, even though there be evidence of local excitement. In these cases, a moderately stimulant plan of treatment, consisting chiefly in nutritious diet, a moderate use of wine and tonic medicines, is often more successful; and should the local affection indicate too great excitement, this may be moderated by small detractions of blood from the neigh-

bourhood of the part, and such other local measures of an antiphlogistic kind as circumstances may require. In short, the practitioner must have in view, on the one hand, not to retard a salutary process, nor, on the other, to increase or renew the action by which the suppuration has been induced.

When suppuration succeeds to phlegmonous inflammation of the external parts of the body, various topical applications are found useful. Warm applications are most suitable not only from their soothing, but from their supposed power of promoting the process of suppuration. Fomentations of simple warm water, or of decoctions of anodyne or emollient substances, are to be frequently applied, and the part afterwards covered with a large poultice of bread and water, or of lintseed flour, some contrivance being adopted to prevent the escape of the heat and moisture. These applications are to be frequently renewed, as soon, indeed, as they become cool, the principal benefit being derived from their warmth and moisture.

When fluctuation can be detected, whether the purulent matter be collected in a distinct cyst or abscess, or be diffused in the cellular tissue, it becomes a subject of consideration whether the pus should be evacuated by an opening made into the part, or be allowed to discharge itself by the gradual process of ulcerative absorption or spontaneous rupture.

If the abscess be situated near the surface of the body and at a distance from any important organs, surgical interference may generally be dispensed with. There are some circumstances, however, which render it advisable to open abscesses as soon as matter can be detected. For example, when the abscess forms in the neighbourhood of an organ important to life, such as the larynx or trachea; near a large joint; in the vicinity of any of the great cavities; when the matter is deep-seated, or being resisted by an unyielding texture, becomes diffused among other parts where less resistance is offered, as in abscess beneath the fascia covering muscles, in the sheaths of tendons, or under the periosteal covering of flat bones—an early opening should be made for the discharge of the purulent matter. The cavity of the abscess becomes afterwards gradually obliterated by the process of granulation and cicatrization, but this stage of the curative process frequently requires the attention of the surgeon.

The treatment of chronic suppuration differs in many respects from that of the acute. It is often surprising how little constitutional disturbance precedes or accompanies these chronic abscesses, which have sometimes been observed to give no indication of their formation, till attention has been directed to an indolent swelling, which on examination is found to contain fluid. They are frequently observed in individuals of an unhealthy constitution, and more especially in those of a strumous diathesis. Hence, in the treatment, the improvement of the general health must form a more prominent feature than even the local management of the abscess.

Chronic abscesses evince a great disposition to increase in size, but the matter has a tendency rather to become diffused than to approach the

surface, or, as it is termed, *to point*. The propriety, therefore, of opening them requires, in general, little consideration, though the mode in which this is to be done is a matter of greater nicety. Mr. Lawrence, in his lectures on inflammation, has very clearly pointed out the local and constitutional effects which follow when these chronic abscesses are opened in the same way as a phlegmonous abscess. If an aperture be made so as to evacuate the matter, and a poultice be afterwards applied, as is the practice in phlegmonous abscesses, the entrance of the air produces decomposition of the matter; the surface or cyst of the abscess inflames; the purulent secretion is altered, becoming thin, fetid, and very irritating to the parts with which it comes in contact. The constitutional disturbance which is thus excited aggravates the local disease, which, in its turn, reacts on the constitutional irritation to such a degree as seriously to disturb the general health, and frequently to destroy the patient.

The mode of treating chronic abscesses adopted by the late Mr. Abernethy obviates the risk of inflammation of the cyst, and the constitutional effects to which it gives rise. This consists in making a small oblique opening into the abscess so as to allow its contents to escape, the ingress of air being carefully prevented; the aperture is then to be closed, and pressure applied so as to allow of its uniting by adhesion. The object of this practice is to diminish the cavity of the abscess, so that, after it has become contracted, it may be again opened, and afterwards treated in the same way as a phlegmonous abscess, and at the same time to obviate the constitutional irritation which arises from exposing the cyst of a large abscess to the action of the external air.

This mode of treatment is, however, not invariably successful; the cyst often continues to secrete pus so as to distend the abscess to its former size, or, if it be diminished, a fistulous opening leading to a large cavity remains. In these cases, surgeons have succeeded in producing inflammation and adhesion of the cyst of the abscess by passing a seton through it, or by injecting irritating fluids.

The general health is to be improved by nutritious diet, vegetable or mineral tonics, and residence in a pure atmosphere.

The treatment of ulceration must depend on its local or constitutional origin, the acute or chronic character of the inflammation by which it is accompanied, the causes by which it is induced, and the structure in which it occurs.

1. Ulceration may be strictly a local affection, as when it arises on an external part of the body from an external cause, such as a wound or other kind of injury. In this case the ulceration may be either accompanied with little or no inflammatory action, or with considerable local as well as constitutional disturbance. It is evident that in the former, mild local applications, and avoiding exercise or use of the part, will speedily effect a cure; while in the latter, antiphlogistic measures, even general or local bleeding, must be combined with topical applications.

2. When ulceration arises from constitutional causes, in addition to the local treatment it is necessary to attend to the general health. Thus,

when ulceration of an external structure arises from syphilitic, syphiloid, cancerous, scorbutic, or scrofulous diathesis, it is in vain to attempt to heal the ulceration by local measures alone; or should these succeed, the cure cannot be considered permanent until the particular constitutional malady be subdued.

3. Though almost every tissue of the body is liable to ulceration, it occurs more frequently in the skin and mucous membranes. In the former the treatment is often tedious, depending in many instances on the state of health and previous habits of the individual. The local treatment requires attention also to the kind and extent of the local inflammation: this is in some cases of an active inflammatory character; in others it is of a low or chronic kind, the one demanding an antiphlogistic, the other a stimulant plan of treatment. It is inconsistent with this outline to enter more minutely on the treatment of ulcers, and as this belongs more properly to the province of surgery, we beg to refer to the writings of Home, Lawrence, Thomson, Cooper, Bell, Brodie, and others, for much valuable information on this subject.

Ulceration in mucous membranes is more common in some situations than in others, the gastrointestinal mucous membrane being by far its most frequent seat. We have repeatedly alluded to the latency of gastro-enteritis, and even when it proceeds to ulceration, the symptoms are no less equivocal. Hence arises the uncertainty of any method of treatment except that which tends to arrest inflammation in this tissue. We do not affirm that ulceration of mucous membranes does not cicatrize: this has been demonstrated by the most satisfactory process, not only in genuine cicatrix of ulcers of the stomach and colon, but even in the small intestines. The exhibition of mineral tonics and astringents—sulphate of copper, or the superacetate of lead, in combination with opium—in intestinal ulceration have been found successful, though some physicians speak of the more powerful vegetable tonics, sulphate of quinine, strong infusion of catechu or logwood, as equally efficacious.

When ulceration occurs in the bucco-pharyngeal membrane from the syphilitic or syphiloid poison, the treatment must be entirely constitutional; therefore mercury, sarsaparilla, and nitric acid must be given according to circumstances. Phagedenic ulceration of the genital organs requires the application of a powerful escharotic, for example, the concentrated nitric acid. We have seen the action of this *specific* in those cases powerfully assisted by liberal doses of opium, to the extent even of a scruple in the twenty-four hours.

Mortification is a frequent termination of inflammation, but it arises also from a variety of other causes. It is obvious, however, that in this place we can only consider the treatment of that form which is the effect of inflammation, and refer for information as to the measures to be adopted, when it takes place from other causes, to various articles in this work, and to the article MORTIFICATION.

The general principles on which the treatment of mortification originating in inflammation is to be conducted, vary according to the circumstances

with which it may be associated; for it is inconsistent to suppose that one general rule can be applicable to every case that may occur. Dr. Thomson has justly remarked, there can be no general plan of treatment equally suitable to the differences which occur in the seat, form, progress, and state of the disease, nor to the various affections of the general system by which it is invariably accompanied.

In all cases of mortification there are some circumstances to be considered before any plan of treatment is determined. 1. Mortification, in respect to its seat, is distinguished as it affects an internal or an external part. 2. It is necessary to determine whether the mortification arise spontaneously, (i. e. from some causes connected with the general system, which are not very obvious,) or whether it originate from some external cause or local injury; and, 3, whether it be of an acute or chronic character.

When inflammation of an external organ terminates in mortification, it is almost invariably fatal, the acute inflammation of which it is the effect being often of itself sufficient to destroy life; when it is not, the system is seldom able to withstand the additional irritation which the mortification induces. If, therefore, the violence of inflammation in an internal organ be likely to terminate in gangrene, the only indication of treatment is to prevent its taking place by active antiphlogistic measures, since it is well known that death almost invariably follows mortification of an internal organ, unless, as very rarely happens, the gangrenous inflammation has stopped spontaneously, and the mortified parts have separated and been afterwards expelled by a natural outlet.

In every disease it is obviously necessary to ascertain and to remove, if possible, its causes; and this is no less important in mortification. When it arises from inflammation, it is necessary to discover whether this action still continues, or has abated or entirely ceased. If the inflammation still continues, it is proper to ascertain its degree, both as respects the general as well as the local symptoms; for we often find that there is considerable local action going on, with very moderate excitement of the constitution. When the causes and degree of gangrenous inflammation have been ascertained, the object of the treatment to be adopted is to prevent mortification taking place; or if it have already occurred, to arrest its progress; and if seated externally, to promote the separation of the mortified from the living parts.

To fulfil these indications, the measures to be adopted must have reference to the acute or typhoid character of the symptoms. It is scarcely necessary in the present day to state that no reliance can be placed in the antiseptic medicines recommended by the older authors, on the mistaken idea that mortification depended on putrefaction or decomposition of the solids. Their principles of treatment consisted in endeavouring to prevent or arrest mortification by administering, internally and externally, medicines which were known to prevent the decomposition of dead animal matter. These were chiefly the more powerful vegetable and mineral tonics, and various local stimulants, applied to the mortified parts. It is true that in certain states and stages of mortification the same

measures are in the present day employed, but on very different principles, no one attributing their good effects to a supposed power of preventing putrefaction by their chemical operation, but to their action as general corroborants or stimulants. The practical error committed by those who ascribed the advantages which occasionally resulted from the exhibition of these remedies, was not only in the principles on which they were administered, but in their indiscriminate adoption in every stage and form of mortification, even in cases which originated with acute inflammation. We shall presently show that they have their value even among modern pathologists; and in stating our opinion, we wish to impress on the reader that we are desirous of guarding the inexperienced against erroneous principles of application, rather than against the remedies themselves.

In acute mortification, the general and local excitement require the adoption of antiphlogistic measures, modified according to circumstances. General bloodletting, if the pulse be full and hard, and there be great local pain and redness, will be necessary, and must be repeated till the pulse become soft, and the other symptoms are moderated. The other parts of the antiphlogistic treatment, consisting of purgatives, saline diaphoretics, and abstinence from stimulating food, must be at the same time enjoined. These measures are necessary in the early stage of acute inflammation, not only to prevent mortification, but, when it has begun, to check its further progress. The extent to which bloodletting and the other antiphlogistic measures are to be carried, requires nice discrimination, and especially reference to the age, powers, and previous habits of the individual, as well as to the stage of mortification. The pulse in these cases is often a fallacious guide, more especially when the mortification occurs in a vital organ. The practitioner must, therefore, consider rather its particular character with regard to fulness or hardness, than to frequency. If it be soft, though frequent, and if the skin be cool,—moreover, if the individual be of an irritable habit, and somewhat advanced in years, the lancet must be withheld, as under such circumstances detraction of blood would increase the irritability of the heart's action, weaken the patient, and favour the progress of the mortification. Such symptoms, which are often mistaken for inflammation, require attention to the state of the bowels, the moderate use of opium, the exhibition of mild nourishment, and the moderate use of wine. In other instances the state of the general as well as of the local symptoms indicates subacute inflammation—a condition intermediate between acute and chronic mortification, requiring a modification of the antiphlogistic treatment, according to existing circumstances. A full bleeding from the arm may be necessary or advisable, to diminish the velocity and force of the circulation, though, in many instances, this may be dispensed with; local bleeding, by the application of leeches at a short distance from the mortified part, purgatives, antimonials, mercury, and low diet, being generally sufficient to arrest the progress of the mortification.

When the treatment adopted has succeeded in abating the inflammation, and when the progress of the mortification is consequently arrested, fur-

ther antiphlogistic measures must be suspended, and the powers of the patient reserved for what the system has yet to accomplish—the separation of the mortified from the living parts. In the external parts of the body this is indicated by a red line, which shows the boundary of mortification, and, at the same time, that the process has stopped.

A certain degree of inflammation is necessary to carry on the separation of the dead from the mortified parts; and if the powers of the system be feeble, it is evident that this salutary process cannot proceed. In this stage the patient must be supported, especially if advanced in years, by animal food, in the form of strong broths or jellies, and in some cases wine and other diffusible stimuli may be given, according to the indications. It is necessary to be very cautious, however, that these measures be not adopted too early, or before the inflammatory action be sufficiently reduced; and if they seem to renew the inflammatory excitement, they must be administered in small quantities, or altogether withdrawn, and mild vegetable nourishment substituted. A similar tonic plan of treatment is requisite when the general fever assumes a typhoid type, which it frequently does very early: in these cases the mortification often proceeds with great rapidity, and the only chance of arresting it is by the liberal administration of stimuli, animal nourishment, cordials, and wine.

From the supposed virtues of the Peruvian bark in preventing or arresting mortification, it is necessary to allude to it more particularly. About a century ago it had acquired considerable reputation for its supposed antiseptic powers, and was extolled as a remedy possessing great power in the treatment of mortification. It is probable, however, that its indiscriminate adoption led to frequent failures; it consequently fell into disrepute, and its exhibition is now confined entirely to mortification accompanied with typhoid symptoms, in which other remedies of a stimulant and tonic kind are found useful. It is obviously an improper remedy when there is inflammatory excitement, when there is derangement of the stomach and bowels, or when the mortification succeeds to inflammation, produced by external injury. When it is indicated, the sulphate of quinine is the best form of administration, in doses of two grains repeated at suitable intervals. When either the bark in powder, infusion, or decoction, or the sulphate of quinine disagrees, or proves too stimulating, an infusion of some of the lighter vegetable tonics, cascarilla, gentian, or calumbo, may be substituted; to an effusion of either of these an aperient, such as the infusion of rhubarb, may be added, should the state of the bowels require the combination.

Opium, when administered in proper cases, is an invaluable remedy in mortification; it soothes pain, and diminishes the restlessness and irritability with which mortification is so frequently accompanied, and often procures sleep. In the acute stage of mortification, it is improper until the excitement has been subdued; it may then be given at distant intervals in combination with calomel. One grain of opium combined with two of calomel in a soft pill may be given every six or

eight hours, if there be pain, irritability, and wakefulness; and should this quantity fail to procure sleep, two grains of solid opium may be given once, or perhaps twice in the twenty-four hours. This remedy is more especially indicated should spasms or convulsions arise in the progress of the mortification. The late Mr. White, of Manchester, recommended, in spasmodic contractions and convulsions arising during mortification from external injury, large doses of musk and volatile alkali, which he asserted removed the singultus, subsultus tendinum, and convulsive spasms, while at the same time the mortification was stopped. We agree, however, with Dr. Thomson as to the doubtful efficacy of these remedies under the circumstances mentioned by Mr. White, more particularly as this eminent surgeon candidly confessed he had been disappointed in the effects of this combination, when it was tried in mortification arising from other causes.

When mortification on the surface of the body has terminated in sphacelus, the separation of the mortified from the living parts may sometimes be assisted by local applications. In former times, the practice of surgeons was to make incisions or scarifications through the dead down to the living parts, in order to apply stimulating, and, as was supposed, antiseptic substances, such as turpentine, balsams, and even essential oils, regardless of the degree of local inflammation which already existed or might be produced by such applications. Mr. Samuel Cooper has very well remarked, that though such things are indeed really useful in preserving dead animal substances from becoming putrid, a very little knowledge of the animal economy is requisite to make us understand that they cannot act in this manner on parts still endued with vitality; but on the contrary, that they must have highly prejudicial effects in the cases under consideration, by reason of the violent irritation which they always excite when applied to the living fibres.

Any local application is unnecessary, and often injurious before the mortification has stopped. This, as we have seen, is indicated by a defined red line, which shows the separation of the mortified from the living parts: the living portion adjoining the sphacelus assumes a red colour, ulcerative absorption commences, by which the mortified are gradually removed from the living parts.

The object of local applications is, 1. to soothe the local irritation: 2. to allay any excitement in the part that may arise: 3. to accelerate the process of separation when it proceeds too slowly; and, 4. to correct the fetor.

The most soothing application is a common poultice made of stale bread or lintseed flour and water, and in nine cases in ten this forms the best local application in mortification. When the heat of a poultice produces too much irritation, a cold lotion, or if more agreeable to the feelings of the patient, a tepid lotion may be applied by means of one or two folds of linen. It should be remembered, however, that while heat increases the local action, cold, on the other hand, though it at first diminish or repress vascular action, when too long applied produces debility, and may be consequently injurious.

When it appears expedient to stimulate the living parts, several local applications are employed by surgeons. Mr. Lawrence recommends the nitric acid, of which from four to ten drops may be added to an ounce of distilled water, and lint moistened in this lotion applied to the part. The pyroligneous acid has also been applied with advantage, more especially in hospital gangrene. A liniment, composed of oil of turpentine and resinous ointment in equal proportions, is an excellent stimulating dressing in mortification. The mode of applying this liniment is to moisten lint in it when made warm by putting the vessel in which the liniment is contained in boiling water, by which it is soon liquefied. The lint soaked in this liniment is to be put on the part, which is to be afterwards covered with a large warm poultice. This dressing may be renewed once or twice a day or oftener, according to circumstances.

Various kinds of stimulating poultices have been recommended. The common yeast poultice, prepared by adding to the grounds of stale strong beer, as much bread crumb or lintseed flower as will make a poultice, answers very well: or some surgeons prefer the effervescing poultice, prepared by adding to an infusion of malt as much oatmeal as is necessary to form a poultice, and afterwards mixing with it a table-spoonful of fresh yeast.

When the ulceration looks healthy, and the process of separation goes on satisfactorily, the stimulating ingredients in the dressings must be diminished or wholly withdrawn. Dr. Thomson has shown that the ulcerating surface is, in the progress of separation, liable to pass, under every mode of treatment, into the state of a painful and irritable ulcer; and in this state it may require to be treated with anodyne fomentations, or with poultices made of carrot, turnip, or fresh hemlock leaves. In these cases, as in sores from other causes, the applications require to be frequently changed, which has often a most beneficial effect on the ulceration.

With the view of correcting the fetor arising during the process of separation of mortified parts, charcoal has been employed. The common charcoal poultice is made by adding to a common bread and water or lintseed poultice, two ounces of finely levigated charcoal: this application generally destroys the fetor arising from the mortified parts.

The disinfecting agents which have been lately introduced—the chloride of lime, or of soda—when applied in proper strength to a gangrenous sore, remove very effectually the unpleasant smell, and may, therefore, be employed in conjunction with the other local measures. We distrust, however, the accounts given by the French writers of their power in arresting the progress of mortification; in our opinion, they are useful only in correcting the fetor, and cleansing a foul sore.

When an extremity has become mortified, it is necessary to remove it to save the patient's life. The general rule adopted by surgeons is, to defer amputation until there is decided evidence that the mortification has stopped; but for information on this important point, we beg to refer to the writings of those surgeons who have discussed the point of practice.

It is necessary to advert to the treatment of mortification arising from unequal pressure on

those parts on which the body rests, when an individual has been long confined to bed. The parts which are most liable to mortification from this cause are thinly covered with flesh, viz., the sacrum, hips, scapulae, elbows, and sometimes the cartilage of the ears, and the skin covering the cranium. It takes place more especially in diseases attended with debility, as in the advanced stage of continued fever, in the typhoid forms of which there appears to be a tendency to gangrenous inflammation; it occurs also in bad compound fractures, in cases of tedious suppuration, and in paralysis; it is much favoured also when the evacuations are passed involuntarily.

According to Dr. Thomson there are two forms of disease arising from pressure, which are not always accurately distinguished; the one is mortification; the other a chafed, excoriated, and ulcerated state of the same parts; the mortified state, however, being always an indication of a greater degree of weakness. They not unfrequently occur in the same diseased surface, a part in which a mortified slough or eschar has been formed, passing very readily into ulceration, so that a sore, which at first was small, often acquires in this way a very large size.

The treatment depends on the circumstances with which each case is accompanied. When mortification occurs from pressure in the low or typhoid forms of fever, the strength must, as a general rule, be supported, unless special symptoms arise to render the tonic plan inexpedient. It is important, however, to discriminate the irritative fever which the mortification frequently induces, after the primary febrile symptoms have nearly or entirely disappeared.

When ulcerative or gangrenous inflammation arises in diseases in which the system is less disposed to mortification from failure of the vital powers, as in paralysis, bad compound fractures, and long-continued suppurations, there is less necessity for stimulants; mild nourishment, great attention to cleanliness, and suitable local applications, with attention to relieving the unequal pressure, forming the best plan of treatment.

For the purpose of obviating the unequal pressure sustained by those parts on which the body rests, various contrivances have been invented. A soft down pillow, or an air-cushion, may afford temporary relief. The bed invented by Mr. Earle is well adapted for many surgical diseases which require for their cure long confinement in one posture. The frequent failures of these various contrivances, however, led our scientific friend Dr. Arnott to construct a *hydrostatic* or *floating* bed for invalids, on the following ingenious principle—that the support of water to a floating body is so uniformly diffused, that every thousandth of an inch of the inferior surface has, as it were, its own separate liquid, so that no one part bears the load of its neighbour; that a person resting in a bath is nearly thus supported; and that, though the pressure of the atmosphere on our bodies is fifteen pounds per square inch of its surface, yet because it is uniformly diffused, it is not felt. He also reflected that the pressure of a water-bath of depth to cover the body is less than half a pound per inch, even on the under side, where it is greatest, and similarly unperceived; and therefore concluded,

that if a patient were laid upon the surface of a bath, over which a large sheet of India-rubber cloth (which is quite impermeable to water,) is thrown, the body being rendered sufficiently buoyant by a mattress placed under it, the invalid would repose on the face of the water without sensible pressure on any part, and almost as if the weight of the body were annihilated.

A bed constructed on this principle and made in the following manner has been found to effect this desirable object. A trough of convenient dimensions (six feet long, thirty-two inches wide, and eleven inches deep, are good common dimensions) is to be lined with lead or zinc to make it water-tight; this trough is to be half filled with water, and over it is to be thrown a sheet of the India-rubber cloth as large as will be a complete lining to it if empty. The edges of this sheet are to be touched with spirit-varnish, to prevent the water creeping round by capillary attraction, and to be afterwards secured, in a water-tight manner, all round to the upper border or top of the trough, the only entrance left being through an opening at one corner, which can be perfectly closed. Upon this dry sheet a suitable mattress is to be laid, and a bed is thus constituted ready to receive its pillow and bed-clothes, and cannot be distinguished from a common bed but by its surpassing softness or yielding.

When an invalid is placed on this bed, the body, being (as is known to swimmers) nearly of the specific gravity of water, displaces water equal to his own body, in weight as well as in bulk, and is supported as the displaced water would have been. If a mattress of a certain thickness be placed under the body, after the weight of the body has forced two cubical feet (the average bulk of the human body) of that under the level of the water around, he will float with four-fifths of his body above the level, and will sink much less into his floating mattress, than in an ordinary feather-bed. If unusual positions be required, by having the mattress formed of different thickness in different parts, or by placing a compress of folded blanket or of pillow under the mattress in certain situations, any desired position of the body will be easily obtained.

The hydrostatic bed does not admit of the perspiration being carried off, and unless the invalid can leave the bed so as to admit of its being aired daily, like an ordinary bed, it is necessary to adopt a plan of ventilation in order to prevent the perspiration from being condensed on the water-sheet

below. This Dr. Arnott has proposed to effect by placing under the mattress, arranged like the bars of a gridiron, small flexible tubes of copper wire, wound spirally, with their ends open to the atmosphere, either directly or through two larger tubes, crossing and connecting their extremities near the ends of the mattress, and then issuing at the corners of the bed from under the clothes.

This bed is therefore admirably adapted not only to every disease requiring long confinement to bed, but to cases of fractured bones, palsy, and diseases of the hip and spine. It also allows the patient, when capable only of feeble efforts, to change his position almost like a person swimming, and thus even to take a degree of exercise. It also enables the attendant to dress wounds, apply poultices, or to place vessels under any part of the body, as the elastic mattress may at any part be pushed down, so as to leave a vacant space, without the support being lessened for the other parts.

With regard to local applications, when the skin is merely inflamed without excoriation or detachment of the cuticle, the part should be frequently bathed with camphorated spirits of wine, or a solution of the acetate of zinc, or with a liniment made by triturating equal parts of alcohol and the white of an egg, and afterwards covered with soap cerate spread upon leather. When the skin is excoriated, spirituous applications are improper, the mildest emollients—the lin. calcis, simple cerate, or the zinc ointment—are suitable, and, if there be much irritation, an emollient poultice may be placed over the dressing.

When mortification, terminating in sphacelus, has taken place, a bread-and-water or carrot poultice is the best application, and if the separation of the sphacelus proceeds too slowly, a stimulant dressing, such as the resinous and turpentine before mentioned, may be applied for a short time, but it must be removed if it produce pain and irritation.

When the sphacelus has been completely detached, the sore is to be treated as a simple ulcer, the dressings being varied according to the state of the ulcerations.

A. T.
ADAIR CRAWFORD.
A. TWEEDIE.

[The portion of this article which precedes the initials A. C. is written by Dr. Crawford, and the succeeding portion by Dr. Tweedie.]
