This combination of gastro-intestinal with pulmonary inflammation takes place equally in affections of the mucous membrane, of the parenchyma, and serous investment. It is also an almost constant attendant on phthisis, in which its supervention exercises a remarkable influence on the progress and curability of the disease.

One of the most frequent forms of disease in Dublin is that which may be termed the gastro-catarrhal fever. It is a disease in which there is an inflammation both of the pulmonary and gastro-intestinal mucous membranes. It is one of great danger, and from the following circum-

stances:—1. the existence of an intense gastro-enteritis; 2. the fact that the bronchitis is almost always double and universal; 3. that at the time when the bronchitis is passing into the second or secretive stage, there is generally profound debility, so constant in gastro-intestinal disease; expectoration cannot take place, and the patient dies of asphyxia. These are sufficient to prove the danger of this disease; and we may add that, as in the complication with cerebral disease, the gastro-enteritis in this instance is *constantly observed without pain, tenderness, or vomiting*.

In such cases it would appear that the mucous inflammation is in some instances the cause, in others the consequence of the fever; but whether it be cause or effect, it is to its reduction that the efforts of the physician are to be mainly directed. How important, then, must be the recognition of the gastro-enteritis! Independent of any theory, an extensive experience has led us to conclude that in these cases all practice tending to relieve the chest by revulsion to the gastro-intestinal surface, whether by nauseating or purgative medicine, is improper. The chest will not be relieved, and the gastro-enteritis will invariably be aggravated. The true principle of treatment is to deplete both the respiratory and digestive systems, and this is to be effected chiefly by local bleeding and counter-irritation. We say local bleeding; for in many of these cases general bleeding is inefficacious and sometimes injurious. This result appears due to the gastro-intestinal complication; for in simple bronchitis the lancet is constantly of the greatest utility.

There is a remarkable fact connected with this disease, to which we have alluded in the article ENTERITIS,—namely, that the inflammatory action seldom possesses the same degree of intensity in both systems at once; we observe a species of alteration of intensity. Thus, when the swelling and tenderness of the belly, the diarrhoea, the redness of the tongue, and the typhoid symptoms are best marked, we find the face least livid, the breathing and cough easier, and the stethoscopic signs of disease by no means so evident. But in the progress of the same case the gastric affection will appear to subside, to be replaced by all the signs of an intense bronchial inflammation. In the course of a gastro-catarrhal fever this change of symptoms may occur several times. The knowledge of this is of practical importance, for the apparent diminution of the symptoms of gastro-enteritis does not imply that the parts have become healthy; and if we practise on this supposition, we may be sure that the abdominal disease will re-appear with violence. This we have seen to occur from a dose of tartar-emetic, or a purgative pill. In some cases where the patients have died during the exacerbation of the bronchitis, we have found numerous intestinal ulcerations, although the surrounding mucous membrane was pale. (See ENTERITIS.)

The practical conclusions which the knowledge of the gastro-intestinal complication leads us to, appear to be the following:

1. That, as a general rule, the lancet is to be used with much more caution in this complication than in simple bronchitis.
2. That we are to place our chief reliance on

local bleeding and counter-irritation, on both the chest and abdomen.

3. That the emetic and purgative treatment is in these cases highly dangerous.

4. That the combination of mercury with opium exhibited so as to induce ptyalism, appears to be the remedy most entitled to confidence, after local bleeding and the use of blisters.

5. That the apparent subsidence of one class of symptoms does not imply that the disease from which they arose has subsided.

6. That in the convalescence of these patients peculiar attention must be paid to the state of the gastro-intestinal tube, as a slight error in diet or an over-dose of laxative or purgative medicine may be productive of the worst results.

The existence of a bronchitis is much less likely to induce a gastro-enteritis than the latter to induce the former. This, however, is only one of the exemplifications of the fact that the digestive system is endowed with more powerful sympathies than any other. Facts are still wanting on the subject of thoracic disease supervening on abdominal, but every observer must admit its frequency. We have thus a key to the explanation of the tussis verminosa, the tussis hepatica, the dyspeptic phthisis, &c. A circumstance of not uncommon occurrence well illustrates the danger of the empirical treatment of gastro-enteric inflammation. When the disease predominates in the lower part of the tube, diarrhoea, as formerly stated, is a common symptom, either as occurring from acute or chronic enteritis. Nothing is more common than the treatment of this by astringents, or by stimulants, such as the turpentine. Now we have frequently observed that, where the secretion was thus arrested, the diseased action appeared to be immediately translated to the bronchial surface, and these cases are always of the worst description. All the results of inflammatory action on the lung may be thus produced, yet the evil is seldom attributed to its proper source. The best mode of avoiding this accident in cases where we are forced to resort to the astringent and stimulating treatment of diarrhoea, is at the same time to determine to the skin; and the means which have succeeded best in our hands are the warm bath, counter-irritation on the abdomen, and the use of flannel next the skin. We should also in the treatment of such a case diligently watch the state of the respiratory function, and on the first appearance of disease, as shown either by symptoms or the stethoscopic signs, immediately omit the remedies calculated to arrest the abdominal secretion.

Of the combination of pneumonia with disease in the digestive tube, we have witnessed a vast number of cases, and it appears highly probable that the disease termed by the older authors the *putrid pneumonia*, *pneumonia typhodes*, &c. is an example of this combination. About two years ago, so many cases of this disease were admitted into the Meath Hospital, that it might be considered as epidemic in Dublin. The patients generally presented the following symptoms. There was great prostration, often much more than could be accounted for by the extent of the pulmonary affection as observed by the stethoscope. The skin was generally cool and clammy, and fre-

quently covered with small livid petechiæ; the pulse small and feeble, and the countenance collapsed and anxious. But little pulmonary oppression was complained of; there was cough, and in some cases the rusty sputa occurred, while in others nothing but a little colourless mucus was expectorated. The detraction of a few ounces of blood almost invariably produced syncope, and did not afford any relief to the patient. In a few cases the blood presented the inflammatory crust, but in the great majority this appearance was absent. In addition to these symptoms we remarked a red and crusted tongue, and, frequently, sordes on the teeth; there was thirst, some swelling of the belly, which was tender, particularly in the epigastric and right iliac regions, and often diarrhœa. The intellect was obtuse, and occasionally a low delirium supervened. On examination by the stethoscope and percussion, the usual signs of the different stages of pneumonia were observed, and in several cases the disease, contrary to its usual course, occupied the superior portions of the lung.

This was an extremely dangerous and unmanageable disease; many of the cases proved fatal, and in those where the disease was arrested, the convalescence was very tedious and doubtful. The pulmonary congestion resolved with great slowness; and where hepatization had occurred, the dulness on percussion continued for a great length of time. The patients remained in a semihectic state, and nutrition went on slowly. In the fatal cases death appeared to be induced much more by the abdominal than the thoracic disease, which was seldom so extensive as to account for the fatal termination. On dissection, the various appearances of the different stages of pneumonia were found. The stomach was generally more or less vascular and softened; but it was in the lower third of the ileum that the greatest destruction was found. Here the mucous membrane was intensely injected and of a purplish-red colour. The glands of Peyer and Brunner had become extensively ulcerated, and in some cases suppuration of the mesenteric glands was observed to a great extent. The blood was fluid and dark-coloured, and the peritoneum had a livid hue.

If we compare the description given of the *nervous peripneumony* by P. Frank, we must observe a striking resemblance between it and the disease under consideration. In both we have the pulmonary inflammation conjoined with a group of typhoid symptoms. He also speaks of an epidemic pneumonia combined with gastric symptoms, and in both cases points out the inability of the patient to bear free bloodletting. From the light which the study of the phenomena of gastro-enteritis has thrown upon the nature of typhoid inflammations, there can be little doubt that in these cases much of the typhoid character is owing to the abdominal complication, and we may consider the nervous and putrid pneumonia of the older writers as of this nature.

But does the mere existence of this gastro-enteric inflammation necessarily produce a typhoid state in cases of pulmonary disease? or are both the pulmonary and gastric symptoms the result of the secondary inflammations so constant in

fever? We incline strongly to the latter opinion, as we have seen an intense enteritis with pneumonia where the typhoid symptoms were absent, and where the patient bore large bleedings well. But in a practical point of view, this question is not of great importance; because, whether the gastro-enteritis be the primary affection, or secondary to the typhoid state, its existence is of the greatest importance in the prognosis and treatment of the case. This we have mentioned in the article *GASTRITIS*, where it is stated that the tartar-emetic treatment of pneumonia, as recommended by Laennec, is full of danger in these cases. The opinion of this author, that a gastro-intestinal complication does not contra-indicate the use of tartar-emetic in large doses, in cases of pneumonia, is one of the few errors in the work of that great man,—an error which it is much to be feared he was led into by his too great prejudice against the doctrines of the physiological school.

We have not observed in this disease, as in the gastro-catarrhal fever, those remarkable alternations of symptoms between the chest and abdomen; the character of the disease being seldom changed throughout its course.

The practical conclusions which the knowledge of this complication of pneumonia leads to, are the same as indicated when speaking of the gastro-catarrhal fever. In this disease the strength of the patient must be supported by farinaceous foods, jellies, and chicken-broth, from an early period, even while we are using local bleeding to the chest or abdomen. The best internal remedy seems to be the combination of calomel with Dover's powder, given with a view to induce ptyalism. This should be assisted by mercurial frictions. As soon as the gums are decidedly affected, the inflammatory action often begins to subside. At this period we have also found the greatest advantage from the use of the polygala senega, exhibited in the following manner:

R Decoct. polygalæ senegæ, f. ʒvii.

Tinct. scillæ marit. f. ʒii.

Tinct. opii camphorat. f. ʒvi.

Carbonat. ammoniæ, gr. xv.—ʒi. M.
capiat coch. ampl. i. secundis horis.

If this remedy be given before ptyalism is induced, it will not be found beneficial; but after this effect has occurred, it will seldom disappoint the practitioner. This will be generally the time to administer small quantities of wine, regulating its use by the effect on the pulse and fever. When, after the use of wine, the frequency of the pulse is diminished, and its fulness increased, we may be sure that the remedy was indicated.

We must never forget that for the successful treatment of the case, both during its acute stage and convalescence, *the double seat of the inflammation must be constantly kept in view.*

The occurrence of inflammation of some part of the digestive tube in cases of phthisis, is a circumstance of extreme frequency in this disease, and one that exercises a powerful influence on its progress and the chance of recovery. It most usually presents itself under the symptoms of what is called the phthisical diarrhœa, but has been observed in a much more acute form.

As in cases of idiopathic gastro-enteritis, and in

that supervening in fever, so in this disease we may meet with the inflammation in some cases predominating in the upper, in others in the lower part of the tube. The lesions of the mucous membrane of the stomach are indicated by loss of appetite, nausea, bilious vomiting, and epigastric pain; the tongue may or may not be indicative of the gastric disease. These symptoms we regret to say are generally disregarded in cases of phthisis, and in numerous instances we have seen the worst consequences from this oversight. The vomiting in particular is attributed to the effect of coughing, as in pertussis, and there is no doubt but that it may be thus induced; but in those cases, as Louis has remarked, the appetite is good, the digestion easy, and the epigastric pain is wanting. It is further to be recollected that vomiting independent of disease of stomach most commonly occurs in the early periods of the case; but that in the more advanced stages it is almost always the result of gastric inflammation. On this subject, however, it would not be right to omit the following remark of Louis:—"Nevertheless, in this instance, as in a thousand other circumstances, there are facts which defy the sagacity of the observer, and form exceptions to the most general laws. Thus in the last months of his existence, one of our patients had epigastric pains, nausea and vomiting, both during the cough and its intervals, although the mucous membrane of the stomach was perfectly healthy." (*Recherches sur la Phthisie.*)

As an encouragement to our paying particular attention to the state of the stomach, it may be mentioned that there are facts on record which prove that, even in phthisis, an ulcer of the stomach may become cicatrized. The gastritis in this disease is almost always secondary to the tuberculization of the lung; but by interrupting nutrition, and by the prostration of strength which it induces, it exercises a most fatal influence on the progress of the disease. Seldom recognised, and constantly exasperated by the introduction of stimulants under the name of tonics and expectorants, it adds incredibly to the sufferings of the patient; and where from this mistaken treatment, and from the use of stimulating diet, it becomes acute, the respiration grows hurried and laborious, and additional blisters are mercilessly laid on the patient's chest, while the source of his increased suffering is wholly overlooked.

But the most striking as well as most frequent indication of abdominal disease in phthisis, is the occurrence of diarrhoea, a symptom the nature of which is not yet sufficiently appreciated by medical men. From the fact that this symptom is occasionally suspended when the perspirations are copious, an occurrence by no means so general as has been represented in books, it is looked on as a sort of vicarious discharge, and its cause, which is an enteritis, is seldom recognised. From this error great injury constantly follows. Diarrhoea in phthisis is an almost certain indication of disease in the mucous membrane and glands of the ileum and colon; a chronic inflammation, terminating in ulceration of these tissues. In the present state of pathology, it may be laid down that diarrhoea in phthisis almost never occurs without enteritis; and further, that in this disease we may have some

degree of enteritis without diarrhoea. This, however, is a rare case, and in our experience has only occurred where the colon escaped alteration. The experience of more than a hundred cases, in which we have made a post-mortem examination, has convinced us that in phthisis the diarrhoea is the result of inflammation and ulceration of the intestine,—a conclusion which we look upon to be as free from exception as any doctrine in medicine can be; but one, however, which, though not new, is far from being sufficiently recognised. It is most important to consider this secondary enteritis, in cases of phthisis, both with a view to the curability of consumption, and also to its palliative treatment. Of one fact we are convinced, namely, that the absence of enteric inflammation greatly prolongs the existence of a phthisical patient, and of course increases the chance of a cure. We know that in most cases of chronic phthisis an attempt at cure is established by nature, the mechanism of which has been developed by the immortal Laennec. For the success of this attempt two conditions appear requisite,—one, that the life of the patient shall be prolonged so as to allow time for the cicatrization of the abscess; the other, that the tuberculization of the lung shall not advance so as to produce too extensive disorganization of the part. Now the first of these is mainly influenced by the supervention of the enteritis. In all the cases of very chronic phthisis which we have observed, the intestinal disease either did not occur, or only supervened at the very close: in these cases the disease lasted for years. But we believe also from observation, that the second condition is greatly influenced by the state of the digestive system; as, after the diarrhoea has commenced, the disease, as observed by the stethoscope, has advanced with increased rapidity; a circumstance not at all strange to the pathologist, and explicable by the sympathetic irritation and lesion of nutrition.

We have now had the good fortune to witness the recovery of several patients in whom the stethoscope unequivocally indicated the existence of tuberculous cavities. *In none of these cases was there any enteric complication.* The disease advanced slowly, and time was given both for the efforts by nature, and the operation of remedial measures.

From considering phthisis in all cases merely as a pulmonary affection, and from not estimating the importance of gastro-intestinal disease as influencing its progress, a fatal error is commonly fallen into: this we have often witnessed. A young female ceases to menstruate; this may or may not have been preceded by pulmonary irritation; but in most instances some affection of the lungs is present: she gets worse, and consumption is apprehended; the symptoms are attributed to the amenorrhoea, and the cure is attempted by forcing the uterine action by the medicines called *emmenagogue*. A variety of substances, all highly stimulant to the gastro-intestinal surface, are exhibited; many of them, such as aloes, savine, &c. &c. of a drastic nature; the result of which is, that a diarrhoea is established, attributed at first to the medicines, but from its obstinacy showing that it proceeds from a diseased state of the bowels. The phthisical symptoms advance rapidly; the

menses do not re-appear; and the patient dies of what is called a *galloping consumption*. We have actually known cases where the emmenagogue system was continued after the phthisical diarrhoea was established, and cavities formed in the lung. Such lamentable circumstance may well be appealed to by those who ridicule medical science; but the opprobrium ought to fall on the individual practitioners who will not stoop to learn what the science is capable of teaching.

Although so instrumental in accelerating the fatal termination of phthisis, enteritis is seldom a cause of sudden death in this disease. Notwithstanding the number and extent of the ulcerations, yet perforation of the intestine and consequent peritonitis is extremely rare; a most interesting fact, and one which we have endeavoured to explain in the article *ENTERITIS*. The only case of phthisis in which we have found perforation of the intestine was an example of acute development of tubercle, accompanied with intense pulmonary irritation and obscure abdominal symptoms. On dissection, several perforations were found, but the fecal matter had not escaped into the serous cavity. The disease in the intestines was most extensive, and could never have been suspected from the symptoms;—another instance of the latency of abdominal inflammation when other disease exists. This case is published in the fifth volume of the Dublin Hospital Reports. We have witnessed one case, where sudden death occurred from hemorrhage of the bowels. The patient in an advanced stage of phthisis, while at stool suddenly fell down dead. A large quantity of blood was discovered in the night-chair; and on dissection the colon was found extensively ulcerated and filled with blood. This termination of phthisis is, we believe, not noticed in any of the systematic works. The case will be found in the Transactions of the Association of the College of Physicians of Ireland, 1827.

In the more acute forms of phthisis, the complication with enteritis may also exist; but on this subject facts are still wanting. In some instances we have seen the disease commence with violent symptoms of bronchitis and dysentery, and pass into those of phthisis and diarrhoea. These cases were not unfrequent after the late epidemic fever in Dublin, and were observed chiefly in the convalescent patients. One case occurred during this period which is remarkable, as it presented the symptoms of an intense irritation of the gastro-intestinal mucous membrane, yet on dissection this tissue was found generally healthy. The solid viscera of the abdomen, however, were universally tuberculated, the tubercles being in great quantity and in various stages from the miliary to the crude state. The lungs were completely filled with miliary and granular tubercles, and the bronchial mucous membrane highly vascular. From the symptoms referable to the abdomen, we fully expected to find an intense gastro-enteritis; there being tenderness of the abdomen, with tumefaction, purging, the tongue dust-coloured, great thirst, delirium, and involuntary evacuations. The only morbid appearance in the tube was a slight vascularity and softening of the ileo-cæcal portion, with some enlargement of the muciparous glands—an extent of disease quite insufficient to account

for the symptoms. How far these are to be referred to the condition of the solid viscera is a subject for further investigation.

In the treatment of phthisical diarrhoea it is of consequence to bear its true pathology constantly in mind, even though we should despair of effecting a cure. The disease itself is so full of danger, and the symptoms so distressing, that its palliation is an object of great importance; and this will be best effected by acting on pathological principles. Although astringents are not unfrequently our only resource, yet their indiscriminate use is dangerous, as the checking of the secretion may be followed by increase of fever, and great aggravation of the pulmonary symptoms. This is more commonly observed in cases where the disease has not arrived at its last stages. The mind of the practitioner should be impressed with the fact that the disease is an enteritis, and to be treated as such; and we can safely assert that in hospital practice we have found the application of a blister to the abdomen seldom fail in arresting the diarrhoea, and giving the greatest relief. In this practice there is no danger, for it is not empirical; we do not arrest a secretion without removing or modifying its cause. In more than one case in which astringents and opiates had failed, this practice was followed by a permanent removal of the diarrhoea.

In our treatment of phthisis we should never lose sight of the following facts and conclusions with respect to the gastro-intestinal system:—

1. That a complication with some form of gastro-enteritis is exceedingly frequent.
2. That this complication is to be guarded against as far as possible, as its supervention exercises a fatal influence on the progress of the pulmonary disease, a result explicable by the lesion of nutrition and the sympathetic irritations.
3. That when the disease predominates in the upper portion of the tube, we have the usual symptoms of chronic gastritis superadded to those of phthisis; and when in the lower, diarrhoea is the most prominent phenomenon.
4. That where the signs of disease of the stomach exist, the diet must be of the most unstimulating kind, and that we cannot hope for benefit from tonic, stimulating, or expectorant medicines.
5. That in all stages of the disease, purgative medicine, particularly of the drastic kind, must be avoided.
6. That the diarrhoea of phthisis is the result of an enteritis with ulceration of the intestine, and that hence the *indiscriminate use* of astringents is as objectionable in this as in other forms of intestinal disease. (See *DIARRHOEA*.)

III. The limits of this article will not permit us to enter on the interesting questions of the connection between gastro-enteritis and disease in the circulatory and genito-urinary systems; but we shall say a few words on its complication with *hepatic disease*.

There is no part of the digestive apparatus to which the attention of physicians has been so long directed as the biliary system. The diseases of the liver, indeed, have been more studied than all the other lesions of the digestive apparatus; a circumstance mainly arising from the long reign of the humoral pathology, which attached such import-

ance to the composition of the bile, and referred so many diseases to its alterations. Much of this doctrine still remains, although modern medicine has shown, whilst still allowing the necessary importance of the biliary apparatus, that we must consider it, both physiologically and pathologically, as secondary in importance to the gastro-intestinal surface.

The general similarity of symptoms that arise from abdominal disease tended much to retard our knowledge of the importance of diseases of the digestive tube; as in thousands of instances these were and still are described as examples of hepatitis either acute or chronic. This is an error so great, and one so universal in these countries, that it is no exaggeration to designate its consequences as dreadful.

Hepatitis in these countries is much less frequent than inflammations of the digestive tube,—a fact established by pathological anatomy, and one, the more extensive recognition of which would be fortunate for the British public. From mistaking gastro-enteritis for affections of the liver, two great evils result;—one, the neglect of the actual disease; the other, its exasperation by the means supposed capable of removing the hepatic affection. Revulsion to the mucous membrane is attempted; in other words, a tissue already in a state of inflammation and the source of the symptoms, is submitted to a double stimulation. Disorganization is thereby effected, and what was at first a simple and curable disease of the mucous membrane, becomes a chronic and incurable lesion, not only of this tissue, but of the solid viscera of the abdomen. The patient dies; and in the hepatic and splenic disease then observed, the practitioner sees a vindication of the treatment which has assisted to produce them.

The relation which exists between secreting organs and the surfaces with which they communicate, is not sufficiently recognised by practical men. It is a subject full of importance to the practice of medicine. Without denying that the glands in question may primarily contract irritation, yet Bichat has shown that the natural mode of excitement of these organs is a stimulation exerted on the surface of relation with which they communicate; a stimulation which, in the state of health, will only induce the physiological action of the organ, but which, if excessive or too constantly repeated, will ultimately induce disease in the secreting organ itself, by the operation of one of the best established laws in physiology or pathology. We must admit that in declaring, as a general rule, that all inflammations of the liver are secondary to a gastro-enteritis, Broussais has come to a too sweeping conclusion. He deserves great credit, however, for demonstrating the frequency of the sympathetic irritation going on to true inflammation, and thereby rendering the liver itself a centre of fluxion. These remarks apply more especially to the supervention of chronic hepatitis on long-continued stimulation of the stomach and duodenum, the consequence of a life of luxury or indulgence in ardent spirits. When the liver-disease is established, it is plain that a principal indication will be to remove or modify the original exciting cause, and to adopt such treatment as may have least chance of exasperating the diseased state of the mucous membrane.

The production of hepatitis consequent on gastro-intestinal inflammation is a subject not yet wholly cleared up. In all probability its most common cause is the sympathetic irritation or increase of the excitement which the surface of relation naturally exercises on the secreting organ. But there are cases in which additional causes seem to have acted. Thus it is believed that in some instances, inflammation has spread by continuity of surface from the duodenum along the biliary ducts,—an opinion, however, which requires further confirmation before it can be adopted. Bouillaud and Ribes believe that in many cases the inflammation is conveyed to the liver along the internal coat of the vena portæ and its ramifications; and in the *Clinique Médicale* by Andral, two cases are recorded confirmatory of this opinion. The first is of a patient who was attacked with fever and gastro-enteric symptoms, followed by painful tension of the right hypochondrium and slight jaundice. On dissection, the stomach, lower portion of the ileum, and the cæcum were found inflamed. The liver was enlarged, very red, and much engorged with blood. It was further found that the internal surface of the inferior mesenteric veins, the trunk of the porta, and its ramifications, was intensely red, while the splenic vein and the cava appeared natural. The aorta was white; and hence it was concluded, and we think justly, that this was an example of inflammation of the abdominal veins,—a phlebitis, which being propagated to the liver, was the cause of the hepatic disease. In the second case the first symptom was a diarrhœa, followed by pains in the region of the liver, jaundice and ascites. On inspection, the liver was found in the state of red induration, and the internal surface of its veins vividly red. The same was observed in the trunk of the porta and its hepatic branches, the internal membrane of which was soft, friable, and in many places lined with an unorganized false membrane. The gastro-intestinal system presented marks of extensive chronic disease; and it is only to be added, that the general vascular system was found perfectly healthy; so that we cannot attribute the appearances in the porta to any thing but inflammation.

These cases are probably analogous to that described by Reynaud, in a patient who had experienced several attacks of jaundice, in which the right branch of the porta and the inferior cava had become obliterated. A collateral circulation was established principally by means of the external veins, not however sufficient to prevent the occurrence of dropsy.

The following conclusions seem fairly deducible from the recent researches of anatomists, with respect to the connection between gastro-intestinal and hepatic disease:—

1. That in most cases of hepatitis there is a complication with gastro-intestinal inflammation.
2. That in the majority of instances where this complication has occurred, the hepatitis has been secondary to an acute or chronic gastro-enteritis.
3. That in such cases the supervention of the hepatitis does not imply the subsidence of the gastro-intestinal disease.
4. That in the smaller number of cases the hepatic disease has preceded that of the intestine.

5. That idiopathic hepatitis may occur without any gastro-intestinal complication whatsoever. This is the rarest case.

6. That in cases where the complication does exist, we cannot always find that the intensity of the one disease is proportional to that of the other.

The influence which inflammation of the upper part of the digestive tube, particularly of the duodenum, exerts in producing hepatic disease, has been much insisted on by the physiological school. That many instances of hepatitis are thus induced, there can be no doubt; but it is true that cases have occurred where this portion of the tube was found perfectly healthy. (See the works of Louis, &c.) We formerly alluded to the production of jaundice from gastro-duodenitis, and believe that it is its most common cause. It is a curious fact, that in the yellow fever, where gastro-enteritis is so frequent, inflammation of the liver is rarely observed, although considerable alteration of the colour and consistence of this viscus is common.

IV. But we have yet to handle one of the most important parts of this subject, namely, the connection between gastro-enteritis and the phenomena of fever. Were we to enter into this at full length, we should far surpass the limits of this article; but we shall content ourselves with inquiring how far that part of the doctrine of Broussais, which refers continued fevers to a gastro-enteritis, is capable of proof. Here we wish to correct an error which is general,—namely, that Broussais attributes *all* fevers to a gastro-enteric inflammation. Such is not the fact, as all candid persons will admit who consider the two following propositions of his doctrine:—“*Les irritations intenses de tous les organes sont transmises au cœur; alors il précipite ses contractions; la circulation s'accélère, et la chaleur augmentée de la peau détermine une sensation pénible: c'est ce que l'on doit appeler la fièvre, qui est ici considérée d'une manière générale.*” (Prop. cxi.) “*La fièvre n'est jamais que le résultat d'une irritation du cœur, primitive ou sympathique.*” (Prop. cxii.) (Broussais, Commentaires des Propositions de Pathologie, 1829.)

The following is the opinion of this author on the subject of the connection of gastro-enteritis and fever. He believes that acute gastro-intestinal inflammation, when exasperated, will represent what has been called the putrid, adynamic, or typhoid fever; and that in those cases where the sympathetic irritation of the brain is considerable, the disease will represent the malignant ataxic or nervous fevers. The truth of this proposition is not to be denied; but when he declares that all the essential fevers of authors are to be referred to a simple or complicated gastro-enteritis, we believe that he has not made out his case.

It cannot be denied that this doctrine, received at first with such contempt, and scouted so generally by medical professors, especially in this country, has gained ground to a remarkable extent; and although few, except the immediate pupils of its founder, go to the full length of his opinions, yet all who look at disease with an unprejudiced eye, and who enjoy opportunities for observation, now admit that in the production, progress, and phenomena of fevers, the digestive tube takes a most important part. In fact its pathology furnishes

a key to the treatment of a vast number of cases formerly termed essential or idiopathic fevers; a denomination, happily for mankind, now beginning to be forgotten.

Will gastro-enteritis cause the phenomena of fever? and what will be the character of that fever? The state of the science on this subject can be shortly expressed. Gastro-enteric inflammation may cause all the phenomena of fever. It will especially cause prostration, headach, delirium, subsultus, coma, thirst, anorexia, sordes, morbid tongue, tympanitis, petechiæ. All these symptoms may subside under treatment calculated to remove a gastro-enteritis, and will be exasperated by an opposite treatment. This inflammation further may present this group of symptoms without pain or tenderness of the abdomen. On this subject we shall quote from Andral:—“Confirming by our researches the admirable observations of M. Broussais on the painless character of a great number of intestinal inflammations, we stated in 1823, that we might be exposed constantly to overlook the most intense enteritis, if we only admitted its existence in cases where pain occurred. Since the publication of these researches, numerous works published by disciples of the most different schools, have shown that the intestines may be very profoundly affected without pain being present. We have seen this pain wanting, 1st, in cases of simple erythema of the mucous membrane; 2d, in those where numerous exanthematous patches covered the small intestine; 3d, where the large intestine was affected; 4th, where there were ulcerations, either in the ileum, cæcum, colon, or rectum. We have found the deepest ulcerations in subjects where there was no pain; and it is to be remarked that we only speak here of cases in which the intellect of the patient was not affected.” (Clinique Médicale.)

The knowledge of these most valuable facts requires to be spread much farther than has been hitherto done. Many practitioners cannot separate the ideas of pain and inflammation, and it has again and again happened to us to see the most fatal results from this scholastic error.

One of the most constant characteristics of the fever in this disease is prostration; and there is no local inflammation which will so peculiarly induce this state as an acute gastro-enteritis. The fever may be inflammatory or typhoid in its symptoms; it is commonly similar to the synochus of Cullen; it may be remittent or even intermittent. To prove every part of this proposition thousands of cases may be cited. (See the works of Andral, Louis, Bouillaud, Bretonneau, Rœderer and Wagler, Boisseau, Hewett, Bright, Abercrombie, Cheyne, &c. &c.) Gastro-enteritis may, then, occur with every form of fever; but it may also exist without fever; from which fact an argument may be drawn against the doctrine that the typhoid or adynamic fevers are nothing but examples of gastro-enteritis either simple or complicated. It is plain that these affections present a pretty constant and peculiar group of symptoms, and that, even supposing gastro-enteritis to exist in them all, there must be something else to give the disease its peculiar character.

Let us examine the state of the digestive tube in fevers, particularly that of the stomach and small intestines. Now there is abundance of facts to prove that when death occurs in the course of a

fever, we may find the stomach healthy, and even in the cases where alterations of this viscus are found, they have no peculiar appearance so as to constitute an anatomical character; nor, as Andral remarks, are they different from those in the bodies of others who have died of various acute and chronic diseases. We cannot then affirm that every continued or typhous fever implies the existence of a gastritis, or that this disease will cause the phenomena of fever in all instances.

But the alterations of the small intestine are much more constant, and it was from this circumstance that the doctrine of Broussais mainly arose. We apprehend that an inflammation of the mucous glands is much more frequent in Paris than in this country; and it was natural to consider the disease in the intestines, with regard to the fever, in the same light as an inflamed state of the lung was considered with regard to the symptoms of pneumonia. Louis also, one of the most accurate and trustworthy investigators, has declared that the inflammatory development of the mucous glands is the anatomical character of typhous fever. But even admitting that such was universally the case, still the doctrine that the symptoms of fever in these cases proceeded from this disease would not be proved, because the intestinal disease may as well be considered as secondary to the fever as the pustules of small-pox to the state of the system induced by its contagion. No one would say that the cutaneous eruption was the cause of small-pox, and we cannot help believing that the "*intestinal exanthem*" in many fevers is produced by a similar process, and bears a similar relation to the constitutional affection. (See the experiments of Gaspard, Magendie, &c. *Journal de Physiologie*.) But whether the intestinal disease be primary or secondary, it becomes absolutely necessary, in cases where it is recognised, to direct our treatment towards its removal, and carefully to avoid every thing that can exasperate it. We believe that the disciples of Broussais may have carried the antiphlogistic plan too far in fever; but if they have killed their thousands, the followers of Brown and Hamilton* have killed their ten thousands. In the treatment of fever there are two great points for the practitioner to look to.—one, the strength of the patient; the other, the state of the viscera. In the majority of cases his practice should be to remove local inflammation, for it is of this that ninety-nine out of the hundred die; but should a case arise where, from the condition of the patient, he cannot attempt to fulfil the latter indication, let him at least not exasperate the disease.

What is the common treatment of fever? a bottle of wine on the one hand, and a bottle of purging medicine on the other; and this for all fevers and all stages of the fever! We do not wish to be understood as decriing the use of tonics or purgatives in all cases, but we do protest, in the name of common sense and humanity, against their indiscriminate employment. The experience derived from the treatment of several thousand cases of fever has convinced us of this fact, that in the treatment of this disease, particularly in its

early periods, we shall be more certain of advantage from leeching the abdomen, cold drinks, and emollient enemata, than any other treatment whatsoever.

We cannot conclude this hasty review of the subject better than by the following quotation from Andral:

"Does this coincidence of lesions and symptoms suffice to show that the *dothin-enteritis* causes the whole disease? We would willingly reply in the affirmative if we did not take the following great facts into consideration:—

"1. When, from injecting different putrid substances into the veins of an animal, we produce all the symptoms of the severe fevers of the human species, there are cases where at the same time we cause various lesions in the intestinal mucous membrane, particularly various degrees of follicular tumefaction and sometimes ulcerations. At other times in these experiments the same symptoms were produced without any trace of lesion being found in the intestine. In this second case, we cannot attribute the symptoms to a lesion of the digestive tube which did not exist. In the first case it is plain that the intestinal lesion was an effect, and that it was only developed by the introduction of deleterious substances into the circulation. 2. Observations formerly cited do not permit us to doubt that in the human species symptoms completely similar to those which coincide with *dothin-enteritis*, may occur without it, and without any lesion of the digestive tube. 3. The intensity of the lesions which characterize *dothin-enteritis* is not always in relation to the severity of the symptoms observed during life." (*Maladies de l'Abdomen*.) [See the remarks on Typhoid Fever, vol. i.]

But even with the facts as stated above before us, it must be admitted, that when all those facts recorded in the present article and the two preceding so often referred to, are duly considered, the doctrines of Broussais, with respect to gastro-enteritis, are highly worthy of a careful examination, and do not deserve to be designated, as they so constantly are, as the vague fancies of a heated imagination. When we reflect on the vast influence which gastro-intestinal inflammation exerts in the phenomena of most fevers; that in many of the eruptive diseases it is present and constitutes their danger; that in the varieties of cholera it is a common occurrence; that dysentery, diarrhoea, and a host of abdominal affections are its results; and that it produces the most important modifications in all other diseases,—complications, on the recognition of which their successful treatment mainly depends;—we cannot help expressing a feeling of gratitude to the great pathologist who has awakened the attention of the world to this universal and destructive disease. It is absurd to reject facts because their discoverer may have made use of them to form a theory which the progress of science has partially disproved; and it is worse than ungenerous to deny him that civic crown which he has so truly and gloriously earned.

WILLIAM STOKES.

[GLANDERS, *Equinia*, French, *Morve*, is the most formidable of all the diseases to which the horse is subject. It has been recognised from the time of Hippocrates; and according to a recent

* We must admit that much of the abuse of purging in fever has originated in a misconception of the real doctrine of Hamilton.

veterinarian, (W. Youatt, *The Horse*, p. 129, Amer. edit. Philad. 1843,) few modern veterinary writers have given a more accurate or complete account of its symptoms, than is to be found in the works of the father of medicine. Until within the last few years, the disease was considered to belong exclusively to the horse, the ass, and the mule; but unquestionable cases have occurred, showing that it may be communicated to man in either the acute or the chronic form. (Copland, *Dict. of Practical Medicine*, art. GLANDERS; and Ollivier, art. MORVE, in *Dict. de Médecine*, xxv. 258, Paris, 1839.) To this affection, the term *equinia* (from *equinus*, 'of or belonging to a horse,') has been appropriated, but it has been extended by M. Schedel (*Tweedie's Library of Medicine*, Amer. edit. i. 422, Philad. 1842) so as to include two different affections;—the one, a mild pustular disease, derived from the matter of grease in horses; the other, a disagreeable scourge, of a pustular character, and proceeding from the glandered horse.

1. **Equinia Mitis, or Grease Pox**, occurs on the hands of those who attend upon horses and dress their heels, when affected with grease. The pustules are large; very similar to those of ecthyma (q. v.); elevated; and with a red purple, tumid base. About the eighth day, they are filled with an unquestionably purulent fluid; which, about the tenth or twelfth day, begins to desiccate, forming thick scabs, and leaving well-marked cicatrices. It was at one time thought by Jenner, that the matter of grease was the source of natural cow-pox; but he subsequently modified his opinion as to the cow-pox being derived exclusively from the horse, and the idea is now entertained by few if any. (Schedel, *op. cit.* and the article VACCINATION.)

The treatment of grease-pox requires but little attention. Antiphlogistics internally, and emollient applications externally, are alone needed.

2. **Equinia Glandulosa** is the serious affection produced by the glandered horse. It may occur either in the acute or chronic form.

Acute glanders commences with symptoms similar to those of acute rheumatism; and along with these there is much heat about the nose and trachea. A copious discharge takes place from the nostrils, which become swollen; the nose and surrounding parts are of a bright red; and afterwards of a livid colour; and the swelling extends to one or both of the eyelids. A profuse tenacious mucus, at first of a deep yellow, but afterwards of a bloody or dark sanious appearance, is discharged from one or both nostrils; and at times from the eyes. There is great agitation and tremour; the skin is hot; the pulse frequent, and usually soft and weak; the respiration short and rapid; tongue dry; thirst intense, and the mind incoherent or wandering. Livid patches appear on the sides of the nose, cheeks or forehead, which are soon followed by copious sweats, and a gangrenous state of the diseased parts, succeeded by delirium, tremour, and death in a few days. This form of the disease is said by M. Schedel (*op. cit.*) to be rarely, or never, accompanied by pustules or tumours. In the large mass of fatal cases, however, pustular eruptions and tumours are seen, which

constitute *farcy glanders*, the *morve farcineuse* of the French.

The eruption, which usually appears about the eighth day, consists of large pustules in livid patches, and of small tumours on different parts of the body. The pustules are round, often umbilicated, and contain a purulent fluid, with a little coagulable lymph, in the form of a white, soft substance, very similar to that contained in variolous pustules, and in the pustules induced by the application of tartarized antimony ointment; the umbilicated form is, however, by no means constant. The size of the pustules varies from that of a pea to that of a mulberry: to the latter they often bear a great resemblance in their deep purple colour. Gangrene occasionally occurs in some of these.

Along with the eruption, small tumours appear on different parts of the body, having a shining red appearance, which soon changes to a dark livid brown. At first, they are hard and painful, but their surface soon cracks, and discharges a thin acrid sanies. These tumours sometimes mortify, but more frequently, they communicate with deep-seated abscesses, formed in and between the muscular parts. They have even been found to communicate with the cavity of the thorax. Other eruptions appear occasionally at the same time; not at once, but in successive crops, sometimes as late as the twentieth day. The pustular eruption does not seem to be confined to the surface of the body. It is found in the Schneiderian membrane, in that of the frontal sinuses, mouth, fauces, larynx, and even, it is affirmed, in the mucous membrane of the intestines.

The general symptoms are, great prostration, thirst, frequent tremours, agitation and delirium: and, according to M. Schedel, all the cases of acute farcy glanders, yet on record, have terminated fatally. The discharge from the nostrils is not always apparent, and this has been explained by the matter making its way into the throat, owing to the patient lying on his back.

Examination after death has exhibited the lining membrane of the nasal cavities studded with clusters of small, flat, unequal, white pustules, with irregular ulcerations, and mortified surfaces of varied extent. The septum nasi is almost always ulcerated, and sometimes perforated; and the nostrils and frontal sinuses contain a dark viscid frothy mucus. On dividing the gangrenous tumours, the muscles often appear decomposed: they are of a dark colour; exhale a peculiar fetid odour, and contain specks of purulent matter, with which the muscular tissue appears to be infiltrated. White pustular eruptions, like those in the nasal cavities, sometimes also exist in the mucous membranes of the small and large intestines. Between the muscles, too, large abscesses often form; and lymph or pus is found, at times, in some of the articulations.

Chronic glanders is not, in general, accompanied by any eruption. It is confined to one or the other nostril. At other times, tumours appear slowly and successively on different parts, and suppurate, constituting *chronic farcy glanders*. Sometimes, both affections appear simultaneously in the same individual. The disease does not

essentially differ, except in tardiness, from the acute form. Chronic farcy may terminate in acute glanders.

In the acute form, death may occur in a few days; but it more frequently happens about the twelfth day or later. The chronic variety may be protracted for weeks or months, and then terminate in health, or fatally.

Causes.—According to general opinion, the diseased secretion from the glandered horse must be brought into absolute contact, to induce the disease in man; but some believe that it may be received through the air in respiration. It would not seem that glanders is a very contagious disease amongst horses; for the results of observation in France showed, that of 100 horses exposed to contagion, only seven or eight suffered; and on one occasion, when more than 600 glandered horses were collected together at Alfort, not one of the persons who had charge of them was affected in the slightest degree. It would seem, that in Ireland glanders in man is of frequent occurrence, so much so that Dr. Graves (*Clinical Lectures*, Amer. edit. by Dr. Gerhard, p. 314, Philad. 1842) thinks the legislature is called on to imitate the wise example of the Prussian government in placing glandered horses under the surveillance of the police. It would not seem, however, that the average susceptibility to the poison is great, as but little precaution is generally taken by grooms and veterinary surgeons.

Cases are on record in which glanders has been communicated from man to man.

The analogy between the disease and that occasioned by the reception of some other morbid poison into the system is striking. Wounds, received on dissection, or from handling the skins of animals that have died under peculiar circumstances, induce cutaneous affections, deep-seated abscesses, and febrile phenomena of an analogous nature, and often prove fatal. (See ANTHRAX.)

The disease is extremely dangerous, almost hopeless, in its acute form, and full of danger in the chronic.

Treatment.—It is not practicable to lay down any precise plan of treatment. It has been suggested, that the chlorides of lime or soda should be given internally. It has, likewise, been proposed that they should be used as gargles or injected into the nostrils. Turpentine embrocations have likewise been advised, employed as warm as they can be borne, and turpentine has been prescribed internally in small doses frequently repeated. In the chronic form, Dr. Elliotson (*Lancet*, June 20, 1833, and in his *Principles and Practice of Medicine*) found great benefit from the use of creasote. In two cases, he effected a cure in the course of a few weeks, by the sedulous employment of an injection of a dilute solution (creasot. gtt. i.; aquæ f. ʒj.) thrown up the affected nostril; combining, in one of the cases, the internal use of the remedy. In one case, which terminated favourably to Mr. Travers, a principal remedy was the frequent exhibition of emetics. Fumigated or medicated warm baths, and the vapour bath, have been proposed by M. Schedel. In all cases, both acute and chronic, much has to be left to the judgment of the practitioner; who must be guided by the phenomena that present

themselves. The internal use of iodine, creasote and sulphate of quinia have been advised by M. Delaharpe.

The writer has never met with a case of glanders in the human subject. His description has been, therefore, drawn from others.

ROBLEY DUNGLISON.]

GLOSSITIS, (derived from γλῶσσα, the tongue,) *inflammation of the tongue*. Although in strictness of language the term glossitis may be applied to the partial inflammations of this organ, frequently induced by the direct application of irritants, whether taken into the mouth with food or drink; of corrosive or acrid substances, or occasioned by mechanical injury, such as the forcible inclusion of the tongue between the teeth, or by friction against the ragged edges of such as may have been broken or decayed; it is nevertheless generally used to denote a specific inflammation either of the substance or coverings of the tongue, or of both, induced through the medium of the system, or sustained by a peculiar condition of the organ itself. Some diseases of the tongue, however, of which inflammation has only been one of the conditions, and others in which all the characteristics of it have not been present, have been occasionally described under this name.

The partial inflammations just noticed seldom require further therapeutic consideration than the avoidance of those causes which may renew irritation, and the removal of others that may continue to exist; the operation of nature under such circumstances being almost always sufficiently sanatory without the interference of art. It must indeed excite surprise, that an organ so constituted, so frequently exposed to the action of irritants, and so often exhibiting changes sympathetic with morbid conditions of other parts of the body, should be so little prone to incur either this or any other idiopathic disease. The little liability to extension of inflammation excited by mechanical or chemical irritants is within proof of every one's experience; but in some instances in which the disposition to scirrhus has been latent, its development has soon followed the inflammation consequent to the injury;—a sufficient reason for inculcating the necessity of avoiding all causes by which it might be aggravated.

The same remarks are applicable to general inflammation of the coverings or substance of the tongue, to which some peculiar predisposing state of the organ itself, influenced probably by a particular state of the constitution, added to that of an inflammatory habit or sanguineous temperament, is conducive. Of the nature of these predisposing causes we are yet ignorant, and rather than waste time in discussing the mere conjectures which have been offered to explain them, we shall avail ourselves of the technicality of science, and include them under the term *idiosyncrasy*.

The exciting causes doubtless consist of those which are common to inflammations in general, and are such as contribute to repletion, either by food or drink; the suppression of accustomed discharges or of natural secretions, particularly of perspiration, either general or local, from exposure to cold; the immoderate use of stimulating liquors; and the direct application of corrosive or acrid

substances. The same mechanical and chemical irritants which we have stated to be exciting causes of partial inflammation may also produce the general affection which it is our present design to discuss.

Idiopathic inflammation of the tongue, or glossitis, is a very rare disease, and very formidable in itself, as well as in reference to its influence on the functions of respiration and deglutition, both of which are in general materially impeded by its presence; the former so much so as to endanger life. It commences with the usual constitutional symptoms common to inflammatory diseases, accompanied with some uneasiness of deglutition; the tongue is rendered painful, and the patient sensible of its enlargement, which is evident on inspection: its surface, at first very red, soon becomes coated, except at the tip and lateral margins, with viscid whitish mucus; the articulation is indistinct, and any attempt to move the organ, or pressure upon it, increases pain: the saliva appears to be profusely secreted, but the inability and disinclination of the patient to remove it from the mouth accounts, in a great measure, for the accumulation and dribbling which are always going on. The local pain increases with the progress of the swelling, which is very rapid; speech and the natural motions of the tongue are consequently more and more difficultly performed; and the augmented bulk, encroaching posteriorly on the space assigned to the passage of air and nutriment, increases the difficulties of respiration and deglutition. The pressure also is a source of irritation to the larynx, and occasions a cough, which under the circumstances of the disease is peculiarly harassing; and the cavity of the mouth being too small to contain the tongue in its increased volume, the organ is consequently protruded. In this state it is obvious that a mechanical impediment must exist to the free course of the blood to and from the head; and from this cause there takes place a throbbing of the arteries, an undulatory motion in the jugular veins, lividity of the complexion, an unnatural prominence of the eyeballs, altogether occasioning an appearance of fulness of the face similar to that consequent to strangulation from any other cause: the accompanying sensations are pain of head, and generally in the ears, vertigo, sometimes indistinct vision, and confusion of mind, or even delirium; considerable pain is also often experienced in the tract of the spinal cord and parts adjacent, from the cervix downwards.

The constitutional or febrile symptoms are influenced by the local affection: the pulse is frequent, full, and hard, but smaller as the disease advances, and as the impediment to respiration becomes greater; the skin, which in the early stage is dry and burning, at length is bedewed with accessions of cold perspiration; there is excessive thirst, the bowels are confined, the urine is red, sparingly secreted, and deposits the lateritious sediment. The patient in this state can rarely sleep, and the irritability of the nervous system rapidly leads to an alarming degree of exhaustion. It occasionally happens that the inflammation is confined to one-half of the tongue, the raphe being the line of demarcation between it and the unaffected side. In such cases the con-

stitutional as well as local symptoms are materially modified; so also are they by a variety of other circumstances, such as the extent of the inflammation, the age and temperament of the individual, and the habit of body which may have immediately preceded the accession of the disease.

The progress of glossitis is like that of other inflammations, and terminates either in resolution, suppuration, gangrene, and change of structure, or conversion into other disease. When the inflammation of the mucous membrane of the tongue has been excessive, the lymph effused has been formed into a distinct expansion, like that which usually is found to take place in cynanche trachealis; and as the tendency is probably always the same, the occurrence, we conceive, would be more frequent but for the constant interruption to its formation, to which, in the mouth, it is necessarily liable. A case of this nature has been recorded by Frank of Vienna, who has referred to a preparation illustrative of the disease in another instance, preserved in the Museum of Hunter. (*Acta Inst. Clinici Univ. Viennæ, Anno sec. p. 51.*)

The period which glossitis occupies, and its several stages, are very variable in different cases, and influenced by the modifying circumstances already noticed, as well as by the remedial means which may have been adopted. Its disposition to terminate in resolution is in some cases manifested so early as the second or third day, but seldom before the fifth or sixth. The indications are, a progressive diminution of the morbid bulk of the tongue, and of the pain accompanying it; its surface becoming moister; the thick coat with which it was covered disappearing; a progressive return of power and inclination to use it; with a proportionate decrease or even cessation of febrile symptoms, as well as of those stated to be consequent to plethora in the vessels of the head.

To illustrate the progress of the disease, and its auspicious termination, we subjoin a short sketch of a case described by the writer just alluded to.

A healthy youth, nineteen years of age, was suddenly attacked with febrile symptoms, together with pain in the head and throat, difficulty of deglutition, and cough: these having been neglected, increased, and during the night he experienced very acute pain at the end of the tongue, increasing in extent and severity with its progressive swelling, which was rapid and considerable, filling the whole cavity of the mouth, and rendering him unable to articulate. The following day he complained of pain in the head, especially towards the forehead, with increase of sensibility of the eye to the impression of light; the tongue was remarkable for its red colour, increase of size, rigidity and heat: the patient could neither draw it inwards nor extend it; the sublingual glands and tonsils were tumefied; he was incapable of speech and deglutition; complained of great thirst, had a dry burning skin, and a frequent strong pulse. Copious perspiration of a sour odour came on in the night, the swelling of the tongue and tonsils subsided, and with it the febrile symptoms; the tongue became moist, deglutition easy, and the following day restoration to health seemed to be established.

Suppuration succeeding to glottis is indicated

by some diminution of excitement of the system, with an accession of coldness over the surface of the body, or a distinct rigor, the local pain being somewhat diminished if the abscess be superficial, but the swelling increasing, and at no distant time, in one part or another, becoming particularly prominent. Under the same circumstances the appearance at the pointing part differs from that of the surrounding structure, and to the sense of touch it is soft and elastic, showing plainly the existence of an abscess, which, if not artificially opened, at length by natural process allows its contents to escape. When, however, the pus is deeply imbedded in the substance of the organ, there being little cellular membrane in the construction of the latter, it separates the parts in proportion to the quantity secreted without diffusing itself, and therefore acts as a wedge, and, from the condensation and sensibility of its structure, the organ is little if at all relieved, as usually happens in most other parts by the effusion of this fluid. By active treatment, however, adopted in the early stage of the disease, suppuration may generally be prevented; but when the presence of pus is ascertained, no time should be lost in relieving the organ of it.

The termination of glossitis in gangrene is a very rare occurrence, and has happened only in constitutions extremely debilitated by intemperance or disease. The reduced state of the vital powers manifested in the feeble performance of the general functions of the body, and the blackened appearance of the tongue, the peculiar odour, and loss of sensibility, of pain, and of heat, will denote the morbid changes in progress. It has been remarked that the separation of the mortified from the living parts has been particularly rapid when gangrene has taken place in this organ.

A careful consideration of the symptoms of idiopathic glossitis already detailed will afford the readiest index to determine its presence, and to distinguish it from symptomatic inflammation, as well as from other morbid states. The connecting links between local injury and consequent inflammation can be too easily traced to admit of error; and the enlarged states of the tongue arising from the specific operation of mercury, and sometimes consequent to the absorption of particular poisons, are attended with symptoms too peculiar to themselves, and not sufficiently characteristic of idiopathic glossitis, to render any discussion on their diagnostic distinctions necessary. The same remark is applicable to the tumefactions of the tongue which sometimes occur in fevers of a malignant type, as in typhus and variola; or those metastases of inflammation which, though most rarely indeed to this organ, have been found to occur in arthritic and rheumatic cases with its simultaneous subsidence in the part originally affected.

Idiopathic glossitis must at all times be considered a very formidable disease, and the degree of danger, in a previously healthy subject, will be proportionate to the obstacle which the tumefied organ may present to respiration, and to the opportunity which may be offered of subduing the inflammation on which it depends. From active treatment in the early stage a favourable issue may reasonably be anticipated, particularly if a

mitigation of symptoms is seen to follow the successive application of remedial means; but if the disease be neglected in the early stage, or the volume of the tongue increase, in resistance to the measures resorted to, respiration will be performed with proportionably greater difficulty, threatening extreme danger to life by suffocation; and in persons predisposed to apoplexy or other cerebral disease, in an additional degree, by the impediment occasioned to the free return of blood from the head, and the consequent aggravation of these diseases. Diminution in the volume of the tongue, whether by artificial means directly applied, or through the medium of the system, will proportionately subtract from the danger and increase the rational hopes of recovery; but if the inflammation should have proceeded to gangrene, the danger to life will be influenced by the probability presented by constitutional circumstances of arresting its progress, and, when effected, by the extent of the mortified part: the tongue being the organ of taste, and necessary to the perfection of speech, of mastication, and of deglutition, these functions will be affected commensurately with the local destruction.

When suppuration has taken place, and the bulk of the tongue is diminished by the natural or artificial evacuation of pus, and the distress of the system lessened by a freer state of respiration and circulation, a recovery may fairly be anticipated; but the proneness in this organ to the development of scirrhus, in constitutions predisposed to it, is a circumstance which the practitioner should be prepared to meet after this or any other excessive local irritation.

Treatment.—The rapid progress of idiopathic inflammation of the tongue, arising spontaneously in a subject previously in good health, and not induced by the action of poisons or mercury, renders it of great importance that the antiphlogistic regimen should be early adopted and actively pursued. Bleeding from a vein in the arm, in proportion to the excitement of the system, or from the external jugular vein when the brain is oppressed or likely to suffer, should be immediately resorted to, and repeated a second or even a third time, at intervals of eight or twelve hours, until the inflammatory action of the system be subdued; other means having been adopted in aid of the same intention. Leeches should be applied in considerable numbers to the tongue itself; and when the oozing of blood has subsided from their wounds, a piece of ice, or very cold water, should be frequently applied. Active purgatives, such as calomel and jalap, or sulphate of magnesia with infusion and tincture of senna, must be given without delay, and their operation aided by a stimulating enema: indeed to keep up the free action of the bowels, so essential in the treatment of this disease, a frequent repetition of this remedy will be necessary if purgatives cannot be swallowed; and, under more favourable circumstances, their counter-excitant action being immediate, they are calculated to prove highly advantageous. The usual diaphoretics and diuretics will be useful adjuvants in effecting the end in view; and, from the small bulk in which they may be given, digitalis and tartarized antimony are to be preferred. Immersion of the feet in hot water, or in some

cases even a general hot bath might be prescribed with advantage. A blister should be early applied across the throat, extending nearly round the inferior margin of the lower jaw, as far as its angles.

When respiration is so obstructed by the augmented bulk of the tongue that its increase or continuance threaten to impede it entirely, two or three deep scarifications must be immediately made from the base to its apex, taking care to avoid the *arteria ranina*, for the means of suppressing excessive hemorrhage from them would probably excite a degree of irritation which would counter-balance the advantages consequent even to a moderate loss of blood.

Several instances of the advantage of incisions in extreme enlargements of the tongue have been transmitted to us by M. de la Malle. (*Mém. de l'Acad. de Chirurgie*, vol. v.) Camerarius has recorded a case in which the patient was rescued from impending death by this operation; and Zacutus Lusitanus, another of a child, ten years of age, where the usual remedies had failed of affording relief, and the symptoms yielded to deep scarifications. Job a Meckoen, a Dutch surgeon, who lived in the seventeenth century, (*Dict. des Sciences Méd. Art. Glossite*), adopted this practice on several occasions with the most complete success; and it is probable, as Mr. Samuel Cooper has remarked, that a fatal issue from suffocation, subsequent to various kinds of enlargement of the tongue, might in many instances have been averted by its timely adoption. In the twenty-eighth volume of the *Edinburgh Medical and Surgical Journal*, page 77, an interesting case of the disease is recorded, in which the free use of the scalpel was attended with the best effects; allowing an exit for puriform matter. In the twenty-first volume of the same work, page 235, there is another case, illustrative of the advantage of incisions of the tongue, in a case of its inflammation, apparently consequent to suppression of the menstrual discharge from exposure to cold.

It must be acknowledged, however, that incisions are not always successful; and it may be of importance to the practitioner's credit in proposing an operation which at least has the appearance of extreme severity, that he should advise it as essential in the urgency of the patient's circumstances, and the most conducive, though by no means a certain step to his recovery. An example of the inefficacy of this and several other therapeutic agents in a case which proved awfully rapid, terminating fatally within forty-eight hours from its commencement, was detailed in the second volume of the *Lancet* for the year 1827. It occurred in the Winchester Hospital, and had the advantage of the attendance of an eminent surgeon of that establishment in a little more than twelve hours after the earliest symptom of the disease.

If incisions should fail in producing the anticipated relief, there yet remains an alternative by which life may be sustained and an opportunity provided of conducting the disease to a favourable issue: we allude to the operation of bronchotomy, for the success of which in a case of this kind we have the recorded testimony of Mr. Benjamin Bell. The tongue had been alarmingly swollen from the excessive action of mercury, and no relief was obtained, although a variety of remedies had been

used, until an opening was made into the trachea to keep up artificial respiration. With the same view Desault would have preferred the introduction of an elastic gum catheter from the nose into the trachea, (*Œuvres Chir. de Desault*, par Bichat, tom. ii. p. 406); a method, we conceive, which the preternatural irritability of the parts in particular instances can alone render objectionable.

It will be inferred from our preceding remarks, (and the state of the patient will dispose him little to regret the privation,) that in the early stage of the disease, when the excitement is considerable, stimulating food and drink should be prohibited; it will also be necessary, of course, that the food should be in a soft state, and that both the food and drink should be cool, bland, and unirritating. In some instances the impediment to deglutition may be so great as to make it necessary to administer both medicine and food through the nose by means of a canula passed into the gullet; and in circumstances requiring such a measure, nutritive injections may be had recourse to.

When the inflammatory stage of the disease has been subdued, and the tongue is assuming its natural appearance, little else will be necessary than care to avoid the direct application of irritating and acrid substances; and, if need be, the restoration to a healthy state by the remedial means severally proper in the particular conditions of those organs the defective actions of which may have served to promote the accession or violence of the disease.

When suppuration has taken place, or is about to do so, it will be necessary to relax in the pursuance of antiphlogistic measures, and, as soon as possible, to make a free aperture for the escape of pus, with a lancet or scalpel. From the observations we have already made on suppuration in this organ, it will be understood that a deep incision may often be necessary to reach the cavity of the abscess. A striking illustration of this has been recorded in the *Glasgow Medical Journal*, by Mr. Orgill, with other instructive cases of the disease. The patient, a farmer, fifty years of age, had suffered for some days from glossitis, and besides other treatment had undergone local bleeding by cupping and leeches, as well as two incisions *half an inch deep* from as far as the scalpel could be made to reach to the tip of the tongue. The incised wounds bled freely, and the swelling was a good deal reduced, but in the evening of the same day it became as great as ever; it was scarified still more deeply, and a castor-oil enema prescribed; this also gave great relief; but next morning the swelling had returned, with a peculiar lividity at the tip of the diseased half of the organ. An incision *an inch deep* was made with a scalpel, which gave exit to a gush of pus in a very offensive state, and in eight days the patient was well. The sensibility of the organ on the affected side remained imperfect for a year afterwards, but at length was restored.

When the tongue has been relieved of the painful distension occasioned by the impaction of pus, the sanatory quality of the saliva may generally be relied on for the completion of the process of cure. Astringents in most cases will be unnecessarily stimulating, but a simple admixture of ho-

ney and barley water, or some gargle equally un-irritating may contribute to the patient's comfort by diluting the saliva, and thus forming a cool and more bland application. On some occasions it may be requisite to have recourse to other detergents, such as borax or tincture of myrrh in the common form of gargle.

The indications as to constitutional treatment in this stage are, to allay the irritability of the system, and to restore the disordered functions of the body to their healthy state. As the means must be selected on general principles, it would be needless to particularize them here.

When inflammation of the tongue has unfortunately terminated in gangrene,—a very rare occurrence in this rare form of disease,—its treatment is subject to the same laws as gangrene in any other part: reliance, however, is chiefly to be placed on the means of improving the condition of the constitution; though it is to be feared that in most instances there can be little probability of effecting this object. For the particular means we refer to the article INFLAMMATION, rather than occupy time and space unnecessarily by any formal detail on a subject which has little notice in the records of medical literature, probably because science has been unavailing in the few opportunities which have occurred for its application.

The enlargements of the tongue, (some extraordinary instances of which are on record,) which have been occasionally consequent to the exhibition of mercury, usually yield to purgatives, or injections of the same nature, bleedings, and the discontinuance of the mercurial medicine. In some cases of extreme obstinacy it may be requisite to make incisions into the organ, or to adopt the other means of treatment which have been proposed: other particulars relative to this state will be discussed under the article PTYALISM.

In those tumefied states of the tongue which occur in typhoid and variolous fevers attended with an atonic condition of the system, the local affection requires little consideration apart from the general disease, unless, indeed, the magnitude of the organ should threaten suffocation; when free incisions, in the manner we have already described, and the other mechanical means pointed out, may materially relieve, if not save the patient from impending death.

In such instances as are the results of metastasis, as of gout or rheumatism, the first step will be to invite the inflammation to its original seat, by applying to the latter a sinapism or blister, or by immersion of the extremity in which it may have been situated in hot water, rendered still more stimulating by the addition of flour of mustard or common salt: should this fail in producing the desired effect, or if the habit of the individual should be favourable to the continuance of inflammation, the method of subduing it must be adopted at the same time, bearing in mind that under such circumstances the local affection will partake of the same peculiarities, and require a corresponding consideration, with the general disorder.

[When the surface of the tongue is covered by a dry, white pellicle, and is ulcerated or perforated, a condition which has been described by Dr. Mar-

shall as *psoriasis of the tongue*, (*Principles of the Theory and Practice of Medicine*, p. 468: Lond. 1837,) it is necessary, as in chronic cutaneous affections in general, to act on the general system. This can be done by eutrophics, in other words, by agents that modify the condition of the system of nutrition,—of which arsenic and iodine are among the best, especially if given in syrup, which, of itself, is capable of modifying the chyle, and, through the blood, the nutrition of the tissues. At the same time nitrate of silver may be applied to the tongue itself.]

W. KERR.

[GLOTTIS, ŒDEMA OF THE, (SEE LARYNGITIS.)]

GLOTTIS, SPASM OF THE. This very formidable affection, which is by no means of rare occurrence in infancy, was till of late years but ill understood, being for the most part confounded with croup and other inflammatory affections of the air-passages. One of the first obscure notions of it is that by Millar, under the name of the acute asthma of infants. He seems, in some respects, to have confounded it with the first stage of croup; and yet, if early discovered, he thought it might always be cured by the plentiful exhibition of assafœtida, and the subsequent employment of bark.

A further step towards the diagnosis of the disease was made by Underwood, in his division of croup into the chronic or spasmodic and the acute or inflammatory. The former of these, which seems to answer to what is now called spasm of the glottis, he states to have been known to continue so long as two months, and then to have yielded to opium. "Instances have likewise been met with of children crouping for two or three days, and being then seized with whooping-cough, which has instantly removed the croup. These circumstances," he continues, "seem to prove that species of croup to be truly spasmodic. I have seen it frequently in this form attend the cutting of teeth, being then the mere consequence of irritation, as we see cough and various other symptomatic affections induced at this period." In addition to assafœtida and bark, Underwood recommends the occasional use of emetics and cicuta—"one or other of which must be persevered in as long as any symptom of the disease, and particularly the croaking noise, shall remain. He seems, however, to have had but a very imperfect notion of the disorder, confounding it in one part of his work with croup, with which it has really no affinity, the membrane lining the larynx presenting no traces of disease on dissection; and treating of it in another place under the head of inward fits, which is an imaginary disease. Dr. Ferriar, likewise, in recognising a spurious species of croup, seems to have met with the affection in question, though he did not attain to a correct idea of its nature.

One of the first accurate accounts of the disease is that by Dr. John Clarke, in his *Commentaries on the Diseases of Children*. He describes it under the name of "a peculiar species of convulsion in infant children," often mis-called spasmodic or chronic croup. The child, according to this writer, is suddenly seized with a spasmodic inspiration, consisting of distinct attempts to fill the chest, between each of which a squeaking noise is often

made; the eyes are staring, and the child is evidently in great distress. The face and extremities, if the paroxysm continue long, become purple; the head is thrown back and the spine bent, as in opisthotonos; at length a strong inspiration takes place, a fit of crying generally succeeds, and the patient, much exhausted, falls asleep. The paroxysm may occur often in the course of the day, and is most apt to take place on awakening, or on exposure to slight causes of irritation. If neglected, it may go on recurring frequently for two or three months, until at length general convulsions ensuing, the parents become alarmed. It seldom occurs, he thinks, after the third year, or in children who have lived by suckling alone till they have got some of their teeth, and thus escaped those derangements of the health which are connected with an unsuitable diet in extreme infancy. This, as well as other convulsive affections of children, he ascribes to disease of the brain, which may be induced, he thinks, by over-feeding, keeping the head too hot, the sudden cure of ophthalmia, or of cutaneous eruptions, the occurrence of fevers, &c. In one fatal case he discovered, on dissection, both fulness in the vessels of the brain and water in the ventricles.

A peculiar species of hydrocephalus, ushered in by spasm of the glottis, has been mentioned by Monro; and a case which seems to have been of this kind is also alluded to by Underwood. Gölis, in treating of the predisposing causes of hydrocephalus, places this affection amongst them, and describes it as "a peculiar disorder of respiration, in which infants after sudden waking out of sleep, or from terror or anger, often too without any cause, are suddenly seized with a deep shrill respiration, which for many seconds, sometimes even for minutes, threatens suffocation; the whole body becomes stiff; the face, hands, feet, and particularly the finger and toe-nails black or blue, and the little patients lose their breath and consciousness; at length, however, with a cry of alarm, they again recover both."

Dr. Cheyne has given, in the following passage from his work on hydrocephalus, a more satisfactory account of this affection, since called spasm of the glottis, than any of his predecessors:—"Another disease of infancy required to be briefly adverted to in treating of the diagnosis of hydrocephalus. This disease has been known to some authors under the titles of inward fits, chronic croup, &c. It begins with a crowing inspiration, like that which takes place in the commencement of a paroxysm of pertussis. As at first there are long intervals between these spasmodic inspirations, (several days perhaps;) as they appear to be connected with a disordered stomach and absence of bile in the bowels; to arise from sudden exertion, or fits of passion; and as the child often continues to thrive notwithstanding, the disease is not much attended to. At last, however, the spasmodic inspirations excite just alarm; they occur frequently without any apparent cause, when the child is perfectly tranquil; the complexion becomes purple, insensibility follows, and not unfrequently universal convulsions or rigidity of the muscles, with the thumbs clenched in the hands: these convulsions, in seven instances to my knowledge, have ended in death. However, after con-

tinuing many weeks, or even months, this affection often terminates favourably with the cutting of one or more of the teeth, or it may be relieved by effectually scarifying the gums, changing the air and diet, and alternating mercurials with carminative purgatives. The pathognomonic of this disease is a crowing inspiration with purple complexion, *not followed by cough*. In some cases this affection is attended not merely with a permanent clenching of the hand upon the thumb, but also with a very remarkable fixed spasm of the toes, particularly the great toe, which gives a look of swelled deformity to the upper part of the foot." For a further account of this peculiar swelling of the hands and feet, first accurately described by Dr. Kellie, the reader is referred to the article DENTITION, DISEASES OF. [The presence of these symptoms has given occasion to the names *carpo-pedal spasm*, and *cerebral spasmodic croup*.]

Spasm of the glottis cannot be considered a rare disease, as Cheyne had seen previous to the year 1819, when his work was published, no less than twenty cases, of which one-third were fatal. He, like Clarke, has no doubt that the brain is the seat of the disease; but what is the precise morbid condition of this organ giving rise to these peculiar symptoms, or whether there be any invariable one, has not yet been accurately made out. The results of dissection in three cases are given in the appendix to this work. In the first of these, two tumours, apparently of a scrofulous nature, were found imbedded in the substance of the brain; in the second, the convolutions were nearly obliterated, and the cerebral substance appeared uncommonly firm; in the third, the veins on the surface of the brain were turgid with blood; a considerable quantity of serous fluid existed between the tunica arachnoides and the pia mater, giving a gelatinous appearance to the surface of the hemispheres; whilst about an ounce of water was discovered in the ventricles. Disease of the brain has not, however, always been detected. Thus in two cases mentioned by Dr. Merriman, of children who died in these fits, no appearance of cerebral affection could be discovered. The principal deranged structure was a collection of small glandular swellings in the neck pressing upon the par vagum. In none of these cases was there any trace of inflammation in the larynx or trachea.

Gardien's description of this affection, under the title of "*Spasme du Thorax et de la Glotte*," differs in some respects from most other accounts of it. He remarks on the impropriety of many of the names which have been bestowed on it. Thus by Lieutaud and Baumes, who seem to have had a pretty accurate idea of its true nature, and its alliance to convulsive or nervous affections, it has been absurdly called "*catarrhe suffocante*." The appellations of "*acute asthma of children*," employed by Millar, or "*spasmodic asthma*," used by Rush, appear to him equally objectionable. The disorder, as described by Gardien, consists in a spasm of the diaphragm, muscles of the chest and larynx, and is, he thinks, almost always fatal, if suitable remedies be not employed during the commencement of the disorder. It occurs chiefly in children, though in some rare instances it has been observed in adults also, chiefly in nervous women and old persons. The night-mare, or a

habit of suddenly awakening from sleep in a state of terror, he looks upon as a premonitory symptom, or as the first stage of the disease. Children who are liable to it are observed to cry very frequently during the day, and are frightened and agitated by the slightest causes. Its attacks are sudden, and occur chiefly in the night. The appearance of the face during the continuance of the spasm is variable; in some instances being pale as in syncope, whilst in others it has an apoplectic character. It occurs most frequently, he thinks, between two years old and seven; in which he differs from most other writers, as it is usually placed amongst the diseases of early infancy and of dentition. Children who are old enough to explain their sensations complain of a feeling of suffocation and constriction about the chest, as if it were bound with cords, and of palpitations and convulsive efforts of the thorax, with a sense of strangling about the larynx; the respiration is sometimes momentarily interrupted, and is at all times extremely difficult, and accompanied with a peculiar sound, which can be heard at a considerable distance. The stomach and intestines are distended with air, and the patient seems as if he would die of suffocation, if eructations or vomiting did not come to his relief. His description, in some of its parts, suggests to us the idea of an hysterical affection. Spasm of the glottis, as already stated, has also been mentioned by Dr. Meriman. He thinks it by no means an uncommon affection of children, and attributes it chiefly to improper food and close and confined apartments.

Wichmann, the Hanoverian physician, and Schmalz, in his work on diagnosis, have taken peculiar pains to point out the distinctions which exist between this disease and croup. The latter seems usually to depend on a cold damp air and sudden atmospheric vicissitudes; its inflammatory nature is manifested as well in the character of its symptoms, as by the beneficial effects of antiphlogistic treatment, and by the appearances on dissection. Spasm of the glottis, on the contrary, is excited by passions of the mind and other sources of momentary irritation, existing often in distant parts of the body; catarrhal symptoms form no essential part of the disease; it occurs chiefly in those who have a general disposition to convulsive affections; its attacks are intermittent, and are most susceptible of relief from agents acting on the nervous system; and it presents after death no traces of inflammation in the respiratory organs.

Spasm of the glottis has been described by Mr. Pretty in the Medical and Physical Journal under the singular name of "*cerebral croup*." It has also been noticed by Richter, Henke, Jahn, and several other writers in Germany. [Of late years it has attracted more attention, and by many of the German and other writers has been termed, in consequence of their views of its pathology, *Asthma thymicum*, *A. thymicum Koppii*, and *Laryngismus stridulus*,] and in France it has been treated of by Guersent under the title of "*pseudo-croup nerveux*." Though it has been thus recognised by so many respectable authorities as a distinct and well-characterized disease, yet Autenreith and Hecker, and more recently Jurine and Albers, have treated it as a mere mo-

dification of croup. From this, however, we repeat, it is broadly distinguished, as well by its intermittent nature as by the usual absence of cough and fever, and by the sudden death which not unfrequently occurs in it. Even if a slight cough happen to co-exist, the disease may still, as Dr. Hamilton has remarked, be satisfactorily distinguished by the cough not being a peculiarly hoarse one, and by the breathing in the intervals remaining perfectly free.

The latest and by much the best account of the disease, is that by Dr. Marsh. The disorder, as described by this writer, begins by the muscles of the glottis; but if neglected or mismanaged, it may extend to those of the extremities, and even terminate in universal convulsions. Its occurrence is by no means rare, and its result not unfrequently fatal. It sometimes appears to be a purely idiopathic affection; but in far the greater number of cases, as Dr. Marsh observes, "it is complicated with painful dentition, derangement of the digestive functions, a cachectic state of the system induced by an impure atmosphere, fever, and occasionally with effusion into the ventricles of the brain. The child is observed to awake suddenly from sleep in a state of alarm and agitation, to struggle for breath, and, after repeated efforts, to recover from the paroxysm with a long and sonorous inspiration," usually described by nurses as a whoop or crowing sound. The face is swollen and purplish during the fit. As the disease advances, similar attacks occur even while the child is awake, — "sometimes without any perceptible cause, but more frequently when it is vexed and about to cry." Robust as well as delicate children are liable to it, but it especially attacks those which are of a passionate and irritable disposition, and the subjects of it are observed to be easily startled even by the slightest noises. It is only in its more advanced stage that Dr. Marsh has observed the peculiar swollen state of the hands and feet, and the rigid contraction of the thumbs and toes, already alluded to.

[We have much to learn in regard to the **pathological characters**. It has been thought to be, in the first instance, a spasmodic affection of the muscles of the glottis, and that until the disease has increased in severity, and general convulsions have supervened, the brain or its meninges do not become the seat of disease. The seat of the primary lesion has been presumed to be in the brain. By others, the disease has been referred to hypertrophy of the thymus gland, producing pressure upon the heart, lungs, and great vessels, and it has been maintained to be owing to the enlargement of the bronchial or deep-seated lymphatic ganglions of the neck, pressing upon the recurrent nerves, and inducing paralysis of the muscles supplied by them. (Ley, *An Essay on the Laryngismus Stridulus*: Lond. 1836.) Judging from the character of the phenomena, the disease would seem to be primarily and essentially encephalic; and it has been suggested by Dr. Marshall Hall, that even the enlargement of the thymus gland, which is sometimes met with, may be "a natural effect of the violent convulsive efforts observed in this terrific malady."]

In the **treatment** of the disease the chief indications consist in removing any complications

which may exist, and in improving the general health, and especially the tone of the nervous system. Difficult dentition is a very frequent exciting cause of this affection: when it is suspected to have this origin, the swollen gums must be immediately divided. In those cases where a careful investigation into the state of all the functions of the body detects no complication, a mildly tonic plan of treatment should be had recourse to. The sulphate of quinine, or some of the mineral tonics, are here found very useful. Antispasmodics too often disappoint expectation, and are of very secondary importance in the treatment of the disease: ether and ammonia are the only medicines of this class in which Dr. Clarke had the slightest confidence. The *tinctura fuliginis* of the older pharmacopœias is spoken of by Dr. Marsh with some commendation. In all cases we should endeavour to improve the general health and strengthen the nervous system by country air, a well-regulated diet, and attention to the state of the bowels. By giving the child the advantage of a pure air and of a succession of good nurses during the whole period of dentition, more good has appeared to be done than by all other measures put together. Dr. Marsh remarks that all his cases occurred in children of a scrofulous constitution; a fact which leads him to insist still more strongly on the importance of a pure atmosphere, healthy nutriment, and tonics. Dr. Cheyne, also, as we have seen, dwells much on the utility of change of air and of diet. Free exposure to the open air, and daily sponging of the body with cold water, are amongst the most effectual means we possess for lowering the nervous excitability in this and many other spasmodic disorders.

When the convulsions threaten to become general, leeching the temples, cold applications to the head, and fomentation of the extremities, will generally be required. In the case of a delicate child of two years old, mentioned by Marsh, in which the paroxysms were of very frequent occurrence, and were accompanied by general convulsions, a tobacco enema (five grains infused in six ounces of water) was administered; it produced its specific effect in a very marked manner, and no appearance of convulsions was observed for a month after. Removal to the country appeared to confirm the cure. The symptoms, however, recurred on again returning to town to a house which had been recently painted. Several other instances are mentioned, where the disease seems to have been excited by the unhealthy atmosphere of newly painted rooms.

Dr. Merriman is of opinion that this disease, when early attended to, will commonly yield to aperients, so given as to procure at least two copious evacuations daily, together with the continued use of soda, or a strong infusion of burnt sponge, and proper attention to the diet and regimen:—"When the head is manifestly affected, cupping-glasses behind the ears are required; but when the patient has cold, pale, flabby cheeks, abstraction of blood is rather injurious than beneficial." Dr. Hamilton has found Dalby's carminative a useful medicine in this affection after the bowels have first been freely opened. We have known the disorder, after resisting the influence

of purgatives and change of air, cease finally on the occurrence of a spontaneous diarrhœa.

Spasm of the glottis has occasionally been mistaken for an inflammatory affection of the lungs or air-passages, and been much exasperated by a consequent perseverance in the antiphlogistic treatment, and by confinement to the close air of a heated apartment. Even in its simplest and mildest form it should never be neglected, as in the absence of every complication, the spasm of the muscles of the larynx alone has often proved suddenly fatal. Dr. Johnson knew a case recovered by the immediate employment of artificial respiration, after death had apparently taken place.

Before terminating this article, we may state, that fatal spasm of the glottis in adults occasionally takes place, under the influence of irritating causes in the neighbourhood of the larynx. Thus, in an interesting case recorded by Mr. Kirby, spasm of the glottis and death were caused by the irritation of a mouthful of food sticking in the œsophagus; and we have seen a patient with many of the symptoms of acute laryngitis die rather unexpectedly, when, on dissection, very little if any redness or swelling were discovered in the membrane lining the larynx, and scarcely any other morbid appearance than one or two minute ulcers. It is probable that the fatal result, as well as the sonorous breathing, and many of the other symptoms in such cases, depend on a spasmodic contraction of the glottis.

W. B. Joy.

GOUT, *gutta*, *la goutte*, a drop or defluxion. A name is of slight importance, provided it does not mislead by imputing to a disease a hypothetical character. If used only to express the individuality assigned, for purposes of convenience, to an aggregate of functional disturbances or structural lesions, and limited to this sense without involving any speculative conjectures respecting the cause or nature of disease, it need not be rigidly criticised. That which heads the present article, while it is one of the most ancient, being traceable so far back as the thirteenth century, and the most generally adopted, a corresponding term having found its way into all the languages of Europe, is also the one in common use to designate the disease; and as the false theory which gave rise to it has been long exploded, and is now incapable of biasing any one's judgment, it seems little worth while to change it for any other, especially as, of the substitutes introduced or proposed, none is so unexceptionable as to entitle it to a preference.

An elaborate treatise on gout would be unsuitable to the present purpose, while it would be valueless if it could be introduced. To record all that has been said in the lapse of centuries would be wearisome labour to the writer, and profitless to the reader. Much has been written which may well be passed over. The facts are few, the speculations many, and these too often the mere phantasms of the brain. The former are the same now that they ever were, and therefore cognizable by every observer; and far better is it to study them in the book of nature than to take them on trust from any authority, however high: the latter have produced but little worth remembering; theories have chased each other like shadows in a magic

lantern, none abiding to announce to us the essential nature of gout. After ages of inquiry, we know it only by the order and character of its phenomena, and have yet to learn its intimate nature or the special cause which produces it. Happily the knowledge within our reach is sufficient to guide us to much useful practice, as well in averting accessions of the malady as in mitigating them when they do occur, and in preventing the disorganization and decrepitude to which gout, when neglected or maltreated, so often consigns its miserable victims. If, from our inability to penetrate nature in her inmost recesses, we cannot detect the essence of gout, we can at least note the succession and character of the phenomena which constitute it; we can mark the deviations from health which precede and attend the attack, and by contrasting them with the healthy condition, can arrive at some knowledge of what is amiss: we can thus direct our efforts to restoring healthy function where this is sensibly impaired, and by so doing can second the efforts of nature in remedying the special disorder, even when ignorant of what essentially produces it. In fine, by adopting a pathology founded solely on facts, unalloyed by hypotheses, and conformable to all that we know of the physiology of animal life, we may establish a system of treatment supported by rational principles, and capable of rendering much more valuable service to those who need our assistance, and look to us for relief.

We have it in our power in a great degree to avert the accession of the gouty paroxysm by correcting that state of the constitution which ministers to it; we can greatly mitigate the sufferings of the attack, abridge its duration, and prolong the period of exemption; by so doing we can prevent those horrid disorganizations which protracted or oft-renewed gout so constantly occasions, and also obviate still more fatal consequences which result when gouty action extends to vital organs and other parts essential to well-being. The brain, lungs, heart, stomach, liver, kidneys, may any or all participate in the derangements occasioned by unrelieved or maltreated gout; and the sufferings and danger which thence result may be numbered among the most formidable to which disease can subject the animal frame. Palsy, epilepsy, gravel, and other direful inflictions are too often the attendants on protracted gout, and intensely do they aggravate its sufferings. These views are hastily sketched, for the purpose, not of magnifying the disease or attaching to it any undue importance, but of claiming for it that scrutinising investigation, vigilant observation, and sober judgment which may bring its practical treatment within the pale of rational principles, and divest the subject of the mysticism which has been too long suffered to surround it, to the discredit of medical science and the encouragement of charlatany.

On no subject has empiricism been more assiduously or more mischievously pursued; and where its nostrums have not proved absurd from their inertness, they have been too often pernicious from their activity: witness the numberless victims who fell a sacrifice to the delusive efficacy of the *eau medicinale*. Until the treatment of gout shall be established on the same principles

which are found applicable to all other diseases; until the contemplation of its inscrutable, or at least undiscovered, essence shall be superseded by a fixed attention to its obvious and intelligible phenomena, and the proper treatment which these demand be adopted generally and systematically by the profession, quackery will continue to practise its deceptions, and gouty sufferers, hopeless of relief from the regular practitioner, to surrender themselves the willing dupes of every confident pretender.

A history of gout that would comprise all its alleged forms and modifications would be both tedious and uninteresting; nay, instead of elucidating, it would but obscure the subject, involving it in inextricable confusion. Much that has been attributed to gout belongs not to the special disease so much as to incidental derangements, either antecedent to, coincident with, or resulting from it, and no more an integrant part of gout than when they occur in connection with any other malady. The incidental derangements of a gouty habit are numerous enough, and often to be met with; but it can serve no good purpose to represent all these as characteristic of gout, which, on the contrary, will be best and most clearly comprehended when viewed in its natural form, divested of those complications which, however occasionally intermixed, do not necessarily belong to it. It has been too much the custom to attribute every morbid action occurring in a gouty habit to the influence of gout; and, however obvious their nature or character, to render their treatment subservient to the notions of gout which the medical attendant chanced to entertain. In this way have the apprehension of debility, the belief of a tonic treatment being requisite in gout, and the fear of injuring the constitution by any interference with the gouty paroxysm, misled many into pursuing a stimulant regimen under circumstances which, but for this delusion, would have been seen to indicate a very opposite course; and to the conflicting experience derived from observations made under such misconceptions, may be ascribed much of the uncertainty and caprice which mark the treatment of gout, both popular and professional, even at the present day.

The best history of gout for all useful purposes must be that which represents the disease in its simplest form, giving such a description as will enable the young practitioner to recognise it when presented to his view. This being illustrated, and the principles of treatment explained, the various modifications may then be advantageously discussed in connection with the derangements which occasion them, and with the treatment which they respectively require; in which course of inquiry, it cannot fail to be remarked how much this treatment is dependent on the same general principles which guide the practice in all other diseases, and how very little consideration it admits for the special nature or character of gout.

The definition of Cullen characterizes the disease clearly and succinctly. "*Morbus hereditarius, oriens sine causa externa evidente, sed præeunte plerumque ventriculi affectione insolita, pyrexia, dolor ad articulum, et plerumque pedis pollice, certe pedum et manuum juncturis potissimum infestus, per intervalla revertens, et sæpe cum ven*

triculi et aliarum internarum partium affectionibus alternans." That this as a definition is open to objections we admit. As a description of the disease, however, at once concise and correct, it seems to answer every purpose; and we are not aware of any preferable or less exceptionable character of the malady having been yet proposed. The object of a definition is so to characterize a disease that the name used to denote it shall be applied always to the same morbid condition. But it is a general character only that can be thus assigned. Perfect accuracy is not within the compass of any definition; and it is fruitless to cavil at imperfections of nosology, when of the branch of science which classifies disease the very foundations are yet undeterminate. It may be confidently alleged that of all the methodic classifications yet proposed, not one rests on a stable basis; and both physiology and pathology must be greatly advanced ere any arrangement bordering on a natural and scientific classification of diseases can be practicable. The derangements of the constitution which usher in diseases, the local disturbance to which they give rise, and the re-action by which these aggravate and complete the disordered state in which they originate, are too little understood for any classification of diseases founded on their essential nature or character to be yet attempted. To the labours of the pathological anatomists now so diligently pursued, and to the lights which these shed on morbid actions, and the lesions which result from them, must we look for guidance in this respect if the object is ever to be attained. So unsettled are opinions respecting diseases of the most frequent and extensive occurrence, that it is yet disputed whether fever is a local or constitutional disease; and this ambiguity is likely to endure so long as consideration of diseased conditions of the frame is taken up at the advanced period at which a nosological disease presents itself, without sufficient regard being had to the previous deterioration of health to which so many of these morbid conditions are traceable, and without a clear knowledge of which their nature and progress never can be thoroughly understood.

Much of the complexity displayed in any minute history of gout results from several circumstances being comprised which do not essentially belong to it. Left as it has been to work out its own cure, derangements have ensued in its unchecked progress, which a more efficient treatment of the incipient disease would have wholly prevented, and which should, therefore, be considered rather as contingent and derivative than as forming a primary or essential part of the malady. Peculiarity of constitution, too, whether natural or acquired, continually varies the aspect of the disease; and here to discriminate what is truly gouty from what is but casual is surely preferable to confounding the whole assemblage of symptoms by representing them as all characteristic of gout. The best mode of imparting just and clear ideas on the subject seems to be, to discuss first the disease in its simplest form; and having illustrated, so far as our knowledge permits, its nature and treatment, to extend inquiry to those complications which protracted malady or peculiarity of constitution occasions, instead of regarding these

as distinct and peculiar varieties; in which course of investigation the several modifications distinguished as atonic, retrocedent, and misplaced gout, will be necessarily included.

Histories of gout have been rendered with a minuteness of detail highly creditable to those by whose patient observation and faithful delineation they have been supplied. So copious has been the record of symptoms, whether antecedent to, accompanying, or consequent on a paroxysm, that there is scarcely a derangement of the frame which has not at one time or other been noticed and included. It is full time to lay aside this tedious and profitless minuteness,—to classify those individual symptoms according to the functional derangements which they indicate,—to ascend from the manifestations to the causes which produce them, tracing to the disordered functions the several symptoms which denote their disturbance,—to look to the nature and character of such disturbances, and their connection with the disordered functions, as the only real source of useful knowledge, the only sure guide to rational or effectual practice in this or any other disease,—to distinguish what really belongs to the disease from mere contingencies, dependent not on the specific cause of gout, but on deviations from health local or constitutional which have no necessary connection with it, and which require to be treated precisely as if they occurred independently or in connection with any other malady. Divested of this source of confusion and obscurity, gout becomes as intelligible as are many diseases with which we consider ourselves better acquainted; and though after all our investigations the influencing cause of its peculiar and distinctive character is still a mystery, we may attain quite as intimate a knowledge of its pathology, as far as regards practical utility, as we possess of small-pox, rheumatism, or any other disease of the intimate nature of which we are ignorant, and which we are content to know only through the medium of the constitutional and local disturbances which mark their accession and progress.

In this view a paroxysm of gout can be regarded only as a constitutional disturbance of an inflammatory character, attended with local inflammation of a peculiar kind in one or more joints, running a determinate course, and in the earlier accessions terminating in health, for the most part within a very few days. Such being the character of simple gout, there is no reason why the complications so much dwelt on should be considered as specially belonging to it, or regarded otherwise than as accidents arising from peculiarity of constitution, contingent derangements of health, or the lesions or morbid tendencies entailed by preceding accessions.

That the paroxysm of gout manifests invariably an inflammatory character is a truth which all admit. The inflammation both local and constitutional occurs in every variety of degree; still an inflammatory character marks the whole. In consequence of the disease being identified with the local inflammation, and supposed to commence only when this appears, the seizure is generally represented as taking place suddenly, the previous good health being gratuitously assumed. This,

however, is a great fallacy, no disease evincing so much constitutional disturbance or local inflammation, arising from a cause acknowledged to exist within the body itself, being ever of sudden occurrence. Ample warnings of the approach always exist, and would admit of ready detection, but that the parties, unsuspecting of what is pending or thinking lightly of the unhealthy deviations, overlook or disregard them; and as medical aid is not sought until the accession of the paroxysm, the premonitory indications are rarely submitted to the observation of the medical practitioner; whence a stage of the disease of the first importance, and that which is calculated to throw light on all the subsequent changes, has not received that scrutiny to which it is eminently entitled, nor been allowed the share which it ought to have, both in determining the true pathology of gout, and establishing the practice best suited to its relief.

In the active gout of robust habits, the plethoric state of constitution attendant has been too conspicuous to be overlooked, and accordingly it has received its full share of attention, although the indications of treatment which it presented have not always been acted on to the extent which they ought. It is of importance to understand that in cases where plethora is less obvious, its existence is not the less real nor the less entitled to the practitioner's serious attention. The subject of plethora, its intrinsic nature, modifications, and phenomena, is too extensive to be introduced in this place, a separate discussion being required to elucidate it, which will be found under its proper head. So connected, however, is plethora with gout, that a brief notice of its pathology becomes a necessary introduction to the further consideration of this disease.

The elements of nutrition being supplied to every part of the body by the blood, and this deriving its nutritive matter from the aliment taken, it is obvious that redundancy of nutritive matter may take place in the blood, either from sustenance being inordinately taken, or from a diminished expenditure of it in the ordinary appropriations. In either case the healthy proportions of the elements of which blood consists are altered, and a corresponding effect is produced on the several processes to which the blood is subservient. An accurate investigation of the actions and changes thus induced would go far to explain the origin and progress of many diseases. They should be traced, not by speculative conjectures of what might be ingeniously supposed to take place, but by carefully noting the phenomena which indicate them, and, by induction from well-ascertained facts, guided by a sound physiology, ascending to that point which connects the state of health with the morbid changes. These phenomena have been much overlooked or misconceived, and the semblance of debility which they present has been the source of much bad practice.

The plethora of a healthy and vigorous habit is familiar to all, is readily acknowledged, and seldom misunderstood. That which arises in habits more weakly by nature or depraved by vitiating influences, is less known, and its appropriate phenomena are more liable to mislead. When fullness of habit arising from redundant nutriment

takes place in a healthy constitution, its earliest effects display what may be termed exuberance of health rather than a state of disease. The several functions of the body are more vigorously performed, the nutrition of its several structures is more abundant, and it acquires increase of bulk, especially if the habits of life are not of an activity capable of rendering the appropriation of blood in the several secretions commensurate with the nutriment inordinately supplied. Though this state cannot well be denominated disease, it yet approaches very nearly to the confines, as is continually exemplified in instances where acute diseases of formidable intensity assail persons considered as being antecedently in unusually good health. If the excess be casual or inconsiderable, the self-adjusting powers of the body are amply sufficient to dispose of it so as to prevent the accession of actual disease. And this is done simply by the stimulus of the too nutritive blood exciting the several secretories and excretories to an increased exercise of their several functions. But when, from extent or continuance, the excess is such as to urge these powers beyond a certain point, then these corrective energies fail, and irregular actions and distributions of blood take place, laying the foundation of a large proportion of the special diseases to which the human body is liable. The general character of the diseases thus induced is congestive or inflammatory; by depletion and abstinence the disturbing cause is corrected, and, thus relieved, the natural powers of the constitution soon re-establish a state of health. The more early such relief is afforded, the more prompt and effectual will it be, and the more certainly will those lesions and derangements be averted which protracted plethora is sure sooner or later to occasion. But to relieve it thus early so as to obtain these advantages, it is necessary to be able to recognise its existence by those evidences which denote it, antecedently to the stage of excitement known to us as fever or inflammation. These evidences present an equivocal character to those who have not closely observed the rise and progress of plethora, and they are continually misconceived as rather indicating a state of debility requiring support from nutriment and stimulants, than as calling for abstinence and depletion. When plethora (by which is understood not a mere redundancy in the quantity of the blood, but an excess in the proportion of the elements, chiefly the gluten, which supply nutritive matter to the several tissues) increases so as to exceed what the excited energies of the frame can healthfully dispose of, these energies, incapable of sustained over-exertion, become weakened, and a condition results which is very liable to be confounded with pure debility. The pulse becomes low, oppressed, irregular, and a state of general languor is experienced. Sooner or later this condition passes into one of permanently increased action of the blood-vessels, attended with additional phenomena, the assemblage of which constitutes that state to which we apply the terms fever and inflammation. For the full consideration of this subject we must refer to the article PLETHORA, as it would encumber too much the present essay. Some notice of it in this place was indispensable from its connexion with gout,

and the necessity of referring to it both in elucidating the character and progress of the disease, and in establishing the principles on which the treatment should be conducted.

A paroxysm of gout is seen to consist of a peculiar constitutional disturbance terminating in a local inflammation, the occurrence of which latter, so far as the simple paroxysm is concerned, seems the natural remedy of the preceding disturbance. If the various derangements which usher in an attack of gout, instead of being promiscuously enumerated with a minuteness and to an extent which confound all clear conception, were classed according to the functions severally depraved, the representation would be much more simple and intelligible. All of them admit of being traced to lesions of the circulation, alimentary canal, the nervous system, and the several secretory and excretory organs. Pursuing the inquiry, it is not difficult to mark the connection of these with each other, or to detect the primary derangement in which they have their origin. Excess of nutritive matter in the blood, whether absolute or relative, has been seen to disturb the circulation, occasioning, first, a high activity of healthy function; secondly, an interval of diminished energy; and, lastly, a state of permanent excitement. By absolute excess is meant that which would be excessive in the most healthy state of the individual constitution, and which is always the result of inordinate nutrition; by relative, that which, though it might not exceed what a state of health with active exercise might safely endure, is yet relatively redundant when health has from any cause declined, or when from defect of wholesome exercise, the healthful appropriation has been more or less impeded. Under all these states of vascular action the several secretory and excretory functions become first excited and afterwards more or less depraved, and nervous affections of various kinds ensue, produced either by irritation of the splanchnic nerves, giving rise to endless sympathies, or by disturbance of the brain itself, occasioned either by too rapid circulation, or by remora of blood within it. The series of phenomena here noticed may be traced with considerable precision, and in the ordinary succession, although, so far as regards the nervous derangements, these admit of considerable variation. The best proof of the correctness of these views is to be found in the efficacy of the practice to which they lead.

It is this plethoric state of constitution that invariably leads to the accession of gout, and the premonitory signs of the approaching paroxysm may always be detected by those who seek them in the derangements of function which indicate a state of plethora. These could not have been so long considered as questionable were it not for the delusive appearance which some of the phenomena present, the suspicion of debility which they arouse, and the timidity of the class of patients most subject to gout, which, shrinking from all active treatment, and clinging to accustomed indulgences, has in all ages, even the present, biassed the judgments of practitioners; who, even when they see the right mode of treating gout, are unable to pursue it, and compelled to follow the established routine, however inert or mischievous,

until from never witnessing the salutary effects of simple and direct treatment, they lose sight of its advantages, and at length cease to be conscious of any such being attainable.

A state of plethora, absolute or relative, precedes every accession of gout, and is the principal if not immediate cause of it. The intensity and duration of the paroxysm, too, are dependent on the degree of plethora prevailing, although other circumstances may contribute to prolong the attack. But, notwithstanding this, gout is not simply plethora leading to or ending in local inflammation. There is something more from which gout derives its distinctive character, and this ideal, at least unexplained, existence it is which constitutes the essence of gout. As we are utterly ignorant of it, save through the modifications of inflammation which it produces, our best and safest course, so long as this ignorance continues, is to pay no regard to it farther than to observe the phenomena which denote its existence; to mark their order and succession, with the deviations from the ordinary course of inflammation which they display; and to preserve our practical procedures free from any influences derived from mere speculations of this unknown cause, however ingenious, resting them solely on well-established facts and enlightened experience.

In simple gout we know of no good reason why the treatment applicable to the same degree of general fever and local inflammation occurring from other causes should not be employed. Its general safety and efficacy we can faithfully attest, nor are we aware of any peculiar caution being required beyond what the accompanying state of constitution and the attendant symptoms must necessarily suggest. In all diseases, however inflammatory, the state of constitution requires to be taken into account in judging the activity of practice that may be safely ventured on; and the same consideration is needed in gout, but assuredly none is due in this respect to the imputed essence of gout, nor to the apprehension of interfering with it which has been too long suffered to paralyze the efforts of the practitioner in contending with this hitherto unconquerable foe.

The constitutional disturbance which ushers in gout leads to a local inflammation, after the occurrence of which the constitutional derangements subside. As this inflammation in the earlier accessions quickly subsides, leaving the parts affected unimpaired, it is fair to consider it the crisis of the malady, and also its natural cure; though how it accomplishes this cure is a mystery which we are unable to solve. And were the disease to end here, the interference of art would be superfluous and improper; but it is far otherwise: renewed plethora leads to successive attacks; these progressively increase in intensity, duration, and extent of ravage; and woful experience amply proves that the mere efforts of nature, unaided by regimen, are quite incapable of extinguishing gout. Whenever gout occurs, therefore, it is always expedient so to assist nature as to accomplish more than her unaided efforts are capable of performing, both in rendering the attack milder and the recovery more perfect. The more speedily the constitutional disturbance is corrected, the less is the risk incurred of the gouty diathesis becoming confirmed, and

the greater the security against the derivative ailments entailed by protracted or oft-renewed gout; the sooner the local inflammation is subdued, the less will be the ravages made in the structure of the inflamed joints, and consequently the less the liability to that decrepitude which rigidity of joints, whether arising from thickened ligaments, effusion into the bursæ, or the deposit of solid concretions, occasions.

The gouty paroxysm, involving as it does a state of constitutional plethora, attended with local inflammation, and a latent influence directing and modifying that inflammation, must always be contemplated in its compound character; but so far as practice is concerned, this must be regulated by reference to the inflammatory state, which is fully within our comprehension, rather than to the latent influence, of which we know nothing. The former, with sure and steady light, directs us safely on our way; the latter is much too indistinctly seen to afford us any guidance. If the first attack of gout were treated with due activity, as an accession so decidedly inflammatory would assuredly be were it not for the prejudices so long and so pertinaciously maintained, and if the diet and regimen were afterwards regulated as the tendencies of the constitution and the degree of the gouty diathesis would demand, the future ravages of the malady would be slight indeed, and its victims few. To disregard of the real nature of the malady, to timidity and inefficient treatment of it when it first occurs, and to the pernicious effects of ease and luxurious indulgence in the intervals, when active exercise and abstemious regimen afford the only means of counteracting the morbid tendencies that exist, may be traced all those horrid disorganizations and broken constitutions which have rendered gout the opprobrium of medical science.

As two elements concur in the formation of gout, the plethoric state and the unknown influence, it is clear that these may combine in every variety of proportion, and that the results will be conformable to the degree in which either may prevail. Where the gouty predisposition is strong, a slight degree of plethora will suffice to call it into activity: where the plethora is inordinate, a slight degree of gouty diathesis will give that direction and character to inflammatory action which will identify it with gout. In either case it is the plethora and inflammatory state which chiefly claim the practitioner's attention, and to which his remedies can be most beneficially directed,—with this difference, that in proportion as the diathesis, whether hereditary or acquired, is strongly marked, should the means corrective of plethora and inflammation be assiduously and perseveringly employed, within those limits which a sound discretion would enjoin. In the distinction, so much insisted on in the foregoing pages, between the constitutional condition and special influence which conjointly minister to gout, it is by no means designed to withdraw attention wholly from the latter, or to decry any inquiry by which a precise knowledge of it may be attained. The discovery, whenever made, must render essential service, and no opportunity of effecting it should be neglected. But until profound research or some fortunate accident shall disclose what has hitherto been

hidden from our view, we must be content, if we would render our practice either consistent or effective, to follow that guidance which our familiar acquaintance with febrile and inflammatory affections so amply affords.

If the character of gout in its simplest form and highest intensity be unequivocally inflammatory, it is difficult to conceive why its various shades and modifications should be otherwise regarded. The differences are not greater than are continually met with in several other diseases; nor, when they do occur, is there any difficulty in referring the peculiarities to the particular constitution, the effects of previous disease, and other contingent circumstances amply sufficient to account for them. These circumstances may, and in numberless instances do require that the appropriate remedies of inflammation should be applied with caution; but they can by no means warrant the principles of treatment founded on the inflammatory nature of gout being wholly reversed, as is too often witnessed. There has been too much disposition, arising from timidity, ignorance, and false theory, to transfer to simple active gout the cautions and the apprehension of interference which contemplation of the complex and less active modifications has given rise to. The converse of this reasoning, if more generally adopted, would have led to happier results, to more prompt and effectual relief of gouty sufferers, and to a juster estimate of the practical benefits capable of being afforded by medical science.

Having thus prepared the way for a clear and intelligible discussion of gout, we shall proceed to treat the subject more methodically, and, so far as we are able, elucidate the circumstances which give rise to its various degrees and modifications, so as to enable the young practitioner to discriminate in the use of his remedies, and neither to withhold from gout the treatment which its prevailing character demands, nor to carry this beyond the point which sound experience warrants.

The paroxysm of gout has already been cursorily noticed. It is necessary to present it more fully, so as to mark distinctly the peculiarities which distinguish it from simple articular inflammation. Cullen defines regular gout as, "*podagra cum inflammatione artuum satis vehementi, per aliquot dies perstante et paulatim cum tumore, pruritu et desquamatione partis recedente.*" Accounts of the symptoms which precede and accompany the fit are rendered by all authors who have treated of the disease, to whose works we must refer those who wish to know all the morbid phenomena which may precede or attend the paroxysm. Sydenham, who, when he wrote his treatise on the gout, had been a personal sufferer from the malady for four-and-thirty years, has detailed those symptoms with a minuteness and accuracy that cannot be surpassed. He represents the attacks of gout as in general coming on suddenly, with scarcely any signs of its approach, except that the patient has been afflicted for some weeks before with bad digestion, crudities of stomach, and much flatulency and heaviness, which gradually increase until the fit begins; this, however, being preceded for a few days by a numbness of the thighs and a sort of descent of flatulencies through the fleshy parts thereof, along with con-

vulsive motions; and the day preceding the fit the appetite is sharp but preternatural. The patient goes to bed and sleeps naturally until about two in the morning, when he is awakened by a pain which usually seizes the great toe, but sometimes the heel, the calf of the leg, or the ankle. The pain resembles that of a dislocated bone, and is attended with a sensation as if water just warm were poured on the membranes of the affected part; and these symptoms are immediately succeeded by a chilliness, shivering, and slight fever. The chilliness and shivering abate as the pain increases, which is mild in the beginning, but grows gradually more violent every hour, and comes to its height towards evening, adapting itself to the numerous bones of the tarsus, the ligaments whereof it affects, sometimes resembling a tension or laceration of these ligaments, sometimes the gnawing of a dog, and sometimes a weight and coarctation or contraction of the membranes of the part affected, which become so exquisitely painful as not to endure the weight of the clothes, or the shaking of the room from a person's walking thereon; and hence the night is not only passed in pain, but likewise with a restless removal of the part affected from one place to another, and a continual change of posture. Nor does the perpetual restlessness of the body which always accompanies the fit, and especially in the beginning, fall short of the agitation and pain of the gouty limb. Hence numberless fruitless endeavours are used to ease the pain by continually changing the situation of the body and the part affected, which, notwithstanding, abates not until two or three in the morning, that is, till after twenty-four hours from the first approach of the fit, when the patient is suddenly relieved by a moderate digestion and some dissipation of the peccant matter, though he falsely judges the ease to proceed from the last position of the part affected; and being now in a breathing sweat, he falls asleep, and upon waking he finds the pain much abated, and the part affected to be then swelled; whereas before only a remarkable swelling of the veins thereof appeared, as is usual in all gouty fits. Such is Sydenham's description, which we have given in his own words as translated, being reluctant to weaken the force of such graphic delineation by any attempt at abridgment. The little admixture of theory evinced in the reference to digestion and peccant matter, cannot detract from the truth or value of this clear and circumstantial recital. For some days after this accession he represents that slighter degrees of pain and fever recur each evening, continuing until morning, after which all disease ceases, and the patient is restored to more vigorous health both of body and mind than he had antecedently experienced. This is the simplest course of a gouty paroxysm, and that which it usually runs on a first attack. On succeeding seizures, especially when the constitution is robust and plethoric, inflammation, on subsiding in one joint, becomes renewed in another, and eventually several joints are attacked in succession, and often two or more at the same time; so that in this progress every variety of intensity, extension, and duration becomes ultimately encountered. To dwell on these different degrees would be useless, as they are all but extensions and modifications

of the simple paroxysm, requiring no modification of treatment beyond what the severity of the attack and the existing state of constitution enjoin.

The attack of gout is said to take place suddenly, and with scarcely any previous warning. Yet the very accounts which so represent it give abundance of premonitory indications, which are stated as preceding the attack even for some weeks. Dyspeptic derangements, with some nervous ailments, are the precursors usually noticed; and the assertion of good health existing up to the period of the gouty accession seems to have rested, not on any positive examination or knowledge of the fact, but on the mere circumstance of the patient not having his consciousness so aroused by any precise or considerable indisposition as to complain of being ill. So far as we have had opportunity of noticing the state of health which precedes the gouty seizure, we utterly disbelieve this assertion, and are satisfied that if the phenomena which mark incipient plethora and progressive febrile action were duly noticed, the same constitutional derangements which precede other inflammatory affections would be found uniformly to usher in gout. Disturbances of gastric and nervous functions are acknowledged; those of the circulation would be no less manifest if practitioners were more familiarly acquainted with the changes which the pulse undergoes in progressive plethora, from the stage of oppression marked by a pulse low and irregular both in force and frequency, to that of the permanently excited action of fever or inflammation evinced by a quick pulse, hot skin, and furred tongue.

One of the earliest instances of the introductory stage of gout which came under our observation occurred many years ago, and served to confirm impressions which our mind had for some years preceding been gradually receiving, from a careful observation not only of gout, but of all other inflammatory diseases. The case was detailed in some pathological and practical observations published in the *Edinburgh Medical and Surgical Journal* in 1814, from which we now extract it. It will show at least how much constitutional disturbance, perfectly obvious and unquestionable, may exist while the person affected is unconscious of being otherwise than in perfect health. "A gentleman about forty years old, and of full habit, had been subject to gout for several years. He arrived in this country in the course of last summer from America, where he had suffered several attacks of the disease. The treatment experienced under them I cannot specify, but in the intervals he was enjoined to take a pint of wine daily, in consequence of his gouty habit. This he acquiesced in from unwillingness to put his own judgment in competition with that of his physician, although he disliked the remedy, and thought himself always worse both from wine and full living. He called on me in autumn last, to know if he should drink the Bath waters, as recommended by his American physician, at the same time stating himself to be particularly well and free from complaint. I found his pulse full, strong, and nearly 100, and his tongue whiter than it ought to be. I consequently discounted any trial of Bath waters, and gave my opinion that he stood much more in need of blood-

letting and evacuations. As he professed himself, however, to be so very well, I did not feel myself warranted in pressing this, though satisfied that his habit of body approached much too nearly to a state of inflammation. This conversation took place on Wednesday, the 14th of October; and on Thursday, the 15th, he was attacked with gout in the right knee. On Friday, a second attack took place in the left foot; and on Saturday, I was sent for. I found his skin hot, tongue white, and pulse 106, full and strong. Sixteen ounces of blood were drawn, after which the pulse fell to 84. A full dose of a purgative, consisting of colocynth, calomel, and antimonial powder, was given at bed-time, and a solution of Epsom salt the following morning. On Sunday he was better in every respect, but the pulse was again up to 96. It evinced clearly a necessity for further bloodletting; but as the purgative was then operating and the local disease abating, I was satisfied to order the bloodletting to be repeated the following morning. It was not in time, however, to avert a third attack, which took place during the night in the right elbow. Next morning I found the pulse as much reduced as if bloodletting had not been practised, although it did not take place in consequence of the state of the arm. Whether this effect was owing to relief to the general circulation being afforded by the formation of the local disease which had occurred during the night, or whether it proceeded from a degree of syncope and nausea which were experienced at first rising, or whether they were all dependent on some common cause, I shall not pretend to determine. At this time the knee was nearly well and the foot much better; and as the tendency to syncope had not entirely gone off, and he felt reluctant to have both arms incapacitated, he expressed a wish that the bloodletting might be deferred until the gouty arm got better. On Tuesday the foot was almost well, and the elbow getting better. The pulse, however, was again 96, full and oppressed, which determined me against incurring any further risk, and on having recourse once more to the lancet. About fourteen ounces of blood were taken, which induced some faintness. On Wednesday the pulse was 84, and there was no renewal of gout. Purgatives, salines, and low living were the only means employed thenceforward, and from this period he rapidly recovered. On the 26th he walked to my house, and could have done so some days earlier had the weather permitted. He expressed himself much gratified at the treatment he had undergone, as confirming the correctness of those views of the disease which he had always entertained, and declared to me that he had never thrown off such an attack so quickly, so perfectly, or with such unimpaired powers."

On the treatment pursued in this case we shall only remark, that had it occurred to us later in life, when our judgment was more matured, and our conviction of the safety and efficacy of active practice in gout confirmed by more ample experience, we should have hesitated less in affording the appropriate relief, and the result would have been still more favourable. The case, independently of the result, is of value on two accounts,—as exhibiting the unequivocal state of constitutional inflammation which precedes the gouty paroxysm,

and as showing how far constitutional disturbance may prevail without the party having any consciousness of its existence. Were it not for the accidental examination made on the day preceding the attack, this person, on the evidence of his own consciousness, would have been pronounced in perfect health up to the period of the gouty accession. The inferences deducible from the facts here stated have been uniformly confirmed by all that we have seen of gout from that period to the present time.

Although gout, then, may arise without any evident external cause, a cause sufficiently manifest may be discovered in the attendant state of constitution by those who seek for it. It is true that where the gouty diathesis is strong, a slight degree of plethora may suffice to call it into activity, and in these instances the plethora and inflammatory tendency may, if not closely investigated or if only loosely observed, escape detection. Our firm persuasion, however, impressed by all that we have seen of the disease, is, that in every case of spontaneously occurring gout, more or less plethora either absolute or relative, and of inflammatory tendency sufficiently discernible, precedes the gouty accession: and that in proportion as this state is borne in mind, and the treatment regulated with reference to it, will the fit be more speedily and effectually relieved, the period of exemption prolonged, the ravages in the joints prevented, and the contingent maladies averted. From this view of the subject, it is clear that high feeding and indolence are very properly enumerated among the predisponent causes of gout. From these fulness of habit arises, and this, as will be more fully shown in the article PLETHORA, leads to a series of phenomena, which indicate first an overloaded and oppressed state of circulation, and afterwards one of increased action. When the latter attains its full activity, it constitutes what we call fever or inflammation, and any accident may determine the part which is to suffer most, and the function which is to be most depraved. When this plethoric and inflammatory state arises in a gouty habit, the result is an accession of the disease.

A remarkable peculiarity of gouty accession is, that the supervention of the local inflammation gives relief to the constitutional disturbance, and that, having effected this, it quickly and spontaneously subsides, at least in the earlier attacks, leaving the part so lately the seat of formidable derangement, somewhat weakened indeed, but otherwise in perfect health. The dyspeptic derangements connected with gout are no doubt traceable in a great degree to the luxurious living and consequent irritation of stomach habitual with those who chiefly suffer from this disease. But this is not their sole cause, for independently of the various excitements to which the stomach is subjected, the direct effect of plethora is to induce a congestive state of the capillaries of the mucous membrane of both stomach and intestines, and an increase of its appropriate secretions,—a condition which is the fruitful parent of gastric and intestinal maladies of various kinds. In the absolute plethora of robust habits, especially when the gastro-intestinal membrane is excited by full living and stimulants, this increased secretion of mucus

in the stomach and intestines is considerable, and its production is readily accounted for. The efficient cause seems to be excitement of the secretory vessels by determination of blood to the capillaries, and by the blood possessing, from the redundancy of nutritive matter, more stimulant properties; the end,—increased appropriation of the nutritive matter of the blood, and consequent relief to the overloaded circulation from that redundancy which oppresses and disturbs it.

In the less vigorous and more temperate a corresponding state arises, when from diminished appropriation of blood, through sedentary life, inactive habits, or any other cause, the relative quantity of nutritive matter becomes greater than can be healthfully disposed of. And this serves to explain how a state of plethora and of febrile tendency so often occurs even in habits naturally spare; and where no obvious intemperance has been practised. Yet even in these the evidences of a plethoric state are readily discernible, and at an early period, if the phenomena which indicate it are rightly understood; and the effects, as displayed in the gastric and intestinal secretions, are in them even more signal than those which positive plethora usually displays, the morbid condition of the mucous membrane being generally of longer continuance and more confirmed ere attention is directed to it. These effects, though modified, are essentially the same in both, and require similar treatment; this differing in degree only according to the different powers of the constitution so affected, and being modified only by the state of the mucous membrane, and the greater or less time during which the congestion has been suffered to endure.

If the treatment, therefore, required for the more active and simple state of disease be once established, that of the lower gradations and more complex conditions will be sufficiently apparent, differing not in kind but degree, and combined with auxiliary remedies as incidental derangements may require. In weakly habits, and where the constitution has been suffered to struggle long under unrelieved plethora, these derangements are numerous and proteiform, harassing the patient and confounding the physician. So long as they are regarded as special maladies, and treated without direct reference to the state of constitution in which they originate, and by which they are upheld, the aid of medicine must be precarious and its success uncertain, conferring little benefit on the sufferer or credit on medical science. When assailed at their source by relieving the overloaded circulation, and restoring to more healthy action the several functions over which our remedies have direct and acknowledged powers, they readily give way, yielding oftentimes to the general improvement of the constitution without any special means whatever being needed for their relief. To the gastric and intestinal derangements, and to those which evince disturbance of nervous function, these observations more immediately apply. Digestion is impaired, and weakness of stomach is pronounced, for which cordials and tonics are deemed the appropriate remedies. Transient relief perhaps ensues in some improvement of sensation, some increase of appetite, and thus error becomes confirmed. But, unless evacuations be

adequately and discriminately combined, such remedies ever do more harm than good. Administered alone and as the chief agents of cure, they tend directly to aggravate and perpetuate disease, repressing those efforts by which the overcharged vessels would, through increased secretions, unload themselves, and ultimately establishing organic lesions of different kinds. By continuance in their use, impression is made on the mucous membrane, diminishing its morbid secretions, and thus appearing to correct them, while the stimulants conjoined impart some feelings of renewed strength. Both effects, however, are eminently delusive. By suspending increased secretion, which, rightly understood, is the direct result of a congestive state of the capillaries, and the natural means of relieving them, disease is only transferred, not removed. It may for a time quit the capillaries, or rather its character in them is altered; but it is only to be driven back on the larger vessels, where it leads to deep-seated congestions and to disorganization of various kinds. If the constitution be still entire, it is pretty sure under such circumstances to become aroused sooner or later to some febrile or inflammatory effort, for which evacuations become indispensable, and thus relief to the oppressed and overloaded organs is at length afforded; if languid or much depraved by long continuance of the morbid condition, and still more if this condition have been aggravated by abuse of cordials and stimulants, and by the neglect of evacuations, then the constitutional efforts are feeble, they are disregarded or misunderstood, and a more assiduous use of wine and sustenance is urged for nurturing that strength which such means so applied never can restore. In like manner the various nervous maladies connected with this state of constitution run a similar course. Stimulants, antispasmodics, and narcotics, all lend their aid, but it is to palliate only, while in reality they do mischief. These maladies depend much on nervous sympathies arising from disordered stomach, but they are also in part owing to direct disturbance of the brain itself, through irregular circulation and morbid condition, chiefly of a congestive character, of its substance or investing membranes. Stimulants may, and oftentimes do, relieve this state for the moment, by rendering the cerebral circulation more active, and thus giving greater energy to nervous function; but the disease is not thus cured,—scarcely mitigated: the effect lasts no longer than the brief period during which the stimulus maintains its influence, and the state which ensues is still further removed from that of health. This can only be restored by so regulating the circulation that the mass of blood shall neither by its quantity or quality cause any extraordinary excitement of the vessels which convey it, nor need any increased efforts on their part for its disposal; and afterwards by rendering such assistance to the several secretory and excretory functions as shall re-establish them in the healthy and efficient exercise of their respective offices.

In judging of the instances in which tonic and stimulant regimen is supposed to be beneficial, and which are continually adduced in proof of its propriety, it is necessary not to decide hastily or absolutely from the immediate effects, but to watch

such cases to their close, when the consequences will be sufficiently demonstrated. Many alleged cures are thus performed for which the parties have little cause to be grateful. Sooner or later formidable disease is sure to ensue, its form depending on the accidental excitements to which the body is subjected, and on the peculiar tendencies to which it is prone. In a gouty habit, reproduction of gout, and its confirmed establishment in its most aggravated shape, can hardly fail to be the result of such a regimen.

They who see much of what are termed chronic diseases must have ample opportunity of verifying by observation what is here stated. These cases present every species of internal congestion to which plethora, unrelieved by due evacuation and aggravated by stimulants, can give rise. Too often are the lesions of structure thus occasioned beyond the reach of art, while the exhaustion and attenuation are such as to preclude all attempts to relieve, save by temporising palliatives. How much of this kind of evil the constitution can bear, however, and how long an oppressed and overloaded circulation may endure without annihilating all hope of relief by rational treatment, is continually exemplified. Where there is no particular tendency to local or specific disease, and the effects of plethora and of febrile action are diffused over the whole frame, they may continue for months or years, still retaining all their original character, and still admitting of valuable relief from appropriate and duly active practice. Nay, even where a special disease is engendered, if it be one of slow progress and which does not immediately affect life, it may continue for years to cause extreme distress, and yet be capable of relief from rational treatment. The following case may illustrate these several positions. A delicate female had for ten years laboured under varied and extensive disease, which from all that we could learn had been throughout of the character which we have described. Being weakly, however, and exquisitely nervous, her complaints were referred to debility, and she was pampered and stimulated with tolerable assiduity. Symptoms of general dropsy were superadded to her other complaints, and were making rapid progress when she applied to us. The character of the disease was obvious enough; the remedies were equally so; but great caution was necessary in resorting to them, both from the extreme exhaustion, and from the constitution being extensively and miserably depraved. Yet was there no alternative, for without bloodletting effectual relief could not be afforded, and from the rapid progression of disease she must have speedily sunk. We drew blood in small quantity, which was thickly buffed and cupped; purged freely, and enforced low diet. The relief was prompt: the dropsical swellings subsided, nervous maladies declined, all her feelings were improved, and even strength was increased. Blood was afterwards taken repeatedly and more freely, and she ultimately became relieved from all her complaints so far as her broken health and the ravages sustained by long-continued disease would allow. For some years she has, in consequence of this relief, had much more enjoyment of life; and so satisfied is she of the remedy to which she is chiefly indebted, that she is herself the first to call for the lancet,

when, as occasionally happens, recurring plethora or febrile action indicate its employment. This case, though not one of gout, serves to demonstrate the state of constitution which we wish to illustrate, and which is continually met with in connection with gout; such cases, whether gout be incidental or not, require that the healthy balance of circulation and of the circulating fluid be restored, as the first requisite; and that the several secretions and excretions be corrected and promoted according as their respective derangements demand. When this is done on the principles applicable to all diseases, then may the special nature of gout receive any peculiar consideration to which it may lay claim. But so long as a plethoric state of constitution exists,—a point on which no deceptive appearances should be suffered to mislead,—and the several secretions and excretions are depraved, must all special treatment of gout by imputed specifics be subordinate to those corrective measures by which the constitutional derangements are rectified, and general health restored.

As some have cavilled at the term constitutional as thus applied, and with a subtilty of criticism more ingenious than profitable, have denied that any such thing as constitutional disease can exist, inasmuch as every morbid action must affect some part of the system, I shall here remark that I employ the term constitutional in reference to the general condition of the frame, and the collective exercise of its several functions, the due balance of which constitutes a state of health. Derangement of these functions is more or less attendant on all diseases, yet it is not always considered as forming a part of them, and is in consequence too apt to be overlooked. The general health dependent on these functions we consider as having a claim to attention in every disease, even superior to that of the special malady; it is this state to which the term constitutional is applied, and we know not how it could be so well expressed by any other. In gout it is this which is entitled to our very first consideration, for not only is constitutional derangement attendant on every accession of gout, but some degree of it is essential to the formation of the paroxysm. In proportion as gouty diathesis prevails, will greater or less degrees of constitutional derangement arouse it into activity; but some previous disorder of the general health, some antecedent disturbance in the healthy balance of functions, is necessary to this end, for without such there would be no paroxysm. On a just conception of this truth all prophylaxis must depend.

After the foregoing discussion of the nature and character of gout, we might at once proceed to the curative treatment, were it not that this essay, which is to serve for an elementary as well as practical treatise, demands a detailed exposition of several circumstances which have not yet been noticed. For the sake both of perspicuity and brevity, we shall, in what remains, follow the order which methodic treatises on diseases usually observe.

Our general remarks on gout have been hitherto confined to those circumstances which more particularly indicate its character, and mark the morbid conditions which tend to produce it. Several

others, however, require to be noticed; and here, as well as in the subsequent sections into which the subject will be divided, we shall occasionally borrow from what we have ourselves already published; and this not from indolence, but from the persuasion which we entertain, that where opinions are founded in truth, the original expression of them is more likely to be terse and correct than any repetition clothed in a different phraseology.

Dr. Cullen's definition represents gout as an hereditary disease. It is so generally, but by no means universally; and so far this character is improperly introduced into a definition. The general truth, however, of a predisposition to gout being entailed on offspring, is too well established to admit of dispute. Cases no doubt continually present themselves where no hereditary taint can be traced, manifesting that this is not essential. Dr. Scudamore, in some interesting tables, has shown that of a given number the greater portion acknowledged no hereditary claim to the disease. The fact of hereditary disposition, however, is not thus set aside, but has been too strikingly exemplified in numberless instances to be easily shaken. From the very slight influence which this point has either on pathology or practice, it is, in truth, of little real importance. The only consequence of admitting such predisposition seems to be, that when it is supposed to exist, gout may be expected to take place under circumstances which, independently of this tendency, would not have power to originate it; and that hence a salutary caution may be suggested to those who have any consciousness of hereditary claim, to guard with particular care against the various causes which excite gouty action. While false theory prevailed, and the establishment of gout in the extremities was considered essentially desirable as relieving the constitution from peccant humours supposed to be thrown on the affected joint; and when the suspicion of a gouty diathesis led to a free use of stimulants as a means of repelling the enemy from vital parts; when the supposition of hereditary taint was not harmless, the regimen enjoined tending directly to arouse what might have lain dormant, if not to create what might otherwise never have existed. But if rational principles of gout, its nature and treatment, were generally established, the admission of its being hereditary could lead to nothing but good, and might effect such changes as would in time cause the evidences of hereditary disposition wholly to disappear. Indeed it would be well if the fact of hereditary transmission were more generally received and more deeply impressed, as many who would prefer the liability to gout to any sacrifice of luxurious indulgences, so long as they regarded the choice as affecting their own persons alone, might exercise some self-restraint if assured of the consequences which their excesses might entail on their offspring and descendants.

Though the paroxysm of gout usually occurs in the way described, and without any evident external cause, yet any accident or injury of a joint occurring in a gouty subject, may, instead of simple inflammation, bring on a fit of gout, or rather the local inflammation excited may assume all the characteristics of that disease.

The precedence of gastric derangement is not

necessary to constitute gout, many being unconscious of any such up to the accession of the local inflammation. In advanced cases, however, and in broken constitutions, this premonitory indication is rarely absent.

Pyrexia so generally attends that it may well be considered a characteristic feature. In those cases where, from languid or enfeebled powers, it is less obvious, and where to superficial observation it might appear not to exist, more careful investigation of symptoms would rarely fail to detect it.

Women, though not exempt from gout, are less subject to it than men. Dr. Gregory used to state the proportion as one to fifty in England, one to one hundred in Scotland. For this relative immunity in females they seem indebted to their greater temperance, and also to the facilities which the female constitution possesses of throwing off redundancies by natural outlets. Dr. Gregory had observed among his patients, that the women who suffered from gout had antecedently been subject to profuse hemorrhages, such persons being generally plethoric through indolence, sedentary lives, and high feeding, and hence predisposed.

Vigorous and robust constitutions are most subject to gout, though no spareness of habit affords security against it. The cholero-sanguine temperament is said to be that which is most liable.

Gout is most generally a disease of middle and advanced life. Its attacks usually occur from the age of thirty-five onwards. When the predisposition is strong, however, it may commence much earlier. Dr. Gregory met with it oftentimes among his pupils, young men from 18 to 22, and who had not earned it by intemperance.

The relief to the general health imputed to the supervention of the paroxysm, though an observation partially founded on truth, becomes progressively less speedy and less signal as the disease advances. It has ever been too much relied on, and has led to much pernicious practice, both medicinal and dietetic.

So many causes, both remote and immediate, have been assigned to gout, that they require to be noticed; for though most of them are merely contingent and accessory, they all merit attention where regard to the *juvantia* and *lædientia* is so important.

Hereditary disposition has been sufficiently discussed, as have also the influences of plethora and of the unascertained cause from which gout derives its distinctive character. Whatever induces a state of plethora may become a cause of gout, whence luxurious living, indolence, and sedentary habits, have ever been the chief means of exciting or producing it. By these is the gouty predisposition urged on to active disease; and, so far as our knowledge extends, they are fully capable of originally producing it. The extremes of luxury, or of indolence, however, are not required to produce this effect. Lesser degrees may induce plethora sufficient to destroy the balance of health, and thus beget disease. A slight redundancy of nutritive matter in the blood, whether arising from excessive supply or diminished expenditure, may create an inflammatory state, which, in a habit predisposed, may lead to gout, even where the

habits of living may appear temperate, and where moderate exercise is taken. No terms are more loose in their general application than temperance and exercise. Credit is continually claimed for the former, where the animal food and wine habitually taken far exceed what nature requires or can bear; and the name of exercise is oftentimes given to bodily exertions so gentle that they lead to no increased expenditure of blood, while, by increasing appetite, they too often tend to augment and enrich it. Gout is a disease of the rich and indolent, not of the poor and laborious; and this truth, so obvious and incontrovertible, ought to have had more influence on medical opinions than it has been allowed to exercise. If there were no other fact whatever ascertained, this alone might suffice to point the way to the efficient prevention and treatment of gout. In Scotland there is an old saying worthy of being held in remembrance, that any man may free himself from gout by working for and living on sixpence a-day.

Next to plethora, whatever causes induce debility of stomach have been regarded as principally influential in bringing on gout. The observation is to a certain extent true; yet the facts on which it rests have been egregiously misconceived, and much pernicious practice has in consequence resulted. Weakness of stomach being assumed, tonic and invigorating regimen was of course considered as indicated, and long and pertinaciously has its use been persisted in, notwithstanding the utter failure of such treatment to mitigate, much less subdue the disease. Had the nature of this assumed debility of stomach been more closely investigated, it would have been seen to present a character very different from what tonic or stimulant remedies could essentially relieve. It might, at least in the earlier stages, have been clearly traced back consecutively to inordinate and depraved secretions, turgid condition of the mucous membrane, congestion of the capillaries, and general plethora, all readily relievable at the commencement by evacuations and abstinence, all aggravated by nutritive diet, stimulants, and tonics. All reference, therefore, to debility of stomach as a cause of gout should extend, not merely to the alleged weakness, but to the several causes, both coincident and consecutive, by which the important function of digestion becomes weakened or disturbed.

Various causes are instrumental in exciting the paroxysm, but they are all subordinate to those mentioned, and incapable of such effect unless where depravation of health has prepared the way. Excess of venery is an acknowledged exciting cause, as is also abuse of spirituous liquors, as well as indigestion, whether occasioned by the quantity or quality of the food taken. To the immediate effects of this last cause may be referred many cases of imputed gout in the stomach, which have been wholly independent of gout. Dr. Gregory used to relate a case where he was called to a patient said to have been seized with gout in the stomach; but he found his complaint caused, not by gout in the stomach, but by pork in the stomach, of which difficultly digestible food he had too liberally partaken. By getting rid of it he was perfectly relieved, and there was nothing more heard of gout for that time.

[A recent writer, (Dr. W. Budd, in *Tweedie's Library of Medicine*, 2d Amer. edit. iii. 587, Philad. 1842,) is disposed to think — and the observation of the writer leads him to the same belief — that malt liquors tend, even more than wine, to produce a gouty diathesis, and the evidence, which he adduces on this subject, is striking (see vol. i. p. 179).]

Intense study has brought on gout. It is stated by Sydenham that one of his most severe attacks was occasioned by immoderate application in writing his essays on the disease, and that gout returned as often as he attempted to go on with the work.

Purging has been said to bring on the paroxysm, and such a coincidence no doubt occurs; but it would be a great error to suffer this observation to deter from a judicious use of purgative remedies.

Continued costiveness is a more probable cause, yet this can only be regarded as an incidental derangement, depraving, so long as it continues, several other functions, and adding to the disorder of the general health.

Change from activity to indolence has been often noticed as leading to gout, a circumstance readily understood. Change from low living to high is equally intelligible. But sudden change of the opposite kind has been marked by the same effects, as was signally exemplified in the patients of the celebrated Dr. Cheyne. He, as all know, was the advocate of temperance, and having enjoined it to his gouty patients rather too absolutely, and without sufficient discrimination, he had the mortification to find that his directions, so far from obviating the attack, hastened the paroxysm, which afforded great exultation to the opponents of his doctrines. Their triumph, however, was far from complete, although it served for a while to confirm existing prejudices.

The hypothesis of gout being caused by a special morbid matter, eliminated and expelled by means of the paroxysm, has been fully and ably refuted by Dr. Cullen. There is no proof whatever of any such existing; and assuredly it is not, as was long imagined, identical with the concretions deposited in gouty joints.

Cold, heat, external injury, depressing passions, too great exercise, especially in walking, have all been enumerated among the causes capable of exciting gout; but they can only be regarded as mere accidents, having no power to induce the disease, save when the habit is on the very verge of the paroxysm.

The diagnosis of gout must be derived from its history and general character, for there is no pathognomonic symptom whatever to distinguish it from rheumatism, the only disease with which it is liable to be confounded. Each disease, perfectly formed, is sufficiently distinct from the other; but the intermediate degrees approach each other so nearly, that to discriminate with absolute certainty would require a more intimate acquaintance with the essence of both diseases than we can take credit for possessing. All that can be done here, then, is to note the peculiarities of each, and then to leave it to the practitioner's own judgment and observation to decide to which any equivocal case may belong.

Gout is generally a disease of advanced life, not

occurring for the most part till thirty-five; rheumatism most frequently attacks the young, that is, from the age of eighteen to thirty. Yet the converse of this is so often true, that the observation furnishes no ground of accurate diagnosis; rheumatism attacking every age, while, as has been shown, not even childhood is exempt from gout. Gout in its earlier attacks fixes on one joint, extending not beyond; rheumatism, even on its first seizure, most generally involves several. Gout, while simple and incipient, runs a definite course, the local inflammation spontaneously and completely subsiding in a few days; rheumatism has less tendency to spontaneous decline, and, unless arrested by prompt and active treatment, usually continues much longer. The subsidence, however, of local inflammation in rheumatism under active treatment resembles very closely the natural abatement of gout. In gout the constitutional disturbance sensibly abates on the supervention of the local inflammation; this does not appear to be the case in rheumatism, where, on the contrary, the articular inflammation is often attended with increase of fever. In gout the part inflamed is red, tense, shining in a high degree; in rheumatism it is less so in all these respects. Desquamation of the cuticle has been regarded as a criterion of gout; but the cuticle is oftentimes detached in rheumatism much more extensively than ever occurs in gout. We have seen the cuticle so completely separated from the hand and wrist in rheumatism as to admit of being drawn off like a glove. In gout the pain is exquisite, even when the part affected is at perfect rest; in rheumatism it is much more moderate when the part is at rest, though most acute on the slightest motion. Gout is more apt to be preceded by gastric derangement than rheumatism. After all that can be said on the subject of diagnosis, much uncertainty must still attach to many instances, while there are modifications which partake so much of both, that it would be impossible to assign them with certainty to either; and accordingly we find the term rheumatic gout, though not recognised by nosologists, in familiar use among the vulgar, and not scorned even by practitioners. Are we yet prepared to decide to which the very peculiar disease known among medical men as a nodosity of the joints belongs? It is usually classed with rheumatism, yet there are quite as many grounds for allying it to the gout. After all, the distinction is of little real importance, for if the pathology of gout, which we believe to be true, be established, the treatment of the individual case will not be very different to whichever genus of disease it may be assigned.

The prognosis of gout must depend on so many circumstances, that it would be impossible to affirm it positively or with any precision. Simple gout occurring for the first time runs a determinate course, ending generally in health, and cannot therefore be regarded as a disease of much danger; on the contrary, it has, by a strange delusion, been customary to hail its presence as conservative of health and a guarantee for longevity! However the supervention of the paroxysm may occasionally obviate greater evils, we should greatly doubt the desirableness of its occurrence, and must leave it to gouty sufferers to appreciate both the

value of the remedy and the enjoyment of the years so prolonged. In advanced gout the state of constitution, the ravages already sustained, the organs incidentally affected, and even the principles on which the treatment of the particular case is conducted, must be taken into account ere any conception either of the probable duration or event can be formed.

It has been customary to represent gout as incurable, and for ages it has been pronounced the opprobrium of medical science. Ere proceeding to discuss the treatment, it may be worth while to consider how far this reproach has been justly attached. Whether there be or not a cure for gout, is a question of which the answer must depend on the sense in which the term cure is used. It is a common error to contemplate diseases as if each, instead of consisting of an aggregate of functional disturbances, were itself something individual and specific,—some element superadded to the frame producing a specific derangement of health, and capable of being corrected or neutralized by its proper remedy, as a poison by its antidote. Thus the doctrine of specifics has ever prevailed, and it continues to hold its ground even at the present day. It has even been imagined that as mercury is an imputed specific for syphilis, cinchona bark for intermittent fever, there must for every disease exist in nature some peculiar and appropriate remedy which it is the business of physicians to discover. No disease has been more signally subjected to this misconception than gout, and the search for a specific capable of extinguishing it has been often and anxiously renewed. To those who thus judge of diseases and their treatment, it may be confidently replied that there is in medicine no cure for gout, for no remedy capable of realising such expectation ever has been discovered, or ever can be. To such delusion gouty sufferers are peculiarly inclined, for, habituated for the most part to luxurious indulgences, and reluctant to forego them, they lend a willing ear to every vain boast which affects to cure them without a sacrifice of their sensual enjoyments. The consequences of this error have been doubly injurious, not only by diverting attention from that investigation of the disease which could alone explore its real nature and devise its proper treatment, but also, where any remedy of peculiar efficacy was happily discovered, by causing such indiscriminate application as to render it in the end more injurious than serviceable, and at length to destroy the reputation to which it might justly lay claim. But if gout be regarded as it really is, an assemblage of functional derangements, traceable respectively to intelligible causes, and, when rightly understood, admitting of correction by suitable agency, then, though there be a superadded cause in the essential principle of gout, of the precise and intimate nature of which we are still ignorant, the disease may be pronounced curable in the same sense in which we apply the term to other maladies, provided practitioners, instead of vainly seeking for specifics, pursue the course of treatment which true medical science enjoins, and patients be content to follow that regimen by which alone the end can ever be attained. By medicine alone we can do little to obviate the predisposition which leads to gout; but by suitable regimen duly and

inflexibly persevered in, we may render it harmless, so that even in cases of high susceptibility, where, notwithstanding our best care, paroxysms may occasionally recur, these will be slight, and productive of but little evil. But even this liability, if manifested in the earlier periods, should be regarded as owing to some imperfection in the use of preventive means; for if these be fully and judiciously employed, the renewal of paroxysms may, as long as the general constitution is still uninjured, be wholly and effectually prevented.

This assertion, as now expressed, is of course limited to those cases where gout on its first accession is subjected to proper discipline both remedial and prophylactic; for where the predisposition is strengthened by repeated accessions of the disease, and disorganizations have taken place in the joints, or any of the viscera have, through the effects of gout, become depraved, the hopes of complete success must be proportionally weakened. In this sense, then, it may be boldly averred that gout is not an incurable disease. We can cure the paroxysm, and can restore the patient to perfect health, which it is in his own power afterwards to preserve; and if he, in defiance of right counsel, renews the disease by continuing the luxurious and indolent habits which foster it, the reproach should lie, not on medical science, the precepts of which he disregards, but on his own weakness and wilful perseverance in injurious practices. Other diseases as well as gout, nay all, are liable to recur on the predisposing and exciting causes becoming renewed; yet they are not thence considered incurable, nor are they deemed a reproach to medical science merely because medicine alone cannot secure against relapse. There is no reason why relapse of gout should not be equally referred to a renewal of the causes which lead to it, and as the principal of these are obvious and capable both of prevention and correction, the incurableness of gout should not be alleged so long as the means of cure are neglected or inadequately employed, nor should medical science be reproached when its clearest dictates are discredited, and its most urgent remonstrances unheeded and despised.

The most important treatment of gout is the preventive; for if this, however successfully the paroxysm may be relieved, be not assiduously pursued, disease will recur, and acquiring force by repetition, will eventually inflict all its wonted penalties. The principles, too, of the preventive treatment are the same which should govern the practice through all stages and conditions of the disease, modified only by contingent circumstances, but never superseded nor reversed; on which account a full discussion should be given in the first instance to the prophylaxis of gout.

If the views exhibited in the foregoing pages be not wholly fallacious, the establishment of a rational and efficient prophylaxis of gout can be neither difficult nor doubtful. It has been seen that to constitute gout two circumstances must concur,—a predisposition to this form of disease, and a loss of balance in the constitution through excess of nutritive matter, creating what is termed plethora, and arousing the predisposition into active disease. It would be useless to dwell on, or affect accuracy in deciding which of these conditions is the more active, which the more passive,—which

should be called the predisposing cause, which the exciting. The main point to consider is, that their concurrence is essential; for if there be no tendency to gout, plethora may induce any other form of local inflammation or fever, but will not give rise to gout: if there be no plethora, even a strong hereditary disposition may lie dormant, and the elements of gout, of whatever nature they be, will not show themselves by the formation of a paroxysm. Of these causes one is utterly unknown to us, and consequently we are unprovided with any positive or direct means of acting on it; but the other is completely under our control, and however great the tendency to it in any instance, we have ample power when it does arise to remove it by means of depletion and abstinence, and to prevent its recurrence so as with certainty to keep within the bounds of health by temperance and exercise. To these few and simple instruments of prevention may be referred all the procedures required for prophylaxis; all further discussion of which must consist of pointing out the degree in which they may be severally required, and the modifications necessary in applying them so as to attain the end desired without hazarding other evils, to obviate redundancy of nutrition without withholding adequate sustenance; to repress hypersthenic orgasm without inducing asthenic debility; and, in averting an inflammatory disease, not to beget others of an opposite character, but to preserve the constitution in that due exercise of all its functions which perfect health implies and requires.

Though the instances may not be many of gout being eradicated or kept quiescent by means of regimen, inasmuch as gouty subjects have been at all times singularly averse to pursuing such discipline, yet have they been quite sufficient to establish the fact of the capability; and it should be borne in mind that by no other means has the end ever been attained. The late Dr. James Gregory of Edinburgh was a signal instance of the perfect success of the regimen which he ably advocated and strenuously enforced. With a strong hereditary predisposition, gout having existed in his family for generations, and his father having been an early victim of it, he was himself seized with the disease at a very early age; but subduing it by abstemious living, he was disposed to congratulate himself on having obtained exemption. The effects, however, of slight indulgence during a casual visit to Oxford, admonished him that he could take no liberties; and from that period he abided steadily by the regimen which he had laid down for himself, the safety and efficacy of which he had proved, and by adhering to which he was never afterwards visited with gout. This account of himself he used to deliver annually to his class; and when the writer of this article heard him do so in the sessions of 1802 and of 1803, he had reached his fiftieth year without experiencing a return.

In instancing his own case, Dr. Gregory's object was not so much to adduce proof of the efficacy of preventive regimen, as to show that the very spare living and bodily labour which some had inculcated, and which deterred many from attempting to pursue a rational course, were by no means requisite; but that a very moderate degree of both would, if persevered in with steadiness, fully suf-

fice. He was accustomed to appeal, in proof of this, to his own person, the robust form and fresh complexion of which gave ample assurance of its being sufficiently nourished, and to conclude his remarks with saying, "You will allow, gentlemen, that I am no starveling."

The consideration of preventive regimen may be conveniently subdivided under two heads,—the prevention of plethora, and its removal whenever its appropriate phenomena denote its presence. For the first, it would be impossible to lay down any express rule of diet that would be suitable for all habits and constitutions; and to this head all the doctrines advanced in the article PLETHORA apply. Where there is a predisposition to gout, with a tendency to fulness of habit, great care should be taken not to minister to fulness by too much or too nutritive diet. Animal food should be sparingly taken, and fermented liquors should be cautiously avoided. The quantity of food necessary for full health and strength is very moderate, especially where bodily exertion is inconsiderable; and the majority of mankind consume habitually far more than is good for them; whence arises a large portion of their diseases. The doctrine is unpalatable, and the physician who enforces it will hardly be a favourite with the many; but it is not the less sound; and so long as mankind persist in closing their eyes to the truth, they must suffer the consequences of their wilful blindness. When the time arrives, as come it must, that a knowledge of the animal economy shall form a part of liberal education, and each individual shall be capable of comprehending the structure and functions of his own frame, such truths will be more readily acknowledged, and physicians will have fewer obstacles to contend with in the conscientious discharge of their duties. The temperance necessary for lessening the tendency to gout has been often and ably enforced; yet, judging from the ravages daily witnessed, and from the accounts of early treatment and of regimen pursued which such sufferers report, but little progress has yet been made in establishing generally sound principles of management for gouty subjects. Nutrition is still encouraged as a means of supporting strength, wine is enjoined to keep gout from the stomach, and excesses of every kind are committed; while credit is taken for moderation merely because they are not carried to extreme, nor as far as inclination might prompt. Whatever is taken beyond what the wants of nature demand is excess; and numbers are guilty of it who are unconscious of being so. In a healthy frame the natural energies are ever active in appropriating and throwing off the redundancies, and in this way apparent health may be long preserved; but if the excess be continued, disease is sure sooner or later to result, when medical discipline, now indispensable, carries off, by one outlet or other, what the constitution can no longer endure. It is the part of wisdom to avoid this issue by maintaining habitual temperance, the practice of which will ever ensure a rich reward.

Dr. Cullen has judiciously laid down as indications of treatment in gout, to moderate the paroxysm, and to prevent its recurrence. The practice of many gouty sufferers seems exactly the reverse, namely, to hasten the paroxysm and to increase

its violence, under the false impression that a severe attack eliminates and expels from the system more gouty matter than a weak one. The doctrine claims to be founded on fact and experience, yet is it eminently untrue. The fact that the accession of gouty inflammation brings relief to pre-existing constitutional derangement belongs only to the earlier seizures, and does not hold true generally of gout; and the belief of the paroxysm purifying the constitution of gouty matter in proportion to its violence, resulted entirely from a false hypothesis respecting the *materies morbi* of gout, and though supported by the high authority of Sydenham, is utterly untenable. There can be no doubt at the present day, that the indications of Cullen are those which ought to be followed.

Next in importance to regulating the ingesta, is preserving a state of free and adequate excretion. However moderate the diet, if through neglect of exercise or other causes nutritive matter be imperfectly appropriated, and excretions become defective, a loss of balance must result; the blood must become charged with both nutrient and excrementitious matter in excessive proportion, decline of health ensue, febrile excitement become aroused; and in a gouty habit, such progressive depravation will be pretty sure to end either in a paroxysm, or in an abortive effort of the constitution to form one. These are the cases which have involved the subject of gout in so much obscurity, and by their equivocal character have led to the abuse of stimulant treatment. It is obvious that the state of constitution here referred to may be relieved in two ways, apparently opposite; either by exciting the constitutional powers to increased efforts for appropriating and expelling the redundant matter, or by diminishing this so as to keep it within the ordinary powers of nutrient action and excretion. On a fair comparison and just estimate of the relative value of the two modes, there can be little room for hesitation in giving a decided preference to the latter. Far better is it to prevent plethora by temperance in diet, and to promote appropriation and excretion by exercise, than to keep the energies of the frame overstrained by continued use of stimulants. The superiority would be great were we to regard only the general ill effects of continued excitement, which not only exhausts power, but creates a necessity for the stimulus to be progressively increased; it becomes far more so when we take into account the destructive lesions of important organs, to which stimulation of overcharged vessels almost necessarily gives rise. If plethora be obviated by temperance and exercise, or removed by depletion and abstinence, the several organs and functions of the frame are left in their natural and healthy state, in which the natural powers, unaided by stimulants or tonics, are fully capable of preserving them. But when it is attempted to remedy plethoric ills by increasing the energies which nature exerts for their removal, the several functions, even when successful in effecting temporary amendment, become exhausted and debilitated, their ordinary efficiency is impaired, congestions ensue, leading to local inflammation and organic lesions; and a host of maladies severe and untractable are the eventual result. By rational prophylaxis all such conse-

quences may be effectually and certainly prevented, while daily observation too clearly shows how little they gain who combat such ills by stimulants and tonics. So long as temperance is observed, the several functions of health will be so performed as to need little assistance from art. Still, as no casual care may suffice to give full security against casual derangements, attention should be given to the several excretions, the most important of which are those of the bowels and the skin. The bowels should be kept free, and the skin perspirable; mild aperients will serve the former purpose, active exercise the latter.

After temperance in diet, and adequate excretions, the next agency available for obviating plethora by promoting the appropriation and final expulsion of what is taken into the system is exercise, which in the prophylaxis of gout is of the highest importance. However complete and undeviating the temperance which a person threatened with gout, and anxious to avert it, may observe, the aid of active exercise will still be necessary to give the security which he seeks, and which his case admits of. Indolence in him may beget evils directly analogous to those which repletion produces, and, though modified by circumstances, leading to similar results. Whatever the sustenance taken, it requires to be expended in all of its several appropriations; and the effete matter which it continually displaces needs to be discharged from the system by active and adequate excretion. If nutritive appropriation fail in healthful energy in any of the tissues of the frame; if, through defective exertion, the effete matter continually passing through the appropriate outlets be not fully thrown off, both nutritive and excrementitious matter must accumulate in the blood in undue proportion, and induce a condition of the body generative of disease. To promote both purposes, adequate exercise is the natural agent, the use of which cannot be superseded by any medicines however valuable or however lauded. Bloodletting may remove redundant nutritive matter from the circulation; purgatives, diaphoretics, and other evacuants may succeed in rendering the excretions more active and efficient; but no sound mind, judging even by common sense, much less if at all aware of the relative effects of preventive and remedial courses of procedure, can hesitate which to prefer. It is much better not to overfill than to be obliged to empty; it is far more healthful to prevent accumulations of excrementitious matter through active exercise, for which the body is so admirably constituted by nature, than to remove them by any evacuants, however certain in their operation. The two simple terms, then, temperance and exercise, convey whatever is essential in the prophylaxis of gout; and, if rightly understood so as to be strictly practised, they would be amply sufficient for all useful guidance. Further discussion could only regard the degree to which each should be carried so as to ensure its good effects without hazarding contingent evil. To pursue the subject minutely in this place would swell this article beyond its allotted extent. They who comprehend the doctrines advanced, and imbibe their spirit, will be at no loss so to regulate regimen as to produce nothing but good. It may be remarked that extremes in either respect are

quite unnecessary; and the evidence of Dr. Gregory's personal experience has sufficiently shown that gout may be thus effectually prevented without extraordinary macilency, or any privations incompatible with rational enjoyment of life.

But notwithstanding all the care which the most cautious can take, irregularities of diet, interrupted exercise, and other inevitable deviations from the prescribed course, will induce occasional plethora leading to derangement of health. The evidences of this, and the means of abating it, become then the next subject of consideration. When fulness of habit begins to appear, the diet, however moderate, should be still further abridged; animal food should be more sparingly taken, fermented liquors discontinued, the bowels kept more free, and the exercise rendered more effective; and these attentions would be expedient even while the increasing fulness presented no evidences but those of health. Should they suffice, nothing more will be needed. But if plethora advance so as not to be thus removed, if consciousness of health becomes disturbed by morbid feelings, and these be accompanied by a labouring circulation; if, finally, a hot skin, quick pulse, and white tongue, denote the stage of febrile action to have commenced, then, though no local congestion or inflammation should yet have occurred, blood should be taken, purgatives employed, and the whole regimen should be strictly antiphlogistic. It may be deemed that at this incipient stage bloodletting may be dispensed with, and certainly it is not the general practice so to employ it; but this we attribute to practitioners not being sufficiently aware of the real state of constitution, nor of the great advantages derivable from early bleeding. It is true that this stage is not immediately dangerous; that it may be suffered to advance somewhat without much hazard, it being the consecutive derangements rather than the incipient plethora or febrile action which beget danger; that it may even get well, and without ulterior mischief, although bloodletting be not practised. But these admissions will not alter the question either of the real nature and tendencies of plethora, or of the remedies which most safely, promptly, and effectually relieve it. Of these remedies the most direct, and unquestionably the most eligible, is bloodletting. It removes the cause of disease more effectually than any other remedy; it more promptly restores to the several functions the healthful energies of which plethora with its consequences deprives them; it supersedes the protracted use of other evacuants; and by quickly suspending the exhausting effects of continued febrile action, it virtually preserves strength instead of wasting it. For this purpose large or repeated bleedings are never needed. A single venesection to twelve ounces, with purging and low diet, will oftentimes suffice to arrest progressive disease, and re-establish the sanative efficiency of the natural powers. And here, again, early bloodletting saves even blood, if this were an object, (and it is an object that it should never be unnecessarily nor superfluously taken;) for moderate bleeding early employed will avert severity of disease, which, where it does ensue, often demands profuse depletion to save life, and thus consigns to tedious convalescence, if the party be fortunate

enough to escape a more fatal result. It might be beneficially laid down as an axiom, that, abstractedly, bloodletting is the direct remedy of febrile action, its use and modifications being determined by circumstances. In idiopathic fevers produced by miasmata, and attended with prostration of power, its employment may be questionable, and great caution at least is required in applying it; yet when early and judiciously employed, it has proved a powerful agent in arresting the progress and mitigating the symptoms even of typhus, as the records of medicine abundantly prove. In such cases much requires to be taken into account, which the skilful practitioner will not overlook; and especially the character and tendencies of the prevailing epidemic should be allowed their full influence on his judgment. In febrile action of an ordinary character the same caution is not necessary; and here the solicitude should be not to escape bloodletting, but to discover sufficient evidences of a labouring and disturbed circulation to encourage the having recourse to it; for when timely used, the duration of disease is materially shortened, the necessity of medical discipline considerably diminished, while the constitution is spared the ravages which protracted fever, even when ultimately cured, too often entails. With these remarks on the means of preventing plethora in a healthy subject, and of remedying it when it does occur, we may now dismiss the prophylaxis of gout.

From all that has been stated in the foregoing pages of the nature and character of gout, it is obvious that antiphlogistic treatment is that which is essentially required for its cure; and were it not for the complications produced by false theories, improper regimen, and the perverted use of remedies, the establishment of this truth might almost suffice for all practical guidance. When the prophylaxis of gout shall be more clearly understood, and more generally practised, these complications will decline, and simple treatment will alone be needed. But until that happy day shall arrive, it must be necessary to specify the various practice required, so as to mark its adaptation to the several varieties of constitution, stages of disease, and morbid complications, which are sure to present themselves for a long time to come. On the practical instructions which follow we wish to observe, that, however they may seem to flow from the principles laid down, they have not resulted from merely speculative views, but are supported by the best experience of the profession, as handed down by distinguished writers for ages, and are established to our own firm conviction by all that we have ever seen of the disease or its treatment.

A first attack of gout affords, of course, no opportunity for prophylactic treatment. It comes on, if not unannounced, at least unexpectedly, the party being first warned of it by the actual seizure. The treatment of the paroxysm, therefore, in its simplest state, becomes the first subject of practical illustration. There can be no doubt that the more this is treated on general principles, and the less the special nature of the disease is heeded, the more prompt and effectual will be the relief given, and the more perfect the correction of that morbid condition of the system in which the attack has

its origin. If there be a full habit, with active fever, as marked by a full and frequent pulse, hot skin, and white or loaded tongue, then bloodletting, purging, and antiphlogistic treatment, should be employed as freely as if the fever and local inflammation passed under any other name. In mild attacks and where constitutional disturbance is less strongly marked, such active treatment may, perhaps, be waived, and the tendency to spontaneous subsidence already noticed, be trusted to without immediate ill-consequence resulting, especially if, after this admonition, a prophylactic regimen be steadily pursued. Still, however mild the attack, except it take place in a broken constitution, or under circumstances decidedly adverse to direct depletion, we would deem it wise practice to take some blood, so as to render more complete the purposes for which nature institutes the paroxysm. Of this treatment of a first paroxysm we certainly cannot adduce cases; but as in more advanced gout we have bled freely, both on the approach of the paroxysm, at its height, and on its decline, regarding only the state of constitution, and not the special malady, and this not only with perfect safety, but with eminent advantage, we feel fully justified in applying to a first attack of gout the principles which we would not hesitate to follow at later periods, and under circumstances less favourable to their full and beneficial operation. It has been seen that the simple paroxysm runs a definite course, terminating in a few days in renewed health. And if the gouty effort be slight, and the existing plethora inconsiderable, this alleged restoration of health may be so complete as to need no interference from medicine. But if there be much plethora, then the fever aroused may not subside on the gouty crisis having effected its purpose of establishing a local inflammation. The pulse may remain high, the skin hot, the tongue loaded, with the various other depravations usually attendant on a febrile state. Under these circumstances no question can arise on the propriety of effecting by art what nature fails to accomplish. Bleeding, purging, cooling salines, with antimony, and low diet, should all be employed in proportion to the acuteness of the symptoms, and the constitutional energies displayed. But whatever hesitation there might be in interfering with a first paroxysm, on the ground of its not being needed, and of nature being equal to accomplishing her purpose, there can be none, when the disease recurs in a constitution otherwise healthy and vigorous, in resorting to the same constitutional treatment which would be applicable in any other active inflammation. The plethora and inflammatory action are abundantly demonstrated by the attendant symptoms, there being a full, strong, bounding pulse, with hot skin, white tongue, and all the concomitants of active fever. The local inflammation, so far from militating against the employment of active practice, affords additional reason for promptly resorting to it; for if not speedily allayed by suitable depletion, severe pain is unnecessarily prolonged, disorganization is hazarded, and greater debility of parts ensues, with more impeded motion of joints, and more tedious convalescence. On the accession, therefore, of the paroxysm in an otherwise healthy subject, if no earlier opportunity be

afforded, a full bloodletting should be employed, and the bowels should be freely purged with a competent dose of calomel and colocyath, followed by a saline cathartic. If these means succeed in making impression on the system so as to reduce the pulse nearly to the healthy standard, the general fever may be treated by saline antimonials and aperients, like any other febrile excitement. Should the pulse again rise in frequency, force or hardness, with renewed heat of skin and whiteness of tongue, the bleeding and purging would require to be repeated. The only distinction which we know between such an attack and any of the simple phlegmasiæ, regards the topical applications; for so long as the local inflammation is removable by constitutional treatment, topical remedies should not be employed, unless demanded by an urgency of suffering, such as, when constitutional treatment is properly employed, will very rarely occur. The local inflammation has a natural tendency to subside, as has been stated; and it is perfectly justifiable to await this, at least for the usual period, without resorting to topical remedies. When it lingers, the fault lies not in the joint, but in the constitutional state, which keeps up the inflammation, and to this state are remedies best directed.

There is a distinction, both in the febrile state and local inflammation, that deserves to be noticed. Both to a certain extent belong to the paroxysm, constituting it and subsiding with it; but both may continue beyond the time when the paroxysm, running its natural course, would spontaneously subside; and this is dependent, not on the gouty nîsus, but on the constitutional condition. Relieving this condition by depletion and febrifuge regimen will subdue disease in both respects. If the local inflammation, however, have been suffered to establish itself, it may keep its ground even after the plethora and febrile action have been sufficiently abated; and here it is that local treatment may be needed for expediting and completing the relief of the inflamed joints, and averting these structural lesions which protracted inflammation is sure to occasion. To abstract blood locally before the general circulation is sufficiently unloaded, gives no effectual relief; for if the constitutional state be not corrected, the local inflammation, however it may be allayed by topical bleeding or cooling applications, is pretty sure to recur, while some risk is incurred of the inflammation being transferred to some other joint, if not to some vital organ. Leeches, therefore, though their use is sanctioned by high authority, should assuredly not be employed in the ordinary treatment of the paroxysm, nor until the continuance of local inflammation after the removal of the constitutional disturbance manifests that the local disease has acquired an independent existence. In this state leeches and other local remedies may be safely and beneficially applied, but antecedently to it their use is not appropriate. If leeches be unsuited for what may be strictly regarded as the paroxysm, repellent applications are still more so; and though in slight cases they may appear to succeed, their use as a general remedy for gout is eminently hazardous. If the constitutional treatment be conducted as it ought, they will be rarely needed; and far better is it

that the local inflammation should yield to the constitutional correction, than that it should subside under local remedies. In the one case its decline affords evidence that radical relief is obtained, an assurance which must be incomplete when topical treatment is trusted to, however successful it may in any particular instance prove. That the final cause of a gouty paroxysm is the relief of the system, and that it accomplishes this to a certain extent, are truths sufficiently established; and if the relief were complete, the interference of art would be superfluous and improper. But there is strong reason for believing that the paroxysm does not sufficiently relieve the surcharged system; and hence the assistance of art becomes necessary for seconding the operations of nature. But this assistance requires to be directed to the constitutional state rather than to the local ailment. So much is effected by the gouty effort, whatever its intimate nature may be, that it would be unwise to interfere with it otherwise than by removing the necessity which incites it. This may always be safely done by abating plethora and restoring general health; but until this precaution be taken, it cannot be expedient nor always safe to arrest suddenly the local malady by local bloodletting or repellent applications. As subsidiary to the constitutional treatment, there can be no objection, in highly nervous temperaments, and where inordinate sensibility prevails, to soothe by cold or tepid sponging, or by any equally harmless adjuvant; but as was before remarked, if the constitutional treatment be adequately employed, such remedies as these will be little needed. In treating the paroxysm of gout, the indications are to relieve the constitution, and to moderate the local inflammation, so as to prevent the disorganization to which its violence or continuance would give rise. Both are best fulfilled by the constitutional treatment already directed. The converse of this practice, or that which, disregarding the constitutional derangement, directs its efforts to subduing the local inflammation by any means capable of producing such effect, has been at times confidently advised, and was revived with high commendations some years ago, but no treatment can be more hazardous nor more at variance with sound pathology. By promptly relieving the paroxysm through means of constitutional treatment, suffering is abridged, danger averted, convalescence accelerated and rendered more perfect, the recurrence of disease obviated so as to be thoroughly capable of prevention by prophylactic regimen, and at least rendered more distant; and the gouty diathesis, which the long continuance and repetition of paroxysms invariably strengthen, is weakened and suspended. Were incipient gout always treated on these principles, and the premonitory signs which give notice of its recurrence detected in sufficient time to employ the depletion and abstinence necessary for averting the paroxysm; and were prophylactic treatment afterwards pursued to the extent and with the steadiness necessary for ensuring its effects, the victims of reiterated gout would be few, and the disease would soon cease to be the opprobrium medicorum which it has been so long considered.

It must be borne in mind that the foregoing remarks and practical instructions apply to gout as

occurring in its simplest form, and in a constitution otherwise healthy and of unimpaired vigour. When it arises in a habit naturally feeble, vitiated by other diseases, or injured by repeated accessions of gout itself, the treatment, though similar in principle, must yet be greatly modified; and on the accuracy with which the necessary measures of relief are adapted to the existing powers, and suited to the concomitant derangements of function or structure, will the ultimate success depend. The perfect health of each and every function should be the standard by which all deviations should be judged; and the endeavour should be to restore severally, and by the treatment appropriate to each, whatever may appear disordered. Far preferable is this simple and intelligible proceeding to regarding any symptom as characteristic of gout, and applying to it some supposed specific, without reference to the direct operation of the remedy, or the physiological changes which its administration effects. Abiding by such a standard, which has the advantage at least of being real and definite, and ceasing to connect both symptoms and remedial effects immediately with that conjectural and indefinite entity, a nosological disease, practitioners would in all diseases see their way more clearly, and proceed more directly and effectually to their object. Such mode of observing disease, too, would render the misconceptions and discrepancies of practical writers harmless, and enable the practitioner to unravel any complication of symptoms however intricate. As diseases are too much regarded in their complex and individualized character, so is it too much the habit to view the operation of remedies in connection with the more remote curative effects, rather than with their more direct influence on physical functions. The former mode leaves out of view much that requires to be intimately known, and may well be characterized as empirical; the latter alone can lead to just and accurate conceptions of morbid actions and remedial agencies; and in proportion as it takes a lead in guiding the practitioner's treatment, is his practice entitled to be considered rational and scientific.

Some correct views on this subject have lately been presented by Dr. Spillan of Dublin, in a small volume entitled "*A Supplement to the Pharmacopœia*." Even where remedies evince what is deemed a specific operation in the cure of certain diseases, their effects can be very generally resolved into their primary and direct influence on certain functions of the frame, and their curative agency be thus satisfactorily accounted for. This, at least, should be attempted in all cases of alleged specifics, although, however minute and accurate the investigation, something will ever remain undisclosed in the properties of each drug, to give it its peculiar character, and distinguish it from others of the class to which it belongs. Rhubarb, jalap, aloes, colocynth, are all purgatives, and with a view to their purgative effect are they principally employed; yet practitioners discover grounds of choice which lead to selection and preference independently of their relative strength as purgatives. When they are administered, however, it is the purgative operation that is sought for, and through this operation the curative effect is expected. It should be so with all remedies so far as our knowledge of their

direct agency admits. To this agency we should more particularly direct our attention, at the same time that we avail ourselves of every advantage which unexplained properties may afford in combating diseases. A specific for gout has always been considered a desideratum, and mankind have ever been deluded by the vain hope that one would be discovered. Absurd as is the search pursued with this view, it has conferred one advantage at least, by making us familiar with a medicine which, though not entitled to be called a specific, is yet highly valuable, not only in gout but in almost all inflammatory diseases. The medicine to which we allude is colchicum, and from a tolerably extensive employment of it for several years, we can faithfully add our testimony to the several records which attest its virtues and utility. When we were first induced to make trial of it, we took some pains to ascertain by close observation its real powers, and the best mode of administering it; and as our subsequent experience has made no change in the conclusions at which we then arrived, we cannot do better than transcribe here the account which we rendered of it in a small volume published in 1822. "A full dose of this medicine purges copiously, allays pain, and lowers the pulse. These effects are produced with greater certainty if the fulness of circulation be previously reduced by bloodletting, and the mucous secretions of the intestines evacuated. When inflammation is high, as marked by a strong bounding pulse, hot skin, and loaded tongue, bloodletting should always precede the use of colchicum. But in cases where arterial action is more moderate, and direct depletion from any cause questionable, this medicine may be resorted to with peculiar propriety and eminent advantage. Its operation seems to combine the several advantages of bleeding, purging, and sedatives, and is therefore particularly adapted to those cases where active depletion is inexpedient. In treating hereafter of the several modifications of gout, in so many of which venesection must be sparingly employed, or wholly withheld, I shall have occasion to recommend the free employment of this valuable remedy. And as the forms in which this medicine is given, and the modes of administering it are of much importance, I shall fully explain my own practice in both respects, without presuming, however, to limit the application to those methods which I have been led to prefer. Various preparations and different modes of exhibition may, in the hands of other practitioners, be quite as salutary as those which I employ; for as I observed on a former occasion, the effect, not the form, of prescription deserves regard. The preparations which I have tried are the vinous tincture of the root, the vinous and spirituous tinctures of the seeds, and the powdered seeds. Of these I decidedly prefer the tinctures of the seeds, as being more uniform in strength, and more certain in operation. It might be reasonably expected, from the virtues of colchicum being found to reside in the seeds as well as in the root, that the former would yield a medicine of greater uniformity, being in a state of more perfect and determinate maturity, requiring less care in the collection and preservation, and being less liable to have their powers impaired. My experience of the several preparations fully confirms this supposition.

"It has been already remarked that colchicum purges, abates pain, and lowers the pulse. Its sedative powers, though sensibly connected with its evacuant, are not, however, wholly dependent on them. The motions produced are copious, frequent, and watery, and the operation seems more analogous to that of the saline purgatives than of any other cathartic. The number of motions is sometimes considerable, without any proportionate depression of strength ensuing. I have known even twenty stools occasioned by a dose of colchicum, the patient not complaining of the least debility.

"These circumstances will guide our employment of this medicine as a remedy for gout. Where the plethora is considerable, undoubtedly bloodletting should precede its use, for colchicum seems to remove the more fluid parts of the blood only: and these being quickly renewed, the relief obtained by this medicine alone cannot be so perfect or permanent as when bloodletting is also employed. Though the sedative powers of colchicum are valuable assistants to bloodletting in abating arterial action, they are yet no perfect substitute for this remedy in cases of high inflammation: neither are its evacuant qualities capable of superseding those cathartics which expel mucous secretions. In cases, then, of active gout occurring in a full habit, we would invariably bleed, and purge with calomel and antimony before having recourse to colchicum. It is possible that colchicum might occasionally diminish pain and abate inflammation more speedily if administered earlier; but it should never be forgotten that in the treatment of this and all other diseases the important object is not to allay pain or combat symptoms, but to restore general health with the least possible injury to the functions or structure of particular parts. In this respect the physician's province seems analogous to that of the Roman dictators, who were appointed, not to combat an enemy nor quell an insurrection, but to take care that the commonwealth received no injury. In like manner the physician should provide not for the relief of a mere transient or other incidental ailment, but should so conduct the disease to its termination that no permanent injury be inflicted on the constitution. Unhappily, far from being left to the uncontrolled exercise of his judgment in accomplishing this end, he is too often compelled by prejudice and caprice to adapt his practical treatment, not to the real nature of the disease, but to the preconceived notions, impatience, and ignorance of those by whom he is surrounded. When colchicum is to be employed, it may be given either in full doses so as to purge actively, or in divided doses frequently repeated. A drachm, drachm and a half or two drachms, of the tincture of the seeds should be administered at night, and repeated, if necessary, next morning. This quantity will generally purge briskly, but if it fail, a third dose the following night will be pretty sure to succeed; at least I have seldom found it necessary to exceed these doses. The full operation being thus obtained, I usually continue its use in smaller doses, ordering twenty minims three times a day in any of the common saline mixtures. Even this dose will occasionally purge so actively as in a short time to require its discontinuance, in which case the antimonial salines should be given with-

out it, so long as febrile symptoms render necessary."

Such were the views which careful observation of the properties and medicinal effects of colchicum led me to form ten years ago, and it is somewhat in proof of their accuracy that a tolerably extensive use of the remedy in the intervening period has induced no change in them, while it has increased our confidence in the efficacy and utility of the remedy when used as an auxiliary to more active and direct treatment. What might be regarded as its specific powers seem resolvable into those more simple and direct influences which it exerts on the animal frame. It purges, allays pain, and lowers the pulse. These effects are accounted for by assigning to it a cathartic and sedative operation, and it is this combination perhaps to which its peculiar virtues are to be ascribed. The reduction of pulse might appear a result of its purgative operations, but it can, without purging, lower the pulse. That it possesses sedative properties is abundantly shown by its effect in allaying pain, and this where no purging is occasioned; and, so far as we have been able to observe, we should consider the reduction of pulse as produced by its sedative rather than its evacuant properties. We are also disposed to regard the sedative properties as those from which it derives its chief value. These discussions are important, as they assist in reconciling the discordant testimonies which are still offered on the subject, and when finally closed, will establish that discriminating use of the remedy which will ensure its fullest advantages.

It has been alleged, repeatedly and on highly respectable authority, that colchicum does no good unless it purges. This we disbelieve, because our own experience contradicts the fact, and because it is inconsistent with what we have witnessed of the other properties possessed by colchicum. On the principle of a purgative effect being required, several practitioners combine the remedy with purgatives, and with advantages well calculated to confirm the propriety of so doing. This mode we repeatedly tried in our early use of the medicine, but saw no inducement to pursue it. On the contrary, if we had a difficulty in exhibiting colchicum, it arose from its too great readiness to purge, and the consequent necessity of relinquishing it. When we need its availing powers in allaying the inflammation of gout, rheumatism, or any other disease, we are always best pleased when it does not speedily purge. In other words, we look for benefit more to its sedative than its evacuant operation; the latter can be supplied by other and better means; in the former it possesses advantages peculiarly its own. The explanation of these different opinions is not difficult: it must be sought in the views of those who administer the remedy, and the practice which they conjoin with it. If it be used as a specific, and without previous bloodletting, then we can readily understand that unless it purge it will be of little avail; but if the pulse be lowered by adequate bloodletting, and the bowels cleansed by calomel and colocynth, we would then say that a purgative effect from the colchicum itself is not needed, nor at all essential to its beneficial operation. For the active gout of vigorous habits we would not give

colchicum in full doses; or with a view to purge, but we would bleed and purge as in the ordinary treatment of the phlegmasia, and then conjoin colchicum in small doses with the ordinary febrifuge salines. Even when given in this way it will oftentimes purge actively, and, as we consider, to a disadvantage; for when it begins to excite the bowels, it must be at once relinquished, the continued irritation becoming intolerable, and, as we suspect, not very safe, although, having ever been cautious, we have never witnessed an instance of mischief thus occasioned. The views here presented we would wish to be scrutinized, for if correct, they would lead to a use of the remedy more precise and direct than yet obtains, and encourage practitioners to profit by its aid even when no sensible effect is immediately produced by it.

And here we cannot resist offering a remark which appears to merit attention. In former times, the *Materia Medica* was encumbered with a mass of frivolous and inert medicine, and thence rendered so unwieldy that some retrenchment became indispensable. The more worthless were cut off with no sparing hand, and it may be doubted whether some were not thus expunged from the list which might have been beneficially retained. However this be, there sprung from this kind of investigation a scepticism respecting the virtues of all medicines which did not evince a direct and determinate influence on some function or other of the frame. The same feeling carried into practice demanded that each dose of a medicine should produce a sensible effect, and from this tendency it is that we think error has sprung. Although in active and urgent disease, requiring prompt relief, we would employ the full and adequate agency of remedies, yet in a large portion of medical practice, and especially where long-established or habitual morbid actions are to be corrected, we are persuaded that more good results from their more gradual and oftentimes imperceptible operation. When morbid actions have continued for a certain time, and still more where structural changes have commenced, the organs and tissues concerned are not capable of sudden change, nor can they by any activity of treatment be brought back immediately to a healthy condition. As the morbid change is gradual, so also must be the corrective process, whether instituted by nature or promoted by art. In effecting it nature is ever slow and deliberate, and in this respect art would oftentimes do well to follow her example. When it is once ascertained that a medicine does possess active properties, it should not be suspected that these should be evinced by every dose of the remedy administered, nor should it be concluded that the remedy is inert merely from the absence of immediately sensible effect. This consideration would be to us a sufficient reason for placing a certain confidence in small doses of colchicum, even if we looked only to its specific or curative effects. When we regard the simpler properties into which these effects are resolvable, we are still more confirmed in the propriety of not withholding such doses on the mere ground of their not acting on the bowels.

Many remedies are continually administered from confidence in their accustomed properties,

without an immediate or directly sensible effect being expected. Antimony is conjoined with salines to render them more febrifuge, and the effect is expected to result from its primary operation on the stomach: yet the evidence of nausea is not always insisted on, nor is it inferred, from the absence of nausea, that the antimony is useless. When the primary operation of colchicum comes to be better understood, it will be given in imperceptibly operating doses, with as much confidence as is now felt in the exhibition of antimony.

[For the different forms in which colchicum is administered in gout, see the author's *New Remedies*, 4th edit. p. 179; or his *Practice of Medicine*, 2d edit. ii. 607.]

By the treatment prescribed in the foregoing pages the paroxysm of gout may be promptly and effectually relieved, the constitution re-established, the powers of the affected limb preserved, and the gouty disposition diminished. A due attention to prophylaxis may afterwards prevent its ever recurring. The value of such practice is most conspicuously displayed when contrasted with the negative treatment so generally resorted to, by which the paroxysm is greatly prolonged, the constitution very imperfectly relieved, the structure of the joints sooner or later utterly disorganized, and the gouty diathesis confirmed and rendered inveterate. If gout were always of an active character, and confined to constitutions naturally vigorous, it is highly probable that the medical treatment would never have been perverted so egregiously as it has been. But this disorder occurs under every condition of health, and in all degrees of animal power, from the highest vigour to that helpless debility which can scarcely generate a paroxysm. Cases of this latter description will not bear active discipline; if employed, the patient must sink rapidly under it; and the danger arising from such maltreatment has no doubt been often the means of exciting an alarm well calculated to make a deep impression on those who are more peculiarly liable to this disease.

The too frequent error, too, of prescribing for the name of a disease rather than its peculiar condition, may have oftentimes caused extensive injury to result from ill-judged activity of practice, and thus have contributed to bring this method of treating gout into disrepute. Be the causes what they may that have so often occasioned active practice in gout to be resorted to by practitioners and again abandoned, it must be evident that, if this disease in its simplest form and highest intensity is so essentially benefited by the measures here prescribed, a modification of the same practice must, upon every principle of sound reasoning, be applicable to all inferior degrees of the same malady. From this conclusion not even the most timid need take alarm, for as the circumstances of each case sufficiently indicate what evacuations may be safely employed, no rational practitioner can ever be tempted by the doctrines here maintained to carry them beyond the point of safe and salutary endurance. Indeed there are many strong inducements to keep far within it; and provided the principles of treatment be not compromised from vain apprehension or too great pliancy of disposition, we should not be anxious

in a great number of cases for the practice to be carried to the utmost limit of even safe and salutary employment; for as medical aid must necessarily be administered by men of various capacities and acquirements, all of whom may not be equally qualified for adapting accurately, in the details of practice, what principles enjoin, it will be the safer course to fall short somewhat of that activity which would most effectually relieve, rather than run any risk of exceeding it. These prudential considerations will have their full weight with every practitioner however enlightened. The more intelligent and experienced will of course feel more confidence in their own powers of accurate discrimination, and will pursue proper means with greater energy and less hesitation. All, however, must yield occasionally to prejudices long established, and to fears which the sensitiveness of friends cannot always relinquish or control. But the practitioner will give way to such impediments with greater safety to his patients and more satisfaction to his own feelings, by keeping steadily in view the principles here inculcated, and regulating his practice in modified obedience to their clear and forcible dictates.

Before dismissing the consideration of the simple and active paroxysm, a few points more are to be noticed. It has been remarked that in the local inflammation two stages may be occasionally distinguished, one being primary, the product of the paroxysm, running a determinate course and spontaneously subsiding; the other secondary, dependent more on the general inflammatory diathesis than on the gouty nîsus, and tending not to spontaneous decline, but to disorganizations destructive of the mobility of the joints, and leading to eventual decrepitude.

Under the natural course of the paroxysm, and especially when the violence of this is subdued by suitable constitutional treatment, the first or purely gouty inflammation needs no local applications. The secondary requires direct and suitably active treatment for its removal. Leeches, cold or tepid lotions, and eventually blisters, may all be necessary. On this head it may suffice to remark that the safety and efficacy of such local treatment must ever be proportionate to the relief antecedently given to the general constitution. If the constitutional derangement be corrected, the gouty nîsus will not recur; and the secondary inflammation may be subjected to ordinary and appropriate treatment without hazard of metastasis either to other joints or to vital organs.

So soon as decline of inflammation, whether primary or secondary, permits, early return to moderate exercise is of the first importance. It becomes then the best agent in restoring free circulation to the several weakened tissues, in obviating morbid depositions, and promoting the absorption of whatever may have taken place; thus preventing the thickening of ligaments, rigidity, and the contractions so apt to ensue, and enabling the party speedily to enter on the more active exercise which prophylaxis enjoins. And the precept is the more to be relied on, as it applies equally to other articular inflammations from whatever cause they arise, whether rheumatism, accident, or any other. Provided the cavity of the joint be not involved, (and in a large proportion of cases the

inflammation is wholly exterior to it,) protracted rest is injurious, and the source of much mischief. Under it parts become rigid, of which early return to exercise would preserve the flexibility; depositions take place, producing permanent thickening of ligaments, or loading the bursæ of the tendons with glairy mucus, in either case impeding motion. The muscles, too, consigned thus to inactivity, in time waste and become enfeebled, and eventually complete decrepitude with broken health ensues. From what has been said respecting the prophylaxis of gout, it must be evident how sedulously every source of impeded motion should be avoided by gouty patients whose joints have yet escaped disorganization. Such patients have themselves remarked that, when compelled by circumstances to use their limbs early after a paroxysm, they have recovered with less impaired powers than when they have been enabled to indulge in rest. The principle is unquestionable, and no sensibility to slight pain, nor any vague apprehension of renewing the paroxysm, should be suffered to prevent the early renewal of moderate exercise, so necessary for promptly restoring the mobility of the joints, and preserving to the individual the power of still further re-establishing his health through their instrumentality. The attenuated limbs of gouty and rheumatic subjects are more owing to suspended exercise than to any effect of the special maladies. So convinced are we on this point, that we would in our own person infinitely prefer hazarding a renewed paroxysm either of gout or rheumatism, to encountering the manifold evils which protracted rest is sure to occasion.

Only one source of constitutional derangement has been hitherto noticed in this essay as connected with gout, namely, that which arises from excess of nutritive matter in the blood. Another no less important requires now to be discussed, as materially concerned in the several modifications of gout which are yet to be considered. It is the vitiation of blood which arises from the excrementitious matter continually carried back to it by the absorbents, not being adequately excreted and expelled. Health requires that the nutritive matter taken into the system should be duly appropriated to all the structures which compose the body; it also requires that the effete matter, which, having done its duty, is displaced by the nutritive particles deposited, and which in the ordinary course of animal functions is carried back into the blood, should through the admirable agency provided by nature, be from thence regularly and adequately discharged. If nutritive matter be taken in excess, it either increases the bulk of the body beyond the bounds of full activity and vigour, or, producing excitement tending to its own appropriation or removal, but also if too long continued generative of disease, it begets a state of fever or inflammation more or less active. On the contrary, if the excrementitious matter be not adequately expelled, it accumulates in the blood, vitiates its quality, and depraves the nutrient and other secretions, thus impairing, by a slow and insidious process, health and strength, and laying the foundation of a direful class of chronic maladies. Temperance in diet is the only safeguard against the former, but it is a certain one; exercise is also necessary for obviating nutritive plethora, by pro-

moting the healthful appropriation of the nutriment taken, while it is the chief means of keeping in due activity the several excretory processes by which the effete matter of the system is eliminated and expelled. Of excrementitious redundancy only a brief account can be rendered in this place, the fuller discussion being more appropriately given in conjunction with PLETHORA, with which it is so continually intermixed.

As excess of diet gives rise to nutritive plethora, and as deficiency of exercise both contributes to the same end by retarding the appropriation of the nutriment supplied, and promotes further vitiation of the blood by loading it with excrementitious particles, it is obvious that the two states of redundant nutritive matter and accumulated excrementitious particles may co-exist in every conceivable proportion. As each in its simplest state is characterised by its appropriate phenomena, the several combinations admit of being detected by enlightened and diligent scrutiny; and to this end would inquiry be far more profitably directed than to searching after specific agency in drugs for correcting evils which, having their origin in a primary depravation of the source of all nutrition, can never be radically cured but by means corrective and preventive of the primary mischief which occasions them. These pathological views point out the high importance of temperance and exercise as means both of preserving health and correcting disease. So far, at least, as the former purpose is concerned, all theories will concur in this recommendation, which is too firmly founded on common sense to be shaken by any speculation, while the advance of true pathology will maintain the equal importance of bearing the principle in mind in combating diseases.

From not being provided with a better term, we have on former occasions designated the accumulations of excrementitious matter in the blood as excrementitious plethora; and though we like not the name, we must continue to employ it. We do so with less reluctance from the necessity which exists for considering both nutritive and excrementitious plethora in conjunction, their various intermixtures being such that it would be impossible wholly to sever the discussion of them. Some future day, when the pathology of the blood shall receive the attention which is pre-eminently due to it, better terms than either can be readily substituted.

Gout being a disease no less of indolence than of repletion, it is manifest that its subjects are among those whose blood is vitiated by retained excrementitious matter as well as by redundancy of nutriment; and this consideration explains why mere abstinence, unassisted by active exercise, can never be expected to eradicate gout. Though the diet be temperate, yet indolence begetting general languor of frame, and this languor being confirmed and perpetuated by the effects of excessive excrementitious matter, causes a languid and imperfect appropriation of whatever sustenance is taken; a degree of nutritive plethora thus relatively ensues, and the elements of acute disease are thus supplied. To distinguish both states and their multiplied combinations, it becomes necessary to display their separate conditions, and by contrasting them

with each other, to furnish indications by which the prevalence of either, or the intermixture of both, may at any time be detected.

The phenomena of nutritive plethora, its increase, and final transition into a febrile state, have already been sufficiently described. Excrementitious redundancy in the blood begets a very different condition, but one no less marked by its appropriate indications. These are a sallow aspect and dusky skin, the pulse low, soft, and easily compressible, the surface of the body for the most part harsh, dry, and obviously deficient in natural transpiration, the tongue moist, clean, red; the appetite capricious, often craving, with an endless train of dyspeptic ailments; the alvine discharges inveterately foul, dark, slimy, pitch-like, and exhibiting no traces of healthy fæces; the urine high-coloured, often fetid, and depositing more or less of sediment: these several evidences, or a certain portion of them, with decline of flesh and strength, are sufficiently characteristic of this state. The condition itself we believe to arise from imperfect elimination of excrementitious matter; and the depraved state of the several excretions we regard as resulting from the laboured though inadequate efforts of the constitution to accomplish its own purification. How much this state is combined with the more advanced and complicated conditions of gout will be readily perceived; and it is by bearing in mind this source of vitiation, as well as that furnished by nutritive plethora, that the treatment will be most judiciously and successfully conducted. The direct effect of excrementitious plethora is unhealthiness of nutrient secretion, producing feebleness of the organs thus imperfectly nourished, and progressive decline of strength. The efforts of the constitution to throw off this oppressive load fail of success, and their ineffectual renewal, as well as the progressive unhealthiness of nutrient secretion, cause still greater feebleness, and eventually attenuate the frame.

According as more or less of nutritive plethora becomes combined with this state, the constitutional efforts are greater, and various degrees of febrile and inflammatory excitement ensue. In proportion as this excitement is energetic, and as suitable means are employed to relieve it, is the vitiated state of the blood corrected, secretions and excretions are improved, and general health and strength are renewed. Increased secretion from the bowels seems the principal discharge by which nature in general aims at getting rid of such impurities, and to promote them by suitable purgatives is clearly indicated, care being taken at the same time to support strength by light yet nutritive diet. When relief to a certain extent is thus afforded, the powers of the constitution rally, and a febrile effort is made to assist in the work of purification. As this advances, depletion requires to be more active, and the diet less stimulating. When sufficient excitement is aroused to warrant the employment of bloodletting, we may then consider the curative process in the most favourable train. Perhaps the powers of the constitution are hardly adequate to rectify any high degree of this peculiar derangement, without the agency which febrile excitement supplies; and hence we see experienced practitioners often hail the ap-

pearance of febrile symptoms in chronic complaints, as announcing a more remediable form of disease.

These remarks on excrementitious plethora, though cursory and imperfect, will suffice to prepare the way for the remaining discussion of gout. To pursue this methodically through all the alleged varieties would be both tedious and valueless. If the principles be clearly laid down, there can be little difficulty in applying them to whatever variety or complication of the disease may present itself.

On a first accession of gout it should be the inflexible determination of the party assailed never to subject himself to a return. That this is practicable is abundantly proved; and if the means so clearly pointed out be not employed, blame should not be imputed either to the inveteracy of the malady or the imperfection of medical science. Nature has endued all matter with determinate properties, and living beings are subjected to certain organic laws, by obedience to which health and physical welfare are maintained, while a violation inevitably begets disease. They who will neither learn those laws, nor abide by them when proclaimed, must suffer the penalties of their own ignorance and perverseness.

When successive attacks of gout have taken place, the hope of effecting complete exemption must be sensibly weakened. Still, if there be no disorganization, the end may yet be attained, and at all events the attempt to accomplish it will be amply repaid; for should attacks recur they will be slight, at long intervals, easily subdued, and will commit no ravages, but leave the general health and even the gouty limbs tolerably sound.

Disorganizations of course enhance greatly all the difficulties. They evince a more confirmed gouty diathesis; the local weakness encourages renewed seizures from slight causes; and the impediment to active exercise cuts off one of the most efficient prophylactic agents. In this state of gout, then, too much should not be attempted, either by bloodletting or abstinence. Active symptoms should be met with such certainty of practice as the accompanying state of constitution may warrant. Fever should be allayed, local inflammation abated, and general health restored as speedily as possible; but all due regard should be given to the degree of constitutional power existing.

In the wretched cases of extreme disorganization, broken health, and exhausted power, no one would think of employing any but palliative treatment; but even this will be beneficial in proportion as it is guided by the principles maintained throughout this essay. So long as there is encouragement to employ bloodletting as part of the treatment, will benefit result from resorting to it. In cases in which the danger to be apprehended from its use is greater in degree than the expectation of benefit, other means must be substituted; and here colchicum is of inestimable value, supplying the place of more active and efficient treatment better than any other drug with which we are acquainted.

As a healthy state of each function is the standard with which the several derangements should be compared, and which it should be the

endeavour to restore, care should be taken to ascertain by direct evidences that each is actually restored to the efficient exercise of its powers. The pulse, skin, and tongue, will demonstrate with sufficient accuracy whether fever is subdued, and will thus afford evidence of the circulation being, for the time at least, restored to its healthy balance. To maintain this ground, however, assiduous care should be devoted to the several excretories, all of which should perform adequately their several functions. The skin, bowels, and kidneys should be active, and their respective efficiency should be attested both by the quantity and quality of their several excretions. Each of these should receive more continued attention than is usually given to them, for if duly noticed, they would announce the advance of disease long ere depraved sensation or other prominent derangement indicate its approach, and would thus lead to a more timely and effective use of suitable correctives.

A closer attention to them, also, during convalescence, would contribute much to render recovery more perfect, and lessen the liability to renewed attack.

The skin should be active, for it is an outlet for the discharge of excrementitious matter of the highest importance. The most effectual and salutary means of keeping it so is active exercise. Warm bathing is a valuable assistant, and eminently so when but little exercise can be taken. The condition of the skin itself should be regarded. In many, large portions of its surface are hard, dry, scaly, and utterly impermeable. These should be restored by warm bathing, by such applications as soften the cuticle, and by frictions both with the hand and the flesh brush. The thorough desquamation of cuticle effected by the process of the Russian vapour-bath, would be a valuable means of restoring many an imperspirable skin to the full exercise of its functions. A freely perspirable skin is powerful in obviating plethora both nutritive and excrementitious.

The bowels should perform effectually the duty which nature assigns them, and in this respect attention is much needed, for considerable depravation is continually suffered to go on unchecked and unheeded. The amount and frequency of stools are too much trusted to as evidences of healthy bowels, while the only one to be relied on is the character of the matter discharged. When this, however sufficient in quantity or regular in discharge, is dark, foul, and charged with mucus, evacuant or alterative medicine is needed, however free the party may be from every other symptom of disease. By this neglect much disease creeps in, and many a constitution is undermined where timely and judicious attention to the bowels would avert all the mischief.

In like manner the urine merits attention, and more especially from the tendency which there is in gout to throw off morbid matter by this outlet. Much profitless scrutiny has been devoted to the different impregnations, the specific gravity, and other properties of gouty urine. The main fact respecting it is that it contains what ought not to find its way into it, and the most effectual way of purifying it is to cut off the morbid supplies by regulating the diet and restoring due activity to

the other excretories, for it is their deficiency which throws upon the kidneys so much extraordinary labour. Light diet, a free skin, and active bowels will clear the urine with little aid from chemical correctives. These are, no doubt, proper as adjuvants, where high degrees of acescency or of alkalescence prevail; but they are utterly inadequate for perfect corrections, and their use at best, if alone trusted to, is uncertain and short-lived. We have no evidence that when taken by the mouth they ever reach the bladder so as to act on the concretions deposited there. This truth the history of calculous complaints establishes. From the same source we learn that when acid calculi cease to be deposited in consequence of the free use of alkalis, if these be continued, alkaline depositions take place, and thus the evil is changed, not removed. Both in calculus and gout our belief is that more may be done in correcting the morbid state of urine, by re-establishing a healthy balance in the constituents of the blood, avoiding all excess of diet or stimulants, and keeping up an active state both of cuticular and intestinal excretion, than can ever be effected by neutralizing remedies. These should not be withheld, but from the circumstance before mentioned caution is required in their use, and at all events they should not, however efficient they may casually appear, be suffered to supersede the far more effectual relief which rectifying the fundamental errors of the constitution is capable of affording.

Little more is needed to complete the discussion of gout, the principles maintained in the foregoing pages being applicable to all the forms in which the disease can present itself. It has been already stated that these complex conditions and alleged varieties are referable, not intrinsically to gout, but to the state of constitution in which it occurs; and to the constitutional derangements should the treatment be directed, without bias from the imputed cause. The varieties, when scrutinized, will be found to consist of gouty tendencies combined with visceral affections and with more or less of debility; and in treating them the object should be to restore general health, and thus reduce whatever gout there may be to its simple and intelligible state, rather than aim at improving health by any specifics supposed to act directly on gout. The latter mode has been tried sufficiently long and by sufficient variety of means to prove its utter inefficiency, and deprive it of all confidence. The history of specifics and their effects would furnish a lamentable display of error and its consequences. The Portland powder appeared to cure, but the result of Dr. Cullen's inquiries was that not one of those who were so cured survived three years. Some died suddenly, while others were attacked with apoplexy, palsy, asthma, hydrothorax, general dropsy, or general cachexia. In this conclusion both Dr. John Gregory and Dr. James Gregory were led by their investigations to concur. The ravages occasioned by the *eau medicinale* are of too recent date to need more than a casual mention.

According as the general health is broken, and the power of bearing active treatment weak, must gouty patients abate in their expectations of cure, and be content to mitigate their sufferings by such means as sound principles sanction; and by ad-

hering to these much may be done even in extreme cases. In all may fever be allayed, plethora prevented, the bowels kept free, the skin perspirable, and contingent derangements receive their appropriate correction.

In proportion as the natural vigour is slight, or reduced by excrementitious plethora, must depletory treatment be cautiously applied to recurring paroxysms; for no promptitude of relief could justify the hazard incurred by even an approach to excessive evacuation. While we contend for the inflammatory nature of gout, and the decided propriety of combating the active disease with proportionally active treatment, we are far from inculcating a rash or indiscriminate use of the lancet, but on the contrary would employ it with great caution, and only under those circumstances in which repeated experience had established both its safety and utility. With a full hard pulse, hot skin, and furred tongue, we would bleed, purge, and give colchicum without hesitation. Even where inflammation was less strongly marked we would employ the same means, provided the evidences of plethora and of febrile excitement were sufficiently discernible; and this treatment has in our own practice had perfect success in abridging the paroxysm, accelerating convalescence, restoring speedily the affected limbs, and greatly prolonging the period of exemption, even in cases of long continuance, where the duration, succession, and severity of paroxysms had induced such helplessness and decrepitude as confined the parties to the couch for two-thirds of the year. The vigour of constitution being the standard by which depletion should be regulated, it follows that when such vigour is deficient, measures of the same activity should not be pursued as are necessary when the habit is robust. In extreme cases, where natural languor and feebleness are confirmed and increased by the effects of excrementitious plethora, when muscular debility is great, the pulse low, soft, faltering, the tongue moist, clean, of a bright red colour, or scarcely whitened, the bowels inveterately foul, the gouty effort feeble and imperfect, —in such cases wine, stimulants, and invigorating regimen must supersede every evacuation save purging. The object in such cases should be to renovate the frame by improving the bowels and giving tone to the whole system. Should the gouty effort, in consequence of such regimen, become more vigorous, and marked by clear evidences of renovated powers, then may an approach be made to the more effective treatment by which gout is so signally relieved.

With respect to the nosological varieties, they may be dismissed with very few observations. Cullen has recognised them; namely, the atonic, retrocedent, and misplaced. The atonic is marked by general debility, feeble attempts to generate a paroxysm, and visceral derangements, chiefly gastric. Light food, regulation of bowels, and the several means suited for improving the stomach and giving tone to the general system, should be the means here resorted to. Light tonic medicines may be combined, but they are of little avail, and they should neither be given largely nor too long continued. The condition of the stomach is here analogous to what obtains in gastrodynia, to which head we may refer for the treatment which

this derangement requires. What is generally called gout in the stomach is but a high degree of this affection; and when the spasm is intense, with prostration of strength, the strongest stimulants, such as brandy, ether, and laudanum, may be necessary to allay it. Immediately after, however, the stomach should be effectually cleansed of its mucous accumulations by full doses of calomel, antimony, and colocynth; and light cordials with aperients should follow rather than direct stimulants or tonics. When there is great debility of stomach, chalybeates may be required, and they are best administered in the form of some natural or artificial mineral water. It is in such cases that the internal use of the Bath waters is so eminently serviceable, although they are valuable in most gouty cases, especially where the stomach requires some substitute for the wine and stimulants relinquished. In such cases the grateful stimulus of the Bath waters gives tone to the stomach, improves appetite, and renovates strength, thus accomplishing an unequivocal good; not, as has been falsely imagined, by the mere establishment of gout in the extremities, but by the reduction of gout to its simpler and more manageable state through the amendment effected in the general health. This advantage is great, provided it be rightly understood. If the mere gouty accession be the object desired, and that on its appearance the end is considered as attained, then indeed the benefit is but slight and transitory, while the false experience thence derived serves but to confirm error and perpetuate evil. But if the accession, when thus elicited by means of renovated powers, be regarded as it ought, and properly treated, the opportunity thus afforded for resorting to efficient measures is most valuable, and the Bath waters, so instrumental in procuring it, should receive the credit to which they are so justly entitled. It is curious to observe the fluctuations which take place in public opinion respecting the value of mineral springs. They become fashionable and again decline, not from any variability in their properties or medicinal effects, but from the misconceptions and caprices to which ignorance is prone. It is lamentable to think how great is the ignorance of the public in all that relates to the structure and functions of their own frames, and how very inconsiderable a portion the science of animal life forms even of that course of instruction which our highest seminaries supply. Formerly Bath was the general resort of gouty patients in all stages and degrees of the disease. The object was not to cure gout, but to excite and hasten it; and as this effect was often produced, their reputation became established. In time it was discovered that in full habits and inflammatory states of constitution their agency was not always limited to bringing on gout, but that other excitements less harmless were apt to ensue. The local practitioners were therefore constantly obliged, in the conscientious discharge of their duties, to withhold the internal use of the waters, however they might allow their external application; and patients who were sent to Bath expressly to drink the waters were naturally disappointed. It came to be doubted, also, whether bringing on the paroxysm was to be considered an unmixed good; and this approximation to just views gave rise to

further hesitation respecting the expediency of using the Bath waters. The consequence is that though vast numbers still resort to Bath for gouty complaints, the waters are not held in that high estimation in which they were wont to be regarded. Yet they still retain all the virtues which they ever possessed; are still capable of rendering most valuable services to gouty constitutions, nay, of effecting, in the improvement of stomach and renovation of strength, what no course of medicine, nor any other mineral spring in these countries, could equally accomplish; and there is no reason, save the capricious fluctuations of opinions, why they should not still maintain the high character which they formerly possessed. The objects in administering them may be different, but the effect of this must be to render them only the more serviceable.

Gout has been called retrocedent when the sudden subsidence of the gouty inflammation has been followed by sudden affection of some internal organ or function. Such affection is no doubt liable to occur whenever the local inflammation is repelled without the constitution being adequately relieved. Where it happens, it requires to be treated precisely as if gout were not concerned. If the substituted malady be marked by spasm and sinking powers, cordials and stimulants must be used; if by inflammation, then must bleeding and purging be employed to the full extent which the urgency of symptoms may demand.

The term misplaced gout seems to have been employed without any sufficient reason. It has been applied to any and every incidental disease occurring in a gouty habit. For the most part such disease has been inflammatory; and when it has attacked the stomach, lungs, or brain, practitioners, impelled by the urgent danger, have not hesitated to bleed freely, however repugnant to such practice their ordinary views of gout might be. It would be difficult to reconcile this practice with the extreme timidity which shrinks from the employment of bloodletting when the inflammation of active gout is situated in the extremities.

GUTTA ROSEA, or ROSACEA.—See ACNE.

HÆMATEMESIS.—This term (derived from *αἷμα* and *ἐκτείνω*) literally imports vomiting of blood, and is therefore properly employed to signify hemorrhage from the stomach. Some nosologists, as Pinel and Mason Good, comprise under this denomination every hemorrhage from the alimentary canal, whether the blood is discharged by the mouth or by the rectum. It is, however, more conformable to etymology and to general usage to restrict the name of hæmatemesis to *gastric* hemorrhage, and to denote *intestinal* hemorrhage by the name of *MELÆNA*, which will, therefore, be the subject of a separate article. There is, however, much affinity between these two species of hemorrhage: and the two articles will therefore be in some measure mutually supplementary.

Hæmatemesis is frequently mentioned by Hippocrates. It is clearly described by Aretæus, and distinguished by him from pulmonary hemorrhage

Among the moderns, Stahl, Hoffmann, Morgagni, Tissot, Portal, and subsequent writers, have contributed to its elucidation. Little has been written on the subject by British physicians. Cullen has not even included this disease in his nosological arrangement, on the ground of its being almost universally a symptomatic affection; he has, however, treated of it at some length in his "First Lines," chiefly with reference to the diagnosis and pathology.

Predisposing Causes.—Women are much more subject than men to hæmatemesis, and are chiefly liable to it during the menstruating period of their lives. Those of a delicate frame, of quick nervous sensibility, or subject to strong emotions, are most prone to this disease; but the sanguine, ruddy, and plethoric are also liable to it as a consequence of defective menstruation. In some females it occurs during pregnancy. Men are seldom attacked by hæmatemesis at an earlier age than thirty or thirty-five, and very rarely after fifty. It is in them almost invariably induced by habits of life unfavourable to health, especially by close and anxious application to business, combined with indulgence in the pleasures of the table, and neglect of bodily exercise. Organic disease of the stomach, liver, or spleen, and probably also of the pancreas, will constitute a predisposition to hæmatemesis; and organic affections of the heart, especially valvular disease and dilatation, by retarding the return of the blood, and hence inducing general venous congestion, are a frequent predisposing cause of this as well as of other hemorrhages. When hæmatemesis has once occurred in an individual, from whatever cause, a predisposition is induced to its recurrence, either spontaneously, or on exposure to some exciting cause which would not in other circumstances have given rise to it.

Exciting Causes.—These may be divided into local and constitutional. The *local* causes are such as produce irritation or sanguineous congestion in the mucous membrane of the stomach, and consequent exhalation of blood; or more rarely a physical lesion of the inner surface of that organ, attended with rupture or erosion of a blood-vessel. Sauvages, Frank, and other authors, enumerate a variety of exciting causes of hæmatemesis, which are confessedly of very rare occurrence, such as the rupture of an aneurism of the aorta, or of some one of its branches, into the cavity of the stomach; the bite of a leech accidentally swallowed; wounds or irritation of the stomach from swallowing a bone, needles, broken glass, &c.; larvæ of insects introduced into the stomach, or generated there; the transmission of an electric shock through the region of the stomach. (Sauvages, Nosol. Method. Frank, de Curand. Homin. Morbis, lib. v. part ii. p. 204. Edin. Med. Jour. vol. vii. p. 326. Percival's Essays, vol. ii. p. 183.) Corrosive poisons are well known to induce vomiting of blood. Other acrid substances will probably have the same effect; and thus drastic purgatives and emetics are included in Frank's list of causes, but perhaps only from theoretical considerations. The effort of vomiting, and other violent strains and exertions, as the expulsive efforts in parturition, (Frank,) are supposed to have produced hæmatemesis. It is also

a well-known effect of severe blows on the epigastric region.

The *constitutional* causes are those which, by some effect, not always easy of explanation, on the sanguiferous system, produce congestion in the vessels of the mucous membrane of the stomach, or a tendency in the blood to escape from them. Violent, and especially *strongly concentrated* mental emotions, as grief, anger, or terror, are undoubtedly exciting causes of hæmatemesis, though probably only in the predisposed. In some malignant fevers, in scurvy, and in purpura, hæmatemesis occurs as a symptom, evidently from a constitutional cause. But the most frequent instance of such a cause operating in the induction of hæmatemesis, is, where it results from the suppression of some natural or habitual evacuation, especially of the catamenia in females, and of the hemorrhoidal discharge in either sex. The connection of hæmatemesis with amenorrhœa has been remarked ever since the time of Hippocrates; and there appears to be no just ground for the denial of this connection by Dr. Hamilton, in his work on Purgative Medicines. Hæmatemesis very commonly supervenes on a *suppression*, from whatever cause, of menstruation already established, and which had hitherto observed its regular periods. In other cases it is related to have attended upon *retention* of the menses, (Frank, op. cit. p. 206,) but such instances are comparatively rare. (See AMENORRHEA.)

Symptoms.—The attack of hæmatemesis is sometimes unattended by any premonitory signs, the vomiting of blood being the first morbid symptom which occurs. But more frequently it is preceded by symptoms similar to those which precede ordinary vomiting: anxiety, faintness, a sense of weight and distension, sometimes amounting to dull pain in the epigastric region; and distressing nausea. The pulse is frequent, but commonly small and weak; and on inquiry it will be found that the bowels are costive. Sometimes there is general chilliness, with particular coldness of the extremities, vertigo, impaired vision, and ringing in the ears; but several of these symptoms ought, perhaps, rather to be considered as indications that internal hemorrhage has actually taken place, than as precursory signs of its occurrence; for rejection of the effused blood by vomiting does not ensue, until either by its quantity or stimulus it excites the stomach and abdominal muscles to contraction. (Chomel, Dictionnaire de Médecine, tom. x. p. 555.) The blood is then brought up with considerable violence in successive fluid gushes, or partly in solid coagula. Sometimes a single large coagulum is brought up, in fact a mould of the stomach. The quantity rejected by vomiting is always considerable, being seldom less than eight or ten ounces, and sometimes amounting to several pounds. It is highly probable that hemorrhage from the stomach may take place in smaller quantity; but then the blood passes off by the pylorus without giving rise to vomiting. The blood is of various shades of colour, from a deep red to nearly black, according to the shorter or longer time that it has sojourned in the stomach, and probably from other causes. It is not to be supposed that when the blood is dark-coloured, it is necessarily the result of *venous*

hemorrhage. This was pointed out by Aretæus; and it is well known that the fluid, and especially the gaseous contents of the stomach and intestines, will impart a dark colour to blood which remains for any time mixed with them. When there has been a sufficient delay for separation of the constituent parts of the blood to take place in the stomach, membranaceous or polypus-like concretions of fibrin are occasionally brought up along with the blood. (Frank, op. cit. p. 202. Dict. de Méd. loc. cit.) It is often mixed, as might be expected, with alimentary matters, with bile, or with the mucous secretions of the stomach. Most commonly blood is vomited only once in the course of a single accession of hemorrhage; but sometimes a repetition of the vomiting occurs after a short suspension. After the vomiting has subsided, the accompanying symptoms commonly cease, leaving the patient in an exhausted state, with a cold surface, pale countenance, and generally considerable mental agitation and alarm, especially in a first attack. Actual syncope, as Frank has noticed, not unfrequently ensues.—Part of the effused blood usually passes the pylorus, and after a few hours produces slight tormina and distension in the course of the intestines, followed by two or three dark-coloured and offensive stools, resembling those in melæna. This appearance of the alvine discharge will continue for twenty-four or sometimes forty-eight hours.

Death has very rarely directly ensued from the loss of blood in an attack of hæmatemesis; but the repeated attacks of this hemorrhage have necessarily a tendency to weaken the constitution, particularly when it is not of a vicarious character. Sometimes after a single attack there will be no recurrence of hemorrhage; but more commonly, as we have already observed, a predisposition to its return is induced, and it will after some interval reappear either spontaneously, or on the application of some exciting cause; or it will assume a periodical or chronic form, according to the nature of the local, constitutional, or organic cause by which it is kept up.

From the above account of the causes and symptoms of hæmatemesis, it will appear that it has generally the character of a *passive* hemorrhage. Sometimes, however, it occurs in individuals of vigorous constitution, is attended with symptoms indicative of increased impetus of the circulation, and puts on the type of *active* hemorrhage. This distinction is not always very clearly marked, but it is highly deserving of attention, with a view to the treatment.

Hæmatemesis has also been divided into *idiopathic* and *symptomatic*; but these epithets have been used by different writers in widely different senses. The most important practical distinction is that derived from the several predisposing and exciting causes, and states of the constitution which give rise to the hemorrhage. These it is always highly important to ascertain.

Pathology.—As the general doctrine of hemorrhagic diseases will be developed in another place, (see HEMORRHAGE,) we shall confine our present inquiry to those circumstances which are peculiar to this individual disease.

Hæmatemesis, when unconnected with organic lesions, so very rarely proves fatal, that anatomi-

cal investigation has thrown but little light on the state of the stomach and its mucous membrane in this disease. Frequently no morbid appearance whatever can be detected in patients who have died very shortly after profuse hæmatemesis. In other cases, *redness* of the mucous membrane could alone be discovered; but this may be the effect of simple infiltration of blood, while in other cases it may denote a congestive, or even an inflammatory state of the mucous membrane, which has caused the hæmatemesis. In some of the dissections recorded by Morgagni and Portal, the stomach and other viscera, after profuse hæmatemesis, were found remarkably pale. Some observers have recorded a dilatation of the venous and arterial branches supplying the stomach as a common appearance after death from hæmatemesis, and the veins ramified on the internal surface of that organ have been even described as in a varicose state; but these allegations are destitute of adequate proof.

In those cases of hæmatemesis which are connected with organic affections, whether of the circulating system or of the abdominal viscera, the appearances proper to these diseases will of course be met with after death. Where the hæmatemesis has arisen from organic disease of the stomach itself, it has commonly been supposed that it was the consequence of ulceration, producing the rupture or erosion of one or more blood-vessels. Such cases, no doubt, are occasionally met with; but it is no less certain that scirrhus of the pylorus often proceeds to extensive ulceration without the occurrence of any hæmatemesis; and on the other hand, as Andral from ample experience assures us, that scirrhus affections of the stomach are attended with repeated hæmatemesis during their progress, where, on dissection, no ulceration nor lesion of continuity in the mucous membrane or its vessels is observable. (Andral, Pathol. Anat. transl. vol. ii. p. 179.)

Hæmatemesis is, then, an instance of *exhalation* of blood from a mucous surface, analogous to what happens in epistaxis and hæmaturia, in uterine, and many cases of pulmonary and bronchial hemorrhage. The causes which occasion this exhalation are referred by Andral to four heads:—1, a mechanical obstacle to the return of the venous blood through the system of the vena portæ;—2, irritation of the mucous membrane of the stomach;—3, sanguineous congestion, not referrible to either of the former heads;—and, 4, certain states of the blood itself, in which it is so changed as to have a universal tendency to escape from its vessels. (Pathol. Anat. transl. vol. ii. p. 179.)

Mechanical congestion is instanced (1.) in those cases of hæmatemesis which depend on enlargement or induration of the *liver*, and sometimes also of the *spleen* or *pancreas*, in consequence of which the trunk or branches of the vena portæ are more or less directly compressed, and the return of the blood from the stomach impeded; hence congestion in its vessels and hæmatemesis ensue. (2.) In cases depending on obstructed circulation from organic disease of the *heart*, and more especially from morbid alterations in its valves, or dilatation of its cavities, in consequence of which the return of blood by the vena cava is

impeded, and general venous plethora is induced. (Ibid. vol. i. p. 64.) Such a state is now well ascertained to be a frequent cause of hemorrhage, especially from the lungs, the stomach, and the uterus; and its existence is a circumstance deserving the most careful attention of the scientific practitioner.

Irritation of the mucous membrane is the direct cause of the hæmatemesis arising from corrosive poisons and other acrid substances.

To *simple congestion* we must, in the present state of our knowledge, refer all those cases of hæmatemesis which are considered as *idiopathic*, including those which are *vicarious*, or *auxiliary* of suppressed or diminished menstruation, &c. "The blood," says Andral, "accumulates in some part of the mucous membrane, and escapes from its vessels, which is all that we can discover."

The subject of *morbid changes of the blood*, will be discussed in other parts of this work. (See BLOOD, PURPURA, SCURVY.) Andral instances, as cases where hæmatemesis results from this cause, "certain cases of poisoning by absorption," typhous fevers, and the black vomit in yellow fever.

Diagnosis.—Hæmatemesis is in general easy to be recognised by the symptoms already enumerated. It is occasionally liable to be confounded with hæmoptysis. "It may be certainly known," says Cullen, "that the blood proceeds from the stomach, and not from the lungs, when it is manifestly brought up by vomiting, and not by coughing; when the vomiting has been preceded by some sense of weight, anxiety, and pain in the region of the stomach; when the blood brought up is of a dark and grumous appearance; and when it is manifestly mixed with the contents of the stomach." (First lines, § 1017.)

When, also, cough and the other local and constitutional symptoms of pulmonary hemorrhage are absent, we may in general safely conclude the case to be hæmatemesis. There are, however, several circumstances which may tend to perplex the diagnosis. Cough and vomiting will materially excite each other, and when they jointly occur, it may not be easy to decide which is the primary symptom and by means of which of them the blood is brought up. In very profuse hæmoptysis the muscles of the thorax will sometimes contract convulsively, so as to send forth the blood in successive gushes, closely resembling what takes place in true vomiting of blood; or the blood brought up by coughing may tickle the fauces, and excite actual vomiting. On the other hand, blood brought up by vomiting may be driven back into the glottis, and excite violent cough. We must also recollect, in order to guard against all error in diagnosis, that the blood, though actually vomited up from the stomach, may be originally derived from a different quarter, as in the case of aneurism already adverted to, or where blood proceeding from the fauces or posterior nostrils has been swallowed during sleep, or is transmitted from a vomica in the lung by a fistulous canal into the œsophagus, as in a remarkable case related by Dr. Mackintosh. (Practice of Physic, vol. i. p. 186.)

Hemorrhage from the stomach, as has been already mentioned, does not necessarily imply the rejection of the blood by vomiting; for in the first place the quantity of blood exhaled into the cavity

of the stomach may be so inconsiderable as not to excite vomiting, and pass off by the intestines; and, secondly, in very debilitated states of the constitution, the relative loss of blood may be such as instantly to destroy life, before any vomiting has taken place. This chiefly occurs in cases of ulceration of the stomach, which organ is found after death distended by an enormous coagulum. Such cases are not of very rare occurrence.

The diagnosis of hæmatemesis is not complete for practical purposes until we have endeavoured to ascertain to what specific cause the hemorrhage is to be ascribed, and whether it be idiopathic or symptomatic, connected with organic lesion or simply with deranged function, and whether it partakes of the character of *passive* or *active* hemorrhage. Attention is therefore required to what has been pointed out on these several heads.

Prognosis.—Hæmatemesis is always a disease of formidable and alarming appearance, from the quantity of blood which is lost, and the delicacy and importance of the organ concerned. Experience, however, instructs us that in many cases it is attended with little danger. Hæmatemesis which is vicarious or supplementary to menstruation is usually a very manageable complaint; though we cannot go so far as some of the older authors, who considered it as absolutely salutary, and not to be interfered with. (Salmuth, Langius, Zacutus Lusitanus, &c. See Dict. des Sciences Médicales, vol. xx. p. 100.) Where, on the other hand, it is not imputable to suppressed evacuations; where it shows a tendency to assume a chronic form; where it is attended with fever or indications of organic lesion; hæmatemesis is a disease of considerable danger, and very difficult of cure.

Treatment.—The treatment of hæmatemesis divides itself into three heads:—1. prophylactic measures; 2. those proper at the time of an attack; 3. those suitable in the intervals, or after the hemorrhage has subsided.

1. When warning is given of the approach of an attack of hæmatemesis by any of the precursory symptoms already noticed, it will be proper to have recourse to timely preventive measures, and especially to prescribe rest and the antiphlogistic regimen, cooling drinks, warm pediluvia or fomentations to the extremities, saline or other purgatives, and, if indicated, the abstraction of blood. Small bleedings have been particularly recommended a day or two before the time at which the catamenia ought to recur, if it is apprehended that they will be replaced by hæmatemesis.

2. The attack of hæmatemesis must be met by remedial measures of the same kind as those which are suited to hemorrhagic diseases in general; and their use must be modified by the character of the hemorrhage, the symptoms by which it is accompanied, and the causes which appear to be concerned in its production.

If there are clear indications that the hemorrhage is of an *active* or inflammatory character, venesection must be promptly resorted to, and followed up by purgatives and a strict antiphlogistic regimen. If, on the contrary, the disease puts on a *passive* or asthenic character, and the constitutional powers evince a tendency to sink rapidly, we must have early recourse to the most effica-

cious astringent remedies, and support the strength by mild but invigorating nourishment, and even cordials, given in small quantities, but frequently. In cases of an intermediate nature, the judicious combination and modification of these two plans of treatment demands the discrimination and skill of the practitioner. Thus it may be necessary to reduce local action by leeches, cupping, and mild laxatives, while proper dietetic means are resorted to to support the strength.

In all cases the most perfect mental and bodily tranquillity must be enjoined, and the patient strictly confined to the horizontal posture, in a cool and well-ventilated apartment, and with as light coverings as possible. Castor oil, the neutral salts, or more active purgatives, are to be administered according to circumstances; or where the irritability of the stomach forbids their use, laxative clysters must be resorted to, to secure an open state of the bowels. Cold liquids, as lemonade, almond emulsion with nitre, or the superacidulated infusion of roses, may be given frequently in small quantities, as a tea-spoonful or dessert-spoonful at a time.

In cases where the hemorrhage is so profuse and violent as to threaten serious consequences, more active measures must be resorted to; and none is so deserving of confidence as the free application of *cold*, which is the most efficacious of all astringents, by diminishing the calibre of the blood-vessels and lessening the impetus of the circulation. We must, therefore, not only give the liquids just mentioned, cooled down to 32° by ice or a freezing mixture, but may with great advantage inject iced water into the rectum, and lay bladders filled with pounded ice on the epigastric region. A very interesting case is related by Michelotti, in the *Philosophical Transactions* for 1731, in which a young gentleman affected with enlarged spleen, and previously subject to epistaxis, was cured of a second attack of profuse hæmatemesis, in the winter season, by drinking excessively cold water, and taking alimentary liquids iced. The quantity of blood vomited in the space of two hours is said in this case to have amounted to twelve pounds and upwards. By means of occasional small bleedings, a fresh attack was averted for two years, at the end of which period the hemorrhage recurred, and was again subdued by the same means. In the remarks appended to this case, the author cautions us against resorting to this powerful remedy in asthenic or dyspeptic individuals, but strongly advises its use in young and vigorous constitutions, and in the active form of hemorrhage.*

[Certain of the saline preparations, as super-sulphate of magnesia, potassa or soda, which may be formed extemporaneously, (*Magnes. sulph. ʒiii; Acid. sulph. dil. gtt. xxx; Aquæ f. ʒvj. M.* Dose one quarter four times a day,) by coming in contact with the vessels that pour out the blood by rupture or transudation, arrest the hemorrhage by their stringent action, and are thus both astringents and revellents; whilst by their cathartic agency they, at the same time, remove from the

intestinal canal any effused blood that may have passed into it from the stomach. In cases, too, of hæmatemesis that are dependent upon amenorrhœa, the cathartic may act beneficially by contiguous sympathy, on the torpid uterus.]

It is, on the contrary, in the *passive* kind, and in relaxed and languid subjects, or where the impetus of the circulation has been already reduced by venesection and antiphlogistic measures, that the vegetable and mineral astringents may with safety and advantage be employed. In hæmatemesis we have the great advantage of applying these remedies directly to the seat of the hemorrhage; and, therefore, they may be the more relied upon. Preparations containing gallic acid, such as Ruspini's styptic, (which Dr. A. T. Thomson has ascertained to be a solution of this acid in diluted alcohol,) are probably the most useful of the vegetable astringents. But no remedy of this class deserves so much confidence in passive hemorrhage as the acetate of lead given in combination with opium, and in such large doses and at such frequent intervals as to secure its effect. (See *ASTRINGENTS*.) Dr. Elliotson, who strongly advocates the *free* employment of this remedy, also mentions, as one from which he has derived great benefit in hæmatemesis and *malæna*, the oil of turpentine, in doses of twenty drops, repeated every three hours. (Elliotson's *Lectures*, *Medical Gazette*, vol. ix. p. 525.) Subnitrate of bismuth, in conjunction with opium, has also been recommended.

3. After the hemorrhage has subsided, or in the intervals of its occurrence, we must endeavour to obviate its return by removing or weakening the exciting causes, and counteracting the predisposition to the disease. A strict regulation of the diet, (passing very gradually from the mildest liquids to more nutritious food,) rest, quietness, the horizontal posture, cooling and astringent beverages, will be proper for several days after the hemorrhage has ceased. The bowels must be kept properly open by the gentlest and at the same time most effectual means; and there can be no doubt that the recommendation of clysters, to clear the intestines of the blood lodged in their course, so much insisted upon by continental physicians, is a judicious and salutary practice. We cannot, however, in this country, go along with them in their unanimous and strong condemnation of *purgatives* in every case of hæmatemesis, at least of such as are more active than manna, cassia, and tamarinds. "*Quæ vi alvum movendi majore instructa sunt, ea,*" says Frank, "*cane pejus et angue vitanda sunt.*" (*Op. cit.* p. 221.) And other continental writers, from Hoffmann down to Pinel, are not less explicit in their reprobation of active, and especially aloetic purgatives. (See *Dict. des Sciences Méd.* tom. xx. pp. 120, 121.) British practitioners, especially since the publication of Dr. Hamilton's treatise, (*Observations on Purgative Medicines*, Edinburgh, 1805,) have placed great confidence in active purging as the best mode of treatment in many cases of hæmatemesis, more particularly in that form of the disease which occurs in young and middle-aged females, and is connected with uterine torpor and a sluggish action of the bowels. In such cases Dr. Bateman states as the result of his experience, that the sue-

* *Philosophical Transactions*, vol. xxxvii. p. 129.—Flouquet refers to two cases cured "*gelidissimo potu*;"—1. *Act. Nat. Curios.* vol. iii. obs. 61; 2. *Commerc. Litter. Noric.* 1732, pp. 294, 351, 351.

cess of Dr. Hamilton's mode of treatment is more decidedly conspicuous than in any other disease in which he has recommended it. (Reports on the Diseases of London, p. 150.) It is remarkable that the benefit of the purgative plan of treatment is not confined to sanguine and plethoric subjects; it is not less signal in chlorotic and leucophlegmatic habits. It is, however, to female cases exclusively that the observations of Hamilton and Bateman apply; and there can be no doubt that the inconsiderate employment of active purgatives in cases of hæmatemesis or melæna occurring from wholly different causes, especially in constitutions exhausted by excess, or debilitated by the progress of organic disease, would be highly pernicious. In such cases certainly the more cautious procedure of our continental brethren is to be commended.

With regard to the restoration of the menstrual function where its suspension gives rise to hæmatemesis, the means by which this is to be accomplished are rather such as act by removing a condition of the general system unfavourable to regular menstruation, than by the employment of specific emmenagogues. If, therefore, the amenorrhœa depend on vascular fulness, we resort to bleeding and suitable purgatives; if on uterine torpor and a chlorotic state, the warmer aperients and tonics, especially the preparations of iron, are to be employed. (See AMENORRHŒA, CHLOROSIS, and EMMENAGOGUES.)

To complete the recovery of the convalescent from the various forms of hæmatemesis, tonic medicines, a suitable diet, exercise, change of air, and sometimes the use of chalybeate mineral waters, will be highly serviceable. But it is not necessary to protract this article by dwelling on these familiar topics. Freedom from care, anxiety, and causes of mental irritation, is of the highest importance in all cases, and especially where we have reason to believe or suspect the existence of organic disease. In such melancholy cases the utmost that our art can aim at is to palliate suffering, to ward off the recurrence of hemorrhage, and to protract to the utmost that fatal event which the resources of medicine, however skilfully wielded, cannot hope to avert.

GEORGE GOLDIE.

HÆMOPTYSIS, from *αἷμα*, blood, and *πρὸς*, spitting.—Were it taken in the full latitude of its etymology, the word hæmoptysis would embrace every discharge of blood from the mouth, without regard to the sources from whence it originally proceeds; but as the sources are various, use has annexed to the term a more limited signification, restricting it to *expectoration of blood*, or that which originally issues from the respiratory organs. This view of the subject has suggested to some the propriety of substituting the term *pneumorrhagia*, as more definite and precise in its signification. We, however, do not recognise, in the proposed substitution, advantages sufficient to counterbalance the evil of disturbing a well-established name. Were we disposed to make any change, it would be to divide the subject into pulmonary hemorrhage and hæmoptysis; the former expressive of the more profuse discharges of blood, the latter of the smaller quantities discharged as

sputa. Still we prefer the general term hæmoptysis taken in its conventional signification.

If there be no subject within the extended field of pathology upon whose precise nature the advancement of anatomical knowledge has thrown more light than hemorrhage, there is unquestionably no organ in the body that has derived more benefit from this circumstance than the organs subservient to respiration, which, both from their organization and from the nature of their functions, are more frequently than any other the subject of hemorrhage.

The term *hemorrhage*, (*αἱμορραγία*, from *αἷμα*, blood, and *ρῥυμι*, to break,) carries upon its face evidence of the imperfect views which prevailed respecting the real nature of this morbid phenomenon, implying rupture of a vessel to be its essential cause; but experience, so far from establishing this as a general cause, has proved it to be of very rare occurrence, even under circumstances which we should have supposed most likely to produce such a lesion. This pathological error has been kept up in the application of the expression "bursting a blood-vessel." Speculation and vague hypothesis filled up the imperfect measure of information upon this important pathological subject, until the invaluable labours of Bichat redeemed it from error, and placed it in its true light. In explaining the phenomenon of exhalation, he has shown that it is effected through the instrumentality of a system of vessels which are continuous with the arteries, namely, the *capillaries*; that these vessels enter into the composition of all our organs; that they become elements of the several tissues of the body; and that their function consists in separating from the blood a fluid peculiar to the tissue of which they form part. Thus the mucous exhalants separate mucus, and the serous serum; and as long as these vessels continue in the unimpaired enjoyment of their vital properties, so long they only admit the colourless fluids, and refuse entrance to the red particles of the blood; but should these properties be so affected, either directly or sympathetically, that they are either altered or impaired, (changes to which they are especially subject from their being more under the influence of the nervous system than any other portion of the vascular apparatus,) they no longer retain this power of closing themselves against the entrance of red blood. In one case they as it were solicit the presence of this fluid, and in another yield to its forced entrance; in the former instance giving rise to *active*, in the latter to *passive* hemorrhage. Between the first of these morbid conditions and inflammation the closest analogy exists: they recognise the same causes; occur most frequently in the same tissues; have often the same symptoms and terminations; and not unfrequently pass into each other.

These considerations lead to the conclusion that the disposition of an organ to hemorrhage is in a ratio compounded of the development of the exhalant vessels in that organ, and of their exposure to the operation of causes capable of producing those changes in their properties upon which hemorrhage, whether active or passive, is found to depend. Applying this to the lungs, we have a ready and satisfactory explanation of the frequency of pulmonary hemorrhage. These organs com-

bine in themselves every condition favourable to the production of this morbid phenomenon, both in its active and passive form: 1. a considerable extent of mucous membrane, the tissue the most richly furnished with exhalant vessels of any in the animal economy; 2. the constant and immediate relation of this tissue with the atmosphere,—a source of irritation not only from the variations of temperature of which it is so susceptible, but also from the different impregnations with which it is continually charged; 3. a loose spongy parenchyma traversed by numerous blood-vessels of every dimension, freely communicating with each other; 4. the proximity of these organs to the heart, and consequent exposure to the effects of every irregular motion of this organ; 5. the continued motion which the exercise of their own functions entails upon them.

In order to appreciate the disposition of the lungs to hemorrhage still further, we shall briefly glance at the two systems of blood-vessels which traverse them, viz. the bronchial or proper nutrient vessels of the organs, and the pulmonary vessels, whose office consists in the transmission of the blood through the lungs, for the purpose of its undergoing the proper chemical changes to fit it for its several uses.

The bronchial arteries are distributed to all parts of the lungs. Their trunks follow the course of the bronchi, and, sending off twigs to all the branches given off from the bronchial tube, accompany them to their ultimate termination. These numerous blood-vessels, after embracing the bronchi, penetrate their coats, and are spread out upon their mucous surface into an incredible number of capillaries. In addition to these branches supplying the bronchi, the bronchial arteries send lateral branches to all other parts of the lungs, which, passing into the tissue of the organ in connection with numerous branches of the pulmonary artery and pulmonary vein, constitute a fine network made up of innumerable capillaries freely anastomosing with each other.

The pulmonary artery, after it has pursued the bronchi to their termination, sends branches to each vesicle; and these branches, anastomosing on all sides, are spread out upon the vesicles. This artery gives off vessels which, pursuing a tortuous course between the air-cells, proceed to take their share in the composition of that network of vessels to which we have before adverted as made up of the ultimate ramifications of the bronchial and pulmonary arteries and pulmonary vein. Through the medium of these vessels, an injection thrown into the bronchial artery fills the pulmonary artery also, though its passage from the latter into the former is much more easy.

The pulmonary veins, made up of branches collected from all points to which the bronchial and pulmonary arteries carry the blood, conduct this fluid back to the heart, pursuing their course along the bronchi and their branches in the same way as the pulmonary artery.

These anatomical details explain to us, so to speak, the machinery of pulmonary hemorrhage, and enable us to understand the mode of operation of the many and different causes which produce this morbid phenomenon. They exhibit to us such a freedom of communication existing be-

tween all the blood-vessels of the lungs, that any derangement of either the general or pulmonic circulation is competent to give rise to it. In certain excitements of the general circulation the blood will be impelled through the bronchial artery, proceeding from the aorta, into the smaller vessels which are spread upon the bronchial mucous surface, and from them into the bronchial tubes. Should the derangement be more particularly confined to the pulmonary circulation, as in case of hypertrophy of the right ventricle of the heart, the blood will then be driven into the small branches of the pulmonary artery which are distributed to the parenchyma of the lung, and being exhausted there, will constitute hemorrhagic engorgement or pulmonary apoplexy; and, should the impetus be considerable, its effects will be extended to the communicating bronchial branches, from whence the blood will be poured into the bronchial tubes, giving rise to bronchial hemorrhage.—See APOPLEXY, PULMONARY.

We are now prepared to understand a circumstance to which we shall have occasion to advert when we come to speak more particularly on the subject of pulmonary apoplexy. Although this affection generally consists in the extravasation of blood into the parenchyma of the organ, and of hæmoptysis more or less extensive at the same time; still this latter phenomenon may be altogether absent, and the hemorrhagic engorgement (which is really the essence of the disease) alone be present. In fact, we regard the addition of the hæmoptysis as a mere accident, though a measure of the intensity of the cause which has given rise to the hemorrhagic engorgement; and we readily account for its frequency by the facility with which an injection is found to pass from the pulmonary into the bronchial artery. The communication which we observed to exist between the pulmonary vein and pulmonary and bronchial arteries, furnishes us with the *rationale* of hæmoptysis dependent upon particular lesions affecting the left side of the heart. Thus, from a narrowing of the communication between the left auricle and ventricle, the pulmonary vein is *prevented* emptying its blood into the auricle; and as it is the channel into which the pulmonary and bronchial arteries empty their contents, the effects of its congestion are necessarily felt in these arteries. Besides, the remora of the blood in the lungs opposes a resistance to the efforts of the right ventricle to drive its blood through the pulmonary artery and lungs, and demanding increased efforts of this ventricle, occasions its contents to be thrown with unusual force into the minuter vessels of the pulmonary artery, and the communicating minute branches of the bronchial artery: it is in this way that we explain the frequent hæmoptysis in this particular lesion of the heart. From the foregoing observations it is obvious that the blood-vessels of the lungs form a circle; and that hæmoptysis may result from derangement of the circulation affecting any part of it.

Though there is no period of life which can be strictly said to be exempt from hæmoptysis, still it is so much more frequent from the age of fifteen to thirty-five, that this has been considered its proper season. This is the period when the energies of the system seem to converge towards the organs

of respiration; and when are developed between them and distant organs those sympathies upon which their susceptibility to certain diseases would seem to depend. This is the period when phthisis strikes its victim; and when we come to speak more in detail of the particular lesions of the lungs which give rise to hæmoptysis, we shall see how often it occurs as a symptom of this disease.

Hæmoptysis sometimes comes on quite suddenly, and without any premonitory announcement. It is, however, in general preceded by chilliness of the skin, lassitude, alternating paleness and flushing of the face, headach, palpitation of the heart, and strong vibrating pulse. To these may be added what we may term the local symptoms, consisting of a painful sensation of weight and tension, and of heat and itching in all or in some part of the chest, with dyspnoea, and a sense of anxiety about the præcordia: these symptoms are due to the congestion which immediately precedes the effusion of blood. Other symptoms are enumerated, which are in reality owing to the blood already effused into the parenchyma of the organ, and into the bronchial tubes. Among these the most remarkable are a sense of ebullition in the chest, (a feeling produced by the mixture of blood and air from the successive movements of inspiration and expiration,) and a great increase of dyspnoea.

When blood is effused into the air-passages, the irritation it produces causes cough, which determines its expulsion; and when the effusion is considerable, (which it is sometimes, to the degree of producing an urgent sense of suffocation,) the muscles of expiration contract almost convulsively, the lungs are compressed, and the blood is expelled with violence through the mouth and nose. Sometimes some of it, passing into the stomach, excites vomiting and is rejected with the contents of this organ; a circumstance which may embarrass our diagnosis as to the original source of the hæmorrhage.

Hæmoptysis varies considerably in the quantity of blood discharged. Its extent is sometimes so great that we wonder how it can take place, and not extinguish life; still we see the same quantity discharged again and again at intervals not very long distant, and this go on for months, nay for years, and the subject of it ultimately restored to the enjoyment of perfect health. At other times, we regard with alarm even the appearance of expectorated blood, when we have reason to look upon it as the index of deeper mischief latent; a single sputum tinged with blood will then bespeak more danger than a loss, frightful in quantity, under different circumstances. From this we may conclude that the extent of the hæmoptysis is not in all cases an exact measure of the amount of danger; and that in general its importance is derived from the circumstances under which it takes place.

We should be acquainted with the appearances presented by expectorated blood, as a circumstance to guide our diagnosis. When it is not in considerable quantity, it is generally frothy or mixed with air, and of a vermilion or arterial colour; if it be considerable, it is not frothy, but has the arterial colour. These appearances, however, are

not sufficiently constant to enable us to rest our judgment on them alone; we must have recourse to other signs and symptoms, both positive and negative, before we deliver our opinion in doubtful cases.

Among the constitutional symptoms of hæmoptysis, some depend upon the actual loss of blood; others are due to the alarm or nervous shock produced by this phenomenon, which is so often associated with circumstances of danger. In this way alone can we explain the exanguious appearance, the tremour, the hurry of the circulation, the irregular action of the heart, the fainting which we find so often to follow the loss of even a moderate quantity of expectorated blood. We constantly observe a loss of blood apparently trifling produce more disturbance in a nervous delicate person, than a very considerable loss will do in one of a strong vigorous constitution: in fact, fright and hæmorrhage have precisely the same physiological operation, and give rise to the same phenomena.

Hæmoptysis is the consequence either of congestion of the lungs, (whether caused by the blood thrown upon these organs with unusual force, or by its remora in them,) or of some lesion of those organs: we shall therefore consider it under these circumstances respectively.

When we reflect upon the organization of the lungs, we cannot wonder that they should often be the organ through which nature relieves herself from a state of morbid plethora; especially should that state depend upon the suppression of a hæmorrhage which ordinarily takes place from an organ between which and the lungs a sympathy is known to exist. Physiology has ever recognised a remarkable sympathetic relation to exist between the organs of respiration and the uterine system; in virtue of which the lungs (especially when possessed of any particular susceptibility of disease whether natural or acquired) seldom remain long unaffected, should there be any interruption to the development or regularity of the functions of the uterus. This is the most fertile source of hæmoptysis, independent of organic lesion of the lungs. In some of these cases we find the hæmoptysis anticipating the period of the establishment of the menstrual discharge, and entirely ceasing when this discharge has been fully established. In other cases we find the hæmoptysis altogether superseding this discharge, usurping its regular periodical appearance, and establishing itself into a function, so connected with the health of the system as to require much caution to be observed in interfering with it. Again,—and which is the most common case,—the hæmoptysis is a supplementary discharge, making up for the deficiency of the menses: in these instances nature seems to make an effort to establish the due order of her functions; pains in the back and loins are felt at the same time as a sense of weight and tightness in the chest, with oppressed breathing; upon these follow a mere appearance of the menstrual discharge, and a more profuse discharge of blood from the chest. This state of things will sometimes continue till the period of life when the menses usually cease, with no more inconvenience than the occasional oppression caused by the congestion which precedes the hæmoptysis. Hoff-

mann mentions a remarkable case in which the hæmoptysis usurped the place of the menses: the subject of it became pregnant, the hæmoptysis was then suspended, and reappeared after delivery, and continued for many years.

Suppression of the hemorrhoidal discharge will give rise to hæmoptysis. Between this and the hæmoptysis connected with suppressed menses, Laennec makes the distinction that the former occurs as pulmonary apoplexy, and the latter as bronchial hemorrhage. This hemorrhage exhibits the same tendency to return as the discharge which it has superseded. Masson (*Dissertation sur l'Hæmoptysie*) records a remarkable case where the hæmoptysis, which succeeded a suspended hemorrhoidal discharge, returned regularly every month for a year, although the original discharge had not observed the same periodical regularity.

Hæmoptysis occurs sometimes, though rarely, as a critical discharge. Nature, in directing her critical efforts to other organs in preference to the lungs, would seem as if she respected these organs in consideration of their importance, and of the danger that might result from their being the subject of hemorrhagic congestion.

Any circumstance, which, by interrupting the balance of the circulation, throws an unusual quantity of blood upon the lungs, may act as a cause of hæmoptysis. It is thus that the bent position of the body, which certain trades require, acts. Tailors are, for this reason, much subject to this affection: their constant sitting posture, with the body bent and head leaned forward, and with the abdominal viscera so compressed as to admit a less than natural quantity of blood into them, favours an unequal distribution of this fluid, which is directed in an undue proportion towards the lungs, and produces in them a local plethora, a frequent result of which is hæmoptysis.

Malformation of the thorax, by compressing the lungs, and thus interfering with the free exercise of their functions, often causes hæmoptysis; a fact already noticed by Morton.

Prolonged pressure upon the abdomen by tumours, whether solid, fluid, or gaseous, produces hæmoptysis, by diminishing the quantity of blood sent to this region, and increasing that which is carried to the chest. In advanced pregnancy hæmoptysis is sometimes so considerable as to demand instant delivery. Stoll mentions a case in which hæmoptysis came on during ascites: it ceased on tapping, and reappeared on the fluid accumulating again. Tympanitis has been known to be attended with a similar result.

Hæmoptysis is often caused by a paroxysm of some of the diseases classed under the head of *neuroses*. Bohn mentions a case of epilepsy, each attack of which brought on a profuse hæmoptysis. We have often had occasion to observe the same in paroxysms of hysteria.

M. Fougnet, Professor at Montpellier, treated successfully with bark a tertian which was always ushered in by an hæmoptysis so considerable that the patient seemed to vomit blood.

Low, asthenic fevers, accompanied with petechiæ, often exhibit this phenomenon. It was much more common in eruptive fevers before Sydenham improved the practice in this class of diseases.

Haller observed, in an epidemic small-pox, that all who were treated upon the cordial heating plan were covered with livid spots, the appearance of which was preceded by pains in the back and chest, and by hæmoptysis. Diemerbroeck, in his description of the plague which ravaged Belgium and Germany in the middle of the seventeenth century, mentions the hemorrhagic flux from the nose, uterus, urinary passages, and lungs. Fracastorius makes the same observation respecting the plague of the fourteenth century.

Besides this accidental complication of fever and hemorrhage, authors admit a hemorrhagic fever, in which the fever is as essentially connected with the hemorrhage, as the fever preceding and accompanying small-pox is part of that disease. This fever may be either sthenic or asthenic in its type, and the accompanying hemorrhage either active or passive in its character. The most striking feature of sthenic hemorrhagic fever is the full, bounding, vibrating pulse, so characteristic of this morbid condition that by it alone we can almost predict an impending hemorrhage.

We have already anticipated our observations upon hæmoptysis resulting from congestion of the lungs, the effect of disease of the heart, and explained its frequency in that particular lesion which consists in a narrowing of the communication between the left auricle and ventricle. The following case will illustrate this point. We had under our care, for three years, a young female who laboured under most distressing palpitation, greatly increased by the slightest exertion or motion: the phenomena of auscultation left no doubt that the lesion consisted in a narrowing of the left auriculo-ventricular opening of the heart. She had repeated hæmoptysis, which became more frequent and profuse as she approached death. Examination of the body after death exhibited both lungs gorged with blood; even the minutest capillaries under the pleura were injected; and there were numerous ecchymosed patches in the cellular tissue subjacent to this membrane. The heart did not exceed the natural size; its right ventricle was both in a state of hypertrophy and dilatation; the left ventricle was smaller than natural; the capacity and muscular structure of the left auricle were unusually developed; the communication between the left auricle and ventricle would scarcely admit the introduction of a crow-quill. The pulmonary artery exceeded its natural size; the calibre of the aorta scarcely equalled that of the common carotid. This is the lesion which we shall find to be most frequently the cause of pulmonary apoplexy; a form of hemorrhage to which we shall have occasion to advert when we come to speak of the morbid conditions of the lungs which give rise to this phenomenon.

Hæmoptysis arises no less from moral than from physical causes. Moral causes operate principally in the production of hæmoptysis through the medium of the heart; in fact, the lungs and heart have such an intimate sympathetic relation, that one cannot be affected without involving the other; so that it is not always easy to determine which has preceded in the order of their derangement. There is no organ in the body more subject to disturbance of its function from the irregular play of passion than the heart; and whether that passion

be of the exciting or depressing character, it is equally capable of producing hæmoptysis. These two orders of moral affections act upon the heart as stimulant and sedative agents do; the former throwing an unusual quantity of blood upon the lungs; the latter, by weakening the impelling power of the heart, giving rise to a stagnation of blood in them. In addition to hæmoptysis proceeding from these palpable causes, we sometimes meet with it under circumstances in which we cannot fathom its etiology; when, perhaps, it depends upon some particular state of the capillaries, which our imperfect knowledge of this portion of the vascular system prevents our appreciating. One of these mysterious cases is that remarked by Dr. Cheyne in the fifth volume of the Dublin Hospital Reports: the subject of it has had, since 1807, frequent attacks of hæmoptysis coming on at variable intervals, but nearer to each other in spring. We have had recent communication with this individual on the subject of his disease, and have been informed that it comes on without any provocation, and when at its height returns three or four times in the course of the day: it is not influenced either by rest or by exercise, and does not seem to yield to remedies, but subsides spontaneously. Previous to the attack a sense of constriction is felt in the chest; there is no fever, the pulse not exceeding eighty-four beats in the minute. A system of small bleedings from the arm, adopted at the suggestion of Dr. Cheyne, gave the first check to his disease, and by following it up he is now enabled to engage in the active duties of his profession as a clergyman, and feels no inconvenience from an unsparing exercise of his voice.

We now come to consider hæmoptysis in connection with actual lesion of the lungs.

Unquestionably the morbid condition of the lungs with which hæmoptysis is most frequently associated is the development of tubercles: this is a pathological fact universally admitted, though the question whether the hæmoptysis, which so often ushers in phthisis pulmonalis, be the harbinger of tubercles, or the index of their actual existence in the lungs, is still *sub judice*, each opinion reckoning among its advocates the highest pathological authorities. Laennec is of opinion that the formation of tubercles precedes the hæmoptysis, and that the contrary opinion is founded upon the hasty application of the axiom, *post hoc, ergo propter hoc*; that though the hæmoptysis is the first symptom of the disease which attracts notice, still, if the chest be examined before its appearance, there will be evidence of the existence of tubercles; and as hæmoptysis often recurs in the progress of the disease, we may conclude that the presence of tubercles is its most frequent occasional cause. He further adds that the mode of their operation in the production of this effect is easily understood, when we consider that they are foreign bodies, which in their development press upon and irritate the parenchyma of the organ; that, on the other hand, we want a positive fact to prove that hæmoptysis alone can produce tubercles; nor can we conceive, anatomically, how that can be the case; for if it were so, we should see hemorrhagic engorgement transformed into miliary tubercles, a circumstance which he had never observed. Besides, he observes, hæmoptysis resulting from vio-

lence is nothing more than a mere accident, unattended by any unpleasant sequelæ if properly treated; whereas tubercular phthisis, long latent, often manifests itself immediately after an hæmoptysis coming on without any appreciable cause, and which has no other cause than the presence of tubercles in the lungs.

Andral, in advocating the opinion of the hæmoptysis preceding the formation of tubercles, and being their actual cause, says he has more difficulty in conceiving how tubercles, which, according to those who espouse the former opinion, have the power of irritating the pulmonary parenchyma to the degree of producing abundant hæmoptysis, can exist for a long time without causing even a slight cough, than that under causes more or less appreciable some portions of the lungs should become the seat of sanguineous congestion, and give rise to hæmoptysis. If this congestion exist in one or more points of the lung, and if at the same time the subject be predisposed to tubercles, these bodies may arise easily, and multiply rapidly, in the midst of a part whose nutrition is modified in consequence of the new state in which it is: it is thus that he would explain phthisical symptoms so often following hæmoptysis, although well-directed treatment will often avert the mischief.

Louis thinks that hæmoptysis, unless connected with irregular menstruation, or dependent upon external violence, furnishes strong presumptive evidence in favour of the existence of tubercles in the lungs; an opinion sustained by actual observation and the analogy of other organs, in which, when hemorrhage occurs, it is the index of some serious alteration in their structure; besides, it is natural to suppose that the same cause which produces hæmoptysis in the progress of the disease, produced it also in the beginning.

We may infer that Broussais is of opinion that hæmoptysis precedes the formation of tubercles, from his observation that the loss of blood is not to be considered the direct cause of consumption, but as one of the inflammatory movements which are the sole cause of phthisis.

Amidst these conflicting opinions, we hesitate to express a decided judgment, while we admit a bias in favour of that which considers the formation of tubercles to precede the hæmoptysis. In the examination of those who have died of hæmoptysis, we have found tubercles, the existence of which was not suspected during life; and we have ever regarded the mode of operation of tubercles in the lungs to be precisely similar to that of foreign substances in other parts of the body, each tubercle or cluster of tubercles acting as a nucleus or centre of irritation, and soliciting to the part an unusual flow of blood.

In admitting the difficulty of deciding between these opposite opinions, it happens fortunately that the difference carries with it no practical inconvenience, as whichever view be adopted, it involves no difference of treatment. So frequent an accompaniment of phthisis is hæmoptysis, that Louis found it to exist in two-thirds of the cases which fell under his care.

Andral observed, that among those that die of consumption, a sixth have never spit blood; three-sixths or a half never spit blood till pulmonary tubercles had given unequivocal evidence of their

existence; and in the remaining two-sixths the hæmoptysis seemed to precede and be the actual cause of the tubercles.

There are three principal sources from whence the blood expectorated in these cases may be derived; either from the mucous membrane of the bronchi, or from a tubercular cavity, or from the parenchyma of the lung. Death is sometimes caused by hæmoptysis, when examination can detect no other source of it than the bronchial mucous membrane, which, in this case, only exhibits a slight blush, or is even paler than natural. As hæmoptysis is found to be more frequent when tubercles are in their crude or nascent state, we may account for the repetition of this phenomenon by the successive development of these bodies through the course of the disease, on the physiological principle above noticed, *ubi stimulus ibi fluxus*. We may perhaps ascribe the frequency of hæmoptysis at this stage of the disease to the obstruction to the pulmonary circulation caused by the extensive tubercular development in the lungs; this obstruction demands an increased energy of the right ventricle, whereby the blood is thrown with unusual force into the lungs, and hemorrhage is thus produced. This we may expect to be most frequently the case when the tubercles have formed rapidly, and not allowed time for the heart to accommodate itself to this sudden encroachment upon the sphere of its operation; and it would be a more frequent occurrence if the strength of the heart were not weakened by this organ sharing in the muscular atrophy incidental to the disease.

The next source of hæmoptysis is a tubercular excavation. In several phthisical patients who have died of hæmoptysis, there have been found large excavations hollowed out in the lungs, and filled with blood either fluid or clotted: in this case the blood is also found in the bronchi and trachea, and the individual seems to have died of suffocation. It is very common to find the purulent matter contained in a cavity tinged with blood. It sometimes happens, though rarely, that the blood in these cavities is poured out from a vessel traversing their sides, in those transverse bands which Laennec has not unaptly compared to the carnee columnæ of the heart: these bands consist of an artery, vein, and bronchial tube matted together. The canal of the artery is generally obstructed, although an unhealthy inflammation pervading the pulmonary tissue will interrupt this provision of nature; and the arterial structure, which might almost be said to enjoy an immunity from the effects of inflammation under its ordinary circumstances, will here yield, and admit of an extravasation of blood.

The next *reputed* source of hæmoptysis is the parenchyma of the lung. The lesion upon which this depends has, from its analogy with cerebral apoplexy, been designated pulmonary apoplexy. It is thought to depend upon a sanguineous exhalation into the pulmonary parenchyma, that is, into the air-cells, whose form is represented by the granular aspect of the surface of a section of a portion of lung affected with this modification of disease. This lesion, consisting of a circumscribed hardening of the pulmonary tissue, is considered by Laennec, who first noticed the subject, to

be the frequent source of these alarming discharges of blood from the lungs which we sometimes meet with. The density of the affected portion of the lung is greater than that which constitutes hepatisation. The hardened portion, different from that affected with hepatisation, presents no trace of the pulmonary tissue, but is of a homogeneous aspect and of a deep black colour, resembling a clot of venous blood. Pulmonary apoplexy would seem to consist in a double lesion, viz. hemorrhagic engorgement and hæmoptysis: this latter, though the most striking feature of the disease, is less essential than the other, and may be absent without changing the character of the lesion. Experience has established this fact, auscultation recognising the engorgement which had not been announced by the ordinarily accompanying hæmoptysis. Nor indeed have we much difficulty in explaining this, if we revert to the observations we made upon the freedom of communication between the pulmonary and bronchial vessels. It is found to occur most commonly from hypertrophy of the right ventricle; the effect of which lesion is to throw the blood with unusual force into the capillary vessels of the pulmonary artery. Should that force be considerable, the blood will not only pass into the bronchial capillaries, and thus into the bronchial tubes, giving rise to hæmoptysis in the common form, but may lacerate not only the tissue of the lung, but also its investing membrane, and be extravasated into the cavity of the chest. We can likewise understand how the blood may be impelled with a force only sufficient to fill the capillaries of the pulmonary artery, without that force carrying it on to the bronchial capillaries; in which case we shall only have so much of the lesion as consists in the hemorrhagic engorgement without the hæmoptysis; whereas, should the influence of this force extend to the bronchial capillaries, ordinary hæmoptysis will be superadded. The external hemorrhage, then, we do not regard as a consequence of the hemorrhagic engorgement, but as a concurrent effect of the same cause.

There is a species of pulmonary apoplexy in which the extravasated blood forms a coagulum in a cavity hollowed out in the substance of the lung. This is the only lesion which in strictness seems entitled to the designation of pulmonary apoplexy, as being that which alone is analogous to the condition of the brain in the true apoplexy of this organ. In this lesion the pulmonary tissue is lacerated by the blood issuing from its vessels, in the same way as the cerebral tissue is lacerated under similar circumstances. A case of this nature fell under our notice not very long since; the subject of it died of a profuse expectoration of putrid blood; and on examination after death a considerable quantity of blood in the same state was found in a cavity occupying the entire extent of the right lung. The attack arose from exposure to cold when the individual was in a state of intoxication.

The modification of pulmonary disease which Bayle has designated *ulcerous phthisis* (phthisic ulcereuse), and which is now recognised as gangrene of the lungs, from the fetor of the breath and expectoration which accompanies it, often gives rise to hæmoptysis to such a degree as to cause death. Though this form of disease is some-

times, nay often, complicated with tubercular developments, the latter are not essential to it; it is, in fact, an unhealthy inflammation of the pulmonary parenchyma, which generally takes place in a bad habit of body, and in its destructive operation respects no tissue. This is the case in which nature seems to neglect her usual precautionary measure of obliterating the canal of the arteries, to provide against hemorrhage; these vessels remaining pervious, and giving way to the disorganizing ulceration, furnishes one of the few instances of hemorrhage arising from actual lesion of the containing canals. A profuse hæmoptysis is often one of the first symptoms that ushers in this disease; but in general the patient for some time previously has had a pain in the side, and a teasing irritating cough, his general health much deranged, languor and lassitude, loss of appetite, &c. Amidst these symptoms he is sometimes suddenly seized with hæmoptysis so extensive as to extinguish life at the moment; an instance of which is related by Bayle in the first case which he gives of this modification of disease. (Observation 25.) In some cases the hæmoptysis has the effect of relieving the system, as it were, from an oppressive load, and the patient feels himself much better after it; but fetid expectoration soon succeeds, and the hæmoptysis is repeated at variable intervals, but with the same feelings of momentary relief. This state of things sometimes continues through this often protracted form of disease. Examination after death exhibits the several tissues of the lung indiscriminately involved in one general sloughy mass emitting an intolerable fetor.

Hæmoptysis has no necessary connection with pneumonia; the prune-juice sputa, however, which Andral regards as characteristic of the third stage of pneumonia, owe their colour to the blood, which is mixed with the other matter of expectoration. Bronchitis, especially when it occurs as an epidemic, is sometimes attended with abundant hæmoptysis. This form of disease seems to differ much from ordinary bronchitis, and to bear some analogy to dysentery; for as this latter often degenerates into diarrhœa, so the former terminates in an analogous form of disease, consisting in a thin, frothy, abundant expectoration. When bronchitis thus occurs as an epidemic, it is accompanied with a small feeble pulse, great prostration of strength, loss of appetite, languor, lassitude, loaded tongue, and high-coloured urine, &c. It is of the last importance that we be acquainted with the form of disease, and be enabled to recognise the hæmoptysis as a symptom connected with and dependent upon a serious constitutional derangement, and whose treatment merges into that of the constitutional disorder. We have known death to follow a mode of treatment which only contemplated the hæmoptysis, and left out of sight the more important cause upon which it depended; this seems to be the disease which Stoll designated bilious hæmoptysis, and which he treated so successfully with emetics.

Independently of organic lesion of the lungs, hæmoptysis may arise from lesion of either the larynx or trachea, and is met with in persons whose profession requires a continued exercise of voice. Hæmoptysis, however, from this source

has been admitted more from analogy than from actual observation, and seems to rest more upon negative than upon positive evidence; more upon the absence of the signs of pulmonary hæmorrhage, than upon any unequivocal proof that the blood comes from the larynx or trachea.

External injury often produces aggravated hæmoptysis; thus, violence directly applied to the chest will sometimes be followed by an immediate and abundant expectoration of blood, an effect which is often attributed to an opening of some vessel produced by a fractured bone, which is sometimes one of the consequences of this violence; but as in many cases the hæmoptysis comes on independently of any fractured bone, it must be ascribed to the commotion of the system produced by the violence. The assassin's poniard is the frequent source of fatal hæmoptysis. Henry the Fourth of France received two strokes of a knife from the hand of the traitor Ravallac; he uttered a few words, threw up some blood, and immediately expired. Examination after death discovered two wounds: one, in the left side of the chest, did not penetrate; another, between the fifth and sixth ribs of the same side, penetrated the left lung, and made an opening to the pulmonary vein, capable of receiving the point of the little finger: the lungs were black and gorged with blood, and there was much blood effused into the cavity of the chest.

Treatment.—Having considered the important phenomenon of hæmoptysis under its different phases, and under the different circumstances both of the constitution and of the organs with which it is connected, we next come to the interesting subject of its treatment; upon which were we to enter as fully as its importance deserves, we should extend this article beyond its legitimate limits, and encroach upon other articles which have to deal with this phenomenon in the relation of a symptom of many morbid conditions both of the constitution and of the organs from whence the blood proceeds. To the several specific articles upon these morbid conditions we would refer for more detailed information upon this important subject, while our observations partake more of a general character. We have seen that hæmoptysis generally occurs either in consequence of congestion of the lungs, or of lesion of these organs: what we shall have to observe upon its treatment will contemplate it under these two modifications of circumstances.

Congestion of an organ so important as the lungs must ever be regarded with alarm, and for this reason Hoffmann observes that of all morbid hemorrhages hæmoptysis is that which is accompanied with most danger. Even when it is connected with suppression of some habitual discharge, and seems to make amends to the constitution for the derangement of its functions, it cannot with safety be permitted to continue, but must be met with an uncompromising hand.

The treatment of hæmoptysis resolves itself into that which is to be employed during an attack, and that which is to be pursued in the intervals of the attacks, with a view to prevent their return. The character of the hemorrhage, as to its active or passive nature, is the point upon which the treatment hinges. In an attack of ac-

tive hæmoptysis, general bleeding, proportionate to the vascular orgasm and to the strength of the individual, must be employed, and leeches should be applied to the chest, or in the neighbourhood of the organ which is the usual vent of the hemorrhage upon whose suppression the hæmoptysis may depend. The auxiliaries to bleeding are derivatives or counter-irritants, either internal or external. The first include purgatives, emetics, sudorifics, and diuretics; in fact, all those medicines which, exhibited internally, produce a derivation to counterbalance the original hemorrhagic movements. The external counter-irritants consist of blisters, mustard cataplasms, frictions, rubefacients, &c. Among the internal derivatives, purgatives of the saline class hold a foremost place; while they determine to the mucous membrane of the intestinal canal, they reduce the mass of the circulating fluid. Emetics present the threefold advantage of causing a revulsion, of producing a sedative effect upon the heart, and of determining to the skin. Sudorifics and diuretics also produce a derivative effect (though in a milder degree) by their action upon organs different from that which is the source of the hemorrhage. Nitre, from its refrigerating properties, has been long regarded as a most valuable medicine in active hemorrhage: it has been reputed to produce an actual change in the inflammatory character of the blood. Digitalis and acetate of lead powerfully co-operate to restrain the violence of the heart's action by their sedative effect upon this organ. Muriate of soda is a popular remedy for hæmoptysis, and one whose efficacy we have often witnessed. Acidulated drinks are valuable adjuvants.

[In this country, it is very common, during the flow, for the patient to be directed to take common salt into his mouth, under the idea that it possesses hæmostatic virtues; but the writer, as he has remarked elsewhere (*Practice of Medicine*, 2d edit. i. 290, Philad. 1844,) has never had the slightest reason for believing that it has been productive of any advantage; nor can he see on what principle it has been recommended. After a time, longer or shorter, according to circumstances, the hemorrhage ceases, whether salt has been employed or not; and hence it has probably happened that the result has been ascribed to the salt, when it may have exerted no agency. By M. Andral (*Cours de Pathologie Interne*) it is referred to as a remedy employed in Philadelphia.

It is important, however, not to allow much fluid of any kind; but to allay thirst in active hæmoptysis, small pieces of ice may be taken into the mouth, or iced lemonade may be sucked through a rag.]

Much difference of opinion prevails as to the place where external counter-irritants may be applied with most advantage; some recommending the nearest point to the seat of the congestion as the fit place for their application; while others prefer a distant point, a preference to which we subscribe, both from reason and experience. The nervous agitation which generally accompanies hemorrhage suggests to us the absolute necessity of repose of both mind and body. There should be a free circulation of cool air around the patient, but not so cold as to cause constriction of the

skin, and thus determine to the internal organs. The diet should be conducted upon the most rigid principle of abstinence from every thing capable of producing the least excitement of the system.

It will sometimes happen that the hemorrhage will reduce the powers of life so low that we shall be obliged to administer stimulants. The proper management of a patient under these circumstances is one of the nicest points in the practice of medicine, as we have to determine the extent to which we can safely employ stimulants without running the risk of exciting the system, and awakening the orgasm which has produced the effect which we seek to redress. In many of these cases there is no proportion between the loss of blood and the constitutional disturbance, the latter being much greater than can be accounted for by the actual hemorrhage, which is sometimes very inconsiderable: the nervous irritability of the individual can alone account for it: here we may advantageously employ antispasmodics, viz., camphor, ether, &c. to calm the flurry and agitation of the nervous system.

If the hæmoptysis *ab initio*, partake more of a passive character, we shall find our most valuable remedies to consist of the mineral acids, conserve of roses, infusion of roses acidulated with sulphuric acid, turpentine, muriated tincture of iron, [tannic acid, creasote,] &c., and sponging the chest with cold vinegar and water. To these cases much advantage is derived from blisters applied to the chest; they restore the tone of the capillary vessels, upon whose weak condition the hæmoptysis depends. A free circulation of refreshing air is no less beneficial in passive than in active hæmoptysis: we have known it to give an immediate check to this affection. We are not obliged to observe the same strictness in diet in this form of hæmoptysis, and may gradually come to that of a more nourishing character, with a moderate use of port wine and water.

We are next to consider the treatment and management of hæmoptysis in the interval of the attacks, with a view to prevent their recurrence. If we can connect the hæmoptysis with the suspension of an habitual hemorrhage, the obvious indication is to restore that hemorrhage. Should a suppression of the hemorrhoidal discharge be the cause, aloetic purgatives, and leeches applied *circa anum*, are the means to be employed. If the suspended menstrual discharge seem to be the cause of the hæmoptysis, we must endeavour, though with caution and without forcing the system, to restore the due order of the functions; and with this view we try to assist the abortive efforts of nature at the ordinary period of the menstrual discharge, by determining to the uterus by means of aloetic purgatives, by leeches applied to the interior of the thighs, and by the hip-bath: but our treatment will especially consist in imparting a degree of vigour and tone to the constitution, upon a deficiency of which this derangement of function often depends. In this case chalybeate tonics furnish us with a valuable resource: sea-bathing, horse exercise, &c. also assist the object we have in view. (See AMENORRHEA, CHLOROSIS, EMMENAGOGUES.)

In some cases we meet with this morbid pheno-

non in a condition of the system precisely opposite to that which we have just described, and in which we have to adopt a mode of treatment and management as opposite. In this latter instance our object is to reduce the fulness and plethora of the system by medicine and diet.

Should the cause of the hæmoptysis be less obvious, the frequency of its association with phthisis, and its being so often the precursor of this fatal malady, must make us ever regard it with alarm. We before remarked that the adjustment of the question as to tubercles being the cause or consequence of hæmoptysis was a matter of indifference as regarded the treatment to be adopted to combat this affection; for, as Laennec has observed, it must be met by bleeding carried to the very limits of possibility. The question, however, assumes an aspect of greater importance when we come to consider the treatment suited to the intervals of the attacks of hæmoptysis: we then feel that it involves a consideration of the most vital moment, how far we can with safety pursue a depletory mode of practice, which may have the effect of indirectly generating tubercles, by producing a habit of body favourable to their development.

The formation of tubercles seems to us to be, in most cases, the result of a deteriorated constitution taking on an action *infra se*. We meet them either in persons imperfectly nourished, or in those who have been wasted by previous disease, as by long-protracted fever. We have observed in phthisical patients a disposition to generate worms and vermin, even in those who, to the latest moment of their existence, bestowed the utmost pains on the cleanliness of their person. The inference we deduce from this is, that these parasitical animals, like tubercles, indicate a degeneracy of habit, or, so to speak, a descending in the scale of the animal being. These points, however, more properly belong to the articles TUBERCLES and PHTHISIS, to which we refer for more detailed information upon them. We would only observe that the causes which call a tubercular diathesis into active operation are such as have the effect, either directly or indirectly, of debilitating the energies of the constitution; and that therefore, though hæmoptysis be a complication with which we cannot tamper, but which we must meet with decision, we cannot but regret the dilemma in which we are placed by a symptom requiring a mode of treatment which we have reason to apprehend may have the effect of increasing that condition of the system which has given rise to the original disease. We would convey our opinion respecting bleeding in phthisis in the words of Laennec, who observes that as bleeding can neither prevent the development of tubercles, nor cure them when they are formed, it should not be employed in the treatment of phthisis, except with a view to subdue an inflammatory complication or acute sanguineous congestion; beyond this it is a gratuitous waste of the patient's strength, and may be superseded by medicines, which have the effect of reducing the powers of the circulation without producing permanent prostration, such as digitalis, tartar-emetic, &c. We would here express our decided conviction that phthisis, of which hæmoptysis is so frequent a

symptom, would be treated with much more success if physicians were not continually haunted with the apprehension of exciting or keeping up inflammation; a feeling which, within due limits, should ever be present, but still when pushed too far, and acted upon too rigorously, it deprives the system of its remaining stamina, and unfits it for bearing the exhausting effects of a wasting disease. A gentleman in Scotland (Dr. Stewart), who has now ceased to be a member of the medical profession, long since ventured to deviate from the routine of practice in this disease, and pursued a mode of treatment which has had most encouraging success: the principle of this treatment was to strengthen the constitution. He argued, that when the tubercles softened and the expectoration became purulent, the treatment should be the same as that required by the formation of matter in other parts of the body, when we have no other view than that of supporting the system. To fulfil this intention he treated the disease with tonic medicines cautiously exhibited, but placed his chief reliance upon cold bathing, exercise, and nourishing diet. His plan with respect to cold bathing consisted in making the patient sponge the entire body in the morning, and the neck, chest, and shoulders at night, with tepid vinegar and water, whose temperature was reduced each day till it was quite cold: this sponging was followed by rubbing for half an hour with flannels, and then with a flesh-brush. By degrees, as the feverishness subsided, the vinegar was laid aside. This was a preparation for cold bathing, and afterwards for sea-bathing. We do not mean to affirm that tubercles do not often form in an inflammatory habit, and that bleeding is not often required in such a habit: we only question its propriety as a preventive measure.

The slighter hæmoptysis, which comes on in the progress of consumption, seldom demands constitutional bleeding; it will in general be checked by acetate of lead, nitre, digitalis, conserve of roses, acidulated drinks, &c.

When the frequency of hæmoptysis in an individual not naturally predisposed to phthisis leads us to connect its cause with some obscure condition of the capillary vessels of the organ exhibiting itself in either active or passive hemorrhage, we have to treat it as an idiopathic disease, and not, as before, as a symptom whose treatment was modified by that of the disease upon which it depended. The character of the hemorrhage, whether active or passive, alone regulates our attention: we are, therefore, relieved from the caution with respect to bleeding which tied up our hands in the management of this morbid phenomenon in phthisis. It was this kind of habitual hæmoptysis to which we before alluded, as deriving so much benefit from small bleedings often repeated; a practice which seems to us entitled to a decided preference over large bleedings which cannot be repeated: for the efficacy of bleeding in these cases depends not so much upon the quantity of blood drawn, as upon the revulsive effect of the operation; the opening in the vein solicits the blood to it, and so diverts it from the source of the hæmoptysis. The older physicians appreciated this point of practice, and accomplished it by closing the opening during the opera-

tion. When we reflect how comparatively independent of the general circulation the capillary system is, we see reason to expect more advantage from means which have more of a local operation, as cupping, leeching the chest, &c. We shall find nothing to exercise such a salutary control over this kind of hæmoptysis as change of air, adapting the temperature to the character of the discharge; if it be active, removing to a warmer climate; if passive, to a colder and more bracing. This hemorrhage is much influenced by moral causes; moral management constitutes an important part of its treatment: the writer has known it to cease immediately upon hearing agreeable news.

Pulmonary apoplexy demands full depletion. Bleeding should be carried to the extent of producing fainting, and should the hæmoptysis still continue, we must adopt every other means calculated either directly or indirectly to lower the energies of the circulation. For this purpose we would employ small doses of ipecacuanha often repeated, so as to keep up a continual nausea. Purgatives are a valuable resource. Laennec has not found tartar-emetic as beneficial in this form of disease as in inflammation. Astringents should not anticipate the chronic stage of the disease.

Hæmoptysis dependent upon gangrene of the lungs requires a mode of treatment adapted to the vitiated constitution in which it occurs. Tonics constitute our principal remedial agents, while we seek to allay the irritation of the cough by opium, hyoscyamus, conium, &c. When hæmoptysis proceeds from the larynx or trachea, and seems to be produced by an excessive exercise of voice, the first thing required is the repose of the organ; nor, in general, is this enough; as the local affection is merely the index of constitutional relaxation, the object of the means we employ must be to restore the tone of the system by exercise, shower-baths, sulphate of quinine, &c. To this we would add sponging the throat with vinegar and water. For further information on this subject we would refer to the articles APOPLEXY, PULMONARY; PHTHISIS PULMONALIS; LUNGS, GANGRENE OF THE, &c. &c.

ROBERT LAW.

HEADACH.—*Cephalalgia*, from κεφαλή, the head, and ἄλγος, pain. From a very early period the term cephalalgia has been employed to designate various kinds and degrees of pain affecting the head. Some authors, indeed, have confined its use to headaches of the more obtuse and transient character; including pain of a more severe, tensive, and continued kind under the term *cephalæa*. But the words are too nearly alike ever to preserve a separate and distinctive meaning. For all practical purposes it will be more eligible to adopt exclusively the term cephalalgia, as answering to our English word *headach*, arranging under it the more marked distinctions of *headach* as species and varieties.

From the intimate connection which subsists between the sensorium and every other part of the system, it is not surprising that the head should participate in the morbid affections of those parts. Disorders of the stomach, liver, intestines, and uterus, especially, have long been observed to pro-

duce pains of the head. Nosologists have accordingly specified many kinds of *sympathetic cephalalgia*; but they have not been equally successful in pointing out the kinds of pain which arise from the diseases of the head itself. In truth, the difficulty of such an undertaking seems to have deterred them from making the attempt. They have too readily acquiesced in the opinion that, with the exception of some organic lesions of the brain, pain of the head almost always arose from morbid affections of other organs. Even the philosophic Cullen has given cephalalgia no place in his nosological system. Yet it would be truly astonishing if the head, itself so susceptible of impression from disorders of other parts of the system, should not suffer pain from some of its own. Many serious structural changes may indeed take place within the head unaccompanied by pain; but it is impossible to deny that numerous other morbid conditions of the brain and its meninges, as well as of the cranium and its coverings, do produce headaches of various and distinctive characters, and requiring a corresponding variety in the treatment.

One of the difficulties connected with the investigation of *headach* arises from the gradual and almost imperceptible conversion of pain, originally sympathetic, into an independent affection, which may remain long after the primary disease has been removed. Thus dyspeptic headaches not unfrequently induce permanent disorder in the head, remaining perhaps for months or years as the habitual malady, although the original symptoms of indigestion may have been entirely lost.

Another source of obscurity may be traced to the frequent coexistence of disease in the head and in some other organ with which the head peculiarly sympathizes; each disease serving to influence and aggravate the other. Under such circumstances it is sometimes difficult to determine which was the original malady.

Allied to this difficulty is a third, arising from the simultaneous operation of several of the more powerful exciting causes of *headach*; such, for example, as immoderate mental excitement and stimulating potations, both upon the head and upon the stomach. Thus, intense application of mind may not only excite *headach* by its direct action upon the brain, but may at the same time produce evident disorder of the digestive organs. Without careful discrimination, such a *headach* would probably be ascribed solely to dyspepsia, to the neglect of the actual state of the brain; whereas the derangement of both head and stomach may be alike dependent on the undue excitement of the sensorium.

In no disease, perhaps, does the subject of *pre-disposition* require to be more attentively considered than in cephalalgia. Of the circumstances which especially predispose to *headach* we may enumerate the following:—

1. Original malformation of the head.
2. A highly susceptible state of the nervous system.
3. Debility, however induced.
4. General or local plethora.
5. The previous occurrence of congestive or inflammatory disease.
6. Habitual or frequent excess in wine, spirits, and other powerful stimulants.
7. Injuries of the head from blows, falls, &c.
8. Continued mental excitement.

The occasional or *exciting causes* of *headach*

are very numerous. Some of them would produce the disease in almost any individual, even under ordinary circumstances; but the greater number only excite pain of head in persons already predisposed to the malady. Hence the great importance of estimating the degree of predisposition. Of the more frequent occasional causes we may specify:—

1. Rheumatic affection of the pericranium.
2. Inflammation, or a more chronic morbid condition, of the pericranium.
3. Inflammation of the mucous lining of the frontal sinuses, or foreign bodies within the sinuses.
4. Intense mental excitement.
5. Strong impressions on the external senses.
6. Excessive impetus of blood to the head.
7. Impeded return of blood from the head.
8. Congestion within the head.
9. Suppression of accustomed evacuations.
10. Inflammation of the brain or its membranes.
11. Tumours, or other morbid changes of structure within the head.
12. Morbid affections of the stomach:—as from over-excitation or distension; from irritating ingesta; from imperfect digestion; the presence of bile in the stomach, &c.
13. Costiveness.
14. Narcotics.
15. Worms.
16. Diminished pressure of the atmosphere.
17. A heated, humid, or deteriorated atmosphere.
18. Sudden changes of temperature.
19. Exposure to a current of air, or to a cold wind, especially from the east.

This enumeration will sufficiently show the impossibility of treating separately every variety of headach in a work like the present. Some leading distinctions of cephalalgia can alone be attempted; and such, we apprehend, may be satisfactorily comprised in the following species:—

1. Cephalalgia muscularis.
2. ————— periosteosa.
3. ————— congestiva.
4. ————— organica.
5. ————— dyspeptica.
6. ————— periodica.

Of these we shall now proceed to treat separately.

I. Cephalalgia Muscularis.—This kind of pain is essentially of a rheumatic character, and particularly affects the occipito-frontalis and temporal muscles. The pain is tensile and remitting, sometimes diffused over the greater part of the head; at other times, varying its situation from the forehead to the vertex or the occiput, or from one side of the head to the other. In some cases, also, the pain extends to the face and teeth. Not unfrequently, the muscles of the neck and shoulders are at the same time affected with fugitive pains. The action of the affected muscles remarkably increases the pain and tension, as does also even slight pressure upon the scalp. The attack may be usually traced to some partial exposure to cold or humidity, as by sitting near an open window, or standing in a current of air after being heated by exercise. It is often preceded by a sense of coldness over the head and along the sides of the face. Some disturbance of stomach usually attends it for the first day or two, accompanied sometimes with slight febrile excitement of the system. These symptoms generally soon subside, even without medical treatment; leaving, however, an increased susceptibility in the parts to a renewal of the complaint from very slight causes. A dose of calomel and antimony, aided

by a pediluvium, at night, and followed by a brisk aperient dose in the morning, considerably expedites the departure of the pain. In some cases of peculiar severity, diaphoretic remedies are required; and if the pain be very acute, leeches to the temples will afford considerable mitigation. But the principal aim of the practitioner should be to prevent a recurrence of the attack, by directing the patient to be much in the open air; to use a shower-bath daily, or, in its stead, the free affusion of cold water over the head; and every other practicable method of restoring the tone of the affected parts, and thus enabling them to resist the influence of cold and humidity.

II. Cephalalgia Periosteosa.—This is an unusual form of headach, and has not, we believe, been hitherto described by authors. The writer of this article first pointed out its nature in a paper read before the Westminster Medical Society in the year 1825. In many particulars, the periosteal headach resembles the muscular. As in that species of cephalalgia, the pain is diffused, tensile, and remitting, increased by pressure and by the action of the occipito-frontalis and temporal muscles. It may also be generally traced to the same exciting causes, humidity and sudden changes of temperature. The very parts affected in the merely muscular headach are equally involved in this; but, in addition, the periosteum is also affected, and the sensorium suffers more excitement. The pain itself is more deeply seated and intense, and is attended with an augmented action of the external arteries of the head, as well as with more gastric and general febrile disturbance. The attack, moreover, does not so speedily subside; for although after a few days the muscular covering of the head can be moved without pain, and slight pressure no longer produces uneasiness, yet the periosteal pain and tenderness remain. Firm and deep pressure is still painful, and excites a sensation of distressing tension over the greater part of the head and face. The same kind of constrictive pain is produced almost invariably by going out of a warm into a cold room, or by taking off the usual covering of the head. The whole periosteum, indeed, of both the head proper and the face is implicated in the disease, although those parts of the membrane suffer most which are but slightly covered. Hence, the upper portion of the nose and the alveolar processes are particularly affected. We may here remark, as a striking proof of the periosteum itself being the immediate seat of the malady, that the pain is frequently transferred for a time from the head to the face, soon, however, returning to its more accustomed seat around the head. It is not less remarkable that an increased feeling of tension may be induced over the whole or the greater part of the head and face by firm pressure upon any one point of the periosteum, whether of the head or of the face. Hence we may conclude that the structure affected is one common to both head and face.

It may, perhaps, be supposed that the periosteal cephalalgia now described is only an aggravated form of rheumatic headach. It is, however, a far more complicated and intractable malady, and occurs, we believe, only to those who have previously suffered from continued cerebral excitement. In truth, a two-fold predisposition appears to be

essential to its production:—first, a highly susceptible, if not also preternaturally vascular condition of the brain or its membranes, such as is often induced by long-continued study, or high mental excitement, as well as by the frequent occurrence of sympathetic headach arising from gastric or hepatic disorder: and secondly, a state of debility and exhaustion supervening upon that excited condition of head, whether occurring spontaneously, or as the result of the depletory measures employed for the removal of the previous cerebral excitement. If an individual, under these concurring circumstances, be exposed to a powerful exciting cause, such as a sudden diminution of temperature, especially if accompanied by humidity, he may have the periosteal cephalalgia induced,—a disease of a singularly obstinate character, and apparently maintained by that condition of the brain or its membranes, which existed prior to the supervention of the external malady. On the other hand, the pain and irritation connected with the external malady tends, in its turn, to perpetuate the morbidly excitable state of the brain. The following case may serve as an illustration.

A gentleman of a susceptible constitution, who had long been subject to occasional attacks of dyspeptic headach, and had frequently suffered from mental application during a long and laborious course of study, was thrown at once into the onerous duties of a large public institution. Much pain and excitement of head ensued. General and local bleeding, mercurial purgatives, antimony, low diet, &c., were considered necessary. The symptoms subsided considerably, but the brain and nervous system remained in a state of extreme susceptibility. On some recurrence of pain, it was judged needful to shave the head, which happened to be done under circumstances of great exhaustion on a cold wet evening. The ordinary covering of a thin night-cap was alone worn during the night. On awaking from sleep, a severe constrictive pain was felt over the whole head, attended with heat and tenderness of the scalp, throbbing of the temporal arteries, considerable cerebral excitement, and vomiting. In truth, an external periosteal disease was thus engrafted upon a head previously suffering from high and continued excitement. After a few days, the more superficial tenderness subsided, but the periosteal affection proved exceedingly intractable. In this case it seems probable that the frequent occurrence of sympathetic headach, aided by the excitement attendant on long-continued study, had induced an undue degree of vascularity and of nervous susceptibility in the head generally; while the remarkable prostration of vital power consequent upon the depletory measures employed, served to increase the nervous susceptibility, and thus concurred to form that two-fold predisposition of which we have before spoken, and without which, we apprehend, the subsequent exposure to cold and humidity would have been insufficient to excite this peculiar periosteal cephalalgia, although it might have produced an ordinary rheumatic affection of the scalp. So exquisitely sensitive does the pericranium remain in these cases, so readily affected by every exposure to humidity or sudden reduction of temperature, and so apt to participate in every occasional excitement of the brain, that

one attack of the complaint has scarcely time to subside before some fresh exposure gives rise to a decided augmentation of disease.

In the treatment of periosteal headach the first object must be to lessen the general cerebral excitement, as well as the inflammatory tendency and morbid sensitiveness of the affected membrane. Local bleeding, mercurial purgatives, antimonials, the acetate or citrate of ammonia, and similar means, are best adapted to fulfil these indications. Opiates are of doubtful efficacy. Should much nausea occur at the commencement of the attack, an emetic would be advisable; after which a dose of calomel and antimony, followed by a saline purgative, will generally be found very advantageous. The utmost quietude of mind should be preserved.

After the acute symptoms have been subdued, vigilant attention will be necessary to guard against a relapse. The susceptibility of the pericranium may be moderated by the gradual use of cold washing, followed by gentle friction of the head, as well as by a free though prudent exposure to the open air in the way of carriage, horse, and walking exercise. A residence in a dry and somewhat elevated situation will materially conduce to the patient's recovery. But it must also be remembered that the morbid condition of the membrane may be maintained by undue cerebral excitement, and that therefore the discipline of the mind, the avoidance of intense or long-continued study, and every engagement and pursuit which may tend to perpetuate that excitement, are absolutely essential to a permanent cure.

Under the division of periosteal headach it may be proper to describe that affection of the pericranium which has been called by Mr. Crampton *periostitis*. (Dublin Hospital Reports, vol. i.) Cases in some respects similar had been previously published by Sir Everard Home, (Trans. of the Soc. for the Improvement of Med. and Chir. Knowledge, vol. iii.) and some important illustrations of the same subject have been recently added by that accurate and distinguished pathologist, Dr. Abercrombie. (On Diseases of the Brain and Spinal Chord.) Fixed pain of the head and tenderness of some portion of the scalp, with a degree of thickening and swelling of the integuments, were the characteristic symptoms. The periosteum was generally found thickened, and, in some cases, the bone itself diseased. In the majority of instances, some affection of the brain co-existed with the periosteal disease. It would seem probable, however, that the periosteum was primarily affected in several of the cases adduced; in those, particularly, in which complete and permanent relief followed the division of the pericranium and the keeping open of the wound for a considerable time. Yet it must be allowed that even pains of head, apparently connected with internal as well as external disease, have been essentially relieved by such an operation. Mr. Brodie and the late Mr. Pearson have repeatedly cut down to the bone in cases of fixed and obstinate pain confined to a limited part of the head, maintaining afterwards a free discharge from the part, and with very decided success.

We might here without impropriety have introduced another kind of headach—that depending

on a diseased state of the bones of the cranium, and attended with constant pain and tenderness at some particular spot; but as such cases are comparatively rare, we are unwilling to present it as a distinct species.

III. Cephalalgia Congestiva.—This species is characterized by an obtuse pain affecting the whole or a part of the head, particularly the forehead and occiput, and is frequently attended with a feeling of general oppression and torpor. It may be observed in three different states of constitution:—in the plethoric; in the delicate and irritable; and in the weak and leucophlegmatic.

1. The congestive headach frequently attacks persons of a *plethoric* habit, who have passed the middle period of life, have lived freely, and have used but little bodily exercise. In such the countenance is often bloated, the eyes are full and red, the veins of the face distended, and the general expression dull and inanimate. It is more especially observed in those who have suffered from gout or from chronic diseases of the liver, and after the cessation of the catamenia. In such it must always be regarded with vigilant attention, as indicative of an apoplectic or paralytic tendency.

2. The congestive cephalalgia also affects the *delicate and irritable*, especially those whose minds have been injudiciously cultivated at the expense of their bodily health and vigour. Hence it is most frequently observed in the female sex. In persons of this temperament the sanguineous circulation is so nicely balanced as to be disturbed on very slight occasions. A vivid emotion of mind, earnest or continued conversation, an unusual degree of bodily exercise, or some irregularity in diet or in the action of the bowels, will occasion in such habits an increased impetus of blood to the head, which, though only producing at the time a sense of heat and excitement, is generally followed by coldness of the legs and feet, and by the dull, oppressive headach of which we are now treating. In some cases the pain is attended with flashes of light or with little floating specks before the eyes, as well as by noises in the ears. This species of headach is particularly observable in delicate females of an irritable temperament, both before and for a day or two after each menstrual period.

3. The congestive headach also attacks the *weak and leucophlegmatic*. It may be recognised in persons who have been reduced by acute diseases, by hemorrhages, leucorrhœa, &c. It is also seen in chlorosis and in various other asthenic conditions of the system. There is usually a slow and languid pulse, a pale, sallow, or even semi-transparent appearance of the skin, and a peculiarly heavy expression of countenance. The lips are generally pale, or of a slightly blue tint; the feet are apt to swell in hot weather or after exercise; and every muscular exertion becomes laborious and formidable. In this variety of congestive headach, the pain is most commonly in the forehead, although in some cases the occiput is chiefly affected.

The *treatment* of congestive cephalalgia must necessarily be adapted to the circumstances of each individual case. We may remark that, in the first variety, that which is incident to the plethoric habit, venesection or cupping, brisk purgatives, a moderate diet, the affusion of cold water upon the head, and stimulating pediluvia, are usually required.

When the attack has been subdued, the patient should be directed to avoid much mental application; to observe regular habits of exercise in the open air, as well as great moderation in diet, and a careful attention to the state of the bowels. The shower-bath should also be daily employed.

In the congestive headach of the weak and irritable, it may be sometimes necessary to have recourse to topical bleeding; but, generally quietude of mind, a stomachic aperient, the application of cold to the head, either by the affusion of water or by evaporating lotions, stimulating pediluvia, and the exhibition of camphor and ammonia or other diffusible stimulants, will prove adequate to the removal of the attack. Every precaution should be used to prevent a recurrence of the complaint by increasing the tone of the system, and thus counteracting the undue susceptibility of impression and the irregular distribution of blood, with which the malady is peculiarly connected.

The third variety of congestive headach, that occurring in the weak and leucophlegmatic, requires nearly the same management as the last. In this, however, the loss of blood can scarcely ever be necessary, although blisters are sometimes indicated. Warm and cordial aperients, the moderate use of wine, camphor, valerian, or ammonia, aided by a mustard or other stimulating bath for the feet, are well adapted to remove the immediate pain; while good air, gentle exercise, a nutritive diet, cheerful society, with the assistance of tonic remedies, more particularly the lighter preparations of steel, are not less calculated to invigorate the constitution, and thus preserve it from future attacks of the complaint.

We now proceed to a very important division of our subject, viz. headach arising from organic disease within the cranium: this we have ventured to name, although the term is not unexceptionable.

IV. Cephalalgia Organica.—So numerous and complicated are those morbid changes of the brain and its membranes which have been found to produce headach, that we must content ourselves with a reference to the most frequent of them; endeavouring chiefly to point out the principal symptoms which distinguish the organic headach from cephalalgia arising from other causes. Among the structural changes productive of headach, tumours are undoubtedly the most frequent. These may be either imbedded in the substance of the brain, or attached to its surface, or to the membranes surrounding it. Such tumours may be of a pulpy, adipose, albuminous, cartilaginous, scirrhus, or even bony consistence. Hydatids are another cause of headach, as are also spiculae of bone attached to the dura mater, or growing from the inner table of the skull. In a case which occurred to the writer a few weeks ago, one of the clinoid processes of the sphenoid bone was found unusually long and formed into a thorny point, so sharp and strong as to pierce the finger when pressed against it. A similar, though not equally long point, was found to have grown from the squamous portion of the temporal bone. In some instances the membranes of the brain have been found thickened and partially disorganized; in others a portion of the brain has exhibited a softening or degeneration of its structure, or one or more abscesses imbedded within its substance.

In many of these diseased conditions, the pain of head may remain, during a considerable period, unattended by any other prominent symptoms: at length, however, some decisive indication of inflammatory action or of cerebral pressure occurs; the sight or hearing, for example, becomes affected, or the powers of the mind become enfeebled, or simple convulsion, epilepsy, or paralysis announces the extension of disease.

The diagnosis of cephalalgia organica is often difficult at an early period, while the pain is unattended by any morbid affection of the senses or of the moving powers. In general, however, we may remark that the pain itself is more fixed, deep-seated, and habitual than in other kinds of headach; more independent of the state of the stomach; more obviously increased by mental application, by close or heated rooms, by stooping, and sometimes even by the horizontal posture. The same degree of cheerful conversation which would chase away, or at least suspend the feeling of ordinary headach, often becomes laborious and almost insupportable in organic cephalalgia. Nor is the effect of stimulants received into the stomach less remarkable. Wine and other fermented liquors produce an immediate aggravation of pain. When the disease has considerably advanced, even a slight motion of the head will sometimes give rise to extreme suffering, and also to vomiting. It is proper to add that the disturbance of stomach which is sometimes present in this species of headach may occur without any apparent disorder of the stomach itself, and in this respect, as well as in others, differs materially from the sickness incident to dyspeptic headach. Moreover, the pain in organic cephalalgia equally remains when the sickness ceases. We have said that the pain in organic headach is fixed and habitual. There are, however, exceptions to this general rule. Sometimes the pain is of an intermitting character, although serious structural mischief may be steadily advancing. In such cases, the most vigilant attention to the collateral symptoms will be required before the real nature of the case can with any reasonable probability be determined.

V. Cephalalgia Dyspeptica.—This may be regarded as the most frequent kind of headach. In many individuals it is induced by very slight errors in diet, or even by remaining somewhat longer than usual without food. It may occur without any remarkable or at least very obvious degree of susceptibility in the brain. We see it, for example, in persons who can bear close application to study without any apparent inconvenience to the head itself, while yet very liable to headach from taking certain articles of food, or mingling them in too great a variety. Yet, in the majority of instances, it must be allowed that dyspeptic headach is most frequently found in those persons who also suffer from much mental excitement, and in whom the gastric disturbance is only one effect of that excitement. In such, the stomach may become either morbidly irritable or in the opposite state of atony, being, in either case, equally unfit for the due performance of the digestive functions, and therefore liable to be still further deranged by any irregularities in diet. The dyspeptic or stomach headach, when severe, more particularly affects the left temple, extending some-

times over the same side of the forehead, and producing tenderness in the corresponding ball of the eye. In other instances, the whole forehead, or even the greater part of the head, becomes painful. The pain may be either dull and oppressive, or of a more acute character, and in both cases renders mental exertion difficult and irksome. It is not unfrequently attended with some tenderness of the scalp, and an increased pulsation of the temporal arteries. The paroxysm of dyspeptic cephalalgia usually commences when the patient first awakes in the morning from a heavy sleep. The pain, at first diffused and oppressive, gradually concentrates itself upon one or other temple, generally the left, and becomes more and more acute. A degree of nausea often supervenes, sometimes increasing to sickness and vomiting. If the latter occur, the remains of an undigested meal, or merely an insipid fluid mixed with frothy mucus, is perhaps first ejected; but if the action of vomiting continue long, some admixture of bile usually follows. In some instances the stomach throws off, on the first attempt, green or yellow bile, or a fluid extremely acid and irritating; in which case, the pain of head is sometimes immediately relieved.

If neither vomiting nor aperient medicine be employed to check the ordinary progress of the paroxysm, the pain generally becomes more severe as the day advances, until it is lost in sleep. Occasionally, it remains during the greater part of the second day. When, however, an active dose of purgative medicine has been taken, the headach often becomes less in two or three hours, and ceases altogether in six or eight. It is remarkable that the beneficial effect of a stomachic and antacid purgative is frequently felt long before the offending matters are expelled from the bowels, clearly indicating that the sources of irritation were either in the stomach itself, or in the upper portion of the intestines.

Such is the usual course of a sick headach when occurring as a distinct paroxysm. The dyspeptic cephalalgia may, however, exist in a more chronic and habitual form, and in every possible degree. It may also be very transient in its duration. Many individuals suffer more or less inconvenience after every principal meal, unless they limit themselves, with the utmost prudence, in respect to the kind and quantity of food; but after two or three hours, the pain of head spontaneously ceases. When the stomach itself suffers from irritating ingesta, drowsiness or headach rather quickly succeeds, attended sometimes with confusion of thought and dimness of sight. In such cases, a mild emetic affords immediate relief. In many instances, however, the pain is not felt until several hours have elapsed, and is then accompanied with a sense of tightness and distension of the scalp and stiffness of the eye-balls. Sometimes the patient sees a mist before his eyes, or even luminous and coloured appearances, before the headach comes on. Under these circumstances, there is reason to believe that the *duodenum* is principally irritated; an opinion which is rendered probable by the sense of distension and uneasiness which is often felt in the exact situation of that bowel. It is sometimes, indeed, fully confirmed by the fact that an emetic under such circumstances does not afford relief, nor even

evacuate any thing material from the stomach; while, on the contrary, a dose of magnesia, either alone or combined with rhubarb or epsom salt, will in two or three hours relieve both the headach and the uneasiness existing along the course of the duodenum. Yet it is proper to add, that when the irritating cause is considerable, both the stomach and duodenum remain in a state of disturbance during several hours.

In a very able paper on headach, inserted in the fourth volume of the Medical Transactions of the Royal College of Physicians, Dr. Warren maintains that the headach arising from irritation of stomach differs considerably from that which is produced by disturbance in the duodenum; that the former "is attended more with confusion than pain," while the latter is characterized by a dull aching of some parts of the head, "coldness and tightness of the scalp, slight giddiness, weight, pain, distension and stiffness of the eye-balls," and sometimes temporary numbness and tingling of the fingers and hand. Although feeling the greatest confidence in Dr. Warren's accuracy of observation, we have not been able satisfactorily to determine that the latter symptoms may not also occur from irritation of the stomach itself as well as of the duodenum; nor are we convinced that the duodenum can be irritated to such an extent, by matters which have lately been propelled from the stomach, as to produce a high degree of cephalic irritation, without its contiguous organ, the stomach, being at the same time somewhat implicated in the disturbance.

The exciting or immediate causes of dyspeptic cephalalgia are sufficiently obvious: long fasting; excess in wine or other powerful stimulants; or in the quantity, quality, or variety of solid food, are among the principal. Particular articles of food, likewise, which are innoxious to most persons, become irritating to certain individuals. But it must not be forgotten that the efficiency of the exciting cause bears an important relation to the amount of predisposition; an article of food, for example, may produce headach to-day, if the stomach or the brain, or both, be unusually excitable, which would not have produced it yesterday when those organs were less susceptible of irritation. Hence the importance of particular investigation with respect to the previous state of the head, as well as of the digestive organs. In many instances it will be found that sedentary habits, excessive mental application, anxiety, the hurry of business, and similar causes, have gradually induced a strong predisposition to headach, although the tendency may not have been developed until some error in diet, acting as the exciting cause, gave rise to gastric disturbance, and thence to sympathetic pain in the head. In truth, a two-fold predisposition may be often said to exist, involving both the head and the stomach. In some cases mental excitement would seem to precede the morbid affection of the stomach. In persons of great susceptibility, a very high degree of cerebral excitation appears to be inconsistent with an adequate supply of nervous energy to the digestive organs; as if there were but a certain portion of vigour to be shared by the different parts of the system, and, consequently, that an undue proportion allotted to one occasioned a corresponding

deficiency in the rest. The fact, however, is incontrovertible, that in many susceptible individuals, intense engagement of mind induces a powerless state of stomach and duodenum, giving rise to dyspepsia and the headach arising from it.

Not uncommonly cerebral excitement occasions a rapid and profuse secretion of bile, which, in its turn, produces a sick or bilious headach in its severest form. We have repeatedly seen the same effect follow an unusual degree of bodily exercise; in which case, it is sometimes attended with both vomiting and purging of a highly bilious character.

The dyspeptic cephalalgia chiefly occurs in early or in middle life, becoming less and less severe as the irritability of the system gradually declines. Sometimes, however, as life advances, there is an apparent transfer of irritability from the stomach to the bowels. Frequent diarrhoea takes the place of bilious headach, being excited by the same circumstances.

The treatment of dyspeptic headach requires a careful adaptation to the peculiarities of each case. An ordinary paroxysm of the pain, if attended with much nausea, may be considerably shortened by an ipecacuanha emetic, afterwards allowing to the stomach and to the head an interval of entire repose. After an hour or two, twenty or thirty grains of magnesia combined with rhubarb, or the sulphate of magnesia and an aromatic, may be given, and followed, after some hours, by a little bland farinaceous nourishment. Where no particular nausea is felt, the antacid aperient may be given at the first. A few grains of the subcarbonate of ammonia, or thirty or forty minims of the aromatic spirit of ammonia may be added with advantage, when the stomach is peculiarly irritable.

In the milder and more chronic forms of dyspeptic headach, much will depend on the discipline of the mind and the regulation of the table. Every individual may be able, by proper attention, to ascertain what kinds of food and what quantity of food he can comfortably digest; and under what particular circumstances the symptoms of indigestion and headach have generally arisen.

A little observation will also discover the connection which subsists between that state of tone and vigour of the whole system which regular bodily exercise induces, and the power of the stomach itself. Thus it will be found that the same kinds and quantity of food which perfectly agree while the individual takes his daily walk in the open air, and employs his brain within moderate bounds, become sources of indigestion and headach when the head is allowed too much duty and the feet too little.

The daily management of the bowels is an object of great importance in this kind of headach. When diet and exercise prove insufficient to secure a daily motion, a mild stomachic aperient, combined, perhaps, with an alkali, may be given every night, or on alternate nights, until the tendency to constipation and headach be overcome. When, however, there appears to be much *duodenal* indigestion, a few grains of rhubarb, or a grain or two of aloes, taken before dinner, will be a preferable mode of increasing the propulsive power of the intestines. We cannot, however,

recommend this as a general mode of regulating the bowels; being convinced that it often accelerates, in an injurious degree, the peristaltic action, and deprives the system of a part of the nourishment which would otherwise be received by absorption. Persons have been found to become manifestly thinner under such a plan. When, as indeed often happens, the biliary secretion is irregular or defective, a mild mercurial preparation may be given for a few successive or alternate nights. Occasionally some aromatic bitter, either with or without soda or ammonia, may be employed with advantage. Horse-exercise, if it be not used to the exclusion of walking, is often extremely beneficial. The shower-bath, or cold sponging, aided by friction of the skin and moderately warm clothing, are also powerful auxiliaries.

VI. Cephalalgia Periodica.—This kind of headach is said to be sometimes hereditary. It may have regular or irregular accessions, and may occur in a quotidian, tertian, or quartan form. It has returned periodically at the regular intervals of several weeks or even months. Most commonly it observes daily accessions, returning either in the morning or at noon. Sometimes a very limited portion of the head, a small spot, is alone affected. Not unfrequently the pain commences at the inner angle of the orbit, producing pain, redness, and tenderness of the eye, and extending towards the nose. This has been popularly called *megrim*. In other instances, one entire half of the head and face is affected, constituting the *hemicrania* of authors. The pain is sometimes so acute as to resemble that of *tic douloureux*; but it may generally be distinguished from the latter by its more regular periodical accessions, by the longer duration of each paroxysm, and by the more complete and protracted intermissions. In many cases, too, the periodic cephalalgia is obviously connected with existing rheumatism or catarrh. The pain of *tic douloureux*, on the other hand, is generally very sudden in its attack, and quite excruciating in its degree, but lasts only for a few seconds. It returns at indefinite periods, being readily excited by the slightest exposure to a current of air, or by the motion of the jaws in eating or speaking. The cephalalgia periodica also bears some resemblance to the muscular or simply rheumatic headach; from which, however, it may generally be distinguished by the greater regularity of its accessions; by its usually affecting a circumscribed portion, or, at most, one side of the head and face; and more particularly, by its frequent connection with intermittent fever. Sometimes, indeed, it appears to be the direct effect of an exposure to malaria, although unattended with the ordinary phenomena of fever. In other instances, a carious tooth or some lesion of the antrum highmorianum has appeared to produce and maintain the disease. Accordingly, the extraction of the afflicted tooth has entirely removed the cephalalgia.

As in every other species of headach, a careful consideration of the peculiarities of each individual case can alone lead to a discriminating and successful treatment. Where no local irritation can be traced, and no congestive symptoms about the head appear, cinchona in substance, or the

sulphate of quinine, may be exhibited in the intervals, as soon as the bowels have been thoroughly cleansed by a dose of calomel conjoined with rhubarb, jalap, or some other effective purgative. In some peculiarly obstinate cases, it may be right to have recourse to the arsenical solution, preserving, at the same time, a regular state of bowels by some mild aperient, in combination with the pilula hydrargyri or the compound pill of the submuriate of mercury. Where the paroxysms are extremely violent, much relief may be often gained by a full opiate conjoined with the compound spirit of sulphuric ether, given just before the expected accession. In the more limited forms of the periodical cephalalgia, the extracts of belladonna and opium, applied to the part affected, sometimes afford considerable mitigation.

[In all the forms of nervous headach, immediate relief is often afforded by the application of strong counter-irritant lotions to the forehead and temples. For various forms of application, and especially for those of Granville and Raspail, the reader is referred to the article COUNTER-IRRITATION.]

In one of the most severe cases of hemicrania that ever fell under the writer's attention, and which, (under the idea that encephalic hyperæmia existed,) had been treated by bloodletting on each attack, so that the patient, a female, was compelled to be bled once or twice a month, and when the writer first saw her, was highly anæmic and impressible, subcarbonate of iron, given in large doses, (℞i.—℞ii. three times a day,) entirely restored her to her family, to which she had been wholly unable to attend for months previously. Since that time—many years ago—she has had no attack.]

T. H. BURDER.

HEART, (DISEASES OF THE)—Diseases of the heart were, until recently, supposed severally to present symptoms of very much the same general character, and therefore to constitute a class of maladies which possessed considerable unity in their intrinsic nature. They are now, however, found to consist of a variety of distinct affections producing very different and sometimes opposite symptoms. Thus, hypertrophy produces increased, and dilatation diminished force of the circulation. In order, therefore, to appreciate the value, and familiarize ourselves with the nature, of each class of symptoms, it is necessary to study the several affections in an isolated form. We are thus enabled, on meeting with a *compound* case—one consisting of a complication of several of the simple affections—to analyze or unravel the symptoms, ascertain the relative importance of each class, and in this manner establish rational and secure principles of treatment. In conformity with this view, the various articles on the diseases of the heart, instead of being assembled under the present head, are, for facility of reference, diffused alphabetically throughout the work. We have here only to put the whole together in a systematic form, so as, by pointing out the affinities between detached articles, to enable the student to prosecute his studies in a consecutive form, and to find with facility any given article or topic to which he may wish incidentally to refer.

Physiology of the heart's action, and physical signs—healthy and morbid. In the article *AUSCULTATION* will be found a sketch of the physiology of the heart's action according to the principles of the writer, adopted throughout this work, and a general exposition of the principles of auscultation in reference to the heart. A more particular and differential account of the signs afforded by auscultation and percussion will be found in the several articles to which the signs respectively refer: viz.—in the article *HEART, (HYPERTROPHY OF THE)* are all the signs characterizing this affection, whether simple or combined with dilatation. In *DILATATION* are the signs of the simple and the attenuated forms of the disease; the other forms, with their signs, being comprised under *HYPERTROPHY WITH DILATATION*. In *DILATATION* the *range of sound*, and in *HYPERTROPHY* that of *impulse*, is more particularly described. Under *HEART, (DISEASES OF THE VALVES OF THE)* are the signs of all the varieties of this affection, with the diagnosis from analogous signs produced by nervous derangements: Under *AORTA, (ANEURISM OF THE)* are the signs of disease of the great vessels, with the diagnosis from nervous affections; and under *HEART, (MALFORMATIONS OF THE, and HEART, (POLYPUS OF THE)* are the peculiar signs, according to the writer's observation, of those maladies.

We would recommend the student to adopt the following arrangement of the articles in studying the various diseases of the heart consecutively. Inflammatory affections of the heart and great vessels, as they give birth to a large proportion of the organic diseases, should take precedence of the rest. Thus *PERICARDITIS* leads to *ANEURISM OF THE PERICARDIUM*, (which subject is discussed at the end of *PERICARDITIS*); and the latter leads to *HYPERTROPHY WITH DILATATION*. *CARDITIS* (which is treated of under *PERICARDITIS*) gives rise to *SOFTENING, INDURATION, DILATATION*. *ARTERITIS*, acute and chronic, contains an account of the morbid alterations of the valves and internal membrane of the heart and arteries, to which it gives origin. Under this head, also, the other probable causes of some of these alterations are fully discussed. *HYPERTROPHY* should next be studied. It embraces the varieties in which it is conjoined with dilatation. After reading this article the student should proceed to *DILATATION*, in order that, by contrasting the respective varieties, the mode of production, and the pathological effects of hypertrophy, and of dilatation, he may be enabled to form a just and comprehensive idea of the relative nature of the two affections. *DILATATION* presents an account of those varieties only in which the force of the heart's action is *not* increased: viz.—*DILATATION WITH ATTENUATION*, and some cases of *SIMPLE DILATATION*; those in which the action is increased being described under *HYPERTROPHY WITH DILATATION*. After reading *HYPERTROPHY AND DILATATION*, the student should proceed to *DISEASES OF THE VALVES*, as he is now prepared to understand how these produce their effects, and become causes of hypertrophy and of dilatation. *HEART, (DISEASES OF THE VALVES OF THE)* comprehends every variety of

these affections, with the signs physical and general; and also an account of cardiac asthma. The following diseases of the muscular structure may next be studied: *PARTIAL DILATATION, OR REAL ANEURISM OF THE HEART; SOFTENING; RUPTURE; INDURATION; FATTY AND GREASY DEGENERATIONS; PRODUCTIONS, (ACCIDENTAL); ATROPHY OF THE HEART. AORTA, (ANEURISM OF THE)* comprising an account of nervous pulsation of the aorta, forms an elaborate article, much original matter being added with a view to establish the diagnosis—one of great importance, and now, we trust, presenting little obscurity: the study of this subject should be deferred till the reader is acquainted with *HYPERTROPHY, DILATATION, and DISEASES OF THE VALVES*, as he will thus be better qualified to understand how disease of the aorta gives birth to that of the heart, and constitutes one of the most formidable complications of cardiac affections. *MALFORMATIONS, ANGINA PECTORIS, POLYPUS OF THE HEART, DISPLACEMENTS, HYDRO-PERICARDIUM, PNEUMO-PERICARDIUM, PALPITATION*, particularly nervous and dyspeptic, are severally brought under consideration in separate articles.

Treatment.—In the article *PERICARDITIS*, the treatment of the inflammatory affections is fully considered. A few remarks are also appended to *ARTERITIS*. In *HYPERTROPHY AND DILATATION* respectively, the observations on treatment are confined to the immediate and peculiar effects of each disease; while *HEART, (DISEASES OF THE VALVES OF THE)* is a general article on treatment, not only embracing all the secondary effects, but giving a detailed account of the manner of exhibiting, and the *modus operandi* of the various remedies employed. In *AORTA, (ANEURISM OF THE)* the mode of spontaneous cure and the medical treatment are fully explained, and remarks are added on the treatment of nervous aortic pulsation.

We shall conclude this brief explanatory and indicative notice with a few remarks on the diagnosis and treatment of cardiac affections in general.

Diseases of the heart were formerly involved in deep obscurity. This is no longer the case. By a *conjunction* (and the necessity for this conjunction cannot be too strongly impressed) of the *physical* signs, or those afforded by auscultation and percussion, with the *general* signs, improved as they have been in consequence of being studied with the aid of auscultation, the diseases in question may be detected with a facility and precision which can scarcely be surpassed in any other class of affections. The *direct* practical advantage resulting from this is, that instead of being almost incurable, as they were formerly regarded in consequence of seldom being detected till they had attained an incurable degree, they now, from admitting of detection even in the earliest stage, can in numerous instances be completely cured; and when not, can in general be so far counteracted as not materially, and often not at all, to curtail the life of the patient. The *collateral* practical advantages are no less important. Apoplexy and palsy, in a scarcely credible number of cases, are directly dependent on hypertrophic enlargement of the heart. Should the cause be detected, the

effect may be obviated; should it be overlooked, the patient would probably fall a martyr to the "active exercise" supposed necessary to reduce his *apoplectic fulness of habit*. No less frequently are the most dangerous cases of asthma, of dropsy, and of epilepsy, referable to disease of the heart; and this malady seldom occasions long-continued obstruction of the circulation without producing enlargement of the liver,—one of the least generally known of the common facts in medical science. Nervousness and dyspepsia very often assume the aspect of disease of the heart; and this, on the other hand, being frequently productive of nervousness and dyspepsia, may be disguised by, and mistaken for them, though with the aid of auscultation the diagnosis presents no difficulty. In acute rheumatism the most formidable source of danger is inflammation of the pericardium. Inflammation of the lungs supervening on organic disease of the heart is singularly rapid, uncontrollable, and destructive. In fever and inflammation in general, the state of the pulse as to fulness, hardness, weakness, or irregularity, may be completely disguised by a co-existent disease of the heart. In all the above instances the appropriate treatment would differ widely and perhaps entirely from that which the practitioner would probably adopt were he to remain ignorant of the affection of the heart.

This brief sketch is sufficient to display the extensive relations and vast importance of the subject of cardiac affections, and to show, that unless the practitioner be conversant with it, not only may he compromise the safety of his patient, but his reputation must be responsible for many mortifying falsifications of his diagnosis, and for the blind impression that danger was remote when it was at the threshold.

HEART, (DILATATION OF THE)—The disease commonly known by this name consists of an amplification of one or more of its cavities. The ventricular parietes may be thickened, natural, or attenuated. The disease accordingly resolves itself into three varieties, corresponding with these states.

1. *Dilatation with thickening*, in which the cavity is enlarged and the walls are thickened.

2. *Simple dilatation*, in which the cavity is enlarged and the walls are of their natural thickness.

3. *Dilatation with attenuation*, in which the cavity is enlarged and the walls are attenuated.

The first variety is identical with that variety of hypertrophy called hypertrophy with dilatation, different names being employed for the two, in order to express, in dilatation with thickening, a predominance of dilatation, and, in hypertrophy with dilatation, of hypertrophy. The second variety is perfectly identical with hypertrophy by increased extent, with natural thickness of the walls; but the term simple dilatation is preferable when the dilatation is so great that its symptoms predominate over those of hypertrophy. Two, or all three of the forms of dilatation are sometimes found together in different parts of the same cavity.

The anatomical characters of simple dilatation and that with thickening will be described in the article on **HYPERTROPHY**. To dilatation with

attenuation we here direct our attention. It seldom affects one ventricle without the other. The emaciation may be such as to reduce the most substantial part of the left ventricle to two lines in thickness, and the apex to a mere membrane, of which we have seen more than one instance. Extreme attenuation is more common in the right than in the left ventricle. In either, the columnæ carneæ appear stretched and spread. The inter-ventricular septum is proportionably much less attenuated and softened than the other parts. Dilatation takes place more in the transverse than in the longitudinal direction of the ventricles, and it accordingly communicates to the heart an unusually spherical form, so that the diameter of the organ near the apex is almost as wide as at the base, the apex itself being often scarcely distinguishable. This alteration of shape is the best criterion for determining whether a heart be dilated or not when the enlargement is so inconsiderable as to render the question doubtful. When both the auricle and ventricle are much dilated, it is not unusual to find the intermediate aperture widened, and its valve sometimes not large enough to close it. The muscular substance, sometimes healthy in every form and degree of this affection, in general is not so. For, when the organ is considerably enfeebled, its parietes are usually more or less softened and flaccid, and in some cases of a deeper red, (a consequence of venous engorgement,) in others paler or more fawn-coloured than natural.

Dilatation may give rise to rupture of the heart, especially as it is so often attended with softening. We witnessed a case of this kind a few years ago, and are acquainted with others.

In order to judge accurately of dilatation of the auricles, it is necessary to have distinct ideas respecting their natural form and dimensions. The four cavities of the heart are very nearly equal in capacity; but, as the parietes of the auricles are thin, and those of the ventricles are comparatively thick, the auricles, when merely full, and not distended, form only about one-third of the total volume of the organ; or, what is the same thing, the volume of the auricles equals about half that of the ventricles. (*Laennec, de l'Auscult. tom. ii. p. 523.*) The right auricle being of a more elongated, flattened form than the left, and being generally found in a state of distension, has the appearance of being considerably larger, though in reality it is only a little so.

Distension, taking place during the last moments of life, and observable, though more rarely, in the left auricle as well as in the right, constitutes the great source of fallacy in determining, after death, whether these cavities are really dilated or not; for the engorgement, though only of a few hours' duration, may stretch them to a magnitude almost equalling that of the ventricles.

M. Laennec has given good criteria by which a dilated may be distinguished from a distended auricle. An auricle simply distended is tense, and through its thinnest parts distinctly shows the dark blood within. One dilated does not present the same appearance of tension, and its parietes are more opaque. When the blood is evacuated through the vessels without cutting into the cavities, the latter, if merely distended,

return at once to nearly their natural size; whereas, if dilated, they maintain almost the same size as they had when full. Dilatation of the auricles is almost invariably accompanied with more or less thickening of their parietes.

The method of distinguishing distension from dilatation is much the same in the ventricles as in the auricles: namely, when merely distended, they are found enlarged, firm, and tense; but these conditions almost entirely disappear when the blood is pressed out through the natural apertures. On the contrary, when truly dilated, they have no appearance of tension, are more or less flaccid, and the enlargement persists after the blood has been evacuated.

Dilatation of the heart is a purely mechanical effect of over-distension. Blood, accumulated within its cavities, exerts a pressure from the centre towards the circumference, in every direction; and when once it surmounts the resistance offered by the contractile and elastic power of the parietes, these naturally yield and undergo dilatation. The rapidity with which this process takes place, and the extent to which it is carried, depend on the degree in which the distending exceeds the resisting force; and as the latter bears a direct ratio to the volume of the muscle, supposing it to be healthy, it follows that those cavities which have the thinnest parietes are, *cæteris paribus*, the most susceptible of dilatation. Accordingly, we find that the right ventricle is more frequently and promptly dilated than the left, and the auricles than either.

In order to produce permanent dilatation, the operation of the exciting cause must either be prolonged for a certain time, or frequently repeated at brief intervals. Contraction of an orifice, for instance, acts in the former manner; and nervous palpitations, or occupations requiring constant reiteration of muscular efforts, produce their effect in the latter way. When the operation of the cause is only brief and transitory, the result is merely a temporary *distension*, from which the muscle recovers itself by its own elastic and contractile re-action so soon as the distending force is removed. This cannot be regarded as a pathological state, and it must, therefore, be carefully distinguished from genuine dilatation.

The exciting causes of dilatation are, 1st, deficient power of the heart, whether congenital or acquired, in proportion to the system; 2d, in general terms, all obstructions to the circulation, whether situated in the orifices of the heart, or in the aortic or pulmonary system. The latter class of causes are, in fact, essentially the same as the exciting causes of hypertrophy; for it depends on the proportion which the resistance of the muscle bears to the distending force, whether the one affection or the other is produced. When, therefore, dilatation occurs in one of the cavities with naturally thick walls, in which we should more properly expect hypertrophy, it must be ascribed either to a congenital disproportion of the heart, in consequence of which the cavity in question is thinner, and therefore more disposed to dilatation, than natural; or it must be attributed to the obstruction, from its nature or situation, bearing more in proportion on that particular cavity than on any other. It is from having overlooked these

considerations respecting the relations of the resisting and distending forces to each other, that some have excluded dilatation from the catalogue of mechanical diseases, and supposed that it takes its rise in any cavity of the heart either by chance or by some vital predilection—some vague, unintelligible predisposition.

Dilatation occasionally affects only a single ventricle, and it is generally the right; but much more commonly it attacks both. The auricles, being protected by their valves from the direct influence of the numerous causes of pressure which operate on the ventricles, are far more exempt than they, both from dilatation and hypertrophy. But when the auricular valves are diseased, whether their state be that of contraction, which impedes the transmission of the auricular blood, or of permanent patescence, which allows a regurgitation of the ventricular, the auricles, suffering unnatural distension, become dilated.

It is seldom that dilatation of the auricles occurs under any other circumstances than those of disease of their valves; so seldom, indeed, that Laennec does not recollect to have seen an instance, though he does not deny the possibility of the occurrence. More instances than one, however, have fallen under our own observation, and we have generally found the dilatation connected with some circumstances incapacitating the ventricle from freely evacuating its contents. It is natural, indeed, to suppose that when such is the case, the stagnation of blood in the ventricles must, for the time, have an effect in distending the auricle equivalent to that produced by contraction of the auriculo-ventricular valve; and considering the frequency of stagnation in the right ventricle, we might at first expect dilatation of the corresponding auricle from this cause to be frequent. But it must be remembered that, for the production of the disease, it is necessary that the operation of the cause be permanent, or at least very prolonged. Such, however, is seldom the case with the stagnation in question; for a ventricle, though so feeble in itself, or so encumbered by an obstacle before it in the course of the circulation, as to become gorged during an accelerated state of the heart's action, will, when tranquillity is restored, transmit its contents with a facility that could scarcely be anticipated. During such intervals, therefore, the muscular fibres of the auricle recover their contractile power, and restore the cavity to its natural size.

M. Bertin contends that dilatation is never a *primitive* malady, but merely a consecutive effect of a pre-existing lesion—of an obstacle to the course of the blood; and that the symptoms produced by such obstacles, viz. vascular engorgement, dropsy, passive hemorrhage, &c. have no other relation to dilatation than as being results of the same cause—the obstruction of the circulation.

We cannot concur with M. Bertin in these opinions. It is true that, in order to produce dilatation, there must exist a weight or pressure of the circulation upon the heart greater than the organ is capable of sustaining; and it is true that such pressure may be occasioned by the mechanical obstacles to which M. Bertin ascribes it, namely, contraction of the orifices of the heart,

diseases of the aorta, and all maladies which impede the course of the blood, whether in the lungs or in the system of the great circulation. (*Bertin*, p. 380.) But it is equally true that the same pressure on the heart may result, not from increased weight of the circulation, but from deficient power of the heart; and such is its cause in those who, by original conformation, have the organ thin in proportion to the size of the body. Another class in whom debility of the heart exists as a cause of dilatation, comprises those who have had the organ softened or otherwise enfeebled by disease; an effect not unfrequently produced by typhoid fever, and by inflammation of the substance and membranes of the heart.

Dilatation, then, occurring under the circumstances described, is as justly entitled to the rank of a *primitive* disease as hypertrophy; for as in both the disease depends, not on the pressure of the circulation, but on the manner in which the heart resists that pressure, in both the organ itself is the part where the disease originates; the only difference being, that in the one case the effect is produced by deficient, in the other by superabundant, power of the muscle.

In the next place, M. Bertin has, in our opinion, attributed far too much to the lesion of which he considers dilatation to be the effect, when he says that this lesion is the sole cause of all the symptoms which authors have been in the habit of ascribing to dilatation. It is true that when the lesion is so great as to constitute an extreme obstacle to the circulation, it may produce the symptoms in question; but it does not produce them, or produces them only in a very slight degree, when the obstacle is not extreme. We have repeatedly witnessed cases in which a well-marked if not a considerable obstacle, as a contracted valve, or a dilatation or aneurism of the aorta, had subsisted for a long period, even for years, without producing any material symptoms of an obstructed circulation; but the moment that dilatation of the heart supervened, the symptoms made their appearance in an aggravated form. We apprehend, therefore, that the heart is the part mainly concerned in their production; nor do we think this opinion less tenable because the symptoms are more severe when enlargement of the heart co-exists with an obstacle than when the enlargement exists alone; for it is natural to suppose that when two causes conspire to produce the same effect, that effect will be greater. But this is not all; for not only does each produce its own effect, but one increases the effect of the other; namely, the obstacle adds so much to the pressure of the circulation on the heart, that this organ labours under a double disadvantage, first, from its own diminished power, and, secondly, from a preternatural pressure upon it. Thus the resulting effect of the obstacle and the dilatation of the heart combined, is greater than the sum of the two taken separately.

In further invalidation of M. Bertin's opinion, we may add that we have seen numerous instances in which all the phenomena of an obstructed circulation were occasioned by dilatation alone, as no other obstacle capable of accounting for them could be detected in the course of the circulation.

According to the foregoing arguments then, it

appears, first, that dilatation may be a *primitive* disease, and that, as such, it is capable of producing all the phenomena of an obstructed circulation; secondly, that when it is consecutive to another lesion, it plays a prominent, and perhaps, even, in some cases, a more important part than that lesion in producing the phenomena of an obstructed circulation.

In order to ascertain the *real* effects of dilatation, it is necessary to confine ourselves, in studying them, to the simple uncomplicated form of the disease.

Taking into consideration this form alone, and admitting, on the foregoing grounds, that it is capable of producing all the phenomena of an obstructed circulation, we have next to inquire how, or by what mechanism, it produces them. To answer this question,—it produces them by putting the muscular fibres of the heart preternaturally on the stretch, whereby their contractile power is diminished; they lose, as it were, in force what they gain in length; and it is this deficiency of power in the main-spring of the circulation which constitutes the obstacle, if it may be so called, to the circulation, in the same way that weakness of the spring of a time-piece retards its movements.

Diagnosis of Dilatation.—*General signs.*—We have shown that the effect of dilatation is to enfeeble the heart, and thereby occasion the phenomena of an obstructed circulation. We have now to examine these phenomena as signs of dilatation.

The heart, when dilated, is subject to palpitations of a feeble oppressed kind, and more or less distressing, frequent, and prolonged, according to the extent of the malady. The attacks are provoked by any over-exertion or mental excitement. The pulse is soft and feeble, and if the debility of the heart be very considerable, it is small. Irregularity and intermittence are rare, except during severe dyspnoea, or when the vital powers are much exhausted, as in the extreme stage of the disease.

The languor of the arterial circulation causes the extremities and surface to be chilly, the disposition to be melancholy, and the character to be deficient in energy. The blood, not being freely transmitted by the left ventricle, accumulates by retardation in the lungs; whence difficulty of respiration; cough, sooner or later attended with copious expectoration of thin, serous mucus; œdema of the cellular tissue of the lungs, greatly aggravating the dyspnoea; terrific dreams, with starting from sleep; and passive pulmonary hemorrhage of dark, grumous blood in small quantities, forming sanious sputa, and generally the precursor of death when it occurs in individuals affected with extreme difficulty of respiration. The lungs being obstructed, the engorgement is propagated backwards to the right side of the heart, to the great veins, and finally to all their ramifications. From this venous engorgement arises a series of striking phenomena, which we shall review successively.

1. *Serous Infiltration.*—This generally makes its appearance first in the lower extremities, because it is in them that the circulation is most languid, the return of the blood being opposed by

its gravity : while about the feet and ankles it is little promoted by the action of superincumbent muscles. Increased serous exhalation takes place in the serous membranes also ; hence hydrothorax, hydro-pericardium, and ascites, one or other of which is almost invariably present when there is much external dropsy.

2. *Discoloration of the Face.*—If the complexion was originally florid, it becomes purple or deep violet, principally on the cheeks, the end of the nose, and the lips, with intumescence of the latter. If originally pale, it becomes cadaverously exanguinous, and has a dusky, leaden cast, especially about the eyes. The lips are either livid or totally colourless. Lividity sometimes shows itself in the extremities as well as in the face.

3. *Congestion of the Brain.*—This produces sub-apoplectic symptoms, as dull headach, felt principally along the course of the great sinuses ; hebetude of the mental faculties ; stupor, convulsions, and eventually complete coma. It is not unusual for these symptoms to supervene a few days before the fatal termination. Sometimes they depend not on congestion alone, but partly also on serous effusion into the ventricles. This, however, is not always the case, as we have ascertained by several dissections.

4. *Injection of the Mucous Membranes.*—It is common to find them after death so vascular as to present the appearance of inflammation. This is especially the case in the stomach and intestines, and it is necessary to be aware of the circumstance, in order to guard against the error of attributing the redness to inflammation.

5. *Passive Hemorrhage.*—This takes place from the lungs, as already stated, from the nose, the stomach, the intestines, and more rarely from the bladder. It results from engorgement of the mucous membranes. The effusion consists of dark blood exuding in small quantities. When from the stomach, it has occasionally the appearance of coffee-grounds.

6. *Congestion and Enlargement of the Liver.*—This is so common a consequence of retardation of the circulation on the right side of the heart, that few persons so affected in any considerable degree are exempt from it. By the obstruction which it occasions in the system of the vena porta, it leads to ascites.

The sign which, with Laennec, we think the most constant and characteristic of the equivocal signs of *dilatation of the right ventricle* in particular, is permanent turgescence of the external jugular veins *without sensible pulsation*. This turgescence does not disappear when the vein is compressed at the upper part of the neck.

Dilatation of the auricles presents no general signs distinguishable from those of disease in the corresponding ventricle or valve, to which it owes its origin ; but its existence may be inferred when the valve in question is either much obstructed or permanently open, or when, from any cause, there is great retardation of blood in the ventricle.

Physical Signs.—The signs of the two first varieties of dilatation, namely, that with a thickened, and that with a natural thickness of the walls, are given in the article on hypertrophy. It only remains for us to describe the signs of the third variety, or *dilatation with attenuation*.

The Impulse.—In this variety the impulse is diminished, and in extreme cases entirely absent, even during palpitation. When felt, it is only a brief percussion of the thoracic parietes, not elevating the ear. When the dilatation is great, the impulse is a little lower down than natural. It sometimes happens that, of several beats of the heart that are *heard*, one only is *felt* ; and if this be vigorous, it warrants a conclusion that the parietes are little attenuated. Though Laennec does not make this observation, we have assured ourselves of its accuracy by numerous post-mortem examinations.

The Sounds.—When the walls of the ventricles are merely thin without being dilated, the first sound (the sound produced by the systole of the ventricles) is louder, shorter, and clearer than natural ; it approximates in its character to the second sound, (that produced by the diastole of the ventricles,) which is analogous to the flapping of a pair of bellows. When there is dilatation, even in a moderate degree, the first sound becomes almost the same, and nearly as strong as the second ; and finally, when the dilatation is considerable, the two sounds cannot be distinguished either by their nature or intensity, but solely by their respective relations of synchronism or anachronism with the arterial pulse. The pulse in remote arteries, as the radial, often being, in dilatation and various other diseases of the heart, later than the ventricular systole, the pulse of the carotid or subclavian should be felt.

In proportion as the sounds of the heart are louder, they are audible at a greater distance over the chest ; accordingly, M. Laennec has proposed a scale by which the extent is made an index of the degree of dilatation and attenuation. Before describing this scale, it is necessary to acquaint the reader with the range of the sounds in the natural state.

In a healthy man, of medium stoutness, and whose heart is in the best proportions, the sounds, according to Laennec, are audible in the præcordial region alone ; that is, in the space comprised between the cartilages of the fourth and seventh left ribs, and underneath the inferior half of the sternum ; also, if the sternum be short, in the epigastrium. We have generally thought that they may be heard a little beyond this range. The sounds are similar and equal on the two sides of the heart, those of the right being most audible under the sternum, and those of the left under the cartilages of the ribs. When audible beyond the limits mentioned, they are heard successively in the following places, constituting the scale alluded to :—viz. 1st, along the sternum and on the left superior anterior part of the chest as high as the clavicle ; 2d, over the same extent on the right side ; 3d, on the left side of the chest, from the axilla to the region of the stomach ; 4th, on the right side over the same extent ; 5th, on the posterior left side of the chest ; 6th, on the posterior right side. The intensity of the sound is progressively less in the succession indicated, provided the parts around the heart are in the same states. But there are so many diversities in these states, which may interfere with the order described, that we have found the scale of M. Laennec of little practical utility in estimating the

degree of dilatation. Thus, in very fat subjects, in whom the impulse of the heart is not perceptible to the hand, the space over which its healthy sounds can be heard by the cylinder is much more limited than natural: Laennec has even found them confined, in some instances, to a square inch, though we cannot say that this has occurred to ourselves. On the other hand, in meagre persons, in those who are narrow-chested, and in children, the sounds are audible much further than ordinary: namely, over the two inferior thirds, or even three-fourths of the sternum, sometimes even over the whole of that bone, and at the left anterior superior part of the chest as high as the clavicle; often, also, though less distinctly, below the right clavicle. In very meagre subjects, we have heard them over the whole chest, both posteriorly and anteriorly. Now, as it is almost impossible to make an exact estimate of the degree in which stoutness limits, and leanness, &c. extend the range of the sounds, this range is not a sure criterion of the degree of dilatation.

Again, a lung in any way consolidated, whether by hepatization, tubercles, or compression by fluid in the cavity of the pleura, transmits the sounds of the heart more readily than a lung that is sound and permeable to air—a phenomenon explicable on the principle that dense bodies are the best conductors of sound. The effect is the same, though there be cavities in a tuberculous lung; for the sound is transmitted, not through the cavities, but through their walls, which are denser than healthy pulmonary tissue.

Under these various circumstances then, the sounds are irregularly propagated, and the progressive scale of Laennec is interfered with. For instance, if the right lung be consolidated, the sounds will be more audible on that side than on the left.

Our own mode of estimating the degree of dilatation is, by observing how far the first sound resembles the second, and comparing the intensity of the first, heard immediately over the ventricle affected, with what we believe, from experience, would be its intensity in the same subject if the heart were healthy. We then corroborate the estimate, if necessary, by the scale of Laennec, making allowances, as far as is practicable, for stoutness, leanness, youth, pulmonary condensation, &c. The manner in which we judge of attenuation by the first sound, is less by its loudness than by its remarkable shortness and clearness; for we think it is often louder in dilatation with hypertrophy, or even with a natural thickness of the parietes, than with attenuation. This opinion is opposed to that of Laennec, who "thinks he may regard it as constant, that the extent over which the beats of the heart are audible, is in the direct ratio of the feebleness and thinness of its walls." So far is this from being perfectly true, that we have met with cases in which the heart was dilated and attenuated to the extreme, yet the first sound was feeble: nor should we expect it to be otherwise in such cases; for when the heart, from extreme dilatation, is too feeble to contract smartly, its sounds must necessarily be weak. Hence they are so in ramollissement, and in the moments preceding dissolution.

Resonance on Percussion.—The resonance of

the præcordial region on percussion is diminished by dilatation. The dulness is situated rather lower down than natural, and as it is always in proportion to the increase of volume of the heart, it is greater in hypertrophy with dilatation than in mere dilatation. Dulness of the præcordial region on percussion may exist independent of the enlargement of the heart; namely, when the anterior borders of the lungs are hepatized, and extend in front of the heart. On the contrary, dilatation sometimes does not occasion deficient resonance when the lungs are emphysematous, and their anterior margins are forced between the organ and the sternum.

Physical Signs of Dilatation of the Auricles.—Auscultation has not hitherto supplied any direct signs of dilatation of the auricles; but as this affection is in general the consequence of disease of the valves, and of enlargement of the ventricles impeding the circulation through the heart, its existence may be inferred from the presence of signs of these affections.

Prognosis.—In many persons the heart, without being dilated, has naturally thin walls: those of the left ventricle, for instance, are not, at the utmost, more than twice the thickness of those of the right. This state presents the same signs as dilatation, but in a less degree; namely, the impulse is diminished, the first sound is loud, short, and clear, and both sounds are more extensively audible than natural. Individuals so affected may live for a great number of years,—even to an extreme old age, in a state of tolerably good health: it is only to be remarked that this conformation is in general accompanied with a delicate constitution, a slim stature, and small muscles. In fevers and diseases of the respiratory organs, the individuals in question experience, *cæteris paribus*, greater dyspnœa than others. If such a conformation augment, even slightly, a dilatation of the heart is the result.

A slight degree of dilatation is not a very formidable affection. The dyspnœa is sometimes not so great as to deserve the name of *morbid*; but the patient has merely a shorter respiration than most men, he more readily loses breath, and experiences palpitations from much slighter causes. With these slight symptoms, however, he generally exhibits some traces of the cachexy proper to organic disease of the heart. The state described, which is that of a great number of *asthmatics*, may subsist very long without occasioning any disorder of a serious nature; it may remain without making progress for a great number of years, and it does not always prevent the patient from attaining an extreme old age.

When dilatation has advanced so far as to occasion *morbid* dyspnœa, it has a constant tendency to increase unless the circulation be kept tranquil by a very quiet life, and by judicious medical treatment when necessary. With these precautions the disease may be kept stationary, sometimes for an indefinite period, if not exasperated by fevers or inflammatory affections, which, by hurrying the circulation, are eminently prejudicial.

When dropsy comes on, and, after having been removed by remedies, constantly shows a disposition to return, we may know that the dilatation tends to its fatal termination: and although the

patient may sometimes rally from five, six, or even more attacks, he generally sinks in the course of one or two years or less. The progress of dilatation with hypertrophy is much more rapid, as explained in the article on *HYPERTRPHY*.

The general prognosis is founded on the above considerations, and is favourable so far as life is immediately concerned. The particular prognosis depends upon the degree of severity of the symptoms and on the constitution of the patient.

Treatment.—The treatment of dilatation with *increased* power of the heart, that is, with hypertrophy, is described in the article on hypertrophy. In this place we have only to speak of the treatment of dilatation with *diminished* power, that is, with attenuation, and sometimes even with a natural degree of thickness of the parietes.

The first indication is, to remove, if possible, the exciting cause of the dilatation; and if this be done before the disease has proceeded to such an extent as entirely to deprive the muscular fibre of its resilience and elasticity, these faculties come into operation and restore the organ to its natural size. Accordingly, if the cause be an obstruction in the pulmonary circulation, as that produced by peripneumony, hydro-thorax, or pneumo-thorax, emphysema, the use of wind instruments; ventriloquism, tubercles, &c., the attention must be primarily directed to the removal of these affections and the prohibition of these habits. If the cause be, too violent exercises or passions, inebriety, occupations which, by placing the patient in a constrained posture, prevent the free circulation of the blood, as in shoe-makers, tailors, &c., the pernicious exercises, habits or occupations must be abandoned and the passions calmed. All the causes enumerated being of a temporary nature, the dilatation resulting from them, if not inveterate, can often be removed. But when the cause is permanent, as the contraction of an orifice of the heart, or a natural or acquired feebleness of the organ in proportion to its function, a cure of the dilatation is scarcely to be expected; but it may often be prevented from increasing, and the life of the patient may sometimes be prolonged even to its extreme limits. In such cases, therefore, the practitioner should steadily and perseveringly pursue a palliative and prophylactic treatment, having first discarded from his mind the impression, no less erroneous in itself than detrimental to the progress of medical science, that organic diseases of the heart are necessarily fatal, and that, therefore, all treatment is unavailing.

The circulation should be kept as tranquil as possible by a quiet life and a moderate unstimulating diet. The food, however, should be rather nutritious, comprising a little animal food or soup twice a day, in order to keep the muscular system in general, and that of the heart in particular, in good tone. The same object may be promoted by a clear, dry, bracing air, (as that of Brighton,) and by the shower-bath; from both of which we have seen the best effects result. Neither of them, however, have we found to suit those patients who have great pulmonary congestion with copious expectoration; as such require a warm humid atmosphere to favour expectoration and the cutaneous function, and they cannot bear the shower-bath on account of its determining too much from

the surface to the heart and great vessels: neither can they well bear opiates, as these remedies partly occasion diminished mucous secretion, and partly accumulation of that already secreted; both of which circumstances increase the dyspnoea. The general health and strength may likewise be improved by the occasional exhibition of bitters, mineral acids, and chalybeates, with aromatics. The stomach, in particular, should be kept in good order, as its derangements—even a little flatulence or acidity—have a surprising effect in disturbing the action of the heart. The same may be said of the biliary secretion. When there is an unequal distribution of nervous power, indicated by hysterical symptoms, &c., antispasmodics, particularly the *piluli galbani composita* and *valerian*, are very useful adjuncts to other remedies.

Febrile and inflammatory affections of every kind, but particularly inflammation of the lungs and bronchi, should be sedulously guarded against, and, when occurring, should be promptly treated. Even a slight pulmonary catarrh should be viewed as a serious affection. To prevent colds and relieve the heart by keeping up the circulation on the surface, flannel next to the skin is almost indispensable; and, if the patient be chilly, as is frequently the case in dilatation, a jacket of wash-leather should be worn over the flannel during winter.

Attacks of dyspnoea are best relieved by immersing all the extremities in warm water, a blanket being thrown round the patient to promote perspiration, and fresh cool air being admitted to satisfy the craving for breath. While this is being done, he should take an antispasmodic draught composed of ether, laudanum, camphor, ammonia, and assafoetida, combined according to circumstances. (See treatment of *HEART, DISEASES OF THE VALVES OF THE*.) It may be repeated two or three times, at intervals of from half an hour to an hour according to circumstances.

Bloodletting should not be resorted to in dilatation with deficient power of the heart, *during the paroxysm*, and merely for the purpose of relieving it. The abstraction of a small quantity has not the effect, and that of a large quantity is inadmissible, as it does more injury by increasing the debility of the heart and the system, than it does good by lightening the circulation; and consequently, an ultimate aggravation of dyspnoea ensues. More than once have we seen a large and indiscreet bloodletting fatal, as the patient could not rally from the exhaustion produced by the attack of dyspnoea to which that from the depletion had been superadded. If there be an absolute necessity for bloodletting—that is, if the dyspnoea be constant, and cannot be relieved by any other means—the quantity drawn should not exceed six ounces at one time; and it should be drawn very slowly, in the recumbent position, and during the intervals or remissions of the fits. In this way the bleeding may be repeated, if necessary, every one, two, or three months, provided it does not diminish, but rather increases, the strength of the patient.

For the treatment of dropsy, cough, &c., we refer the reader to the article on *HEART, (DISEASES OF THE VALVES OF THE)*.

[See on this subject Dr. Hope's *Treatise on*

Diseases of the Heart, Amer. edit., by Dr. Pen-
nock, p. 288,—Philad., 1842.] J. HOPE.

HEART, DISPLACEMENT OF THE.—*Ectopia cordis*, from ἐκτόπιζω or ἐκτόπιος, displaced. The human heart, when occupying its natural position, is situated in the left side of the thorax, behind the sternum and cartilages of the true ribs, and between the right and left lungs. In this situation it is placed obliquely, so that if a line were passed through its axis at the moment of its pulsation, its direction would be downwards, forwards, and to the left side. Its base is placed almost directly opposite the eighth dorsal vertebra, from which it is separated by the œsophagus and aorta, while its apex is turned forwards and obliquely over to the left side; so that it corresponds, when in a state of repose, to the cartilage of the sixth true rib, and strikes during its pulsation between the cartilages of the fifth and sixth left ribs, at a point about two inches below the nipple, and one inch on its sternal side. The inferior or posterior surface of the heart is flat, and rests upon the tendon of the diaphragm, which supports it; its superior or anterior surface is convex, and is overlapped by the anterior edges of the lungs. From this, which may be considered the natural position of the heart, numerous forms of deviation have been observed, from a slight alteration in the direction of its apex, to the total displacement of the organ from the interior of the chest.

Displacement of the heart may occur as a *congenital malformation*, or as the *result of accident or of disease*.

I. Some of the congenital displacements are very similar to those into which the heart is sometimes forced by diseases of the pleura or lungs, or even by certain organic affections of the heart itself; others, again, are liable to be mistaken for aneurismal tumours or other organic diseases of the heart or large vessels, and might, therefore, mislead the physician into the most serious errors of diagnosis, and consequently of practice, if the possibility of their occurring as a congenital malformation were not borne in mind. For this reason we shall give a succinct account of the principal congenital displacements of the heart, referring the reader who wishes for more ample details on this interesting subject to the excellent, "*Mémoire sur l'ectopie du Cœur*," published by M. Breschet in the second volume of the "*Repertoire Général d'Anatomie*," and to Dr. Paget's "*Inaugural Dissertation on the congenital Malformations of the Heart*." (Edinburgh, 1831.)

The congenital displacement of the heart may be divided into two classes: the first comprising those cases where the heart is contained within the chest, but does not occupy its natural situation there; the second containing those cases of malformation where the heart is situated out of the cavity of the thorax.

Cases of this description, though of not very unfrequent occurrence, from the slight inconvenience they occasion, have received comparatively little attention; yet from the resemblance they bear to the displacements produced by disease, they are, perhaps, the most interesting and important to the practical physician. The following are the principal deviations from its natural position de-

pendent on congenital malformation which the heart presents while still situated within the thorax.

Instead of being placed diagonally to the axis of the body, with its apex pointing to the left side, it may be situated, *a.* horizontally; *b.* vertically, with its apex pointing downwards; *c.* vertically with its apex pointing upwards; *d.* diagonally, with its apex pointing to the right instead of the left side; or *e.* transposed altogether to the right side of the chest.

a. The heart has, we are informed, been found in the horizontal position; (*Mémoires de l'Académie des Sciences*, quoted by Breschet;) but this deviation is of very rare occurrence as a congenital malformation, and it may perhaps be doubted whether the effects of disease have not been mistaken for such. We shall presently see that this alteration in the position of the heart is, as was remarked by Bertin, constantly produced by the enlargement of that organ from hypertrophy.

b. The heart has occasionally, though very rarely we believe, been found in the centre of the thorax, occupying a vertical position, as in quadrupeds. A case of this kind is described by Breschet. (*Mémoire cit.* page 17.) The infant was born at the full time, lived six weeks, and exhibited no external malformation: the heart, which was composed of a single auricle and ventricle, was situated exactly in the median line of the thorax, its apex having a slight inclination towards the left side. Another case, described by Klinn, (*Acta Academiae, Cæs. reg. Joseph. tom. 1, page 228,*) is usually quoted as an example of this species of malposition; but there can be little doubt, even from his own description, that the displacement of the heart was caused by the pressure of an effusion which had taken place into the left sac of the pleura.

c. A much greater alteration in the position of the heart, where the organ was so completely subverted that its basis was inferior and its apex superior, is related by Ignatius de Torres. "In a new-born female infant, the heart, destitute of a pericardium, was turned upside down, so that its basis with all the great vessels had fallen down as low as the navel, and its apex, still in the left side, lay hid between the two lungs." (*Phil. Trans. abridged, vol. viii. p. 509.*)

d. The direction of the apex of the heart to the right side, and the situation of the entire organ more or less to the right of the mesial line, is among the most common of the situations which the heart occupies when out of its usual place.

e. Breschet dissected four cases in the Foundling Hospital at Paris, where the heart was situated at the right side, without any of the other viscera being transposed. (*Op. cit.*) Otto, (*Handbuch der pathologischen, &c. Breslau, 1814,*) Moellenbrock, (*Miscell. natur. curios. dec. 1, ap. obs. 76,*) Mohrenheim, (*Wiener Beiträge, etc. tom. 2, page 305,*) and Elvert, (*De phthisi pulmonali, etc. Tubing. 1780,*) have likewise described this species of congenital displacement.

In the greater number of cases where the heart is placed from birth at the right side, there is also a similar transposition of the other thoracic and of the abdominal viscera. A case highly illustrative of this general transposition of the viscera is

recorded by Dr. Bryan in the Transactions of the College of Physicians of Dublin, and the specimen is preserved in the superb museum of the College of Surgeons of that city.

The apex of the heart, instead of pointing towards the left, corresponded to the interval between the fifth and sixth ribs of the right side; its auricles and ventricles occupied a position exactly the contrary of their ordinary relative situations; and the aorta, which gave off those vessels to the right that it usually furnishes to the left, descended along the right side of the vertebral column. The left lung was divided into three lobes, while the right had only two. The pyloric orifice of the stomach was turned towards the left hypochondrium, which was occupied by the liver, the spleen being at the right side. The whole intestinal tube was transposed in like manner, the cæcum resting on the left iliac fossa, &c. &c. In short, all the parts usually situated at the right side were placed at the left, and *vice versa*.

The subject of this case, we are informed, was a woman advanced in life, who had borne several children, and enjoyed good health until a short time before her death. The appearances found on dissection in the kidneys, uterus, and bladder, sufficiently accounted for the symptoms under which she suffered; but no suspicion was entertained that there existed any thing peculiar in her conformation, nor did the displacements lead to any particular symptom—not even to a preference of using her left hand.

We have been informed by Dr. Kennedy, that a respectable middle-aged female presented herself last summer at the Dublin General Dispensary, complaining of dyspnoea and distressing palpitations. On examination with the stethoscope, it was discovered that the heart was pulsating at the right side, and no disease could be detected in any of the thoracic viscera to account for the displacement; in addition to which the woman positively avowed that she had felt her heart beating in the same place as long as she could remember. The physician to whom we are indebted for these particulars seemed to entertain little doubt that the displacement in this case was congenital.

The second class of congenital displacements of the heart, comprising those cases of malformation in which that organ is situated out of the cavity of the chest, may be divided into those where the heart is situated on the surface of the body, and those where it is situated in the interior, but not in the thorax.

“The first kind, in which the heart is on the outside of the body, includes some of the most fatal as well as most frequent cases of exposition of this organ. It is generally connected either with deficiency in the diaphragm and abdominal muscles, or with absence of some part of the walls of the thorax. In the former case, we generally find the heart, liver, and stomach, and often the lungs, and all the abdominal viscera, contained in a sac, sometimes covered only by peritoneum, (*Archives Générales*, tom. 23. p. 511,) sometimes by an extension of the common integuments, (*Meckel, Dissert. inaugur.* page 6, *Acta Helvetica*, vol. vii. p. 56, de fœtu monstr. &c.) and sometimes occupying the sheath of the umbilical cord, (*Rep. Gén.*

d’Anat. tom. ii. p. 25,) forming a variety of umbilical hernia.” (*Paget*, op. cit. p. 33.)

Protrusion of the heart may likewise take place through a fissure, or deficiency in the sternum or ribs. Some cases of this description are quoted by Breschet in the *Mémoire* already so often alluded to; they seem to have arisen principally from a deficiency in the lower part of the sternum from the imperfect development of that bone, and were not accompanied with any other malformation. Such cases are, however, exceedingly rare in comparison with those where the fissure of the sternum and the protrusion of the heart through it are accompanied with other malformations arising from a defective development of the parietes of the different cavities from the circumference towards the centre, such as large apertures in the parietes of the chest and abdomen with hernia of their contents, spina bifida, cleft palate, hare-lip, open perineum &c.

When the heart is situated in the interior of the body, but not within the chest, it may be found either in the abdomen or in the neck.

Heart Situated in the Abdomen.—Ramel relates the case of a girl ten years of age, whose heart was placed from birth below the diaphragm, in the situation usually occupied by the stomach. During infancy she did not appear to suffer any inconvenience from the malposition, and as she grew up it was only on crying violently, or using any particular exertion, that she was seized with palpitations, dyspnoea, and occasionally with epistaxis. Ramel attended her for two years, during which time her health and strength continued to improve, until it seemed at length as if nature had become completely reconciled to this unusual arrangement of the circulating system. (*Journal de Médecine*, tom. xlix. p. 423.) Another case of this species of malposition of the heart was found by Dr. Wilson in an infant seven days old. (*Phil. Trans.* 1798, p. 346.) The central and tendinous portion of the diaphragm was deficient, as was also the inferior portion of the pericardium. The heart, consisting of a single auricle and ventricle, was lodged in a deep groove on the convex surface of the liver. In this case there were several other malformations of the principal blood-vessels, as well as of the abdominal viscera, which were sufficient to account for the death of the individual, independently of the displacement of the heart. But the most extraordinary case of this kind on record is that related by M. Deschamps, (*Journal Général de Médecine*, etc. tom. xxvi. p. 275,) where the heart was found occupying the place of the left kidney. The individual in whom this malformation was found was an old soldier who had served several campaigns, and enjoyed excellent health, with the exception of nephritic pains, to which he had then been for some years subject, and on account of which he eventually obtained his discharge from the service. Notwithstanding the frequent recurrence of these pains, he married, and became the father of three children; at length, however, the symptoms of renal disease became more violent, and recurred more frequently; hectic fever set in, and he died after an agony of forty hours; his abdomen covered with large gangrenous spots. On dissection, the right kidney was found very large

and in a state of suppuration; the place of the left kidney was occupied by the heart, enveloped in its pericardium. In the thorax, there was no trace of the heart to be found, nor was there any appearance to indicate its ever having been placed there. It is remarkable that this extraordinary displacement of the heart was never discovered or even suspected by the individual or his medical attendants, all the functions of the heart being as effectually and as regularly performed as though it had occupied its natural position within the thorax. It does not appear that there was any malformation of the diaphragm, or indeed of any other part in this instance.

Heart Situated in the Neck.—In M. Breschet's excellent Mémoire on this subject, three cases of this extraordinary malformation, which he proposes to designate *ectopia cordis cephalica*, are related. In one of these cases the heart, lungs, and thymous gland, were all situated in the front of the throat, where they formed a large tumour immediately underneath the lower jaw. The apex of the heart was attached to the base of the tongue, and lay between the rami of the inferior maxilla. The chest was filled with the abdominal viscera, which had passed up through an aperture in the diaphragm. As such complicated malformations are manifestly incompatible with the extra-uterine life of the individual, their description can afford little practical interest to the physician; we shall, therefore, content ourselves with thus briefly noticing the existence of this variety of congenital displacement, and refer the scientific anatomist to the original essay on the subject by M. Breschet.

Without entering at length into the causes of the different varieties of congenital malposition of the heart, which would be the more unnecessary as the subject will be fully considered in a separate article on MALFORMATIONS of that organ, we may remark in general terms, that the greater number of these congenital misplacements depend on an arrest of development at a period before the evolution of the fetus is completed. In this way may be explained the imperfect union of the parietes of the different cavities, and the consequent displacement of the organs usually contained within the thorax and abdomen, their protrusion out of these cavities, &c.; to this cause may also be attributed, with considerable probability at least, the situation of the heart in the neck; as all writers on the development of the embryo are agreed that the heart is situated immediately underneath the head during the first period of the evolution of the fetus, and that the aorta, instead of forming an arch, descends directly into the chest. It is obvious that if the development of the heart be arrested at this early period, the organ will remain out of the thorax, in the anterior part of the throat, as in the *ectopia cephalica* of Breschet.

We must not, however, suppose that all congenital misplacements of the heart may be thus accounted for, as there are some which evidently result from a perversion of the natural order of development: to this class belong the inclination of the heart's apex to the right, and the total transposition of the organ to that side, accompanied, as it usually is, with a similar transposition of the other viscera. In this way, also, we must explain

the situation of the heart in the place of the kidney in the remarkable case recorded by Deschamps, inasmuch as the organ never occupies that position at any period of the evolution of the fetus, and, *a fortiori*, could not continue to occupy that position in consequence of an arrest of its development; neither was there any malformation or disease of any of the neighbouring viscera to account for the displacement.

II. Displacement of the heart may likewise be occasioned at any period of life by accident or by disease. Displacement from the former cause seldom falls under the observation of the physician, as any accident which is of sufficient violence to force the heart out of its natural situation seldom fails to prove instantaneously fatal. Indeed, the only recorded exception that we are aware of is furnished in the remarkable "case of probable dislocation of the heart from external violence," published by Dr. Stokes in the Edinburgh Medical and Surgical Journal, No. 108, from which we copy the following account:

"Mr. B., æt. 21, had enjoyed uninterrupted health until the 7th of May, 1822, when he was severely crushed between a water-wheel and the embankment on which the axle was supported. He remained for three hours after the accident in a state of complete insensibility. As soon as an examination could be made, the following injuries were discovered. Two ribs in the lower portion of the left side, the right clavicle and humerus, and the fifth, sixth, and seventh ribs on the right side, were broken. The right side of the face and chest was emphysematous, and there was complete paralysis of motion in the right arm, with considerable loss of sensation. *The patient felt great pain in the right side of the chest, with a sensation as if a foreign body preventing respiration had been introduced into the right lung: the pain was accompanied with violent throbbing and heaving, and it was soon discovered that his heart was pulsating at the right side of the sternum.* He had a short dry cough, but experienced no hæmoptysis; and there was no pain or other symptom of pleuritic inflammation at the left side,—a point of considerable importance in the diagnosis of the lesion.* From that period to the present his heart has continued to pulsate on the right side of the sternum, the pulsation being generally strong, and aggravated by mental emotion, exercise, or the occurrence of pain in the side. He has never had orthopnea, but has always experienced great difficulty of breathing on exercise, or when he has attempted to lie on the left side. Since the accident he has every winter experienced several inflammatory attacks, in which he suffers from violent pain of the right side, with great increase of palpitation and dyspnea. These attacks are only relieved by bleeding, and he thinks he has been bled upwards of fifty times. It is a remarkable circumstance that syncope has never been produced even after the loss of so much as thirty ounces of blood at a time, and that he

* We had lately an opportunity, through Dr. Stokes's kindness, of examining this patient, and of ascertaining the accuracy of the above statement. The patient, when interrogated, stated without the least hesitation, that before the accident his heart had always beat at the left side, and that he was himself the first to notice its change of position after that event.

has taken the powder of digitalis in the dose of eight grains every night for the space of three months, without his pulse ever descending below eighty. When he does not take digitalis, his pulse is generally between one hundred and one hundred and twenty, regular in strength and never intermitting; but when he uses that remedy in his ordinary state, the number of respirations is about thirty in the minute. His habit of body is spare but muscular, and the countenance is not expressive of pain. From August to the latter end of April last he shared constantly in the sports of the field: hunting and shooting were his constant employments.

"On stripping the patient and examining his chest carefully, the right shoulder appears depressed, but the right side inferiorly measures an inch in circumference more than the left.

"The *left side* of the thorax sounds perfectly clear, even to its most inferior portion, and in the situation usually occupied by the heart. Respiration of the puerile character, and mixed with some bronchial râles, is to be heard over the entire lung, and is as distinct in the mammary region as in the other portions. Neither the sound nor impulse of the heart is perceptible in the cardiac region. At the *right side* the upper portion of the lung sounds clear, but from the fifth rib downwards there is complete dulness, and here the integuments are exquisitely sensible. In the upper portion, both anteriorly and posteriorly, the respiratory murmur is of the same character as in the opposite lung, but from the fifth rib downward it is wanting; there is no bronchial respiration or resonance of the voice. The pulsations of the heart can be seen and felt in the right mammary region, between the sixth and seventh ribs, and within an inch of the sternum. When not over-excited, the sounds of the heart are almost natural. There is no sign of valvular disease."

That the heart was actually displaced in this case, there can be no doubt whatever; and that the displacement was caused by the external injury is rendered highly probable, from the fact of its being observed for the first time almost immediately after the accident, and from the absence (as ascertained by auscultation and percussion) of all those diseases of the adjacent parts which usually cause the displacement of the heart from the left to the right side.

Besides the causes of displacement already enumerated, viz. congenital malposition, and accident or external injury, the heart is likewise liable to be forced out of its natural situation by various morbid alterations of the adjacent parts.

On studying the anatomical relations of the heart, we perceive that it is retained *in situ* by the large blood-vessels which form its superior attachment,—by the adhesion of the pericardium to the diaphragm, which attaches it inferiorly,—and by the walls of the mediastinum and the equal pressure of the lungs, which oppose its displacement to either side. But as none of those forces which retain the heart in its natural position is of a fixed or unyielding nature, it follows that, whenever a degree of pressure sufficient to overcome their resistance is exerted on the heart by the enlargement or other morbid alteration of any of the surrounding parts, that organ is pressed out of its

natural situation, and forced upwards or downwards, to the right or left side, according to the direction in which the pressure is exerted.

The following are the diseases which have been observed most frequently to cause displacement of the heart:

1. Effusion into the Sac of the Pleura.—

In nine cases out of ten where the heart is removed out of its natural situation, the displacement will be found to have arisen from empyema or pneumothorax; accordingly this displacement is now generally regarded as the most constant and least fallible symptom of these diseases. Of twenty-seven cases of empyema and pneumothorax that have come under the author's observation, in the extensive hospitals attached to the Dublin House of Industry, the heart was perceptibly displaced in *every instance*. Pathologists have long remarked that effusion into the left pleura, by the pressure which it exerts on the parietes of the cavity, as well as on the organs contained within it, is capable of thrusting the heart over to the right side of the sternum; but they do not seem to have been aware that effusion into the right side, by protruding the mediastinum and pressing on the heart, may cause a very considerable displacement of that organ to the left of its natural position. In a case of pleuro-pneumothorax, with fistulous communication through the lung of the right side, which was lately operated upon by Mr. MacDowel, in the Richmond Hospital, the heart was distinctly seen and felt pulsating between the fourth and fifth ribs, near the left axilla, from which situation it gradually returned to its natural position, as the pressure which caused its displacement was removed by drawing off the air and fluid from the opposite side. In all cases of extensive effusion, whether of air or fluid, into the pleura of the right side, we have uniformly observed a similar displacement of the heart proportioned to the extent of the effusion. This displacement of the heart to the left can in some cases only be detected by minute examination, and even in extreme cases is less likely to attract observation than the displacement to the right of the sternum, which seldom fails to arrest the attention of the patient, even though it should be overlooked by his medical attendant. We have already entered at length into the consideration of the value of this symptom as indicative of effusion into the pleura, and shall therefore refer the reader to the article EMPYEMA, where he will find this subject fully considered.

2. Aneurism of the Aorta.—When tumours of this kind come in contact with the heart, they seldom fail, as they increase in size, to force it to a greater or less distance from its natural position. Dr. Hope records a case of aneurism of the ascending aorta displacing it to the left. The writer has seen an instance of aneurism of the arch thrusting the heart downwards, so that its apex pulsated in the epigastrium. It is evident from their relative anatomy that aneurism of the thoracic aorta may cause displacement of the heart according to the direction which the sac takes; and Drs. Graves and Stokes have shown that considerable displacement of the central organ of the circulation may be produced by aneurism of the abdominal aorta pressing on the diaphragm and

pericardium. In the interesting case which they have recorded, "the heart was at first found to beat in the epigastrium, the impulse having left the usual situation. In the course of a few days it became feebler in the epigastrium, but could be felt pulsating on the right side, at the sternal end of the fifth rib, and ultimately became fixed in the intercostal space of the third and fourth ribs." (Dublin Hosp. Reports, vol. v. p. 10.)

We may remark that in two cases of aneurism of the ascending aorta which we had lately under our care, the sac presented a double sound at each pulsation: in neither case was there any perceptible displacement of the heart, as the tumour took a direction upwards and to the right side; but in one of the cases which we subsequently had an opportunity of inspecting, we ascertained that the aneurism was in actual contact with the pericardium and heart, from which no doubt it received and transmitted the double pulsation. In two cases related by Drs. Graves and Stokes, (op. cit.) the aneurismal tumour gave a double pulsation; and we believe that a similar phenomenon will be observed whenever the aneurism is so situated as to have the double stroke of the heart mechanically communicated to it.

3. **Tumours.**—Tumours of every description developed in the vicinity of the heart, when they take such a direction and attain so great a size as to press upon that organ, may mechanically displace it. In a young woman who died in the Hardwicke Fever Hospital with symptoms of acute thoracic inflammation, we found on dissection, at which we were assisted by the late Professor Bennet, a large *encephaloid* tumour, which appeared to have originated in the bronchial glands situated at the root of the left lung, and thence to have descended between the pleura and pericardium, thrusting the heart over into the right side, and eventually eating its way by ulceration through the pericardium, where its eruption excited violent inflammation. A similar displacement of the heart, and apparently from a similar cause, was found by Boerhaave on the dissection of the Marquis de St. Auban. (Zimmermann, *Traité de l'Expérience*, tom. iii.)

4. **Pulmonary Emphysema.**—Laennec states, "that when a single lung is affected, it sometimes becomes so much more voluminous than the other as to press aside the heart and mediastinum." (Forbes's Translation, p. 152.) Judging, however, from our own experience, we feel inclined to rank this among the least frequent causes of displacement of the heart, as in most instances where one lung is sufficiently emphysematous to produce such an effect, the other participates in the morbid alteration, and by its increased volume maintains the pressure which the heart sustains in equilibrio: such at least we have found to be the case in the numerous dissections that we have made.

5. **Diaphragmatic Hernia.**—It is evident that when the abdominal viscera are forced into the thorax through an opening in the diaphragm, they may exert such a degree of pressure on the heart as to force it from its natural position. This species of hernia is often congenital, and arises from imperfect development of the diaphragm, in consequence of which an aperture is

left, through which several of the abdominal viscera are protruded into the chest by the contraction of the abdominal muscles. We have already recorded examples of congenital ectopia from this cause. It seldom happens that such subjects survive longer than a few hours after birth, in consequence of the obstruction which the respiration encounters. Instances, however, are not wanting of life being prolonged for a considerable period under these apparently hopeless circumstances. In Dr. Wilson's case already quoted, the infant lived some days; but decidedly the most interesting case of this description on record is related by Drs. Graves and Stokes.

"A man about forty years of age died of tubercular phthisis. The œsophagus, after passing through the usual opening in the diaphragm, was found to re-enter the thorax by another very large opening in the tendinous portion towards the left side. The stomach occupied the inferior portion of the left thoracic cavity, its cardiac and pyloric orifices both lying in the opening. A considerable portion of the transverse arch of the colon was also included in the left side of the chest: these viscera, loosely but permanently fixed by means of the serous membranes, all rested on the convex surface of the diaphragm, and *pushed the heart and mediastinum towards the right side.*" (Op. cit. p. 84, 5.) There seems little doubt that the hernia in this case was the result of congenital malformation. Hernia of the abdominal viscera into the thorax, and consequent displacement of the thoracic viscera, has likewise been caused by wounds of the diaphragm, (Essai sur l'Anatomie Pathologique, par J. Cruveilhier,) by rupture of that septum occasioned by a fall; by great exertion, (Richter, on Hernia); and, as has been alleged, by enormous distension of the stomach. (Haller, *Disput. Chirurg.* tom. iii.)

6. **Enlargement of the Liver.**—This is also enumerated by authors among the occasional causes of displacement of the heart; we are not, however, acquainted with a well-authenticated instance of the kind. It is probable that a considerable hypertrophy of the left lobe may elevate the diaphragm and displace the heart; the same effect may likewise be produced by excessive enlargement of the spleen, or by the development of any morbid growth in the epigastrium or left hypochondrium.

7. **Hypertrophy with Dilatation of the Heart.**—When the heart is enlarged, its apex is carried to the left, and its basis to the right side, in such a manner that it lies almost transversely across the chest. This observation, originally, we believe, made by M. Bertin, (*Traité des Maladies du Cœur*, pl. 2me.) has been repeatedly verified by the writer. It has also been remarked by Bertin that in those cases where the size and weight of the heart are very considerably augmented, the organ presses with all its weight on the diaphragm, so that that portion of the septum on which it reposes is thrust before it like a pouch in the abdomen. Sometimes this depression has been known to take place without any visible cause, in which case the affection has received the name of *prolapsus* of the heart. (Laennec, op. cit. p. 615.) Some authors have thought that this prolapsus might be caused by relaxation of

the vessels, by which the heart is as it were suspended in situ. (*Bertin*, op. cit. p. 442.) We think it more probable, however, that the displacement in such cases must have been more apparent than real, as we know from experience that the heart's pulsation may be felt in the epigastrium in a great many persons, particularly when the sternum is short, although the heart retains its natural position.

Diagnosis and Treatment.—Displacements of the heart are now easily detected by the aid of auscultation and percussion: the disappearance of the usual phenomena of the heart's action from the cardiac region, and their appearance in another and different situation, afford unerring evidence of a corresponding change in the position of the organ. As, however, the changes of position which the heart undergoes are, in every instance almost, the effect of more serious organic lesions, their diagnosis becomes a matter of very secondary importance, as compared with that of the disease by which they were caused, and of which they should properly be regarded as a symptom. Indeed, the principal advantage, in a practical point of view, of detecting a displacement of the heart, is derived from the light which it throws on the nature, extent, and situation of the primary disease by which it was produced, and on which the danger of the displacement, as well as its appropriate treatment, in a great measure depends. It is, therefore, to the accurate diagnosis of the cause of the displacement that the scientific physician will chiefly direct his attention; these causes we have already enumerated, and we beg to refer the reader to the respective articles which treat of the particular diseases, for such diagnostic characters as may enable him to decide in any doubtful case the true cause of the displacement.

From the circumstance of displacement of the heart being so constantly combined with other and more serious lesions, it is extremely difficult to ascertain the effects on the system resulting from the simple displacement. In *congenital malpositions* the alteration in the heart's place is usually coupled with other malformations of a more serious character, which either cut short the life of the individual, or else complicate the symptoms of the displacement in such a way that it is impossible to analyze them correctly. In those rare cases where the displacement of the heart was the principal or only deviation from the natural arrangements of parts, little or no inconvenience seems to have resulted from it. In *Ramel's* case already quoted, where the heart was situated below the diaphragm, the individual experienced no inconvenience during infancy; as she grew up she occasionally suffered from palpitations and dyspnoea, and at the age of twelve she is represented to have enjoyed as good health as other people. *M. Deschamp's* case affords a still more remarkable example of the absence of any distressing symptoms from the displacement, though the heart was situated in the place of the left kidney. In this case the great vessels were disposed in the most favourable manner for transmitting the blood from the heart; but when the displacement is caused by accident or disease, the large vessels are necessarily contorted more or less, in order to accommodate themselves to the new position of the

heart; and if to this we add the pressure and consequent obstruction to the due discharge of their functions which the parts that the heart is forced amongst necessarily sustain, we shall see sufficient reason for concluding that the consequences must be most serious and detrimental when the displacement is at all considerable; but even to those untoward circumstances the powers of nature are capable of adapting themselves. In *Dr. Stokes's* case the patient, though occasionally subject to palpitations in the right side, has so much improved in health as to spend his time between shooting and fox-hunting. In all cases of displacement that we have seen, the pulse was rapid and feeble, and the patient suffered from occasional attacks of dyspnoea and palpitation; but in each of these cases the displacement was complicated with empyema or pneumothorax, either of which was of itself sufficient to produce these symptoms. In general, however, we observed that they were immediately relieved by drawing off the fluid, and allowing the heart to resume its natural position. We are, therefore, disposed to conclude that slight displacements occasion little inconvenience, but when considerable they may produce serious functional derangements, especially until such time as the system has become habituated to the change.

The treatment of displacement of the heart must obviously depend on its cause; where that is of such a nature as to admit of removal, no sooner is its pressure taken off than the heart resumes its natural position, unless retained by morbid adhesions. When, on the other hand, the cause of the displacement does not admit of removal, the replacement of the heart is impracticable; and all that the resources of our art can effect is to palliate symptoms as they arise. In all our attempts, therefore, either to restore the heart to its natural position, or to mitigate the symptoms which its displacement produces, we should ever bear in mind that we are only treating a symptom—a mere mechanical effect of pressure; and that, by relieving the primary disease which caused the pressure, we take the most effectual method of remedying the displacement it produces.

On referring to the list of diseases we have enumerated among the causes of displacement, it will appear that many of them, such as aneurisms of the aorta, tumours developed within the thorax, &c. are of such a nature as not to admit of removal or diminution. Congenital malposition is equally irremediable: even in those cases where the heart was placed in front of the chest, immediately under the integuments, it was found that the attempt to force it into the thorax through the fissure in the sternum immediately brought on the most alarming symptoms. (*Breschet*, *Mém. cit.*) In all such cases our best resource lies in the palliative treatment. The patient should be kept as quiet as possible, and every other precaution adopted to prevent the circulation being excited. When palpitations are troublesome, digitalis may be administered with advantage; its exhibition, however, requires considerable attention, as it has been observed not to produce its effects in such cases unless administered in full doses, and we have witnessed the most alarming consequences from its over-action. Counter-irritation

may likewise be employed with advantage; we have repeatedly found blisters applied over the heart most efficacious in controlling this symptom: when a more permanent effect is desirable, a seton may be introduced in the side near the heart. Dr. Stokes's patient, when we last saw him, declared that he experienced the most decided relief after the introduction of a seton into his right side, and that on one occasion when he withdrew it for a fortnight he was attacked with his former symptoms of pain and palpitation, which again disappeared after the seton had been introduced.

We have already stated our opinion that effusions into the pleura are decidedly the most frequent cause of displacement of the heart. By the operation of paracentesis thoracis, these may no doubt be removed; but in deciding on the expediency of this operation there are many circumstances of greater importance than the displacement, which the physician must take into consideration. (See EMPYEMA.)

In the case of diaphragmatic hernia, Laennec suggests the idea of making an incision into the abdomen and drawing back the intestines. We conceive that if such an operation could ever be justifiable, it would only be when the pressure of the abdominal viscera on the lungs threatened immediate suffocation, in which case a doubtful remedy might perhaps be preferred to none: but how are the intestines to be prevented from again returning into the chest through the aperture in the diaphragm?

R. TOWNSEND.

HEART. (FATTY AND GREASY DEGENERATIONS OF)—In individuals of great obesity, and occasionally in others of only moderate *embonpoint*, the heart is sometimes overloaded with fat. It is deposited beneath the pericardium, and not only invests the organ externally, but frequently penetrates a considerable depth between the muscular fibres, which, as if losing (probably by the pressure) what the adipose tissue gains, become attenuated and flabby. Sometimes, however, the intermixture of adipose matter gives the appearance of attenuation, though there is none in reality.

The old authors imagined that this affection was the cause of more or less severe symptoms, and even of sudden death. Corvisart thinks that an enormous accumulation might sometimes be capable of producing such an effect; but, in the persons in whom he had met with very fat hearts, he had seen nothing which could prove to him "that the state was morbid, that is to say, carried to such a point as constantly to derange the function of the organ, and thus constitute a malady." The experience of Laennec has led him to the same conclusions; nor have we seen any thing that militates against them.

It would be natural to suppose that the substitution of adipose for muscular tissue, and the extreme attenuation which the walls, especially the apex and the posterior part of the right ventricle, sometimes undergo from this cause, would be eminently favourable to rupture of the organ; yet this accident is very rarely the result. Morgagni has seen an instance of it, but Bertin has only met with one of rupture of the auricle; while

Corvisart and Laennec have not witnessed an instance at all.

Fatty degeneration is different from that denominated *greasy* degeneration of the heart. This, according to Laennec, is "an infiltration of the muscular substance with a matter which presents all the physical and chemical properties of grease; it is an alteration exactly similar to the greasy degeneration which Haller and Vicq-d'Azyr have observed in the muscles. Laennec has never found it but in a very small portion of the heart, and only near the point. It was of a pale yellowish colour, like dead leaves, and therefore very similar to certain varieties of softening; but he thinks that it may be distinguished from softening by its strongly greasing paper between which it is pressed. We have seen a remarkable case in which a degeneration of this kind occupied the greater part of both ventricles.

J. HOPE.

HEART, (HYPERTROPHY OF THE)—

In this article we propose to develop, with as much brevity as the importance of the subject will allow, many of the leading principles common to organic diseases of the heart in general.

Hypertrophy of the heart is an augmentation of its muscular substance, resulting from increased nutrition. The terms *active* and *passive aneurism of the heart* we discard as vague and inaccurate, and adopt the following classification and nomenclature.

1. *Simple hypertrophy*, in which the walls are thickened, the cavity retaining its natural dimensions.

2. *Hypertrophy with dilatation*. This, the eccentric or aneurismal hypertrophy of Bertin, presents two varieties: viz.—

a. With the walls thickened and the cavity dilated.

b. With the walls of natural thickness and the cavity dilated: i. e. *hypertrophy by increased extent of the walls*.

3. *Hypertrophy with contraction*. In this, the concentric hypertrophy of Bertin, the walls are thickened and the cavity is diminished. This classification is no less convenient than conformable to nature. The form of the second variety was not known to Laennec, though it was to Bertin. That it *really* consists of an augmentation of muscular substance, and therefore constitutes hypertrophy, is too manifest to require comment; but a further proof than mere structure affords is that it sometimes produces the symptoms of hypertrophy,—a fact which the writer ascertained and made known several years ago, before he had any knowledge that M. Bertin had done the same. (Vide an Essay by the writer in 1824, read to the Royal Med. Soc. Ed.)

The terms "eccentric or aneurismal" and "concentric" are not so simple and expressive as hypertrophy with dilatation, introduced by Laennec, and its natural converse, hypertrophy with contraction. There is a further objection to the nomenclature of Bertin. His first variety of dilatation, identical in its nature with his second variety of hypertrophy, is designated by a totally different name, viz. *active aneurism* (Bertin, p. 376), which could scarcely fail to lead the inexperienced student into the erroneous idea that there was a dif-

ference in the nature of the two affections. Now the only difference consists in degree—in a predominance of the one state over the other. The terms, therefore, should be such as distinctly to imply identity in nature, and difference in degree only: and this is done in the simplest manner by giving precedence to the word hypertrophy, or dilatation, according as the one affection or the other predominates. Thus hypertrophy with dilatation denotes a predominance of hypertrophy, while the converse, dilatation with thickening (see DILATATION), denotes a predominance of dilatation. Hypertrophy by increased extent (without altered thickness) of the walls,—the form *b*. of the second variety,—is thus designated when it is accompanied with the symptoms of hypertrophy; but it is called simple dilatation when the symptoms are those of dilatation.

We have thought it necessary to speak thus particularly on the subject of nomenclature, as up to the present moment it has created much confusion, and must continue to do so until the terms active and passive aneurism are forgotten.

Anatomical Characters of Hypertrophy of the Heart.—Before describing the anatomical characters of hypertrophy of the heart, it is necessary to give the reader an idea of the natural dimensions of the organ. Unfortunately, it is impossible to determine these exactly; for as they vary according to age, sex, and other circumstances, there is no immutable standard of comparison which might serve as a criterion. It is only by the eye, therefore, (and an experienced eye is necessary for the purpose,) that it can be determined whether the proportion of the heart to the system, and of its several parts to each other, is natural. The proportions assigned by Laennec approach perhaps as near the truth as it is possible to arrive: they are as follows. "The heart, comprising the auricles, ought to have a size equal to, a little less, or a very little larger than the fist of the subject. The walls of the left ventricle ought to have a thickness a little more than double that of the walls of the right: they ought not to collapse when an incision is made into the cavity. The right ventricle, a little larger than the left, and having larger columnæ carneæ, notwithstanding the inferior thickness of its walls, ought to collapse after an incision has been made into it. Reason indicates and observation proves that in a sound and well-built subject the four cavities of the heart are, within very little, equal to each other. But as the walls of the auricles are very thin, and those of the ventricles have considerable thickness, it results that the auricles form scarcely a third of the total volume of the organ, or the half of that of the ventricles." In the fetus and very young children, the thickness of the left ventricle does not exceed that of the right to the extent described. The right cavities are rather larger than the left, and this is not owing to sanguineous distension attendant on dissolution; for the disparity is found, though in a less degree, in animals destroyed by hemorrhage.

[In another work (*Human Physiology*, 5th edit. ii. 73, Philad. 1844) the writer has given the dimensions of the heart after various observers. (See, also, Dr. Pennock's edit. of Hope on *Diseases of the Heart*, p. 233.) Of late M. Ranking

(*Lon. Med. Gazette*, No. xxiv., 1842) has published the results of measurements, evidently made with accuracy, of upwards of 100 hearts, care being taken to exclude all those that exhibited any trace of organic change. The following were the mean admeasurement of 15 male hearts; the mean circumference was $9\frac{7}{8}$ inches; of 17 female hearts, $8\frac{1}{8}$ inches. The mean length of the male heart was $4\frac{1}{8}$ inches; of the female, $4\frac{7}{8}$. The mean thickness of the left ventricle in the male was $\frac{2}{8}$ ths of an inch; in the female, $\frac{2}{8}$ ths; of the right ventricle in the male $\frac{3}{8}$ ths; in the female, $\frac{6}{8}$ ths. The septum ventriculorum has, in the male, a mean thickness of $\frac{2}{8}$ ths of an inch; in the female, $\frac{1}{8}$ ths. The entire orifice in the male had a mean circumference of $2\frac{3}{4}$ ths inches; the right auriculo-ventricular orifice $4\frac{3}{8}$ ths inches; the left auriculo-ventricular orifice $3\frac{4}{8}$ ths inches. The corresponding parts, in the female, were relatively less. The inferences, drawn by Dr. Ranking from all his observations, are, that the length of the healthy heart to its circumference is rather less than 1 to 2;—that the thickness of the parietes of the right ventricle is to that of the left as 1 to 3 nearly;—that the pulmonary artery is slightly wider than the aorta; and lastly, that the right auriculo-ventricular opening is considerably larger than the left.]

The muscular substance in hypertrophy is usually firmer and redder than natural. These characters, however, are not essential to the disease; and when they exist in a great degree, they constitute induration, a distinct affection, dependent, not on increased, but rather on altered nutrition of the part.

Hypertrophy may be confined to a single cavity, or it may affect several, and even the whole simultaneously; and sometimes one cavity is thickened while another is attenuated. The reasons of this will be explained when we come to treat of the exciting causes. When all the cavities are hypertrophous, and at the same time dilated, the heart attains a volume, two, three, and occasionally even four times greater than natural; its form, instead of being oblong, is spherical; its apex is scarcely distinguishable; and as the diaphragm does not retire sufficiently to yield space downwards for the enlarged organ, it assumes an unnaturally horizontal position, encroaching so far upon the left cavity of the chest, as sometimes to force the lungs upwards as high as the level of the fourth rib, or even higher. When great enlargement is accompanied by adhesion of the pericardium, the organ is secured by the attachments of the membrane in a higher situation than its gravity would otherwise dispose it to assume; and being thus impacted between the spine and the anterior parietes of the chest, it is apt to occasion a preternatural prominence of the præcordial region. We are not aware that this remark has been made by any other writer, but we have seen the phenomenon in so many instances, that we are disposed to assume it as a general fact. (See PERICARDITIS.)

The left ventricle, being more prone to thickening, and not less to dilatation than the right, sometimes attains a volume seldom or never acquired by the right; and when its enlargement is enormous, it occupies not only the left præcordial

region, but extends far under the sternum, where its impulse and sound may be mistaken for those of the right ventricle. (*Laennec*, tom. ii. p. 507. *Treatise on Disease of Heart*, by Dr. Hope: case of Lambert.)

The walls of the left ventricle, the natural thickness of which averages about half an inch in the adult, may be increased to the extent of one, one and a half, or, according to some, of two inches. The cases are rare in which it exceeds an inch and a quarter. The situation of the greatest thickening is usually a little above the middle of the ventricle, where the columnæ carneæ take their origin. Thence, the thickness decreases rather suddenly towards the aortic orifice, and gradually towards the apex, where it is reduced to less than half. When hypertrophy maintains these proportions in the different parts of the ventricle, the state is only an exaggeration of the natural form. The case is different when the hypertrophy takes place inwards and diminishes the cavity; for then the whole ventricle is nearly equally thickened, and it is usually globular and firm.

The columnæ carneæ generally participate in hypertrophy, but sometimes, when there is much coexistent dilatation, they appear to be stretched, flattened, and attenuated. The inter-ventricular septum, though belonging almost entirely to the left ventricle, is commonly less thickened than the external walls of this cavity. When the left ventricle is greatly enlarged, the right, if unchanged, is applied in a flattened form to its superior and lateral part, and by contrast looks singularly small. But if, as generally happens, the right is elongated, it is, as it were, folded around the left.

When the right ventricle alone is hypertrophous, it may descend lower than the left, and constitute the apex of the heart. Its columnæ carneæ, naturally more numerous and interwoven than those of the left, are more susceptible of thickening than the walls themselves. Hence the increased size of the columnæ is commonly the first object that arrests the attention, and to them alone is the hypertrophy in many instances confined. They are sometimes so curiously interlaced and attached as to traverse the ventricle in every direction, subdivide it into various compartments, and in some cases almost totally to fill up its cavity: (as in case 89 by Bertin, and that of Collins, p. 469 of *Treatise of Dr. Hope*.) These changes never take place to the same extent in the left ventricle. The total thickness of the walls of the right ventricle, naturally averaging three lines, rarely exceeds four or five; yet it has been known to attain from eleven to sixteen, as appears from the 88th case of Bertin, and one, by Soins, in the *Archives de Médecine*. In a girl of nine years old we have met with it measuring six or seven lines, which is equal in proportion to nearly double that extent in the adult. Hypertrophy without dilatation is much more rare in the right than in the left ventricle. The greatest thickening of the right ventricle is near its base: towards the apex, though the columnæ carneæ be enlarged, their interstices are usually thin, and not unfrequently translucent.

Hypertrophy may not only be confined to a single ventricle, whether the right or the left, but it may be limited to particular parts only, as the

base, the septum, the apex, the columnæ carneæ, or the external walls; the remainder of the cavity being either natural or attenuated. Again, a thickened ventricle may be contracted in one part, while it is dilated in another. In examining the dead subject in mixed cases, it is necessary to counterpoise the opposite conditions, to balance the hypertrophy against the attenuation, and the dilatation against the contraction, in order to determine which is the predominant affection.

The hypertrophy of the auricles is almost invariably of the second species, or that with dilatation. *Laennec* even states that he has never met with any other. (*De l'Auscult.* tom. ii. p. 524.) The simple and the contracted forms, however, are not without example. The thickening is diffused in a very uniform manner throughout the cavities, the muscoli pectinati being the only parts in which it is more considerable than elsewhere; and as they are larger and more numerous in the right than in the left auricle, it is in the former that hypertrophy proceeds to the greatest extent. It occasionally renders the auricle nearly as thick as the right ventricle. This we have never known to take place in the left auricle. Sometimes the muscoli pectinati are the only parts in which hypertrophy shows itself. The thickening of the auricular walls seldom exceeds double the natural state, and being even then inconsiderable, it may easily be overlooked by an inexperienced eye. When it amounts to a quarter of an inch, which is rarely the case, it is very perceptible.

Mode of Formation and Predisposing Causes of Hypertrophy.—Hypertrophy takes place in the heart by the same process as in any other muscle. Increased action causes an augmented afflux of blood, and there results a corresponding increase of nutrition. Diminished action, on the contrary, has the reverse effect. Thus, the arms of the smith and the legs of the dancer are usually robust; while limbs paralysed or not exercised are pale and emaciated. If, however, the circulation can be re-invigorated in the palsied part, nutrition is increased.

In the same way, when from mechanical obstruction or any other cause blood is inordinately accumulated in the heart,—short, however, of that degree which would paralyse its remittent power—the organ is provoked to extraordinary efforts; it struggles against the obstacle; it frets and labours to overcome it; the coronary arteries are excited to increased activity; augmented nutrition ensues; the parietes are thickened, the muscular power is increased; the effects, superadded to the cause, induce a still greater violence of action; and thus the disease is not only established, but has a constant tendency to increase.

The left ventricle is much more prone to hypertrophy than the right;* and the right, again, than the auricles. This admits of explanation on very simple principles. It is found that hollow muscles resist over-distension by their contents with a force exactly proportionate to their strength. Thus, if we suppose two cavities, one twice the strength of the other, and add to the natural pressure on those cavities such a surplus as will exactly overpower

* [This is the general opinion, but M. Louis affirms, that of 49 cases of hypertrophy of the ventricles, 29 were of the right ventricle.]

the weaker, this surplus will bring into action only one half of the supplementary strength of the more vigorous. Now, as the act of resistance, by stimulating the arteries to increased action, is the cause of increased nutrition, it follows that stronger muscles must be the more susceptible of hypertrophy. Accordingly, on referring to the heart, we find that the relative structure of its several compartments is such as to predispose the organ to those changes which it actually undergoes from over-distension. The left ventricle, being charged with the immense burden of the greater circulation, is proportionably substantial and robust; the right, having the comparatively light task of propelling the blood through the minor or pulmonary system, is little more than one-third as thick and powerful as the left: the auricles, again, having a still less laborious function to perform, have a still more limited muscular provision. Hence, it is easily understood how a given increase of distending force, sufficient to overcome the contractile and elastic power of the right ventricle, might operate merely as a stimulus to the superior muscularity of the left. While the former, therefore, incapable of re-acting on its contents, would dilate, the latter, excited to extraordinary efforts, would become hypertrophous.

It is not however to be supposed, that while the left ventricle is becoming hypertrophous, it may not at the same time undergo dilatation; nor, on the other hand, that the right ventricle, while yielding to dilatation, may not become hypertrophous; for observation teaches us that the combination of hypertrophy with dilatation, either in the left ventricle alone, or in the two conjointly, is the most ordinary form of organic disease of the heart.

For an explanation of the cause why dilatation accompanies hypertrophy, the reader may refer to the article on *DILATATION*. Why hypertrophy sometimes accompanies dilatation of the right ventricle may be here explained, and it admits of an explanation in one or other of two ways. 1. It has been remarked by Laennec (*Traité*, tom. ii. p. 496,) that a large proportion of mankind are born with ill-proportioned hearts, the parietes being a little too thin or a little too thick on one or both sides. Now when this abnormal thickness exists in the right ventricle, it is clear, from what has been said above, that it must impart to that ventricle an increased disposition to hypertrophy. This explanation, however, is not satisfactory, as the existence of the malformation described by Laennec cannot be positively proved: still, as all the other organs and parts of the body are liable to defects of natural conformation, it is consistent with analogy to suppose that the heart may be liable to them also.

2. As augmented nutrition is excited in the left ventricle by stimulating it in proportion to and not beyond its power, so a stimulus bearing the same proportion to the power of the right ventricle, must have the same effect on it also. Accordingly, in the majority of cases of hypertrophy of the right ventricle, an obstacle is found to exist of such a nature as to stimulate it in the manner described. The obstacles which we have most frequently found to produce the effect, are, contraction of the mitral valve operating in a retrograde

direction through the lungs, and that of the semi-lunar valves of the pulmonary artery. These affections being usually slight at their commencement and slow in their progress, oppose an obstacle to the circulation not only moderate in degree, but constant in its operation,—the two circumstances best calculated to induce hypertrophy of the right ventricle.

M. Bertin conceives that the greater tendency of the left ventricle than of the right to hypertrophy, depends upon the more stimulant quality of the arterial blood circulating through the former. This opinion he founds on the circumstance that hypertrophy of the right ventricle in most cases accompanies patescence of the foramen ovale, which lesion he thinks causes an influx of arterial blood into the right ventricle. But, admitting that arterial blood in the right ventricle does occasion hypertrophy, it does not follow that it should have the same effect on the left; for of the former ventricle it is a morbid stimulus, but of the latter it is the natural one. Accordingly, direct proof is to be found in the auricles, that arterial blood is not the cause of hypertrophy; for the left auricle, which on M. Bertin's principle ought to be more subject to hypertrophy than the right, is less so. It will be shown, moreover, in the article on malformations of the heart, that, in the cases on which M. Bertin founds his opinion, the blood does not enter the right ventricle.

Exciting Causes.—According to the foregoing opinions on the mode of formation of hypertrophy, it will be apparent that every circumstance capable of increasing the action of the heart for a sufficient length of time,—a period which must be very considerable,—may be a cause of hypertrophy. These circumstances may be either, 1. of a nervous, or 2. of a mechanical nature. 1. The former class comprises all moral affections and all derangements of the nervous function that excite long continued palpitation. To these we would add protracted rheumatic fevers; for we have known these give rise to hypertrophy, though there was apparently no inflammation of the heart or its membranes. 2. The latter class embraces all physical causes which can either *accelerate* or *obstruct* the circulation, and thus occasion a preternatural pressure of the blood upon the heart. The physical causes which *accelerate* the circulation, are, violent and protracted corporeal efforts of every description. In growing youths, excessive rowing is one of the most efficient. We have met with several in which it has produced the effect. The physical causes which *obstruct* the circulation are very numerous. They comprise smallness of the aorta, whether congenital or acquired; dilatation of the aorta; inequalities of its internal surface; all diseases of the valves of the heart which either contract their apertures or impede their movements; adhesion of the pericardium; all affections of the chest that obstruct the circulation through the lungs, as peripneumony, acute or chronic; emphysema; hydrothorax; chronic catarrh; emphysema; phthisis;* narrowness of the chest, either

* We have not found that phthisis is so decided a cause of disease of the heart as we should be led to suppose from the extreme pulmonary obstruction to which it sometimes gives rise. The reason of this appears to be, that, in the early stages, when the disorganization is not extensive, the circulation is little embarrassed; and in

congenital, or occasioned by curvature* of the spine, &c.; encroachment of the diaphragm on the cavity of the chest from the pressure of tight stays, of the gravid uterus, of abdominal dropsy, aneurism, &c.

In reference both to the nervous and the physical causes of palpitation, it may be said that young persons of a plethoric habit and sanguine temperament are the most susceptible of their influence. Hence it is that very stout and high-coloured females, from the age of seventeen to twenty-five, are peculiarly subject to hypertrophy. We have noticed this fact more especially in servants coming to London from the country.

Order of succession in which the several compartments of the heart are rendered hypertrophous by an obstacle before them in the course of the circulation.—As an obstacle to the circulation operates on the heart in a retrograde direction, the cavity situated immediately behind it is the first to suffer from its influence. Accordingly all the impediments seated in the aorta, its mouth, or the arterial system, act primarily on the left ventricle, which, being likewise exposed to the heaviest burden when the circulation is accelerated, has to conflict against a greater variety of exciting causes of hypertrophy than any other cavity of the heart. On this account, therefore, as well as from the thickness of its parietes, it is subject to hypertrophy in a greater degree than any other.

So long as the left ventricle is capable of propelling its contents, the corresponding auricle, being protected by its valve, remains secure. Hence, in a large majority of cases, the auricle is perfectly exempt from disease, while the ventricle is even enormously thickened and dilated. But when the distending pressure of the blood preponderates over the power of the ventricle, its contents, not being duly expelled, constitute an obstacle to the transmission of the auricular blood. Hence the auricle becomes over-distended, and the obstruction may be propagated backwards through the lungs to the right side of the heart, and there occasion the same series of phenomena. When the obstruction thus becomes universal, as is frequently the case, it may happen either that all the cavities are thickened, or those only which from their conformation have the greatest predisposition to it.

When the mitral orifice is contracted, especially if the aperture be very small, the left ventricle, being insufficiently supplied with blood, is not stimulated to its ordinary contractile action, and consequently becomes emaciated and occasionally flaccid or softened. Meanwhile, the left auricle, having to struggle against the contracted valve in front, and also to sustain the distended pressure of the blood flowing in from the lungs, invariably becomes thickened and dilated. The engorgement, extending backwards through the lungs to the right ventricle, occasions its hypertrophy and dilatation; under which circumstances, namely, hypertrophy

of the right ventricle and contraction of the mitral valve, the lungs suffer in a pre-eminent degree; for being exposed to the augmented impulsive power of the right ventricle behind, and incapable of unloading themselves on account of the straitened orifice in front, their delicate and ill-supported vessels are strained beyond the power of resistance. If, therefore, they cannot disgorge themselves sufficiently by a copious secretion of watery mucus, they effuse blood by transudation into the air-vesicles and tubes, and form the disease denominated *pulmonary apoplexy*. We have found this affection to occur more frequently under the circumstances described than under any other.

When the mitral orifice is permanently patenscent, so that, at each ventricular contraction, blood regurgitates into the auricle, this cavity suffers in a remarkable degree; for it is not only gorged with the blood which it cannot transmit, but, in addition, sustains the pressure of the ventricular contraction. Permanent patenscence of the mitral orifice, therefore, constitutes an obstruction on the left side of the heart, and the effect of this, as of contraction of the orifice, may be propagated backwards to the right side.

When the impediment to the circulation is primitively seated in the lungs, the right ventricle, situated immediately behind them, is the first to experience its influence; and when the cavity is so far overpowered by the distending pressure of the blood as to be incapable of adequately expelling its contents, the obstruction extends to the auricle; the process being exactly the same as that already described in reference to the left ventricle and auricle.

Obstruction in the right auricle, whether from this or any other cause, presents an obstacle to the return of the venous blood, and therefore ultimately causes retardation throughout the whole venous system. Nor is this all; for the retardation is propagated through the capillaries to the arterial system, and thus at length returns in a circle to the heart. In this way is explained what at first sight appears an anomaly; namely, that the left cavities are sometimes rendered hypertrophous by an obstruction situated behind them in the course of the circulation. The left ventricle, for instance, may be rendered hypertrophous by a contraction of the mitral orifice.

The reader must here be again reminded that the exciting causes of hypertrophy are equally those of dilatation, and that, supposing no unknown agencies to interfere, as may sometimes possibly happen, it depends on the proportion which the exciting cause bears to the re-acting energy of the cavity exposed to its influence, whether that cavity become affected with hypertrophy, with dilatation, or with a combination of the two.

It may be said, generally, that when congestion is constant in a cavity, dilatation is more commonly the result; and that when there is only resistance to the expulsion of the blood, without constant engorgement of the cavity, it is more common for hypertrophy to be produced. Contraction, for instance, of the aortic orifice causes hypertrophy of the left ventricle in a greater degree than dilatation; whereas patenscence of that orifice, attended with regurgitation and constant

the advanced stages, the mass of circulating fluids is so much diminished in consequence of deficient nutrition and augmented cutaneous transpiration, that the heart sustains little additional burden from the obstruction in the lungs. In most cases, however, the right ventricle is found somewhat dilated,—a remark which has been made more especially by M. Louis and Dr. Williams.

* The majority of humpbacked persons are ultimately attacked by disease of the heart.

engorgement of the cavity, causes dilatation in a greater degree than hypertrophy.

Hypertrophy with contraction most commonly proceeds from straitening of an orifice. Thus the greatest hypertrophy with contraction of the right ventricle upon record was accompanied with straitening of the pulmonary orifice to two lines in diameter. (Case 87 by M. Bertin.) We have met with a very similar case; and several connected with malformation of the heart are on record.

It may be useful to subjoin a list of the various forms and combinations of hypertrophy and dilatation, and to show the comparative frequency of their occurrence. On the latter point we shall offer the result of our own observation, and we believe that they correspond very closely with those of others.

The diseases are of more frequent occurrence in proportion as they are higher in the following scale.

1. Hypertrophy, with dilatation of the left ventricle, and a less degree of the same in the right.
2. Hypertrophy, with dilatation of one ventricle, especially the left, with simple dilatation of the other.
3. Simple dilatation of both ventricles.
4. Simple hypertrophy of the left, and hypertrophy with dilatation of the right.
5. Dilatation with attenuation of the left.
6. Hypertrophy with contraction of the left.
7. Hypertrophy with contraction of the right.

Of the Auricles.—1. Distension, particularly of the right, from congestion during the act of dissolution.

2. Dilatation with hypertrophy.
3. Simple hypertrophy.
4. Hypertrophy with contraction.

Pathological effects of Hypertrophy, and mode of their Production.—M. Laennec supposes the general symptoms of all organic diseases of the heart to be nearly the same. (De l'Auscult. tom. ii. p. 487.) It may be said without prejudice to one who has done so much, that, on this subject, both he and all the authors who preceded him have entertained inaccurate ideas. They had studied these diseases in the aspect under which they most commonly present themselves, namely, complicated one with another; and it is unquestionable that when so viewed, they display a great similarity in their symptoms. But it had never occurred to those authors to analyze each disease in an isolated form. When so examined, although certain symptoms are common to all, they severally manifest differences of a striking kind, obviously dependent on their respective organic peculiarities, and which may, therefore, be fairly regarded as the essential and diagnostic characters of each.

M. Bertin has the merit of having been the first to display in a clear light the essential pathology of hypertrophy. His distinguished talent for generalization, however, has, we believe it will be allowed, carried him too far. He contends that authors are wrong in having assigned to hypertrophy or *active aneurism* as its symptoms, dyspnoea, suffocation, violet injection of the face, engorgement of the lips and of the venous capillaries in general, passive hemorrhages, and serous infiltration. He contends that these are the signs,

not of hypertrophy, but of some coexistent lesion, as a contracted orifice or any other affection capable of obstructing the circulation; and that pure uncomplicated hypertrophy is characterized by signs of increased activity and energy of the circulation, instead of by dropsy and the other signs of retardation of the blood.

That this is true in reference to the *pure uncomplicated* form of the disease, before embarrassment of the capillary circulation has taken place, will not be denied by any one who has had opportunities of verifying the symptoms by dissection. But M. Bertin is not, in our opinion, supported by sound observation when he says that serous infiltration and the whole class of symptoms bespeaking an obstructed circulation, are totally foreign and repugnant to hypertrophy. The truth we believe to be, that the very same energy of the circulation which gives rise to active hemorrhages, apoplexy, &c., causes, as its next effect, engorgement of the arterial capillary system; the necessary consequence of which is serous infiltration, and more or less of all the other symptoms indicative of retardation of the blood.

M. Bertin is of opinion that the impediment to the respiration which attends enormous enlargement of the heart, results from the encroachment of the organ on the lungs. This, however, is disproved by the fact that tumours of a much larger size, as for instance, aneurisms of the aorta, malignant tumours, &c. have existed in the chest, even for years, without producing similar inconvenience.

The primary effect of universal obstruction of the lungs by engorgement resulting from hypertrophy of the heart, is, to produce oedema of their cellular tissue and dyspnoea. The secondary effect is, to gorge the right side of the heart, and thus impede the return of the venous blood from the system at large; which impediment co-operates with the increased energy of the arterial circulation in producing anasarca.

Hypertrophy, however, does not produce serous infiltration so readily and promptly as a direct, primary obstacle to the return of the venous blood,—a fact which admits of a rational and obvious explanation. When there is an obstacle to the return of the venous blood, suppose, for instance, contraction of the tricuspid orifice, two causes conspire to produce the capillary congestion; namely, the direct pressure of the arterial vis-a-tergo, and the retrograde pressure of the retarded venous blood. But when the latter pressure does not exist, when the veins freely receive and transmit their natural proportion of blood, the force of the arterial circulation must be *very greatly* increased, before it can so far overcome the elasticity of the capillaries as to give rise to engorgement and infiltration.

This satisfactorily accounts for the difference in the history and character of infiltration as resulting, on the one hand, from pure hypertrophy, and on the other from contraction of a valve or other primary obstacle to the circulation. In the former case, it appears late, is generally moderate in extent, and requires for its production an aggravated form of hypertrophy; in the latter case, it appears comparatively early, is more copious, and yields with less facility to remedies.

The same reasons that account for the tardy occurrence of dropsy in pure hypertrophy, account, likewise, for another characteristic of this malady when moderate in degree; namely, the slight and transitory nature of the attacks of dyspnoea. For if the quantity of blood impelled into the lungs by the right ventricle, and the force with which it is impelled, are not very excessive, the pulmonary veins are capable of relieving the engorgement almost as quickly as it takes place: consequently the hurry of the respiration subsides promptly after the removal of its exciting cause; in other words, as soon as the action of the heart becomes a little calm. The sum, then, of all that has been said, is, that pure hypertrophy gives rise to increased force and activity of the circulation, and that, when this force surmounts the natural tonic power of the capillaries, congestion, infiltration, and the other phenomena of an obstructed circulation, ensue.

To these principles an exception presents itself in hypertrophy with contraction, whenever the cavity of the ventricle is too small to be capable of transmitting the natural quantity of blood. In this case, supposing the left ventricle to be the one affected, the arterial circulation sustains a diminution of force and activity; and whether the one ventricle or the other be affected, the disease creates an obstruction tantamount to that produced by valvular contraction: on the same principles, therefore, it generates dropsy and the other phenomena of a retarded circulation.

The effects of hypertrophy of the left ventricle on the brain are so pre-eminently important that it is necessary to advert particularly to this subject, for the purpose of bringing it prominently into view. Since the researches of the present day have demonstrated that even a slight thickening of the walls of the heart constitutes a morbid state, and have unfolded to view the connection subsisting between that state and a train of symptoms formerly either wholly overlooked or attributed to other causes, instances of apoplexy supervening upon hypertrophy have been so frequently noticed, that the relation of the two as cause and effect is one of the best established doctrines of modern pathology. Eight or nine cases of suddenly fatal apoplexy, and numerous cases of palsy, from hypertrophy, have, within a few years, fallen under our own observation. In the majority of them the patient exhibited what is commonly called the "apoplectic constitution;" that is, a robust conformation, a plethoric habit, and a florid complexion: in others, the secharacters were absent; but the total number of the cases of apoplexy from hypertrophy is much greater than we have witnessed, during the same period, of apoplexy from causes independent of hypertrophy; whence we are led to believe, with MM. Richerand and Bertin, that hypertrophy forms a stronger predisposition to apoplexy than the apoplectic constitution itself; and that, in most instances, those persons who present the apoplectic constitution in conjunction with symptoms of increased determination to the head, are, at the same time, affected with hypertrophy.

Nor is it to apoplexy alone, but to cerebral inflammations and irritations of every description, and even to inflammatory action in general, that

hypertrophy of the left ventricle gives a tendency. The history of individuals affected with it frequently presents a striking narrative of violent headaches, brain fevers, various inflammatory complaints, and states of great nervous irritability and excitation. As the ophthalmic artery is derived from the carotid within the cranium, the eye participates with the brain in the effects of hypertrophy, and is vascular, brilliant, and very prone to ophthalmia. The wasting away of the eye which Professor Testa has remarked as one of the effects of disease of the heart, is, with good reason, supposed by M. Bertin to be connected with ossification of the ophthalmic arteries, a frequent concomitant of hypertrophy of the left ventricle.

The shock of an hypertrophous left ventricle may to a certain extent be intercepted, and its effects on the brain counteracted, by contraction of the aortic orifice. A patient was under the care of Mr. Babington, at St. George's Hospital, Sept. 16, 1829, for a surgical complaint, in whom the walls of the left ventricle were an inch thick, without any change of the cavity; and the aortic and mitral orifices were respectively encircled by a ring of bone as thick as a writing-quill. The two valves, though overspread with calcareous scales, were capable of discharging their functions. Notwithstanding this extraordinary state of disease, the patient had attained the age of eighty without manifesting symptoms of diseased heart sufficient to arrest his own attention or that of his medical attendants. His advanced age, indeed, proves that they could not have existed in any considerable degree. In this case, therefore, the valvular contraction appears to have been exactly sufficient to countervail the hypertrophy, and maintain the circulation in a state of equilibrium. The generality of authors, however, have greatly over-rated the power of contraction of the aortic orifice to counteract the effects of hypertrophy on the brain. They have supposed that a moderate and even a slight degree of contraction is sufficient for the purpose. There can be no greater error; and it is one into which they could not have fallen, had they been aware that an inconsiderable degree of contraction has very little effect in diminishing the strength, tension, and regularity of the pulse, as is shown in the article on valvular disease.

To have demonstrated the influence of hypertrophy of the left ventricle on the brain, is equivalent to having shown that of the right ventricle on the lungs. For, in the same way that the brain receives *directly* the shock of the blood, which the left ventricle shoots into the aorta, so the lungs receive *immediately* the impulse communicated to the column of blood, which the right ventricle propels into the pulmonary artery. Consequently, when the walls of this ventricle are augmented in thickness and energy, they impart a corresponding activity to the pulmonary circulation, and sometimes overcome the tonic power of the vessels. Hence ensues hemorrhage, or what was called by Laennec pulmonary apoplexy, from its taking place by the same mechanism as apoplexy properly so called, in cases of hypertrophy of the left ventricle. The hæmoptysis resulting from this cause consists of fluid, red blood, and is generally copious, sudden, and productive of febrile excitement of the circulation. It is, in

short, an active, arterial hemorrhage, and essentially different from that passive species, hereafter to be described, which results from retardation of the blood in the venous capillaries of the lungs. (See PULMONARY APOPLEXY and HÆMOPHTYSIS.)

Diagnosis of Hypertrophy.—The signs of hypertrophy are of two classes: 1. *general*; 2. *physical*. According to our experience, neither of these classes, taken separately, is sufficient to indicate any disease of the heart with perfect certainty; taken conjointly, they render the diagnosis so easy that a material error can scarcely be committed.

1. **GENERAL SIGNS.**—In describing these we shall follow the course of the circulation; commencing, after having noticed the action of the heart, with the circulation through the lungs, proceeding to that through the aortic system, and concluding with that through the veins.

The description of symptoms which we are about to offer, refers, it must be distinctly understood, to simple hypertrophy, unless when it is otherwise stated: the symptoms of *hypertrophy with dilatation*, which will be noticed in passing, are only an aggravated degree of the same—as the reader will sufficiently understand, if duly acquainted with the foregoing principles relative to the formation and effects of these diseases. When the dilatation predominates over the hypertrophy, the symptoms of course approximate more nearly to those of dilatation. (Vid. HEART, DILATATION OF THE). The symptoms of *hypertrophy with contraction* will also be noticed incidentally with those of simple hypertrophy.

Palpitation.—By this is to be understood a morbidly increased action of the heart, both as to strength and frequency. As the hypertrophous heart acts with an energy which, even in its tranquil state, verges on palpitation, and which, under the slightest excitement, actually amounts to it, the patient experiences this symptom more unintermittingly than in any other disease of the organ. It is induced by stimulants of any description: as muscular efforts, particularly that of ascending; mental emotion; flatulence; acidity or bile; spirituous or highly seasoned ingesta, and sometimes by a full meal of any kind. The violence of the attack generally subsides promptly after the operation of the exciting cause has been suspended, and little remains but a slight sense of pulsation in the præcordial region. In the advanced stage, however, of hypertrophy, and still more of this conjoined with dilatation, when the circulation has become embarrassed, the paroxysms are sometimes very severe and prolonged, though they never attain that fearful extreme of violence and obstinacy which is witnessed in cases complicated with valvular or aortic obstruction, or adhesion of the pericardium.

Dyspnoea.—While the enlargement of the heart is moderate, the patient, during a tranquil state of the circulation, feels little or no difficulty of respiration; but he is incapable of making the same corporeal efforts as other persons without losing breath: to use a common phrase, he is "short-winded." After a respite of a few minutes, however, he recovers, and is, therefore, seldom deterred by this symptom from prosecuting his accustomed avocations. We have frequently ob-

served that individuals who pant on first setting out on a walk, are capable of sustaining great exertions without inconvenience when they get warm and the blood is freely determined to the surface. When the disease has proceeded so far as to occasion dropsy, more or less dyspnoea becomes habitual, and it sometimes occurs, conjoined with palpitation, in paroxysms of excessive severity. From this period, indeed, the symptoms are a compound of those of hypertrophy and those of an obstructed circulation, the latter of which are more particularly considered in the article DILATATION. Hypertrophy with contraction, as already stated, is sometimes accompanied with symptoms of an obstructed circulation.

Cough.—There is generally little or no cough in the early stages, but it always supervenes when dropsy appears, in connection with which more or less sanguineous and serous congestion almost invariably takes place in the lungs, and gives rise to the symptom in question. When the hypertrophy is confined to the left ventricle, the cough is milder and later in its appearance than when the right ventricle is affected. We have seen a dry, hacking and wheezing cough amongst the earliest symptoms in young and plethoric females, whom it attacks in paroxysms after any over-exertion, as ascending a stair. It is often also very troublesome on first rising in the morning.

Hæmoptysis.—This may occur at any period of the disease, and the hemorrhage, being *active*—the result of a too impetuous discharge of blood into the capillary system—is generally sudden and copious, consists of fluid arterial blood, and is attended with febrile excitement.

Pulse.—The pulse in hypertrophy of the left ventricle undergoes, from valvular and other lesions, a variety of modifications which disguise its real nature. It must, therefore, be studied in cases totally exempt from complication. In such it is almost invariably regular, and bears strict relations in strength and size to the thickness and capacity of the left ventricle. Thus, in simple hypertrophy it is stronger, fuller, and more tense than natural: it swells gradually and powerfully, expands largely, dwells long under the finger, and is sometimes accompanied with a thrill or vibration. These characters are still more marked in hypertrophy with dilatation, so long as the hypertrophy is predominant; but when the dilatation has proceeded so far as to diminish the contractile power of the muscular fibres, the pulse, though still full and sustained, is soft and compressible. In hypertrophy with contraction of the cavity, it is strong, hard, and tense, but small and cord-like, expanding little under the finger. The action of the carotids corresponds with that of the radials, and they may generally be seen to pulsate from the sternum to the angle of the jaw. In the temporals also a sense of throbbing is usually experienced.

Affections of the Head.—The patient complains of a "rushing of blood to the head" on making any corporeal effort or stooping; of intense throbbing and lancinating headaches, aggravated by the recumbent position, and especially by the act either of suddenly lying down or rising up; he complains also of vertigo, tinnitus aurium, scintillations and other visual illusions; and some-

times of a lethargic somnolency, which so completely subdues the faculties both of the mind and the body, as utterly to incapacitate him for every species of exertion. These symptoms, if not relieved, terminate in palsy or apoplexy. From this catastrophe the patient is often preserved by the opportune occurrence of epistaxis, to which, happily, he is peculiarly liable. From the circulation in hypertrophy being active in the eye, this organ is bright and sparkling, and sometimes vascular or blood-shot.

Complexion.—The effect of hypertrophy is to heighten the colour so long as the capillary circulation continues unembarrassed, but afterwards to diminish and change it. Every individual, however, does not acquire a florid colour. Whether he acquire it or not, depends, in truth, upon the original complexion, the series of changes being different in those who are naturally florid, and those who are pale—a fact not generally known. In the former, the colour becomes remarkably vivid, and being generally accompanied with plethoric turgescence, it gives the aspect of health and good condition. But when the capillary circulation begins to labour, the red changes into a purplish patch on the cheeks, the nose and lips become more or less purple, violet, or livid, and the intermediate skin becomes sallow and cachectic. In great hypertrophy with dilatation the purple and violet colours are sometimes of the deepest dye. In those who are naturally devoid of colour, hypertrophy either does not excite it at all, or merely increases in a slight degree the general vascularity of the face. This vanishes entirely when the capillaries become obstructed, and is superseded by universal cadaverous paleness, extending sometimes even to the lips. They, however, are generally somewhat livid.

Serous Infiltration.—This, for reasons already assigned, seldom appears before the hypertrophy is very considerable or becomes conjoined with dilatation. It frequently shows itself first in the face; a circumstance attributable to the great number and size of the cerebral arteries, and to the force with which the blood is injected into them in consequence of their proximity to the heart. With the dropsy supervene, to a greater or less degree, all the other symptoms of an obstructed circulation.

Signs of Hypertrophy of the right Ventricle.—Hypertrophy of the right ventricle produces, according to Corvisart, a greater difficulty of respiration and a deeper colour of the face than is produced by the same affection in the left ventricle. Another sign is, the more frequent expectoration of pure arterial blood.

Turgescence of the external jugular veins accompanied by pulsation synchronous with that of the arteries, was pointed out by Lancisi as a sign of "aneurism," i. e. *hypertrophy with dilatation*, of the right ventricle; and we have rarely known it absent in this affection. Of such cases, therefore, we regard it as one of the best general signs. Venous pulsation is not, in our opinion, attributable to regurgitation through the tricuspid valve, as Bertin supposes; in substantiation of which opinion we may say that regurgitation would be attended with a bellows or other such sound: this sound, however, is not found to be a

concomitant of jugular pulsation. Is the rationale of the phenomenon as follows? namely, as the ventricle, when hypertrophous, contracts with augmented power, the recoil of the tricuspid valve is preternaturally impetuous: hence, the column of blood in the act of descending into the ventricle is repelled with such an increase of force, that its impulse is propagated as far back as the jugular veins. This effect would be more considerable when the orifice and valve are enlarged, as is usually the case in hypertrophy with dilatation, because the quantity of fluid repelled would be greater. The effect would also be favoured by congestion of the great veins, (a state which generally accompanies hypertrophy with dilatation of the right ventricle,) because, when congested, they are more tense unyielding tubes, and transmit an impulse more readily.

The jugular pulsation is double: a weaker pulsation precedes that occasioned by the ventricular systole. The weaker is occasioned by the auricular systole, and the mechanism of its formation we conceive to be this: at the time that the auricle contracts, the ventricle is in a state of moderate or natural fulness; it therefore offers a certain degree of resistance to the ingress of more blood from the auricle; consequently, so much of the blood compressed by the auricular systole as cannot get forward into the ventricle, is forced back into the veins and causes their pulsation.

A difficulty has sometimes been experienced in distinguishing jugular pulsation from that of the carotid arteries; an error which may easily be avoided by observing that the jugular pulsation is confined to the lower part of the neck, and is far on the humeral side of the carotid. The pulsations of the artery, on the contrary, extend as high as the angle of the jaw, and in the direction of the anterior margin of the sterno-cleido mastoideus muscle.

The jugular turgescence, again, disappears in some degree during inspiration, and reappears on expiration; which movements, therefore, must not be confounded with the pulsations answering to the systole of the ventricle.

General Signs of Hypertrophy of the Auricles.—There are none that are distinguishable from those of disease or obstruction in the corresponding ventricle or orifice, to which the hypertrophy of the auricles owes its origin. The detection of hypertrophy of the auricle is of little importance, the cause that produced it being the source of danger.

II. PHYSICAL SIGNS.—**Impulse.**—In simple hypertrophy, the impulse communicated by the stethoscope while the patient is in a calm state, is usually so strong as distinctly to raise the head of the observer, and sometimes even sufficient to produce a shock disagreeable to the ear. The greater the hypertrophy, the longer this heaving takes for its performance. When the malady exists in a great degree, we evidently perceive that the heaving takes place with a gradual progression; it seems as though the heart swelled and applied itself to the parietes of the chest, at first by a single point, then by its whole surface, and finally sank back in a sudden manner. This sinking back, which we have been in the habit of designating by the term *back-stroke*, [*diastolic im-*

pulse,"] is occasioned by the diastole of the ventricles, during which action the heart sinks back from the walls of the chest with a force greater in proportion to its thickness and capacity. Accordingly, the *back-stroke* is strongest in hypertrophy with dilatation, but it may also be very considerable in simple hypertrophy. In the healthy heart it is not perceptible, neither is it in dilatation without hypertrophy.

A strong, slowly heaving impulse, then, is the principal sign of simple hypertrophy; and the affection may be known to be greater when the impulse is followed by a back-stroke. Both these signs exist in hypertrophy with contraction, but in a less degree, and the back-stroke may be absent if the disease is not great.

In simple hypertrophy and that with contraction, the impulse is seldom perceptible much beyond the præcordial region, except during attacks of palpitation.

In *hypertrophy with dilatation* the signs are a compound of those of hypertrophy and those of dilatation. The contraction of the ventricles can easily be felt by the hand applied to the præcordial region, and we find, especially during palpitation, smart, violent shocks, which strongly repel the hand. If we attentively examine the patient, even when most calm, we see that his head, his limbs, and even the bed-clothes, are strongly shaken at each contraction of the heart. The pulsations of the carotids, the radials, and the other superficial arteries are often visible. The impulse of the heart can sometimes be distinctly felt under the clavicles and on the left side of the thorax; sometimes even in the back, especially in meagre subjects and children.

In hypertrophy with a predominance of dilatation, the pulse is ordinarily not considerable; but it becomes very marked during palpitation, especially if accompanied with fever, and it has a very different character from that occasioned by simple hypertrophy. The beats are strong, hard, and produce a shock analogous to the blow of a hammer; but the blow seems to strike a small space; it expends itself as it were on the thoracic parietes, and does not communicate to the head of the auscultator a heaving proportioned to its force: it differs, in short, from the impulse occasioned by great hypertrophy, in the circumstance that, in the latter, the ventricles in a distended state seem to heave with their whole length against the thoracic parietes, which yield to the effort; while, in the former case, the point only of the heart seems to strike the parietes with a sharp, smart, accurately circumscribed blow, only capable of producing a sort of concussion rather than a real heaving. The same species of impulse takes place in purely nervous palpitations, in reference to which we have called it *jerk*ing.

When the impulse is increased on one side only of the præcordial region, that is under the inferior part of the sternum for the right side, and between the cartilages of the fifth and seventh left ribs for the left, we infer that the corresponding ventricle only is affected; and when it is increased on both sides, we conclude that both are affected, which is more commonly the case.

In hypertrophy, and hypertrophy with dilatation, independent of valvular disease, the beats of

the heart even during palpitation are rarely irregular, unless when they become enfeebled by excessive dyspnoea or by failure of the vital powers on the approach of dissolution.

The impulse of the heart is diminished by loss of blood, diarrhoea, any exhausting disease, rigid and long-continued abstinence, and, in general, by all the causes capable of producing debility. Consequently, a moderate hypertrophy might, without due care, be overlooked in a patient under any of these circumstances.

The impulse of the heart, moreover, may, even in cases of marked hypertrophy, cease entirely when there supervenes intense dyspnoea, connected with some affection of the lungs, especially peripneumony, pleurisy, œdema of the lungs, asthma, and the pulmonary congestions which form during the last moments of life. The sounds likewise diminish, or even entirely cease: no inferences, therefore, should be drawn from an exploration made under such circumstances.

Sounds. — Hypertrophy has the effect of deadening the sounds of the heart. In simple hypertrophy, the first sound, i. e. that produced by the ventricular contraction, is duller and more prolonged than natural in proportion as the hypertrophy is more considerable, and it generally terminates in the second sound without any interval. When the hypertrophy exists in an extreme degree, the first sound becomes nearly and sometimes wholly extinct. The second sound, i. e. that produced by the ventricular diastole, is very brief and dull, and in extreme cases scarcely perceptible. The interval of repose is shorter than natural, in consequence of the first sound being longer. Both sounds are proportionably weaker when the ventricle is contracted as well as hypertrophied. In most cases of this description the sounds can scarcely be heard under the left clavicle and at the upper part of the sternum. Sometimes they cannot be heard farther than the impulse can be felt; that is to say, scarcely beyond the limits of the præcordial region.

Each sound of the heart, though essentially one, consists of the sounds of the two sides united. This is proved by a bellows murmur in the left præcordial region being audible in the right, and vice versa. It does not follow, therefore, that because one ventricle is hypertrophied, the sound of the heart in general should be very limited in its range; for that of the other will be heard over an extent proportioned to its intensity, though not quite so far as when strengthened by its fellow. On the other hand, a morbidly increased sound of one ventricle, as by dilatation or a bellows-murmur, will be heard *alone* at points beyond the range of the natural sound of the other or healthy ventricle. Accordingly, it is only in hypertrophy of both ventricles that we must expect to find the sounds confined within very narrow limits.

We have not been able to verify the remark of Laennec, that "in hypertrophy, often when a strong heaving, without any first sound, is felt in the præcordial region, and the second sound can scarcely be distinguished, the latter is heard alone under the clavicles, and even on the back; and in less severe cases of this kind it is always heard more distinctly in these places than in the præcordial region, especially in meagre and narrow-

chested persons." We cannot understand on what principle it could be so, even supposing the auricular contraction were, as he imagines, the cause of the second sound; for as both the right auricle and ventricle are in immediate proximity and partly in contact with the sternum, it is inconceivable how the sound of either should be less distinct not an inch from its source than at a remote point. We have, however, found Laennec's remark true when the sound was drowned in the præcordial region by a bellows-murmur or pulmonary râle; the explanation of which is, that the second sound, being of a more acute nature than the murmurs, is more readily transmitted to a distance.

On the same principle also, is to be explained another doctrine of Laennec, the accuracy of which we have frequently verified: namely, that "in healthy subjects, but in whom the heart has rather thin walls, the sound is sometimes stronger under the clavicles than the first, although the same difference is not observable in the præcordial region." The reason of this is, that the second sound, being more acute, is more easily propagated.

In hypertrophy with dilatation the sounds are increased. The first is, as it were, a compound of the sound of dilatation and that of hypertrophy: namely, from dilatation it derives a loud, abrupt, or flapping commencement, and from hypertrophy a prolonged termination, like a respiratory murmur. The second sound, though not in general changed in its character, is louder than natural. These sounds may frequently be heard over the whole chest, both posteriorly and anteriorly, especially in children and meagre subjects.

In hypertrophy with dilatation the sound of the ventricular contraction is sometimes accompanied with a bellows-murmur. This we have found to be almost always the case when the heart is extremely large and contracting with vehemence. The sounds of the heart, in every form of hypertrophy, may be diminished by the same causes that diminish the impulse.

Resonance (See much valuable information on this subject in the "Procédé Opératoire" of M. Piorry, Paris, 1820, p. 112, et seq.) of the præcordial region on percussion is defective in simple hypertrophy, provided the heart be considerably enlarged; but, as hypertrophy and dilatation is the disease in which the organ attains the greatest volume, it is that in which resonance is most frequently and most extensively defective. In all cases of considerable enlargement the dulness as well as the impulse are lower down than natural, except in adhesion of the pericardium, by which affection the heart is more or less braced up.

Progress and Termination of Hypertrophy.—Hypertrophy, while moderate, and not complicated with any mechanical impediment to the circulation, is productive of very little inconvenience. This is especially true with respect to children. In them the heart is naturally larger in proportion than in adults; and in many this amounts to a very considerable degree of hypertrophy with dilatation, accompanied with greatly increased impulse and sound; yet the general symptoms manifested by such are often scarcely appreciable, and the increased action itself sub-

sides towards the period of puberty by the establishment of a more correct proportion and equilibrium between the heart and the system.

At the adult age also, and during the whole period of manhood, an individual of an otherwise sound and vigorous constitution may be affected with hypertrophy to a moderate extent, without experiencing any sensible deterioration of the general health (with the exception of being more liable than others to cerebral and phlogistic affections), or any diminution of muscular force and activity; and if his habits with respect to diet and exercise be moderate, he may pass a long series of years, and even attain the extreme period of senility, without being conscious that he is the subject of organic disease. The only general signs denoting the existence of the malady will be, perhaps, a little shortness of breath on exertion, and occasional feelings of slight palpitation. Amongst the labouring classes these symptoms, even in a considerable degree, are so little regarded that their presence is often disavowed by the patient, though palpably manifest to the physician. If, however, an individual affected with hypertrophy abandon himself to intemperate living, or engage in occupations requiring great corporeal exertion, he rarely fails to bring on either apoplexy, palsy, hæmoptysis, or an irremediably aggravated state of the disease, which embitters and curtails his existence.

The celerity with which these accidents are induced depends on circumstances. In general, the progress of hypertrophy is very slow and gradual, but in some cases it is rapid: in several instances we have known it terminate fatally within a year from its commencement. The circumstances occasioning these variations are connected with—1, the form of the disease; 2, its complications; 3, the nature and intensity of the external exciting causes; and, 4, the constitution of the patient. It is of the utmost importance that the practitioner be able to form some estimate of the influence of these circumstances; for it is by this means only that he can foresee the course of the disease, and direct his treatment with judgment and decision. It may be useful, therefore, to enlarge a little on this subject.

1. The progress and termination of hypertrophy are influenced by the form of the disease. *Simple hypertrophy* is more apt than any other form to induce apoplexy while the patient is apparently in perfect health. This is to be accounted for by its tendency to create plethora, while at the same time it does not incapacitate the patient for active corporeal exercise and the pleasures of the table. When premature death does not occur from apoplexy or hæmoptysis, simple uncomplicated hypertrophy runs a more chronic course than any other form of the disease.

Hypertrophy with dilatation, especially if great, is a far more harassing, dangerous, and, if we may be allowed the term, *acute* affection than the preceding. All its symptoms are more violent, and its course is more rapid. It is somewhat less apt to occasion unexpected attacks of apoplexy; probably because the greater dyspnoea which it occasions deters the patient from violent exercise and high living. When once the palpitation and dyspnoea have attained such an extent as *imperatively*

to demand periodical bleedings at brief intervals, the malady hurries with an uninterrupted course to its fatal termination.

2. The progress and termination of hypertrophy are influenced by its complications. When hypertrophy is connected with contraction of an orifice or any other obstacle to the course of the blood, the symptoms are greatly aggravated. For, first, in consequence of that obstacle, the hypertrophy proceeds to a greater extent; and, secondly, the violent struggles of the heart to surmount the obstacle subvert the general balance of the circulation. To speak more explicitly, suppose the obstacle to be situated in the aortic orifice. While the left ventricle is palpitating to disgorge itself through the contracted aperture, the right, acting in concert with it, deluges the lungs with an inordinate quantity of blood; whence ensues a paroxysm of dyspnoea: next, in consequence of the pressure of blood through the lungs, the supply to the left ventricle is increased. This ventricle, therefore, instead of relieving its engorgement by palpitation, only aggravates it, and the fit does not subside until either the heart becomes gradually exhausted by its own efforts, or (what is more common) until the internal congestion is relieved by determination to the surface or a copious discharge of watery mucus from the lungs. The most violent, though perhaps not the most distressing, paroxysms of palpitation and dyspnoea that we have witnessed have occurred in the particular complication described. In others there may exist a greater feeling of suffocation (the source of the greatest distress), as will hereafter be explained in the articles HEART, DISEASES OF THE VALVES OF THE, and POLYPI.

Adhesion of the pericardium, which rarely fails to produce hypertrophy with dilatation, is an extremely formidable complication of this malady. It greatly aggravates all the symptoms, and accelerates the fatal event, which not unfrequently takes place within the period of a year; and we have known it occur in nine months.

Febrile or inflammatory complaints supervening on an advanced degree of hypertrophy exasperate the malady in a surprising manner, so as not unfrequently to carry off the patient in the course of a few days. The effect seems to be produced by the febrile excitement keeping up, as it were, a perpetual fit of palpitation and embarrassment of the circulation, which the constitution cannot support beyond a brief period. Peripneumony has pre-eminently this effect; apparently because it not only excites the heart, but obstructs the circulation through the lungs.

3. The progress and termination of hypertrophy are influenced by the nature and intensity of the external exciting causes.

The principal of these are, over-exertion, excesses at table, and mental perturbation, the latter of which, though not strictly external, may be ranged under this head. The effect of these requires no explanation, but it may be said that the dangerous influence of over-eating is greatest in simple hypertrophy, because it generates plethora and increases the tendency to apoplexy; while over-exercise and intemperance are more prejudicial in hypertrophy with dilatation, because they

increase the dilatation, which is the more dangerous part of the disease.

4. The progress and termination of hypertrophy are influenced in a remarkable degree by the constitution of the patient. The robust resist its encroachments much longer than those who are delicate and effeminate: and if the former, either from bad air or want of exercise, from disease, or from age, become unhealthy, emaciated, and feeble, they are rendered much more susceptible of the effects of the disease. This (if we may indulge in a mere speculation) is possibly in consequence of emaciation taking place to a greater extent in the muscular and adipose tissues than in the internal viscera, whence, the latter becoming predominant in size, the equilibrium between the heart and the system is subverted. This is exactly the converse of what occurs at the period of puberty in those who had laboured under enlargement of the heart when children, for in them the equilibrium is restored by the system enlarging with the growth in proportion to the size of the heart.

Prognosis.—The general prognosis is favourable in the early and unfavourable in the advanced stages of the disease. The particular prognosis must be founded on an estimate of the various circumstances of the case formed according to the above rules.

Treatment of Hypertrophy.—As it is easier to diminish the nutrition of the heart than to increase it, or to remove a valvular or other mechanical obstruction, it is very conceivable that hypertrophy is more susceptible of cure than any other organic affection of the heart.

In the treatment the first care should be to remove any known exciting cause of the malady. It is equally obvious that as this malady consists in an increased power and action of the heart, bloodletting and other reducing and tranquillizing means are the appropriate remedies. Laennec strongly recommends that they be employed with courage and perseverance on the plan of Albertini and Valsalva. We cannot say that our own observation leads us to coincide entirely in this opinion. We shall first, therefore, give a sketch of the treatment alluded to, the sanction accorded to which by names of the highest authority renders it at least deserving of the most attentive consideration; and shall afterwards point out in what respects it appears to us to be objectionable.

This treatment, according to M. Laennec, ought to be prosecuted in an energetic manner, especially in the commencements; and in aiming to enfeeble the patient, we ought much more to fear resting short of the mark than exceeding it. We should commence by abstracting blood as copiously as the patient can support without falling into a state of sinking; and we should repeat the operation every two, four, or eight days, until the palpitations have ceased, and the heart no longer gives, under the stethoscope, more than a moderate impulse. We should, at the same time, reduce to at least one-half the quantity of aliments which the patient ordinarily takes, and diminish even this quantity if he preserve more muscular strength than suffices to take, step by step, a walk of a few minutes in the garden. In a stout adult Laennec usually reduces the quantity of aliments

to fourteen ounces a day, amongst which he thinks there should be only two ounces of white animal food. If the patient wishes to take broth or milk, he counts four ounces of these liquids for one of animal food. Wine ought to be interdicted. When the patient has been about two months without experiencing palpitation, and without strong impulse of the heart, we may dispense with the bleedings, and somewhat diminish the severity of the regimen, if habit has not yet been able in any degree to reconcile him to it. But it is necessary to revert to the same means, and with equal rigour, if in the sequel the impulse of the heart increase again. We ought not to have confidence in the cure until the expiration of a year of complete absence of all the symptoms, and especially of all the physical signs of hypertrophy. We must be afraid of allowing ourselves to be deceived by the perfect calm which bloodletting and abstinence sometimes very promptly produce, especially if we have commenced the treatment at a period when the hypertrophy was already accompanied with extreme dyspnoea, with anasarca, and with other symptoms which gave reason to fear an approaching death.

If we begin the treatment of hypertrophy of the heart at a period when it has already produced severe effects, particularly anasarca, ascites, œdema of the lungs, and a very marked state of cachexy, we ought not on that account to shrink from bleeding and abstinence. To obtain success, it is necessary, according to the same author, that the physician and the patient arm themselves with almost equal patience and firmness; for it is not more difficult for the latter to resign himself to perpetual fast and frequent bloodlettings, than for the former to struggle daily against the opposition of relations and friends, and the discouragement which cannot fail to seize upon the patient in a treatment which ought to continue at least several months, and sometimes to be prolonged during several consecutive years.

Such is the manner in which M. Laennec employs the treatment of Albertini and Valsalva; and he states that he could cite a dozen instances of cures of hypertrophy, either simple or with dilatation, which have not been falsified for several years. One important case which he details, seems to prove that the treatment causes atrophy of the heart; for the organ was remarkably less than the fist of the subject, and was shrivelled or wrinkled in a longitudinal direction.

Our objections to the treatment described are founded on the circumstance that, though we have invariably found the greatest benefit to be derived from sparing abstractions of blood at intervals of two or three weeks or more, we have constantly noticed that when, from the severity of the dyspnoea and palpitation in the advanced stages of the complaint, the practitioner was induced, or thought himself compelled, to resort to frequent bleedings at short intervals, the patient, though perhaps momentarily relieved, progressively declined from that moment, the paroxysms recurring more frequently and with greater violence, until they eventually terminated in his destruction. Now, on comparing a patient under these circumstances with one under the influence of mere reaction from loss of blood, the analogy appears to us to be very intimate. In both, the violence of

the heart's action, so far from being repressed by a reiteration of the bloodletting, is only increased; in both the blood is, and necessarily must be, attenuated and deteriorated in consequence of the fibrinous portion and red globules being replaced to a greater extent than natural by serum, which is more expeditiously regenerated.

These, then, are apparently the causes of the patient's decline. The prejudicial effects of the re-action are sufficiently obvious; and the state of the blood not only contributes in all probability to the re-action, (*Vid. Treatise on Diseases of the Heart, by the writer, p. 75.*) but, by its deteriorated quality, is unsuitable for the due nutrition and conservation of the system.*

It would appear, therefore, that the indications in the treatment of hypertrophy are, to diminish the quantity without materially deteriorating the quality of the blood, and to do this in such a manner as, without producing re-action, permanently to enfeeble the action of the heart and the energy of the circulation. The safest and most effectual means of fulfilling these indications have appeared to us to be the following:

Four, six, or eight ounces of blood should be taken every two, three, four, or six weeks, according to the strength of the patient, and sufficient to keep down palpitation, dyspnoea, and strong impulse of the heart. If the head be much affected, the blood should be drawn by cupping from the nape of the neck. The diet should consist of white animal food and liquids in small quantity, unless, from the advanced state of the disease, the blood be so impoverished as to be insufficient for the maintenance of the system, when a more nutritious though still spare diet may be allowed. Every thing stimulating, as spirituous and fermented liquors, and highly seasoned dishes, should be avoided. Any exercise taken should be so gentle as never to hurry, and, if possible, never even in the slightest degree to accelerate the circulation. When the action of the heart appears to increase, and yet general bleeding is not expedient, three or four copious and watery alvine evacuations should be procured daily by saline aperients, of which none answers better than one or two drachms of sulphate of magnesia in infusion of roses twice or thrice a-day. This may be continued for a week or ten days according to the effect; and either the same or some analogous aperients should be employed habitually in sufficient doses to keep the body gently open, and to procure, if possible, liquid evacuations. When salines are used habitually, their debilitating effects on the intestinal canal may be in a great measure counteracted by adding to the infusion of roses an equal quantity of compound infusion of orange-peel, and six or eight minims of diluted sulphuric acid.

In addition to purgatives we have seen the most decided advantage result from diuretics; and not only when there was dropsy, but equally when

* It does not follow that though the treatment of Albertini and Valsalva be unsuitable for hypertrophy, it is equally so for aneurism of the aorta; as in the latter the object is to produce a sudden and extreme, though temporary reduction of the force of the circulation, in order to promote the formation of fibrinous coagula in the sac: an expedient which is sometimes perfectly successful in effecting a cure of aneurism, but which will not have the same effect on hypertrophy.

there was none. Their mode of operation appears to be ultimately the same as that of purgatives: namely, they drain off the serous portion of the blood. We have found many patients, conscious of the benefit which they derived from this class of remedies, to be in the constant habit of taking cream of tartar, broom-tea, and other similar popular medicines. One patient affected with contraction of the mitral valve to the size of an ordinary pea, by these means warded off dropsy, beyond the slightest œdema of the feet, for ten years. When decided dropsy appears, it must be combated by the most efficient diuretics—the super-tartrate, tartrate, acetate, and nitrate of potass, squill, digitalis, spirit of nitric ether, decoction of broom, &c., with mercury if not contraindicated. As no class of remedies is more variable and uncertain than this, when one fails another should be resorted to; and it not unfrequently happens that a weaker is more successful than a stronger. Should diuretics wholly fail, hydragogue purgatives, as elaterium, tincture of jalap, infusion of senna with tartrate of potass, &c. are often invaluable substitutes.

The state of the stomach and of the biliary secretion should never be overlooked in hypertrophy, as their derangements are amongst the most efficient exciting causes of palpitation. The remedies suitable for dyspepsia and bile are therefore to be resorted to. We deem it unnecessary here to enlarge on them, and on the treatment of dropsy, cough, dyspnoea, &c., as these subjects will be found fully discussed in the article HEART, (DISEASES OF THE VALVES OF THE).

It frequently happens that, notwithstanding the most judicious use of the remedies mentioned, the irritability of the nervous system frustrates their tendency to reduce and tranquillize the action of the heart. In this case sedatives are eminently useful, and the best effects often result from tincture of digitalis, to the extent of *m.xx.* or *xxx.* twice or thrice a-day; from two or three drops of hydrocyanic acid, administered as often; from three or four or more of extr. of hyoscyamus or conium once or twice a-day; and from half a grain of acetate of morphia twice a-day.

The above, and indeed every other mode of treatment is unavailing if not *steadily* pursued, and it must be pursued for one, two, three, or more years. Thus employed, we have found it effect cures in a considerable number of instances, some of which were advanced even to the second degree. In the first degree, especially before the period of puberty, this fortunate event is often obtained although bleeding be resorted to only at long intervals, as of from six weeks to three months. [See Pennock's edit. of Hope, on *Diseases of the Heart*, p. 230.]

[HEART, (INFLAMMATION OF THE)—
See CARDITIS AND PERICARDITIS.]

HEART, (MALFORMATIONS OF THE)
—Under this head we comprehend all those deviations from the natural mechanism or form of the heart which are developed in its original conformation, or in the progress of its early growth. They arise, for the most part, from an arrest or interruption in those successive changes which the

heart undergoes from its first formation until it is adapted to support the double circulation of post-natal life; but as in the case of other monstrosities, they sometimes consist of an irregular, and sometimes of a superfluous, development of parts.

1. DEFECTIVE MALFORMATIONS.—As there is a period in foetal life in which the heart does not exist, so there have been instances in which the constructive process has been at this period interrupted with respect to this organ; so that, while other parts of the body were more or less perfectly developed, the heart was entirely deficient; its place being sometimes occupied by a mere sac or net-work of vessels, as in the zoophytes, and in other cases the communication between the arterial and venous system being direct. In nearly all the cases of *acardia* on record, the brain and spinal marrow were also wanting; but Andral (Pathological Anatomy, translated by Drs. Townsend and West, vol. ii.) quotes an instance from the second volume of the *Répertoire d'Anatomie*, in which the nervous centres were nearly entire, but there was neither heart, nor lungs, nor large vessels. As these are cases more of physiological than of practical interest, we need not dwell longer upon them.

It has not been distinctly ascertained by observation that the heart of the embryo is ever quite of the simple structure of the heart of fishes: in the early stages of its existence, however, it differs only in having the rudiments of a septum at the apex of the ventricle, and probably at a more remote period it is quite simple, consisting of a single auricle and ventricle; and this condition remaining stationary until birth, constitutes a variety of malformations of the lowest order. Of this description we find the record of eight instances.* In these cases the aorta gives off one or more pulmonary arteries, and the pulmonary veins terminate either in the auricle or in the vena cava. Some of these infants lived for several days without any *apparent* irregularity or defect in the performance of their functions, except some dyspnoea and blue discoloration of the skin, which varied considerably in different instances and at different times. In Dr. Farre's case the skin was very pale, and with but slight lividity, while the action of the heart and diaphragm was excessive; and these symptoms are explained by the fact that the orifice of the aorta was much contracted, so that, while the system was ill-supplied with blood, the heart and lungs were kept constantly engaged. Of the two cases related in the Philosophical Transactions, one lived ten days with no other uncommon sign than a purple skin; in the other this only occurred shortly after birth and again just before death, which happened on the eighth day.

The next gradation of malformation is that in which there are two auricles with one ventricle. Of this we have found only two examples recorded, the subject of one of which, quoted by Laennec from Kreysig, (vol. iii. p. 100.) attained the age of twenty-two years. This fact proves that, great as the anomaly in this case was, the body can

better adapt itself to this sort of reptile-like circulation than to those malformations which greatly obstruct the course of the blood.

Nearly allied in effect to the preceding, although their more perfect structure would entitle them to a step higher in the class, are the cases of imperfections or perforations of the septa between the ventricle and between the auricles.* Many of this kind have been described, in a considerable variety of combination. There is commonly a contraction of the orifice of the pulmonary artery, and in the fœtus born with this malformation the ductus arteriosus is either totally wanting, or imperforate. Some subjects of this malformation have survived for several years, (one reached twenty-seven,) but always in a state of great disorder, being affected with blueness of skin, faintings, &c. The foramen in the septum of the ventricle is always nearest to the base of the heart, and it is often so near the origin of the aorta or of the pulmonary artery; that the vessel communicates freely with both ventricles. These all appear to be instances of arrest of development, corresponding with the state of the fœtal heart in the early stages of its existence; and the disorder which they occasion in post-natal life is generally in proportion to the extent of the imperfection, but it is always greatly augmented wherever there is a contraction of the arterial orifices.

The last order of malformations from simple interrupted development or adaptation are those in which the heart retains, after birth, one or both of the peculiarities naturally destined only for the fœtal state, the open state of the foramen ovale and of the ductus arteriosus. As the occlusion of these channels of auxiliary circulation is essential to the well-being of the perfect breathing animal, nature admirably contrives that the first respiratory act shall in normal cases effect this change, and the means by which it fulfils this end are worthy of attention. According to Meckel, there is little difference in thickness between the two ventricles of the heart at the time of birth, the left scarcely presenting any of that superiority which is so evident in after-life. In fact, it appears that before birth the right ventricle, through the ductus arteriosus, assists the left in the systemic circulation; and when the post-natal change takes place, there must be not only an additional outlet given to the blood from the right ventricle, but also an increase of power to the left ventricle, to maintain the aortic circulation; which now depends solely on it. A full and perfect respiratory act fulfils both these objects; by expanding the lungs it gives a free outlet to the blood from the right ventricle, and, by arterializing the blood which returns to the left ventricle, it stimulates it to such an increased energy of contraction as enables it, unaided, to supply blood through the system. This increased energy is soon followed by an increased thickness of the muscular walls of the ventricle, which gives a permanency to the greater

power required in its important function. The ductus arteriosus, thus freed from the current of blood through it, contracts, as in the case of all obstructed or empty arteries, into an impervious cord. The progress of this contraction has been minutely described by Bernt as a test applicable to the investigation of cases of supposed infanticide. (*Handbuch der Gerichtl. Arzneikunde.*)

The obliteration of the foramen ovale is probably a much slower process, and one of less consequence, for its ordinary state at the time of birth is such that, unless there be considerable inequality of pressure between the auricles, it is sufficiently closed by its valves to prevent the passage of blood through it.

From these circumstances we are inclined to consider patescence after birth of the foramen ovale in most cases, and of the ductus arteriosus in every case of its occurrence, to be the result of loss of balance between the effective forces of the two sides of the heart at the time of birth. The ductus arteriosus stands in the same relation to both ventricles, that is, it communicates with the great artery proceeding from each: as long as these two arteries are filled with equal force, there will be no current in the duct; and such is the state under which, in natural cases, it contracts into an impervious tube. But if there be greater pressure on one end, whether from the pulmonary artery or from the aorta, a current must then pass from the stronger to the weaker side. Now the causes of such an inequality of pressure are various; and it will be worth while to point out a few of them, as we shall thereby gain a clearer understanding of the complicated pathology of several kinds of malformation. In several cases on record the open state of the ductus arteriosus has been found in conjunction with a manifestly contracted state of the orifice of the pulmonary artery, and in some with its total obliteration. Dr. William Hunter relates the case of a child born in the eighth month of gestation, which, after exhibiting a livid skin, dyspnoea, and violent palpitations, died of convulsions on the twenty-third day from its birth. On dissection, the pulmonary artery was found reduced to an impervious cord, whilst the foramen ovale and ductus arteriosus were both open. Dr. Farre gives the history of two similar cases, one of which died in a week, the other lived six months. In all these the muscular power of the right ventricle had become useless; in Dr. Hunter's case its cavity was nearly obliterated, and in both of Dr. Farre's a perforation of the inter-ventricular septum made the right a mere appendix to the left ventricle. The part which the ductus arteriosus bore here was important, for, open to pressure only at its aortic end, it must have supplied the place of the pulmonary artery, by conveying the blood in a retrograde course from the aorta to the lungs. The same thing occurs in a minor degree when the pulmonary artery is merely contracted at its orifice. If, on the other hand, the aortic orifice is contracted, so that the artery does not receive the due influence of the systole of the left ventricle, the pressure on the right end of the ductus arteriosus will be greatest, and a current will flow from the pulmonary artery to the aorta. Any obstruction to the circulation through the lungs would have a similar effect, and for the reasons which we have already observed to obtain in fœtal life.

* Farre, op. cit. p. 30, 27, 28; Meckel, Tab. Anat. Path. Fasc. 1, Fig. 1 and 2; Senac, Traité sur la Structure du Cœur, t. ii. p. 404; Dr. Hunter, Medical Obs. and Inq., vol. vi. p. 291-99; Coreisart, sur les Mal. du Cœur, pp. 276, 293, 298; Bartholinus, Acta Hofniens. t. i. p. 100; Abernethy, Surg. and Phys. Essays; Dr. Crampton, Trans. Coll. Phys., Dublin, vol. i.; Dr. Hope, on Diseases of the Heart, p. 468.

Openings in the septum of the ventricle, when combined with decided contractions of either of the arterial tubes, we cannot but view as in most instances the effects of the latter; for it is a simpler idea, and one more consistent with the laws of development, to suppose that an obstruction, which, pathologically speaking, is of frequent occurrence, retains the current of blood in the course which it held in the early period of its formation, than to ascribe a perforated septum to some specific and inexplicable arrest in its natural development.

The most common combination of an open ductus arteriosus is, however, with considerable patency of the foramen ovale; and we would still view this latter in the light of a cause. Any considerable direct communication between the auricles must, to some extent, frustrate the longer intercourse through the lungs; and from the blood passing thus directly in a venous state to the left side of the heart, two things affecting the balance of the circulation must result: 1. the left ventricle, not receiving its proper stimulus of pure arterial blood, does not contract with increased energy, as at the moment of birth it ought to do; 2. this defective force in the left ventricle occasions some stasis of blood in the pulmonary vessels; whence the pressure of the aortic extremity of the ductus arteriosus continuing to be less than at the right end, the blood persists to flow through it as before birth, and its canal is kept permanently open.

2. Irregular Malformations.—The next description of malformations are those which consist of a misplaced or erroneous position or attachment of parts in the heart, constituting the *qualitative* malformations of Meckel. Examples of transposition of the aorta and pulmonary artery are described by Farre, (Op. cit. p. 29); Langstaff, (Lond. Med. Rev. p. 83); and Baillie; (Morbid Anatomy, p. 36.) The subject of one lived five months and died of small-pox; the surface was cold and extremely susceptible, and the skin blue, with incessant cough in any posture but on the right side. During the eruptive fever there was increased heat only in the head, the limbs and body remaining cold. The valve of the foramen ovale was found perforated with five holes; the aorta sprung from the right, and the pulmonary artery from the left ventricle. In Mr. Langstaff's case the child lived ten weeks with similar symptoms, and here both the foramen ovale and ductus arteriosus were open. In two cases related by Sir Astley Cooper, the pulmonary artery communicated with both ventricles, and gave off the descending aorta; the ascending aorta rose from the left and divided into the innominate, and the left carotid and subclavian; the foramen ovale was also open.

A remarkable instance of malformation is described by Dr. Holmes in the first volume of the Transactions of the Medico-Chirurgical Society of Edinburgh. The subject was a young man aged 21, who had from childhood been affected with palpitation, dyspnoea, blueness of skin, pain about the heart, and frequent faintings, with cold limbs. The foramen ovale was found open, and the right auricle, instead of opening into the right ventricle, communicated with the left by a large aperture, which was furnished with a tricuspid valve. The auricle was enlarged to the capacity

of a pint. The right ventricle gave off the pulmonary artery as usual, and must have received blood only through an opening in the left ventricle, immediately beneath the aortic valves.

The valves of the heart have been found in an unnatural state, which many pathologists have considered to be congenital. Laennec describes a union of the laminae of the tricuspid and of the mitral valves at points near their extremities, but leaving apertures through which a finger might be passed. In the same case the semilunar valves of the aorta and of the pulmonary artery were also adherent to one another. Small, smooth, round, or oval openings are occasionally met with in the different valves, which may be regarded as congenital; and Laennec met with a case in which holes of this kind had converted the tricuspid valve into a mere net-work. There have been noticed other irregularities in the valves, such as an inequality in their size, and a superfluity in their number.

3. Superfluous Malformations.—The last order of malformations to be noticed are those consisting of excessive development. Well-described examples of these are not numerous, nor do they bear any remarkable feature. The heart has been found with supernumerary auricles and ventricles, and even double the natural number. Meckel describes instances of these double hearts, all having occurred in double monsters. (De Monstrosa Dupl.) Winslow met with one in a foetus which was defective in the oesophagus and trachea. Andral has seen a heart with three auricles, and another with four ventricles. An appendicular auricle or ventricle is not uncommon: we have met with an instance of the latter. Supernumerary septa, partially or entirely separating portions of the different cavities, have likewise been described. The foramen ovale has been found closed in the foetus (Vieussens sur la Structure du Cœur); and in one case of this kind there existed an unusual communication between the vena cava and pulmonary veins. Bertin quotes a case of a double arch of the aorta.

The pathological effects of malformations of the heart depend on two physical causes, an obstruction to the circulation, and an intermixture of venous with arterial blood. The first of these is probably the most important; for the latter, although decidedly injurious, does not appear to encroach so seriously on the functions of a body accustomed to its effects, as to prove fatal, unless when conjoined with material obstruction to the circulation. These two, moreover, produce and re-act on each other in a manner sufficiently interesting to merit a little consideration.

Some cases of single heart already noticed, prove that the free admixture of venous blood in the arteries is not incompatible with life, as the subjects lived for several days. There was in these cases, besides, some obstruction to the circulation, in the aorta, or in the pulmonary artery; the one being characterized by pallor, and the other by a blue discoloration of the skin: and it is a question whether, but for these impediments, life would not have been considered prolonged; for the simplicity of the moving power would prevent any of that loss of balance which is so frequent a cause of obstructed circulation in the

double heart. This loss of balance, or undue action of one compartment of the heart, is an almost inevitable consequence of any malformation which causes a mixture of venous with arterial blood; and if it be great, it will generally aggravate the evil effects of the malformation; whence, in such cases, the obvious tendency to progressive disorder. In the greater number of instances the right side of the heart suffers more especially. Naturally its task may be said to be lighter in post-natal life than that of the left side, but the various congenital irregularities of mechanism fall heavy upon it; whence, according to the observations of Louis, it is almost always affected with dilatation or hypertrophy. Thus in perforation of the septum of the ventricles, as well as in the open state of the ductus arteriosus with a free pulmonary artery, the right ventricle has to contribute to the aortic circulation as well as to maintain the pulmonary, whence it gradually assumes a more muscular structure than the left ventricle. The right auricle may suffer in a similar way from an open foramen ovale; but as the contractile power of the auricles is but trivial in force, this malformation will scarcely produce great disorder without the addition of another cause. Such a cause is any obstruction to the circulation through the lungs; for example, a contraction of the pulmonary artery. Where this exists, the blood will not proceed so fast as it arrives; there is consequently an accumulation in the auricle, with an unequal pressure and a flow through the foramen ovale. But in the history of cases described, we find the worst complication of this malformation is with an imperfection in the tricuspid valve. This is illustrated in Corvisart's case of the postilion. (Op. cit. p. 279.) The man, aged 57, said to have been previously healthy, was attacked with blueness of skin, palpitation, dyspnea, &c. after injuries from a carriage passing over him, and a violent blow on the epigastrium. From this time he suffered in various degrees, and in four years sank under the usual symptoms of valvular disease of the heart, accompanied by discoloration of skin. The right auricle and ventricle were found greatly dilated and thickened; the left auricle was also dilated, but the left ventricle was both thinner and smaller than natural. The foramen ovale was more than an inch in diameter, and the right auriculo-ventricular opening so much dilated as to admit four fingers, whilst that on the left side only admitted one; the mouth of the aorta was likewise contracted. Laennec ascribed the open state of the foramen ovale to this accident; but we think it more probable that this was congenital, and, as is often known to be the case, harmless in its effects until the period of the accident. The violence may have occasioned a rupture or dilatation of some portion of the tricuspid valve, so that it ceased to close the auriculo-ventricular orifice, whence regurgitation into the right auricle, and such pressure as to drive the blood through, and in time greatly to dilate the foramen ovale. We have said that an imperfect state of the tricuspid valve is the worst disorder of the mechanism that can complicate itself with an open foramen ovale; and the reason is, in addition to what we have just remarked, that the impulse of the right ven-

tricle is propagated through the foramen ovale to the left auricle, and there opposes the course of the blood, which, during the systole of the ventricle, ought to flow into it from the lungs. It may be thus seen why in the above and in all similar cases on record, there has been an excessive oppression of the respiratory function. The contraction of the left ventricle and aorta was obviously the effect both of the small quantity of blood which the disordered mechanism of the right ventricle could propel into it, and also of the unstimulating quality of that blood.

We may remark, in conclusion, that every kind of malformation which leads to a mixture of venous with arterial blood, must, as we have before explained, occasion an obstructed circulation through the lungs, and consequently add to the labour of the right ventricle. Bertin ascribes the frequent occurrence of hypertrophy in the right cavities of the heart, in cases of malformation, to the more stimulating influence which arterial blood obtaining entrance through the unnatural opening, exercises upon them. (*Traité des Mal. du Cœur*, p. 436.) Laennec thinks, however, that the pathological change results from the necessity imposed on the right cavities (naturally the weakest) of a more energetic action, in order to resist the impulse of blood flowing from the left side. (Dr. Forbes's Translation, p. 630.) This opinion is more clearly supported by Dr. Hope, in his valuable work on Diseases of the Heart (Op. cit. p. 463), who remarks on the opinion of Bertin, that the obstructions in the pulmonary artery which so frequently prevail, would throw the current too much in the opposite direction, from right to left, to permit the entrance of arterial blood into the right cavities; and he considers that the greater labour thrown on the right ventricle in supporting the weight of the aortic circulation, is a sufficient cause for the changes in question. The dilatation in the same cavities is the generally acknowledged effect of over-distension; and Dr. Hope considers that this always depends on some obstruction to its course on the left.

M. Louis gives the following numerical comparison of the pathological changes in nineteen cases of congenital malformations. (*Archives de Méd.* tome iii. Nov. and Dec.)

Contraction of the orifice of the pulmonary artery in ten; of the aorta in only one. Dilatation of the right auricle in eighteen, five of which were with hypertrophy, and two with attenuated parietes. Right ventricle simply dilated in five; simply hypertrophied in six; dilated and hypertrophied in four. Left auricle dilated in eight; hypertrophied in three. Left ventricle dilated in four; hypertrophied in two. Tricuspid valve more frequently diseased than the mitral, but neither often.

Symptoms. — Malformations of the heart sometimes give rise to very prominent and well-marked symptoms, whilst in other instances they have only been discovered by the scrutiny of the anatomist after death. When the disease is extensive, and particularly when combined with hypertrophy of one of the cavities or obstruction in some of the orifices, some or other of the following signs are always present;—discoloration

of the skin, varying from a slight reddish purple tinge to a deep purple or livid colour, especially affecting those parts which are naturally red, as the lips, tongue, fauces, and nails, which are sometimes almost black;—considerable diminution of the superficial heat, with great sensibility to cold;—palpitation of the heart coming on in paroxysms, especially after exertion or mental emotion;—the pulse very variable, but generally irregular; occasionally syncope;—in children convulsions;—respiration habitually short and difficult, with fits of severe dyspnoea, which sometimes occur periodically, and after tormenting the patient for a variable period, are terminated with sighs and yawning;—torpidity of bodily habit, with irritability of temper;—severe pain of the head, vertigo, and defective vision;—atrophy, and a disposition to hemorrhage.

It was, until lately, a general opinion that the blue discoloration of the skin, or *cyanosis*, as in its greater degrees it is termed, is a characteristic sign of malformations of the heart which occasion the mixture of venous with arterial blood. This has been called in question in consequence of some cases described by Fouquier, Meckel, and Breschet, in which there existed malformations of this description without cyanosis; and on the other hand an example of cyanosis reported to the Academy of Medicine by Dr. Mare, where no organic disease of the heart, congenital or otherwise, was discovered on dissection. Another opposing argument has been urged by Fouquier, founded on the alleged fact that the blood in the arteries of the fetus is dark without there being any blueness of the skin. Bertin (*Mal. du Cœur*, p. 437) and Ferrus (*Dict. de Méd. art. Cyanose*) have accordingly taken up the idea that the mixture of venous with arterial blood has no necessary connection with cyanosis, but that a stagnation of blood in the capillaries, generally dependent on an obstruction to the circulation in the heart, is the universal cause of the blue discoloration in question: and that the presence of this sign in malformations arises only from the impeded state of the circulation which generally attends them. This view appears to us at least quite as inconclusive as the former one; for we know that the circulation is impeded in almost every considerable disease of the heart or lungs, often without any cyanosis, and never (except, according to Laennec, in emphysema of the lungs) with that degree which is seen in congenital malformations. Moreover, the cases before quoted (from Farre, Langstaff, and Baillie) prove that in some most remarkable examples of constant discoloration of the skin, there were no apparent obstructions to the course of the blood.

We confess that we are still inclined to prefer the old opinion, modified in some degree according to the objections which the foregoing facts bear against it. With respect to Fouquier's argument, it may be stated that the fact of the blood in the fetal arteries being dark is denied by later writers;* and it is familiar to accoucheurs that a newly-born infant is often livid or purple, till it

cries; crying is a proof of complete respiration, and then this colour gives place to a general redness. The absence of cyanosis in the cases of malformations before named was conjoined with a general pallidity of the surface; and it would seem, therefore, that defect of blood in the capillaries was the reason of the absence of a dark colour. It must be remembered that in many cases we often see the countenance and surface so pale that the colour of the blood obviously does not affect them; and it is not to be expected that blueness of the skin should be apparent in a greater proportional number of cases of malformation with free communication between the cavities, than is the redness of the same parts visible in other subjects. Dr. Paget well observes that, "as the colour of any organ is partly derived from the blood it contains, a change of the colour of the blood must affect the colour of the organ;" and we can conceive no cause of this change more efficient than one which throws black blood into vessels which naturally contain it of a visible red. To assert that malformations are the only source of cyanosis would be to take an occasional for a proximate cause: in the collapsed stage of cholera, in asphyxia, and in emphysema of the lungs, we find a similar discoloration of the skin; and in these the same proximate cause must be recognised, the presence of black blood in vessels which ordinarily convey red. In these cases, as in the former, and as also in the healthy state, an additional obstruction, the effect of posture, exposure, or exertion, will be followed by a still further injection of the capillaries, and where an ordinary subject would become florid and flushed, these assume a deeper and more livid hue.

In most of the cases accurately described, a diminished temperature with chilliness of the surface has been remarked in those malformations that are attended with blueness of the skin. Dr. Farre submitted some of these to the test of the thermometer, and found the internal heat to be as usual, but that of the surface depressed in various degrees according to the exposure of the part. In some instances, when a limb has been exposed, it has been observed to become quite cold and livid. The patients commonly like to approach the fire at all seasons, and require an unusual quantity of clothing; when exposed to cold, especially if accompanied with wind, they sometimes become quite torpid and incapable of exertion. This is well instanced in a case described in Dr. Hope's work. (*Op. cit.* p. 470.) [See, especially, Dr. Pennock's *Amer. edit.* p. 449, Philad. 1842.]

The palpitation, syncope, and dyspnoea may generally be said to be more frequent than in any ordinary disease of the heart; but the paroxysms are not often so severe as in the advanced and aggravated forms of valvular disease; nevertheless, when verging towards a fatal termination, they scarcely differ in symptoms from valvular disease, with which in fact they are frequently complicated. The greater blueness of skin, when present, is the most decisive distinction. It would appear that the intermittent form of the dyspnoea depends here, as in other diseases of the heart, in some measure on a sympathetic spasm, excited in the bronchial tubes by the engorgement of the right cavities of the heart. The relief of these

* Bostock's *Physiology*, vol. ii. p. 109. Holland on the *Physiology of the Fetus*, &c. p. 154. See also, an excellent inaugural dissertation on *Malformations of the Heart*, by Dr. Paget, Edinburgh, 1831.

exacerbations by deep sighing and yawning, which favour the oxygenation of the blood and its transmission through the lungs, is more remarkable than in other asthmatic diseases. The torpidity of habit, as well as the vertigo, acute headach, and defective vision frequently present, must be ascribed to the influence of the venous blood circulating through the brain; and the same circumstance renders the nutritive process inactive, whence the subjects are commonly thin and slender.

We have no reason to think that malformations of the heart are characterized by any distinctive physical signs; but the accompanying organic changes may be recognised by their usual signs, which are ably stated elsewhere. (See HEART, AUSCULTATION, HYPERTROPHY, DILATATION, and DISEASES OF THE VALVES OF THE.) Contractions of the arterial orifices would be attended with a hissing, grating, or bellows-murmur during the first sound; and a similar sound, more profound or remote, would probably accompany regurgitation into either auricle. In a case related by Dr. Hope, in which there was a perforation through the septum of the ventricles with a contraction of the pulmonary artery and open foramen ovale, there was a loud, superficial, hissing, bellows-murmur accompanying the first sound. Dr. Hope considered the superficial character of this sound to indicate an obstacle in the passage of blood from the right ventricle. It is probable that a free communication between the ventricles might occasion a murmur with the first sound; but an open foramen ovale can scarcely be expected to have any such effect, as the flow of blood through it, if there be any, would scarcely be forcible enough to become sonorous. Corvisart (*Op. cit.* p. 276) perceived, in one instance, a peculiar *bruissement* in the region of the heart, sensible to the hand. One of the aortic valves was absent.

Treatment.—Although it is obvious that the cure of malformations is beyond the reach of art, yet, as we have seen that their fatal tendency depends greatly on their complication with other pathological conditions, the treatment which is adapted to retard the progress of these will generally delay the fatal subversion of the functions to which both, when united, inevitably proceed. Any thing which causes an additional embarrassment to the breathing, or in any way injures the balance of the circulation, will not only produce a temporary disorder in fits of palpitation or asthma, but will permanently aggravate the organic mischief by increasing the attendant dilatation or hypertrophy, and by favouring the habitual passage of blood through all devious and unnatural channels. Hence it becomes of the utmost consequence to watch those patients who are supposed to labour under congenital disease of the heart, and to keep their functions as near as possible on a balance; forbidding every sudden or violent exertion or mental excitement; enjoying a moderately nutritive but light diet of the most easily digestible kind; carefully excluding from cold a frame so susceptible to its effects; and, if necessary, aiding the excretory functions by the occasional cautious administration of appropriate medicines. The defect of the proper arterial quality

of the blood is probably more or less felt by all the organic functions; in none, perhaps, more than in the secretion of urine, which is generally turbid and scanty. Hence the artificial aid of diuretics, especially colchicum, with nitre and other salts, may prove serviceable. Dr. Farre supposes that the skin may be made in some measure to compensate for the defective action of the lungs in the process of arterialization; and although the experiments of Magendie and others scarcely permit us to believe that the process of oxygenation goes on at this surface, it is probable that, by keeping it in a more perspirable state, more relief may be afforded to the pulmonary and cardiac congestion than by any other measure. The warm bath, partial or general, has been found of great effect in relieving the paroxysms of palpitation and dyspnoea occurring in these complaints; and the application of warmth by gentle frictions with hot flannels is a measure of some utility, and one which may very often be resorted to. In individual cases relief may often be procured during the paroxysms by particular postures; it is important to try to discover these in each case, but no general rule can be laid down.

From what we have before remarked, it may be deduced that malformations may occasionally take their origin at the time of birth from a defective state of the respiration; and we do not deem it quite useless to suggest the expediency of watching this function in the new-born infant, and of exciting it, if any lividity of the skin should show it to be imperfect, through the various channels of sympathy that are familiar to physiologists, such as by sprinkling the face and neck with cold water, or tickling the nostrils with a feather; or, if these fail, by artificial inflation of the lungs.

C. J. B. WILLIAMS.

[HEART, (NEURALGIA OF THE). See ANGINA PECTORIS.]

[HEART, (POLYPUS OF THE). *Polypous, polypiform or fibrinous concretions in the heart.* In ordinary cases of death, the fibrinous portion of the blood is found coagulated in the heart, and either confined to the cavity in which it is chiefly met with, or extending to the arteries proceeding from it. At one time, these concretions were considered to be morbid, and were termed *polypi*, in consequence of their shape. They may take place before death, and, at times, interfere with the circulation of the blood through the heart, so as to give rise to physical signs, which may cause their presence to be suspected. They are, doubtless, owing to impeded flow of blood through the pulmonary artery or the aorta, the consequence of which is, retardation in its flows through the cavities of the heart, and consequent coagulation. Wagner (*Elements of Physiology*, translated by R. Willis, part 2, p. 267: Lond. 1842,) affirms, that the absence of blood corpuscles in their interior is an evidence of their formation some time prior to dissolution; the columnæ carneæ and chordæ tendinæ acting upon the blood in the same manner as the switch acts upon freshly drawn blood, when we beat it to separate the fibrin from it. Many cases have been published in which such impediment to the cardiac circulation has been suspected. At a late clinical lecture at the Philadelphia Hospital, the writer

exhibited to the class a semi-organized fibrinous concretion in the right ventricle, the existence of which he had foretold before dissolution, owing to the sound of impeded transmission of blood through the heart, in a person dying of pleuro-pneumonia; and a similar case, occurring in his service in the Baltimore Infirmary, was published by Dr. M'Neal, (*American Med. Intelligencer*, July 1, 1837, p. 125.)

It appears to be generally admitted at the present day, that blood, under special circumstances, may become organized after coagulation in the vascular system. No one denies the plastic or formative powers possessed by the liquor sanguinis of the blood; and it is not difficult to comprehend that blood itself may be endowed with similar properties.

Diagnosis.—The diagnosis of polypiform concretions in the heart cannot be easy. It has been conceived, however, that if, along with an increased, irregular, and confused action of the heart, there be a sudden and excessive aggravation of dyspnoea, without any obvious cause, the patient being in agony from an intolerable sense of suffocation, remaining restless and distressed till death, with cool surface and extremities, and a livid countenance, occasionally accompanied with nausea and vomiting, the presence of a fibrinous concretion may be suspected. Many of these phenomena, however, are the usual precursors of dissolution; and, as elsewhere remarked, (*Practice of Medicine*, 2d edit. i. 481.) it is not clear what can be the connection between this state of the heart and the affection of the stomach. The nausea and vomiting can only be regarded as an accidental circumstance. Occasionally these concretions are the cause of death by blocking up one of the apertures of the heart.

Treatment.—The diagnosis being so difficult, it is not more easy to suggest an appropriate treatment. When positively diagnosed, indeed, the affection can only be treated according to the phenomena that present themselves. There can be no mode of reaching the mischief. Alkalies have been advised from their property of diminishing the tendency of the blood to coagulate; and the borate of soda has been considered by Dr. Copland the most effective agent in preventing the concretion of fibrin, and in dissolving it when concrete. Little or nothing can, however, be expected from them in this affection.

ROBLEY DUNGLISON.]

HEART, (RUPTURE OF THE,) [*Cardiorrhæxis*.] may be either complete or partial. The rupture is said to be complete when the walls of the heart are perforated or torn through; it is said to be partial or incomplete when it is confined to the tendinous chords or fleshy pillars of the heart.

Complete Rupture.—The immortal discoverer of the circulation was the first to describe this lesion of its central organ. (*De circulat. sang. exercitat.* 3.) Morgagni, who himself fell a victim to the disease, and other pathologists, both in this country and on the continent, have since recorded a considerable number of similar cases, and have clearly shown that not a few of the cases of sudden death, usually attributed to an

apoplectic seizure, are in reality caused by rupture of the heart. But although the disease has now in a great measure lost the interest of novelty, yet its investigation has acquired a still stronger claim on the attention of the physician, from the very fact of its occurrence being now no longer a matter of curiosity. We have ourselves witnessed two cases of rupture of the heart, occurring within the same year, in the Dublin House of Industry; and M. Rostan observed three similar cases during the winter of 1816, and two more in the space of a fortnight, in the year 1820.—Still, however, the lesion may be considered as one of comparatively rare occurrence.

The table on the opposite page, which we have drawn up from the most accurately reported cases that we have been able to select, may serve to illustrate some of the most interesting points connected with this formidable lesion, such as the relative frequency of its occurrence in the different parts of the heart, the sex and age of the individuals, the causes of the lesion, remote and proximate, and the symptoms which precede and follow the event.

From this table it will be seen that the occurrence of this formidable lesion is almost exclusively confined to extreme old age, and that the number of males who fall victims to it is much greater than of females, the proportion being sixteen to nine, or nearly as two to one. As regards the situation of the rupture, it appears that of the *twenty-five* cases recorded, the lesion occurred *nineteen* times in the anterior surface of the left ventricle near the apex, *three* times in the right ventricle, *twice* in the right auricle, *once* in the septum, and in two instances there were more ruptures than one. The observations of Bayle likewise confirm these results as to the relative frequency of the rupture in these different situations. Of *nineteen* cases of rupture of the heart collected by this author, *fourteen* occupied the left ventricle near its apex, *three* the right ventricle, *one* the apex, and *one* the septum. (*Meckel*, vol. ii. note.) So that, from his observations as well as our own, it results that the left ventricle near its apex is, beyond all comparison, the part of the heart most frequently ruptured, the right ventricle comes next in order, and lastly the auricles and septum. This difference in the relative frequency of the rupture in their different situations, may, we conceive, be accounted for by referring to those pathological alterations which usually precede and induce the rupture of this organ. We are aware that several cases have been recorded of rupture of the heart caused by some violent mental emotion or physical exertion, a remarkable instance of which occurred some years since in Dublin, when a gentleman, on reading in a newspaper the death of his only son at the storming of Bergen-op-Zoom, instantly fell from his chair, and expired without a moan. Still, however, mental emotions, however powerful, can scarcely be considered capable of producing so formidable an effect, unless where the heart had been predisposed to rupture by some organic lesion or degeneration of tissue; and therefore, while we do not deny the possibility of rupture of the heart arising in the same way as rupture of the uterus, from the inordinate action of its muscular fibres, we believe that

Table of Twenty-five Cases of Rupture of the Heart, collected from various Authors.

such cases are excessively rare, and that in the great majority of instances which do not arise from external injury, the organic structure of the fibres is diseased before their substance is lacerated.

The alterations of structure which usually precede rupture of the heart, are ulceration, softening, or a disproportion in the thickness of the muscular parietes, arising either from atrophy of the part thinned, or hypertrophy of the other parts of the walls of the cavity, or from both these alterations combined.

Of these morbid changes, some, as ulceration and softening, may attack any part of the heart external or internal; and accordingly the ruptures, or rather perforations, which these morbid alterations give rise to, are found to occur with nearly equal frequency in the right and left ventricles, and in the auricles, whereas those cases of rupture arising from a disproportion in the thickness and strength of the walls of the heart, almost invariably occur in the left ventricle, about half an inch from the septum, and the same distance from the apex. Laennec and Bertin, whose authority ranks deservedly high on such subjects, are both of opinion that perforating ulcers are decidedly the most frequent cause of the heart's rupture, but we cannot reconcile with this opinion the fact that fully three-fourths of the cases of rupture on record have occurred precisely in one determinate point, while the ulcers, which are supposed to precede them, evince no predisposition for that particular part of the heart. It is true that a large proportion of those ruptures which occur in the auricles or in the right ventricle, is caused by perforating ulcers commencing generally on the internal, occasionally, too, on the external surface of the parietes, and burrowing through their substance; but in those more numerous instances where the rupture occurs on the anterior surface of the left ventricle near its apex, the lesion is, in most instances, produced by the parietes having been previously rendered thin in that point, while their thickness was increased towards the basis.

The reason why this is so may, we conceive, best be understood by considering, that although the parietes of the right ventricle and of the auricles are considerably thinner than those of the left ventricle, and consequently the parts which would, *a priori*, be supposed most liable to rupture, yet as they are nearly of the same uniform thinness throughout, the force of their contractions, as also their power of resistance, is equally divided, and operates equally on every point of their surface; whereas the walls of the left ventricle are naturally thinner near the apex than towards the basis, and this inequality is occasionally rendered still greater by disease, especially by that form of hypertrophy by no means uncommon in advanced life, in which the walls of the left ventricle are more or less thickened towards the basis, while they retain their ordinary thinness near the apex, or are even rendered thinner than natural. M. Rostan, who has particularly described this form of hypertrophy, has likewise enumerated four cases of rupture arising from it. According to this author, the disproportion is, in some cases, so great that the muscular walls of the left ventricle measure fifteen or even eighteen lines in thickness towards their bases, while near the apex they are scarcely two

lines thick. This local thinning of the muscular parietes is frequently accompanied with, and as it were compensated by a thick coating of fat, which is sometimes so considerable as to have arrested the principal attention of several distinguished pathologists, who, accordingly, did not hesitate to refer the rupture of the organ to this hypertrophy of the adipose tissue, which, in our opinion, was no otherwise concerned in producing the rupture than as it coincided with the atrophy of the subjacent muscular substance.

Whenever the disproportion which naturally exists between the thickness of the walls of the left ventricle near the apex and towards the basis is rendered still greater, (as in the form of hypertrophy just alluded to,) or when, their relative proportions remaining unchanged, the force of cohesion is generally diminished throughout their muscular structure, as in the case of general softening of that organ;* the apex of the left ventricle being the point which sustains the greatest shock in proportion to its powers of resistance, yields to the distending force; and accordingly we find that aneurismal pouches, as well as ruptures, occur most frequently at this very point, namely, at the anterior surface of the left ventricle, about half an inch from the apex, and the same distance from the septum.

It is not our intention to enter into a minute description of those morbid changes of structure which we have enumerated as the ordinary precursors of rupture of the heart, as they have already been fully discussed in the respective articles assigned them in this work: for our purpose it is sufficient to observe, that when the heart is predisposed to rupture by any of these morbid alterations, the slightest exciting cause is often sufficient to induce the fatal catastrophe. Of the twenty-five cases we have collected, there were eighteen in which no immediate cause of rupture could be assigned—the ordinary action of the heart being of itself sufficient to overcome its feeble powers of cohesion: of the two cases which fell under our observation, one died suddenly while chatting with his messmates; and the other as instantaneously while telling her beads in chapel. In three of these cases the act of vomiting was sufficient to cause the rupture; and in two instances it was occasioned by straining at stool. In one case already alluded to the rupture was caused by violent mental emotion; and we remember to have read of a similar event occurring in the person of Philip the Fifth of Spain, on hearing of the loss of the battle of Piacenza; and lastly, in one of the cases the accident was produced by external violence, the individual having jumped out of a high window.

From whatever cause the rupture proceeds, its occurrence is generally followed by immediate death; but in some rare cases life has been prolonged for several days after the accident, and the perforation has in these instances, we are informed,

* M. Bland, who has published a highly interesting memoir on this subject, regards the softening of the heart's substance as the result of its prolonged action, and as a frequent, if not a necessary consequence of old age; and this degeneration he considers the essential cause of the ruptures which take place in extreme old age, and proposes to designate by the term of "*déchirement sénile*."—*Bibl. Médicale*.

been found plugged up with a coagulum of fibrine. We have not ourselves met with an instance of this favourable termination of the lesion, nor have we been able to discover a single case of the kind in the medical annals of this country. Still we are not prepared to deny the possibility of such an occurrence, as the annals of surgery furnish abundant proofs that the heart may be perforated, and yet that the individual may survive the accident for many years. We might quote many cases in point from the works of surgical writers, but prefer confining our observations to cases of spontaneous rupture. M. Cullerier saw an instance of rupture of the left ventricle, in which the fissure was plugged up with a firm fibrinous concretion; and M. Rostan relates that a woman, aged seventy-four, who had suffered for fourteen years from palpitations, accompanied with excruciating pain in the left side and in the epigastrium, was seized with an attack of indigestion and vomiting, during which she expired suddenly, just as she was congratulating herself on getting over the attack. On dissection, the pericardium was found attached to the heart by albuminous bands, in different stages of organization; an irregular fissure, nearly an inch and a half long, was also discovered on the anterior surface of the left ventricle, and to the left of this fissure the substance of the heart seemed destroyed for half an inch in length and half a dozen lines in diameter: this loss of substance was replaced by a firm concretion, which appeared incorporated with the surrounding tissue of the heart. In the neighbourhood of these changes, the walls of the heart were remarkably thin, and were as remarkable for their thickness every where else. M. Rostan adds, that from the appearance of the cicatrix, he had no doubt that it was the mark of a former rupture, and probably of several years' standing.

From these cases and others of a similar character, we are justified in concluding that, in the event of rupture of the heart, there is a possibility of the aperture being closed by a coagulum, and of this coagulum becoming the medium for the formation of a true cicatrix: this favourable event is most likely to occur when the rupture is small, situated obliquely, and traversed by fibres attached to the ruptured surfaces; the cicatrix thus formed would, no doubt, receive additional strength from the formation of adhesions between the heart and pericardium in the immediate neighbourhood of the injury. This favourable termination is unfortunately of such rare occurrence, that the disease may be reckoned among those which are the most immediately fatal.

The premonitory symptoms of this lesion are, as might be expected, as varied as the conditions of the organ which precede its rupture. "Of the individuals," says M. Andral, "who died under my care in consequence of rupture of the heart, some had for a long time previously manifested the usual symptoms of organic disease of that organ; others had never betrayed any symptom of disease, either of the heart or large vessels; and others again had complained occasionally of uneasiness or pain in the præcordial region, unattended with any other morbid symptom." In most instances the attention of the physician is first awakened by the sudden and unexpected

death of the individual; and in not a few cases it is only on dissection that the true nature of the case is discovered, when on removing the sternum the pericardium is seen presenting a pale bluish tint, and when opened is found more or less distended with blood; most commonly only one rent can be discovered in the heart, but in some cases as many as five or six fissures have been found; in such cases the ruptures are usually the effects of ulceration.

The subject of treatment may, unfortunately, be dismissed in a few words, for as we cannot anticipate the occurrence of this lesion, or recognize its existence after it has occurred, we cannot, it is evident, know when to apply the appropriate remedies; which should, in the first instance, be directed to the removal of those morbid conditions of the heart which predispose it to rupture; and in the second, (after the accident has occurred without producing immediate death,) to support the nervous system under the violent shock it has received, and at the same time to restrain the inordinate action of the heart, with the view of moderating the hæmorrhage and favouring the formation of a coagulum.

Besides the species of rupture just described, the heart is liable to another, which for contradistinction has been termed partial or incomplete: in this latter form of the disease the rupture is seated in the chordæ tendinæ or in the columnæ carneæ.

This species of rupture is, we believe, of more frequent occurrence than the preceding, though, in consequence of its not always causing such violent symptoms during life, or presenting such striking appearances on dissection, its existence is often overlooked. M. Corvisart, who first described this lesion, relates three cases of the chordæ tendinæ being torn across during violent fits of coughing; a sudden and intense feeling of suffocation immediately followed, and terminated in exhibiting all the usual symptoms of disease of the heart. Laennec, Bertin, and Bouillaud, have likewise published cases of this species of rupture, and a very interesting case of the kind is fully detailed by Dr. Cheyne in the Dublin Hospital Reports. We have ourselves met with three instances of one or more of the tendinous cords being torn across; in those cases we have seen, the lesion was found in persons labouring under pulmonary consumption. It does not appear that this species of rupture occurs more frequently in one ventricle than in the other. In some instances the tendons appear to be ruptured or torn from their attachments by a violent muscular effort, and do not exhibit any appearance of previous disease, but more frequently the ruptured extremities present unequivocal marks of the ulcerative process by which the solution of their continuity was effected; in two instances we have seen small globular vegetations attached to the ruptured tendons.

The symptoms of this lesion depend, in a great measure, on the extent and seat of the injury: when only one of the tendons is ruptured, the circulation is in general but slightly deranged; we have found two of the tendons severed in their centre by ulceration where no symptom of any derangement of the heart's action was exhibited during life; the individual was in the last stage of phthisis; but when all the tendons which are

implanted into one of the valves are ruptured across, the valve, being no longer retained in situ, is allowed to flap backwards and forwards, and its valvular office is consequently destroyed altogether. The following observations, abridged from the case related by Dr. Cheyne, will serve to illustrate the formidable symptoms which are produced by this violent derangement of the heart's action. "A musician, *etat.* thirty-four, was suddenly seized with acute pain in the region of the heart, so violent as to render him perfectly frantic,—the pain occasionally intermitted for some days. A month after the first attack, the stroke of the heart was indistinct and tremulous, and appeared to extend over the whole of the left side of the chest, from above the clavicle to below the scrobiculus cordis, without being more distinct at any one point than at another. Pulse 148—unequal, irregular, and indistinct—complexion of a leaden colour—countenance bloated—his eyes staring wildly—memory impaired—inability to lie down. The disturbance of the vital functions was wonderfully increased by walking even a few paces, and while the exertion increased the dyspnoea, it gave strength and distinctness to the stroke of the artery—death ensued without a struggle. Besides other morbid appearances, which it is unnecessary to enumerate here, the parietes of the left ventricle were found thickened, their internal surface much inflamed—several irregular excrescences were attached to the mitral and semilunar valves. The chordæ tendinæ, which connected the larger portion of the mitral valve to the wall of the left ventricle, were torn off just at the point of their insertion into the edge of the valve; four of these ruptured tendons hung loose into the ventricle.

Between the extensive lesion which occurred in this case, and the formidable symptoms resulting from it, and the rupture of only a single tendon, with its comparatively trifling effect on the heart's performance of its functions, several intermediate degrees of rupture may occur, each of which would, no doubt, be attended with symptoms of proportionate severity. M. Laennec frankly admits that these various kinds of rupture can at most be suspected, but cannot be certainly recognized by any positive signs. The only stethoscopic phenomenon which we could observe in a case of rupture that we had an opportunity of examining, was a confused tremulous pulsation, which it was impossible to analyse; and we have been informed by Dr. Stokes, that a similar kind of pulsation, extending over the whole cardiac region, was the only stethoscopic indication that he could detect in a case where, after death, he found the tendons of the mitral valve ruptured.

RICHARD TOWNSEND.

HEART, (DISEASES OF THE VALVES OF THE)—The valves and chordæ tendinæ of the heart consist of fibrous tissue interposed between a production and reduplication of the lining membrane of the organ. The fibrous tissue is prolonged from a dense, whitish zone of the same, which encircles each of the orifices of the heart, and is, as it were, the tendon or point of attachment into which the muscular fibres of the organ are inserted. The lining membrane of the heart, according to Bichât, approximates closely in char-

acter to serous membranes: the valves, therefore, may be said to consist of fibro-serous tissue. This tissue in general, is remarkable for its proneness to cartilaginous and osseous degeneration; whence we derive an explanation of the fact, that the valves and orifices of the heart are frequently affected with these degenerations, while the cavities, where they are invested solely with the lining membrane, are in a great measure exempt. Though disease occupy a valve universally, it stops abruptly where the serous membrane is continued from the circular zone, or the extremities of the chordæ tendinæ, upon the muscular substance. In a few rare instances it advances farther; but we have never seen it attack the membrane on the muscular substance without its being connected with, and apparently propagated from disease of the valves.

It would appear that the disease is more dependent for its origin on the fibrous, than the serous tissue; for, where the former is most abundant, namely, at the base and the free margin of the valves, cartilaginous and osseous depositions are the most frequent and extensive. The depositions appear, indeed, to originate in the fibrous tissue exclusively; for it is common to find the valves encumbered with large masses of cartilage from which the internal membrane can be peeled off in its natural thin and transparent state. In these cases the surface of the morbid deposition is smooth and equable; and it is seldom until it becomes corrugated, rugged, and knotty, that the internal membrane is implicated in the disease. Calcareous depositions in the same way, seem always to commence underneath the membrane. In one case under our care, in which two rings of bone as thick as writing quills encircled the left orifices of the heart respectively, the membrane was stretched like a blue film over the whole of the aortic, and the greater part of the mitral ring.*

Valvular disease is much more rare on the right, than on the left side of the heart. Bichât, indeed, denied its existence at all in the former situation, but his opinion has been fully disproved. Morgagni, Vieussens, Hunauld, Horn, Cruwel, Corvisart, Burns, Bertin, Louis, Laennec, have all met with instances of disease of the right valves. Dr. Latham thinks that in one-third of the cases in which he has seen disease of the left valves, it has existed in the right also. We have notes of eight cases in which it existed in the right, and can recollect several others. In six of the eight the left side was simultaneously affected, and generally to a much greater extent; but the proportion which the whole number mentioned bears to the cases that we have seen of disease on the left side, is less than that indicated by Dr. Latham, not exceeding, we think, one in four and a-half to five.

[In a subsequent work, Dr. Hope thus expresses himself: "Since 1831, I have reason to believe, from the examination of a vast number of cases of valvular disease, mostly without, but occasionally with dissection, that the proportion of affections on the right side, as compared with the left,

* For the lesions of the valves here described, see "Principles and Illustrations of Morbid Anatomy," by the writer, figs. 65 to 74.

is very much smaller than I have specified above. I cannot state, numerically, the exact proportion, as I have not leisure at present to analyze 10,000 cases, which I calculate to yield about four per cent., or 400 cases, of valvular disease; but my general impression is, that, out of the 400, I have not, at the utmost, met with twenty cases of disease of the right valves, — which would only be five per cent., or one in twenty. Dr. Clendenning has met with about one in sixteen, out of 100 cases, as exhibited in the following statement, with which he has obligingly favoured me :

Valves of the left side, <i>alone</i> ,	92.6	or $\frac{9}{10}$ ths.
“ “ right side, <i>alone</i> ,	2.1	or $\frac{1}{5}$ th.
“ both sides,	6.31	or $\frac{1}{16}$ th.

He adds, however, that he neglected to record some instances which might fairly be presumed to have occurred mainly, if not exclusively, under the first head! This would reduce his proportion below $\frac{1}{16}$ th, and bring it nearer to mine, namely $\frac{1}{20}$ th. I suspect, however, that it will eventually prove to be lower still.” (Hope, on *Diseases of the Heart*: Dr. Pennock's edit. p. 343: Philad. 1842.)]

It is remarkable that in all our own cases, and nearly all those of the authors quoted, (with the exception of Dr. Latham, who is silent on this point,) the induration on the right side was merely cartilaginous. When the two sides are affected at once, it very rarely happens that the disease on the right is greater than that on the left: in general, it is much less, being comparatively slight or incipient.

The cause of the remarkable difference which the two sides of the heart exhibit in their liability to induration, has not been positively determined. Corvisart attributed it to a more decided fibrous organization of the left valves, in virtue of which they are more disposed to receive the matter that is to transform them into cartilage, or the calcareous salts that impart to them an osseous or stony hardness. Bertin has ascribed the difference to the different nature of the blood that traverses the two sides respectively, the left receiving blood of a more vital, more stimulating, more irritating quality than that by which the right cavities are moistened. Laennec does not offer a decisive opinion.

We do not pretend to decide which of these two opinions is correct, and whether both causes may not conspire to produce the effect, or whether both may not be groundless. But, in any case, we believe that disease of the left valves is promoted by the greater energy of action of the left ventricle, by which these valves are more strained. This opinion is countenanced by the facts, that ossification of the arteries, particularly those of the brain, is a remarkably frequent concomitant of hypertrophy of the left ventricle; and that this affection of the ventricle is generally attended with, or productive of, a thickened state of some of the valves.—(See ARTERITIS, vol. i.)

The characters of valvular induration are somewhat different according as the disease occupies the auriculo-ventricular or the arterial valves; the cause of which is to be found in the difference which naturally subsists between the valves themselves. We shall therefore describe the degenera-

tions of the two classes of valves separately. It may be premised that there is no essential difference but in degree and frequency of occurrence, between the degenerations on the two sides of the heart; consequently, a description drawn from the left will apply to the right.

INDURATION OF THE MITRAL VALVE.—The appearance presented by the indurated mitral valve differs according as the disease occupies the base, the margin, or the whole of the valve.

When the whole is affected with cartilaginous degeneration, the valve is generally contracted throughout, and what is lost in space appears, as it were, expended in thickening the free border; for this is converted either into a ring, an oval-shaped collar, or a transverse slit like a button-hole. The size of the aperture is various. We have seen it of all sizes from an inch to a quarter of an inch in its longest diameter.* The thickness of the border likewise varies. We have seen it equal a writing-quill. When the valve is thus contracted, it generally projects more or less, in a funnel shape, into the cavity of the ventricle. In one case we found it project so far that the columnæ carneæ were inserted immediately into the ring, the chordæ tendineæ having disappeared. The surface of the induration is smooth, polished, and translucent, until the disease throws out osseous or other excrescences, which, interfering with the integrity of the investing membrane, render it corrugated, rugged, and opaque. Before ossification takes place, the induration described sometimes presents a truly cartilaginous hardness, and sometimes the consistence of fibro-cartilage, or only that of tendon. When divided, the aspect of the section varies according as the disease is cartilaginous, fibro-cartilaginous, or tendinous. In a more advanced degree, cartilaginous induration is transformed into imperfect bone. It seldom happens, however, that more than a very small proportion of the cartilaginous mass is ossified, and the change takes place sometimes at its surface, and sometimes deep in its substance. The bone produced does not exhibit the fibrous structure and peculiar arrangement of natural bone; though, as it contains a large proportion of cartilage, it may be presumed to possess more or less vascularity and vitality.

There is another species of osseous induration of the valves, which is essentially different from the above, inasmuch as it consists of calcareous matter in great predominance, and, like vesical calculi, has no vitality. It presents itself under the form of small, polished, and semi-transparent scales; or of minute, yellowish, opaque granules, the agglomeration of which forms concretions of various dimensions, from a mere point to the size of a horse-bean. The deposition commences underneath the lining membrane, and generally in a small patch of indurated, cheese-like matter, usually called *steatoma*, the surrounding parts being healthy. The scales lie flat and superficial under the membrane, while the granules penetrate more or less deeply into the subjacent tissues. When either the scales or the granules enlarge, and their surfaces become rugged or acuminate, they cause

* Cases illustrating nearly all the diseases of the valves hereafter described, are detailed in “A Treatise on the Diseases of the Heart,” by the writer of this article.

absorption of the internal membrane, and come in immediate contact with the blood.

Some authors believe that ossifications of this latter description are *natural* to old people, because they occur in the majority of those who have attained the age of sixty. Whatever be the character of the ossification, whether it be mixed with cartilage or purely calcareous, to us it appears to be always a morbid production. The circumstance of its occurring in the majority of persons above the age of sixty does not militate against this view; for, as the elasticity of the arterial, as of all the other tissues, is diminished by age, the valves of the heart and the coats of the arteries are, in the aged, less capable of resisting the distending force of the blood, and are therefore more liable to disease. Nor does the circumstance of the ossification being more calcareous and less cartilaginous in the old than in the young, prove that in the former it is a *natural* change. It confirms, indeed, what is proved by every part of the bony tissue; viz. that in age the ossific tendency is greater; but it does not, for this reason, follow that the tendency is natural when it displays itself in unnatural situations, as in the heart and arteries.

Sometimes the membranous portion and free margin of the valve are healthy, while the fibrous zone at the base is cartilaginous, or beset with small calcareous incrustations, or, as sometimes happens, its whole substance is converted into a thick ring of bone. By these depositions at the base of the valve, the orifice is more or less contracted, while the valve itself may remain capable of closing. In many cases, again, the base and middle are sound, and the free margin alone is diseased, its conical processes forming adhesions with each other and contracting the circumference of the valve to such an extent as almost completely to close the orifice. It is not uncommon to find the margin studded with small cartilaginous nodules, or roundish calcareous granules, which prevent the accurate adaptation of the edges to each other, and allow regurgitation during the ventricular contraction. Sometimes the cordæ tendinæ are contracted, so as to prevent the valves from completely closing during the ventricular systole. This is a lesion perpetually overlooked by those whose attention has never been directed to it: yet, being attended with regurgitation, it constitutes one of the worst species of disease of the valves. Much confusion may have been occasioned by such an oversight, the anatomist pronouncing that the organ was sound, while the most marked symptoms had previously indicated its disease. The same formidable effects ensue, and the same remarks are applicable, when, in consequence of dilatation of the orifice, the valves are not large enough to close it; a condition of parts not unfrequent in cases of great dilatation of the heart. Sometimes, the only diseased appearance that the valve presents, consists in brittle scales or patches of pure phosphate of lime between the two component layers of the membranous portion, which they occasionally rupture, and thus come in immediate contact with the blood.

INDURATION OF THE AORTIC VALVES.—Induration of the aortic valves, like that of the mitral,

is more frequent and extensive at the base and free border than in the intermediate space. At the border it originates more especially in the corpora sesamoidea, and these bodies are sometimes enlarged by cartilage to the size of peas. We have seen the margin contracted by the fibro-cartilage into a ring a quarter of an inch in diameter. The valves are sometimes thickened, nodulated, and corrugated by an opaque yellow degeneration, consisting of a mixture of cartilaginous and steatomatous matter. We have seen the angles of the valves detached from their bases and partially wasted away by this degeneration; so that, adhering by their centres only, they hung loose into the artery and were destitute of fulcra by which to oppose the retrograde pressure of the aortic blood. In another instance, the same disease had undermined and detached the bases of all the valves throughout nearly their whole length; and, under one of them, it had led to the formation of a canal, as wide as the little finger, beneath the lining membrane of the heart, leading to an aneurism in the muscular substance of the septum between the left auricle and ventricle.

Such are the cartilaginous and steatomatous degenerations of the aortic valves. The osseous, of which we have next to speak, are perhaps even more frequent in the aortic, than in the mitral valve. The ossification may be either pure, or combined with cartilage. In one case under our observation, an irregular, scabrous, and denuded concretion, the size of a pea, occupied the edge of one of the valves and projected into the cavity of the artery. In another case, a similar mass, of a conical shape, sprang from the base between two of the valves, and presented its apex towards the centre of the vessel. Smaller concretions of this description and in this position, are common. M. Bertin saw an ossification of one of the aortic valves which had attained the size of a pigeon's egg. (Obs. liii.) In one of our cases, already alluded to, the fibrous zone encircling the base of the aortic orifice was converted into a ring of bone as thick as a quill.

When the ossification is confined to the margin and base, while the middle portion is still healthy over a certain extent, the valve, if its thickening is not very considerable, may still rise and fall, and not offer any marked obstacle to the circulation. But when the ossification pervades the middle portion of the valves, they shrink, become soldered together, or curl up upon themselves, in the direction either of their concavity or their convexity, so as to present a rude representation of certain sea-shells. In this state, they may become immovable. If curled forwards, they remain applied along the walls of the aorta, and oppose no other impediment to the course of the blood than what results from their thickness. If curled backwards, they remain fixed in the fallen or shut position, and considerably contract the orifice. Not unfrequently, one of the three valves is curled in an opposite direction to the other two. Corvisart has seen all three ossified in the closed position, and they would only have left an extremely narrow cleft for the passage of the blood, had not one retained sufficient mobility at its base to perform a movement which augmented, by a line or two, the width of the cleft.

INDURATION OF THE VALVES ON THE RIGHT SIDE OF THE HEART.—Induration of the right or venous valves is, as already stated, almost always simply cartilaginous or fibro-cartilaginous, and is comparatively rare, not existing in perhaps more than about one case in five of disease in the left valves. It seldom presents itself without being accompanied by disease of the left valves also, and it is, in general, less advanced than the latter. The tricuspid is more frequently affected than the pulmonic valves. We never happen to have seen the latter diseased, but we have once found them incapable of closing the orifice in consequence of dilatation of the artery, and we have seen the orifice contracted to the diameter of a quill, an inch below the valves. M. Bertin has seen the valves themselves contracted into a circular aperture only two lines and a half in diameter. As already stated, disease of the right valves, whether cartilaginous or osseous, differs from that of the left only in frequency and extent, its characters being essentially the same.

Exciting causes of valvular induration.—These are, first, such as overstrain the valves by increasing the force of the circulation; namely, violent efforts, hypertrophy, increased action of the heart from nervous, febrile, or inflammatory excitement; secondly, inflammation of the internal membrane of the heart, resulting from carditis, pericarditis—especially rheumatic, from fever or from any other cause. It would be an unnecessary repetition to dwell on this subject, as we have treated of it in the article ARTERITIS.

WARTY VEGETATIONS OF THE VALVES.—These excrescences bear a close resemblance to venereal warty vegetations on the external organs of generation. Their form is in general irregularly spherical, oval, or cylindrical: their size varies between that of a small pin's head and a large pea, but when isolated they are occasionally as large as a horse-bean. Their surface is polished, but often lobulated like a raspberry: they are found either isolated, in clusters, or in closely agglomerated patches like the surface of a cauliflower. Their number is various; sometimes there are only one or two, and sometimes they pervade the whole of the valves, the tendinous cords, and a great portion of the auricle. Their colour, occasionally of a greyish or yellowish white, is more commonly heightened, universally or in parts, with pink or red of greater or less depth. Their texture is fleshy and slightly translucent, like the exuberant granulations of an ulcer. Their consistence is variable; in general they are soft and humid, as if only recently and imperfectly organized: and they can then be easily scraped off with the handle of the scalpel; but sometimes they are firm, and cannot be detached without tearing with the nail or cutting with the edge of the scalpel. Firm vegetations are generally larger and more truly warty than soft.

The internal membrane of the part from which vegetations spring, is almost invariably more or less diseased. It is thickened, steatomatous, or cartilaginous, ossified, ulcerated, or ruptured. When vegetations grow from a diseased but *unbroken* surface, they may be numerous and occur in several parts at once; but when they grow merely from a ruptured or ulcerated edge, they

are few in number, often not exceeding one or two, are generally confined to that edge exclusively, and attain a larger size than any others. We have seen them exceed a horse-bean, and with a neck two, three, or four lines long. It cannot be doubted that their origin is connected with the broken state of the membrane.

The base and the free margin of the valves appear to be parts peculiarly favourable to the growth of warty vegetations. Along these, but especially the latter, they are often arranged in a single row. They occur on both sides of the heart, but less frequently on the right. The aortic valves are those most subject to them. They are more rare in the auricles than on the valves, especially in the right auricle. We have seen one-third of the left auricle completely covered with them. When situated at the base, or the free margin of a valve, they contract its aperture according to their size and number.

Laennec thought it "undubitable that vegetations were nothing more than small polypous or fibrinous concretions, which, being formed on the sides of the valves or auricles, become organized by a process analogous to that which converts albuminous false membranes into adventitious membranes or cellular tissue." This opinion is unsatisfactory; for as polypi are most common in the right cavities of the heart, vegetations ought to be so likewise,—the reverse of which is the fact. The valves, moreover, being perpetually in motion, would be the last parts to which albuminous concretions would adhere, as a stagnant state of the blood is most favourable to their formation; yet the valves are the parts most subject to them. It is amidst the intricacies of the columnæ carneæ, where the blood is more stagnant than elsewhere, that we most commonly find *real* albuminous concretions of small size. Finally, if vegetations were merely fibrinous concretions, instead of being rare, they ought to be frequent; for, as the circumstances which, on this view, lead to their formation, are common to all persons labouring under an obstructed circulation, all, or to say the least, many, should be affected with them.

Kreysig attributes their formation to inflammation. MM. Bertin and Bouillaud have espoused the same opinion, resting on the fact that vegetations bear a close analogy to the albuminous granulations occasionally found on serous membranes affected with chronic inflammation. The small and soft vegetations certainly do bear this analogy—a fact of which we have satisfied ourselves by comparing the two as occurring in the same subject; but the like cannot, in the least degree, be said of the large and more properly wart-like vegetations; whence it is to be inferred that inflammation *alone* is not their cause. We are disposed to think that it is inflammation modified by some other morbid action dependent either on the constitution, or on previous structural lesions of the parts affected.

The resemblance which the firmer valvular vegetations bear to venereal warts, led Corvisart to think that they might have the same venereal origin. This opinion, however, is not tenable, as extensive observation in venereal hospitals has proved that vegetations of the heart are not more common in persons affected with this disease than

in others, and it is certain that they have occurred in some who had never been in the least degree tainted with the disease.

Pathological effects of disease of the Valves, and mode of their production.—

Diseases of the valves, whatever be their nature, whether osseous, cartilaginous, or warty, have for their common effect to obstruct the orifices of the heart; and this they do, either by contracting the apertures, or by encumbering the valves in such a manner as to prevent them from opening and closing with suitable accuracy and facility. A mechanical obstacle is thus presented to the circulation, and from the obstruction and embarrassment which it occasions, are derived the symptoms of valvular disease.

The general symptoms, however, when of an aggravated nature, are seldom dependent on the valvular obstruction exclusively; they are partly attributable to a co-existent disease of the muscular apparatus of the heart. For, so long as the organ remains free from dilatation, hypertrophy, or softening, the valvular disease, according to our observation, is not in general productive of great inconvenience.

This opinion is founded on the following grounds. We have seen individuals who were affected in an eminent degree with disease of the valves or of the aorta, maintain for years a very tolerable state of health so long as there was no hypertrophy or dilatation of the heart; but, in proportion as these supervened, the symptoms of valvular obstruction became more and more developed, and eventually assumed their most aggravated form.

We have reason to believe that, in these cases, the symptoms were attributable in a great measure to the hypertrophy or dilatation; because we have seen a greater valvular contraction produce less severe symptoms when the hypertrophy or dilatation was less considerable. It might be supposed that a great degree of contraction would of itself suffice to produce the symptoms of an obstructed circulation in their most aggravated form. This is highly probable, but it does not easily admit of demonstrative proof, as a great degree of contraction is perhaps never found, on dissection, without hypertrophy or dilatation. We therefore infer that these affections ensue as consequences of valvular contraction, and we believe, for the reasons above assigned, that they play an important part in the production of the symptoms.

It is of immense practical importance to keep in view the facts stated, namely, that valvular contraction does not produce formidable symptoms until it has given rise to hypertrophy or dilatation; and that it invariably leads to these affections unless the circulation be kept tranquil. We thus know that the most efficacious treatment of valvular disease consists in employing such prophylactic measures as are calculated to prevent the supervention of hypertrophy or dilatation, and in employing them with the same uncompromising strictness before those affections have appeared, as if they actually existed.

It remains to be explained how dilatation and hypertrophy aggravate the symptoms of valvular obstruction. We have elsewhere shown (See

DILATATION OF THE HEART) that dilatation of the heart, by enfeebling the contractile power of the organ, constitutes as truly an impediment to the circulation as a more direct mechanical obstacle. When, therefore, dilatation exists in addition to such mechanical obstacle, it is clear that the symptoms, having a twofold cause, must be doubly severe.

Hypertrophy aggravates the symptoms of valvular obstruction, because the heart, being morbidly irritable, struggles against the obstacle, and falls into fits of palpitation; and as, during these, a greater quantity of blood than natural has to be transmitted through the contracted aperture, the circulation is performed with increased difficulty.

It is in consequence of these reciprocal reactions of the valvular and the muscular apparatus on each other, that cases thus complicated are more severe than any others.

From what has been said here and in the article DILATATION, the reader will judge how totally some authors have been wrong in referring the obstruction of the circulation to the valvular contraction exclusively, without allowing that the enlargement of the heart contributed in any degree to the effect. Such a doctrine is not only erroneous, but dangerous, as it leads to pernicious practice. For, imagining the valvular contraction to be the only formidable part of the complaint, to it alone those authors direct their attention; and, acting on the inaccurate presumption that the contraction is in *all* cases caused by, and accompanied with, inflammation, they attack it with blood-letting, general and local, abstinence, digitalis, &c.; means which cannot remove valvular contraction when once formed, (as must always be the case before the symptoms can exist,) and which are, therefore, a useless expenditure of the patient's strength. It is true, indeed, that measures calculated to diminish the force of the circulation are useful in obviating the supervention of hypertrophy or dilatation—the paramount source of danger in these cases;—but measures employed for this purpose, and which must be continued for an indefinite length of time, cannot be practised with the same activity as for the purpose of curing an inflammation. We would not be understood by this to mean that valvular disease is *never* accompanied by inflammation, and that, when so accompanied, it should not be treated by antiphlogistic measures: but we mean that they should not be employed unless there is reasonable evidence of inflammation.

Diagnosis.—I. *General Signs.*—Whether the disease of the valves be cartilaginous, osseous, or consist of vegetations, the general symptoms are the same, if the degree of contraction be equal. Keeping in view the principles developed in the preceding section, we should assign to disease of the valves, as its general symptoms, 1. a greatly aggravated form of the same which have already been assigned to dilatation of the ventricles; 2. certain symptoms of a peculiar and distinctive character.

1. The general symptoms are cough, copious watery expectoration, dyspnoea, orthopnoea, frightful dreams and starting from sleep, oedema of the lungs, pulmonary apoplexy, passive hemoptysis,

(i. e. sputa stained with dark or grumous blood,) turgescence of the jugular veins, lividity of the face, anasarca, injection of almost all the mucous membranes, passive hemorrhages, especially of the mucous membranes, engorgement of the liver, spleen, &c., and congestion of the brain, with symptoms of oppression sometimes amounting to apoplexy.

The pulmonary symptoms result from engorgement of the pulmonary vessels, when the left valves are obstructed: and, when the obstruction is in the right valves, they result partly from engorgement of the bronchial veins, and partly from the quantity of blood transmitted into the lungs not being adequate to their demand—an unnatural state, which gives rise to dyspnoea, as will be presently shown. In the latter case hemoptysis is more rare. The symptoms affecting the system in general result from retardation of the blood in the venous system.

2. The peculiar and distinctive symptoms of valvular disease are the following.

a. When the disease is combined with hypertrophy or dilatation, as is commonly the case, the symptoms are more severe than those of hypertrophy or of dilatation alone, the paroxysms of palpitation and dyspnoea in particular, being more violent, more obstinate, and more easily excited.

b. The action of the heart is irregular. This, it is true, may sometimes be the case in hypertrophy and in dilatation, but here it is an accidental, not an essential character. The pulse, which we may regard as the representative of the heart's action, may, in valvular disease, be small, weak, intermittent, irregular, and unequal; and it may even be small and weak while the heart is giving a violent impulse—a contrast which affords one of the strongest presumptions of valvular disease. The least degree of derangement is intermission; for in this the rhythm of the heart's action is not subverted, there being either a total omission of one or more ventricular contractions, or one, two, or three feeble contractions audible by the stethoscope, but scarcely, if at all, sensible in the pulse; yet the next full contraction recurs at the correct interval; that is, supposing the pulse to beat crotchets, the contraction in question recurs at the crotchet. Irregularity is an ulterior degree of derangement, for here the rhythm is subverted, the beats recurring at irregular intervals. It is generally accompanied with inequality, some beats, both of the heart and pulse, being strong, and others weak. The degree to which these characters of the pulse exist, depends on the situation of the valve contracted and the extent of its contraction. We shall, therefore, point out more particularly which of the characters are produced by given states of certain valves; for, this being known, we have a valuable means of ascertaining the situation and extent of the valvular disease.

The characters of the pulse just described, are most marked in contraction of the mitral valve, and in states of the valve admitting of regurgitation. If either the contraction or the regurgitation be great, all the worst characters of the pulse are invariably present: for, in the case of contraction, the left ventricle, not being freely supplied with blood, is not stimulated to contract at the natural intervals and with suitable energy; and,

in the case of regurgitation, the ventricle, not being able to disgorge itself through the aorta, for want of the accustomed fulcrum in the mitral valve, labours under a state of more or less constant repletion, and therefore contracts languidly and irregularly whenever the stimulus of fulness happens to be greater than usual, or its own exhausted irritability allows it to answer the call. In such cases, the pulse is always very soft and feeble—for the obvious reason that the force of the ventricular contraction is determined in a retrograde, as well as in a forward direction.

A slight contraction of the mitral valve (when, for instance, the diameter of the aperture is not diminished more than a quarter of an inch) does not unnecessarily produce an unsteady pulse, as it still allows of an adequate supply of blood to the ventricle. When, however, the circulation is hurried, the pulse generally becomes unsteady. Slight regurgitation, likewise, may not materially affect the pulse.

Contraction of the aortic valves must be very great to render the pulse small, weak, intermittent, and irregular. We have never seen it possess these characters in any marked degree unless the valves were either soldered together by cartilaginous degeneration, or more or less fixed by ossification in the closed position, so that the aperture was only a limited chink.

An induration of the size of an ordinary pea, has little effect on the fulness, firmness, and regularity of the pulse, and slighter degrees of contraction appear to have no effect on it whatever.

The pulse is less irregular when the valvular contraction is on the right side, than when it is on the left; the action of the heart appearing to be less under the influence of the right ventricle than of the left,—in consequence, perhaps, of the muscular apparatus of the latter being stronger and more irritable. The pulse is not so small and weak from a contraction on the right side as on the left, and contraction of the tricuspid valve causes more irregularity than contraction of the valves of the pulmonary artery.

c. Pain in the region of the heart is another symptom of disease of the valves. It is true that palpitation may occasion pain though there be no disease of the valves, and we have frequently met with it from this cause in hypertrophy and dilatation. It is likewise true that palpitation may occasion pain though there be no disease of the heart whatever; we have often found it in hysterical females, and in nervous men. But it is when the valves, the coronary arteries, or the commencement of the aorta, are indurated and inelastic, that pain occurs most frequently and with the greatest severity. Sometimes it is little more than an indescribable sense of obstruction or oppression in the præcordial region; but, in other cases, it is an intense lancinating or tearing pain, felt across the præcordia or scrobiculus cordis, (where it might be mistaken for inflammation of the stomach,) and occasionally extending, with a sense of numbness, down the left arm to the elbow and sometimes to the fingers. Pain of this description has acquired the name of *angina pectoris*. (See *ANGINA PECTORIS*.) We believe this pain to be, in general, occasioned by the inelasticity of the ossified or otherwise indurated parts, which will

not stretch equally with the other portions of the heart, when the organ is labouring under palpitation or disorgement.

When inflammation of the interior of the heart exists, either alone or accompanying disease of the valves, it also occasions pain; but those authors have unquestionably been wrong, who have considered inflammation to be the sole cause of pain, and have therefore assumed this symptom as a proof of the inflammatory nature of disease of the valves.

The exact time and manner of the fatal termination in valvular disease, as in every other organic affection of the heart, is very uncertain. Sometimes the patient is reduced gradually to an extreme degree of emaciation and debility, and dissolution is duly announced by the usual premonitory symptoms. Sometimes he expires suddenly, after any trifling exertion or emotion, though the malady has made comparatively little inroad on the constitution. Not unfrequently pressure on the brain, whether from serous effusion or venous congestion, is the immediate cause of death, and in this case coma gradually supervenes from three to four days or a week previous to the fatal event. In one case of serous effusion under our care, the patient suddenly uttered a shriek and fell at once into perfect coma. The same occurred in another case, in which there was only a small effusion of blood.

Hence, the prognosis must always be general as to time, and, if the case be considerably advanced, it must be guarded with a clause, that the patient is liable to die suddenly and unexpectedly.

II. *Physical Signs*.—Before the discovery of auscultation it was extremely difficult, and in many cases utterly impossible to detect disease of the valves. Corvisart had the merit of discovering, as its signs, certain states of the pulse and a "peculiar vibration difficult to describe, sensible to the hand applied to the præcordial region:"—in other words, the cat's *purring tremor* (*frémissement catinaire*) of Laennec. But, as these signs may occur under other circumstances, they do not denote disease of the valves in particular, and are totally insufficient to indicate which is the valve affected. The accession of auscultation to the other means of diagnosis has rendered it possible to distinguish valvular disease with almost complete certainty: a certainty, it may be remarked, much greater than was supposed by the illustrious author of auscultation himself; for he did not give their full value to preternatural murmurs as signs of disease of the valves, in consequence of supposing that similar murmurs were produced by a spasmodic contraction of the muscular fibre of the heart and even of the arteries. We have elsewhere (in a "Treatise on the Diseases of the Heart," p. 47 and 56) attempted to show that it is not the muscular contraction, but the movements of the blood, which are in all circumstances the cause of these preternatural murmurs. Laennec laboured under another disadvantage: he attributed the *second* sound of the heart to the auricular contraction; whereas, according to the experiments of the writer, it is referable to the ventricular diastole. (Ibid. p. 26 and 36.) The substitution of this view of the heart's action for that of Laennec, fortunately does not falsify any

of his physical signs, except one, viz. that "loudness of the second sound indicates dilatation of the auricles;" it does not, to adduce a single instance, invalidate the fact that murmur of the second sound indicates disease of the auriculo-ventricular valve; but it affords a rational explanation of all the phenomena noticed by Laennec, and renders various others available as signs, which to him were inexplicable and therefore useless.

Bellows—filing—rasping—sawing—and musical or whistling murmurs.—When a valve is contracted, the blood, in passing through it, is thrown into more than ordinary commotion and occasions a morbid murmur. This murmur has a *soft* character, like that of *bellows*, when the contraction has a smooth surface which does not greatly break the stream of blood, as when the morbid deposition consists of cartilage, fibro-cartilage, or vegetations. But the murmur is *rougher* or more grating, like that of a *file* or *rasp*, when the disposition has a rugged, hard surface, as when it is osseous. Murmurs are more *hollow* when they are deep-seated, as for instance, in the auriculo-ventricular orifices; and more *hissing* or *whizzing* when they are superficial, as in the aortic orifice, more especially in the pulmonary orifice, and the ascending aorta. The hollowness of the sound is referable to its remoteness and its reverberation through the chest. The *sawing* murmur is almost identical with the *filing* or *rasping*; it is only less grating and on a higher key.

The *musical bellows-murmur* is a perfect note like whistling or cooing. In the case of a patient who applied to us for "a noise in the chest," we heard it at the distance of two feet. In a case precisely similar, which occurred to Dr. Elliotson, there was a very large and long vegetation in the mitral valve. We imagine that this sound is to be accounted for on the same principle that air emitted from the lips in one way produces merely a blowing sound: in another, produces a whistle. We have repeatedly heard the sound in various degrees.

Purring tremor is another sign of disease of the valves. It arises from the vibrations into which the blood is thrown during its passage through an obstructed orifice, and is felt in the præcordial region and sometimes in the arteries. We have never felt it in the pulse when the patient was calm, unless hypertrophy was conjoined with obstruction of the aortic orifice or with roughness and dilatation of the ascending aorta: but we have felt it during palpitation, though there was neither hypertrophy nor disease of the heart or aorta: whence we infer that it requires for its production in the pulse an increased force or velocity of the circulation, but not necessarily a valvular or aortic obstruction. In the præcordial region it is more easily produced, and we have found it exist here when there was neither hypertrophy nor palpitation; but it was in cases in which the valvular disease was considerable, and the power of the heart certainly not deficient. It may be occasioned by disease, not only of the semilunar, but also of the mitral and tricuspid valves, and in the latter cases it may accompany either the first or the second sound. When accompanying the first, it proceeds from regurgitation through the valve; and when accompanying the second, it

results from the impeded passage of the blood from the auricle into the ventricle during the ventricular diastole. It rarely accompanies the second sound; because, as we conceive, the diastolic current is seldom strong enough to produce it. When from disease of the mitral valve, it is not perceptible in the pulse.

As purring tremor has the same origin as bellows and other murmurs, it often accompanies them; though, as it requires a greater degree of disease for its production, this is not always the case.

Having now given an account of the various murmurs and of purring tremor as signs of disease of the heart in general, we proceed to show in what manner they constitute signs of disease of each of the valves in particular; and it may be premised that, as the sounds of one side of the heart are audible on the other, the sound of the healthy side will partake more or less of the murmur of the diseased side, and *vice versa*.

Signs of Disease of the Aortic Valves.—One of the murmurs above described is heard during the ventricular contraction about the middle of the sternum, and is louder here than elsewhere. It is more or less hissing or whizzing, from being superficial, and it accordingly conveys the idea of being near to the ear. When a murmur of this kind is louder along the tract of the ascending aorta than opposite to the valves, and is, at the same time, peculiarly superficial and hissing, it proceeds from disease of the aorta itself. As a murmur from this source often extends to the situation of the valves, it might easily lead to the supposition that they also were diseased, and it is sometimes very difficult to ascertain positively that they are not. A murmur may accompany the second sound when there is regurgitation through the aortic valves, and its source may be known by its being louder and more superficial opposite to those valves than elsewhere. We have never found it strong, and we doubt whether it can be so; as the instantaneous manner in which the ventricle is refilled by its diastole, must prevent the regurgitation from being considerable.

[The writer has been induced to infer, that where a rough sound accompanies the second, it is not owing always to a morbid condition of the semilunar valves, but to the reflux blood passing over the lining membrane of the aorta roughened by ossific deposits. (See an interesting case in *Med. Examiner* for May 18, 1844.)]

Purring tremor generally requires for its production, by disease of the aortic valves, a considerable degree of contraction of a rugged hard nature, with hypertrophy; especially to produce it in the pulse.

Signs of Disease of the Mitral Valve.—When this valve is contracted, the second sound loses, on the left side, its short, flat, and clear character, and becomes a more or less prolonged bellows-murmur. When the valve is permanently patulous, admitting of regurgitation, the first sound likewise is attended with a murmur. These murmurs are louder opposite to the mitral valve, (viz. at the left margin of the sternum, between the third and fourth ribs, i. e. about three or four inches above the point where the apex of the heart beats,) than elsewhere. They are also more hol-

low than murmurs of the aortic valves. By these two circumstances the murmur of the first sound may be known to proceed from the mitral, and not from the aortic valves: that of the second proceeds, either from the mitral, or, what is much more rare, from regurgitation through the aortic valves. The means of ascertaining when the latter is its source, have been explained above. With respect to the mitral, the murmur of the second sound is diminished when the contraction of the orifice is extreme; when, for instance, the aperture does not exceed two or three lines in diameter; for then the quantity of blood transmitted is not sufficient to create a loud murmur. For the same reason the murmur is diminished when the auricle is obstructed by a polypus; but the diminution under these circumstances is of little importance to the diagnosis; as extreme contraction of the mitral, and polypi in the auricle, can be detected by the characters of the pulse, and the assemblage of other signs.

Purring tremor may be produced by disease of the mitral valve, especially if the ventricle be hypertrophous and dilated, by which the currents through the valve are rendered stronger.

Signs of Disease of the Aortic and Mitral Valve conjointly.—The murmurs above described as characteristic of each, exist simultaneously in the situation of each valve. If the murmurs of the first sound be of a different species in the two situations—if, for instance, the murmur of the aortic valves be of the bellows kind, and that of the mitral resemble filing or rasping, it is still easier to determine that both valves are diseased.

Signs of Regurgitation through the Mitral Valve.—These signs are, a murmur with the first sound, louder in the situation of this valve than of the aortic; and a weak pulse, even though the impulse of the heart be violent. It is generally unsteady also.

Signs of Disease of the Pulmonic Valves.—The signs are the same as those of disease of the aortic valves, with this difference, that the murmur seems close to the ear, and is equally hissing as in disease of the ascending aorta. Disease of the pulmonic valves is so rare that it ought never to be suspected unless the signs described are extremely well marked, or unless there be patency of the foramen ovale, or some other preternatural communication between the two sides of the heart—states, which experience has proved to be in general accompanied with contraction of the pulmonic orifice.

Signs of Disease of the Tricuspid Valve.—They are the same as those of disease of the mitral, except that the murmurs are loudest opposite to the valve: viz. at the middle part of the sternum, opposite to the inter-space between the third and fourth ribs and a little to the right of the mesial line. As this valve is very seldom affected, the practitioner must be very cautious in pronouncing it diseased, especially as the pulse does not afford the same evidence as in contraction of the mitral orifice.

Such are the signs which, together with the general signs, are, according to our experience, the best for the detection of disease of the valves. For several years they have never deceived us as to the general fact whether there was, or was not,

valvular obstruction; and they have seldom failed to indicate, with perhaps more than necessary precision, the situation and nature of the affection.*

To make the signs available, however, it is necessary to attend to several circumstances which might lead to the deception. Bellows-murmur sometimes exists in the heart, though there be no disease of the valves; namely, in nervous persons, in cases of reaction from excessive loss of blood, of pericarditis and adhesion of the pericardium, and of hypertrophy with dilatation. Murmur from these causes may easily be distinguished from that of valvular disease by the following criteria. When from nervous excitement, very common in hysterical females, it may be known by its being intermittent, ceasing when the nervous exacerbation subsides and the action of the heart becomes calm. When from reaction, it subsides with the cessation of that phenomenon. When from pericarditis or adhesion of the pericardium, it may be known by the presence of signs of those affections. When from hypertrophy with dilatation, it may be known by its diminishing or ceasing when the action of the heart is calmed, as by repose, venesection, abstinence, &c., &c.

Contrasted with the above, the distinctive characters of valvular murmur are, that it is not universal over the heart, but confined in a great measure to the part corresponding to the valve affected; that it persists without intermission for an indefinite length of time, even though the heart be kept in a state of perfect calm; and that it is often of the filing, rasping, or sawing kind; whereas murmurs from other causes have almost always the softness of the bellows sound.

[Still, the writer is prepared to say, from his experience, that the diagnosis of valvular disease is at times extremely obscure. Dr. Graves, indeed, expresses the opinion, that the functional derangements produced by disease of any particular part of the heart are seldom sufficiently characteristic to enable us to make out whether the disease be situated in the auriculo-ventricular or in the semilunar valves; and he frankly owns that it has frequently occurred to him to find that all the symptoms supposed to be indicative of disease of the right side of the heart have been occasioned by disease of the left; and conversely. Some observers place the greatest reliance on the physical signs as means of diagnosis, whilst others regard them as altogether uncertain. It has been affirmed by distinguished observers, (Messrs. Graves and Stokes, cited in *American Med. Intelligencer*, Nov. 1, 1838,) *first*, that the physical signs of valvular disease are not fully established; *secondly*, that, taken alone, they are in no case sufficient for diagnosis; *thirdly*, that even in organic disease, the nature and situation of murmurs may vary in the course of a few days; and, *fourthly*, that organic disease of the valves may exist to a very great degree without any murmur whatsoever.]

CARDIAC ASTHMA.—Among the diseases of the heart may be justly reckoned one of the forms of the malady termed in common language *asthma*. The group of symptoms ordinarily ranged under this name, have been too much regarded as independent of disease of the heart. It becomes therefore necessary to notice the subject, formally, in this place, not only for the purpose of showing

the magnitude of the error, but of making the reader acquainted with all the habitudes and aspects of a complaint, which is perhaps the most distressing in the whole catalogue of human maladies.

Corvisart has remarked that the ancients confounded under the name of *asthma*, and erroneously regarded as purely nervous affections, dyspnoeas resulting from various organic diseases, particularly those of the heart and great vessels.

That they were wrong in regarding the latter as purely nervous affections, and especially in confounding them with those forms of dyspnoea that were such, is unquestionable; but they were, in our opinion, correct in embracing under the general term *asthma*, cardiac dyspnoea of a certain intensity, and exhibiting certain characters hereafter to be described; for it is established by the concurrent testimony of all moderns conversant with diseases of the heart, that these diseases, no less than those of the lungs themselves, may constitute the organic causes of asthma.

A theoretical consideration of the subject leads, in our opinion, to the same conclusion; for, on tracing asthma back to its source, we shall find that, whatever be its proximate cause in different cases, it depends, in all, on the same ultimate cause; namely, inadequate oxygenation of the blood, and the *sensation* of want of breath resulting from it. In order to render this apparent, it will be necessary briefly to analyze the several varieties of asthma, and then compare them with each other.

Inadequate oxygenation of the blood results in all ordinary cases from one or more of three proximate causes: viz.

1. Insufficient admission of air into the bronchial tubes and air-vesicles.

2. Insufficient exposure of the blood to the air admitted, in consequence of a less pervious state of the mucous membrane than natural.

3. Insufficient admission of blood into the lungs.

It will be found that to one or more of these causes, all the varieties of dyspnoea and asthma are referable.

All the varieties of asthma—to give an approximate statement probably very near the truth—are comprised under the following heads:—

1. From chronic dry catarrh, and the emphysema resulting from it.

2. From pituitary catarrh, (humoral asthma,) whether acute or chronic, but more especially the latter, and the pulmonary oedema resulting from it.

3. From mucous catarrh, especially chronic.

4. From organic disease of the heart.

5. From purely spasmodic constriction of the bronchial tubes.

We do not include amongst the varieties, one from the compression of the lungs by hydrothorax, by tumours, by imperfect descent of the diaphragm, &c., because these rarely occasion what can strictly be called asthma.

1. *Chronic Dry Catarrh* is attended with intumescence of the internal membrane of the bronchial tubes. The intumescence exists principally in the smaller tubes, which are sometimes completely obstructed by it; but it is also found in the larger. Andral has seen the bronchial trunk of a lung so contracted by this intumescence, that the air could scarcely enter; and in another case,

the third and fourth bronchial divisions were contracted by the same cause. (Clinique Méd. seconde partie, obs. ii. et iii.) Further, the tubes are more or less obstructed by an exceedingly viscid mucus, often as dense as the vitreous humour of the eye; and when the dry catarrh is universal or even very extensive, it is almost invariably productive of emphysema.

2. *Pituitary Catarrh* is attended with moderate intumescence, slight softening, and partial redness of the pulmonary mucous membrane—a state intermediate between sanguineous and serous congestion, but partaking more of the latter. The quantity of phlegm expectorated, always considerable, is sometimes enormous, amounting to from four to six pints of thin glairy fluid in twenty-four hours.

The air-passages being obstructed partly by the intumescence of their mucous membrane and partly by this fluid, it necessarily follows that there is an insufficient admission of air into the lungs.

3. *Mucous Catarrh* is accompanied with more or less tumefaction of the bronchial membrane and obstruction of the calibre of the tubes. The expectoration, though less copious, and different in quality from that of pituitary catarrh, is, notwithstanding, frequently abundant, amounting to one or two pints or more in the day. Consequently, there is an insufficient ingress of air into the lungs.

In all the cases now mentioned, the second cause of inadequate oxygenation of the blood is, likewise, for the most part, in operation, viz. the mucous membrane being thickened, it is less pervious to air; and its mucus, the natural function of which is to expedite the combination of oxygen with the blood, probably discharges this function less perfectly, in consequence of an alteration in its chemical qualities.

4. *Disease of the Heart*.—Sometimes, from this cause, blood exists in the lungs in excess; as is the case when the right ventricle is hypertrophied, or the left side of the heart obstructed; or still more, when these two affections coexist: also when the circulation is merely accelerated, as by palpitation, running, or by slighter efforts in corpulent persons. Now, under all these circumstances, there is inadequate oxygenation of the blood: or, in other words, there is an excess of venous blood in the lungs; first, because the quantity of blood admitted exceeds its due proportion to the air in the organ; secondly, because the overloaded vessels do not transmit the fluid with natural celerity; thirdly, because the engorgement of the mucous membrane on which the blood ramifies, constricts the bronchial passages, and prevents the free ingress of air, as proved by the feebleness of the respiratory murmur. Hence the sensation of want of breath is a necessary consequence of an excess of blood in the lungs.

Sometimes blood does not enter the lungs in sufficient quantity, constituting the third cause of inadequate oxygenation; and this may arise from the weakness of the right ventricle, from an obstruction in its mouth, or from increased resistance on the part of the lungs; as, for instance, during sleep, when the respirative function is less active. Hence results the sensation of want of breath, and dyspnoea. Cases exemplifying this will shortly be adduced; meanwhile, it may be illustrated by a simple physiological experiment, viz. by making

and sustaining a full *expiration*. This is attended, not only with a deficiency of air, but also with a deficient influx of blood into the lungs, as is proved by the lividity of the face which ensues, by the elevation of the fontanel in infants, by the rise of blood in a tube inserted into the jugular vein, and, lastly, by experiment; for we have demonstrated, in the treatise already referred to, that, on suspending artificial respiration in a rabbit, the heart *instantly* became gorged, of a black colour, and distended to nearly double its natural size—a phenomenon which renders it sufficiently manifest that, when the lungs are exhausted of air, the blood does not freely enter them. Now, the sensation of want of breath experienced on making a full expiration is familiar to every one, and it becomes intolerable if the expiration be long sustained.

5. *Spasmodic Constriction of the Bronchial Tubes*.—This is presumed to exist, first, because, according to the researches of Reisseissen and others, the bronchial tubes are provided with muscular fibres, and all muscles are liable to spasm; secondly, because asthma is occasionally found to occur without any organic cause (so far, at least, as our senses enable us to judge) sufficient to account for it: thirdly, because every form of organic disease above described, both of the lungs and the heart, may exist without causing dyspnoea of such intensity and of such a character as to constitute *asthma* properly so called. Thus, many have intense catarrhs, acute or chronic, and profuse expectoration, without any asthmatic dyspnoea; and we have known a patient with a contraction of the mitral orifice to the size of a small pea, and likewise with dilatation and softening of the heart and profuse expectoration, pass through a period of ten years to her grave, without ever experiencing a paroxysm of asthma, though a few steps across the room were sufficient to excite dyspnoea.

Hence we apprehend that whatever be the organic cause of asthma, it requires, for the production of the fit, the super-addition of a state of the nervous system leading to spasmodic constriction of the bronchial tubes.

Admitting that the spasmodic constriction of the bronchial tubes does take place, it is obvious that it will more or less close these tubes against the ingress of air; and this closure, again, by preventing the free expansion of the lungs, will impede the influx of blood: whence there is a double cause for the inadequate oxygenation of the blood, and, consequently, for the production and maintenance of the asthmatic paroxysm.

From all that has been said, we are now led to the resulting inquiry;—what is the essential difference between asthma from disease of the heart and that from disease of the lungs? Putting aside that variety of asthma, which, as not being attended with any *visible* organic derangement, (though it is, notwithstanding, highly probable that one exists,) may be regarded as mainly, if not wholly spasmodic, there does not appear to be any essential difference between the remaining varieties. The organic causes are diversified, but they all ultimately produce the same effect, and it is the effect which constitutes the essence of the disease. This effect is inadequate oxygenation of the blood, which causes the *sensation* of want of breath; and this, when there exists more than what may

be called mere dyspnoea, occasions spasmodic constriction of the bronchial tubes, and its consequence, the asthmatic paroxysm.

We now proceed to a more particular consideration of asthma from disease of the heart: a variety which comprises, according to our observations, by far the greater proportion of the most severe and fatal cases of asthma.

Until the discovery of auscultation had in some degree dissipated the deep obscurity of the affections of this organ, the fact that they were a cause of asthma was scarcely known; and even at the present day, there are few errors more common than that of attributing asthma to other causes, when it originates solely in the heart. For instance, a theory of this description which has, within the last half century, been more widely disseminated than perhaps any other, consists in ascribing asthma to a spasmodic or convulsive contraction of the external muscles of respiration, much dependent on habit.

Now, the action of these muscles, so far from being morbid or dependent on habit, is a natural, instinctive, and salutary effort to prevent suffocation, the stimulus to which effort consists in an exaggeration of that which excites the muscles in ordinary respiration,—namely, as above explained, the sensation of want of breath, from inadequate oxygenation of the blood. Nothing is more common, for instance, than to see a patient with diseased heart, while sleeping tranquilly, start up and begin to respire with violence. Here it is obvious that the necessity for violent respiration preceded the act; and the necessity depends on impeded transmission of blood through the heart and lungs; for starting is invariably accompanied by palpitation, and preceded by frightful dreams or some sensation of præcordial distress, indicating an obstructed circulation. We have frequently examined the heart and lungs by auscultation immediately before the supervention of a paroxysm of dyspnoea, and have always found that the heart began either to palpitate or to act in that irregular, confused, and, as it were, struggling manner, which denotes its engorgement. We were, therefore, enabled to tell the patient that difficulty of breathing was coming on, to which, with some astonishment, he would reply in the affirmative, being himself forewarned of the approaching accession by a feeling of anxiety and straitness in the præcordia. This fact is so universally true, that any one may satisfy himself of it by entering an hospital, and gently placing a patient with orthopnoea from disease of the heart in a rather uneasy position, when the series of phenomena described will become manifest.

Dr. Burrows communicated to us the particulars of a case, under his observation, in which the respiration was alternately violent and tranquil under the following circumstances. The patient dozed for a few minutes at a time, during which his complexion became livid, and his pulse more and more feeble, oppressed, and irregular. He then started up, and, after a few violent wheezing respirations, relapsed into the same calm doze. In this case the mitral orifice was contracted to the size of a pea. Now there can be little doubt that, as, during sleep, the sensation of want of breath is less felt, and the muscles of respiration

are, consequently, less stimulated by it—in simple language, as the respiration is more feeble during sleep,* the lungs were not, in the present case, kept sufficiently expanded to admit of an adequate circulation of blood through them; whence ensued engorgement of the heart and venous system of the body, with insufficient arterialization of the blood in the lungs, and the sensation of a necessity for breathing resulting from it: which series of phenomena was relieved by the succeeding violent respirations.

We have frequently observed this series of phenomena in a greater or less degree. In one case, violent gasping and wheezing respiration, lasting from a few seconds to two or three minutes, occurred at intervals of four or five minutes, during which the patient dozed, even though sitting erect on a stool and undergoing a stethoscopic examination; and this series of actions continued so long as the patient remained disposed to sleep in that situation. (Med. Gazette.)

In all these cases it is manifest that the action of the muscles of respiration was consecutive to the obstruction of the circulation, and that it was not dependent on any spasm of those muscles, but simply on the necessity for breathing, which instinctively excited them to a salutary preservative effort.

Asthma from disease of the heart often imitates the characters of the other varieties; and this perhaps for a very simple reason; that the lungs are in much the same state as in those varieties. Thus, the asthma is *humid* or *humoral*, when there is permanent engorgement of the lungs, causing copious sero-mucous effusion into the air-passages, as in cases of contraction of the mitral valve. It is *dry* when the engorgement is only transitory, as in cases of pure hypertrophy. It is *continued* when there is a permanent obstruction to the circulation; and any of the varieties may be *convulsive* when the heart has sufficient power to palpitate violently. The worst cases of convulsive asthma from disease of the heart are those of hypertrophy with dilatation, together with a valvular or aortic obstruction.

We shall now examine the state of a patient labouring under severe cardiac asthma, and then take a more strictly medical view of the nature and progress of the paroxysm.

The respiration, always short, becomes hurried and laborious on the slightest exertion or mental emotion. The effort of ascending a staircase is peculiarly distressing. The patient stops abruptly, grasps at the first object that presents itself, and fixing the upper extremities in order to afford a fulcrum for the muscles of respiration, gasps with an aspect of extreme distress.

Incapable of lying down, he is seen for weeks, and even for months together, either reclining in the semi-erect posture supported by pillows, or sitting with the trunk bent forwards and the elbows or fore-arms resting on the drawn-up knees. The latter position he assumes when attacked by a paroxysm of dyspnoea—sometimes,

* As the respirations are slower, they might be supposed deeper; but with the exception of those deep inspirations that are taken occasionally during, and more particularly at the *breaks* of sleep, the expansion of the lungs during sleep will be found by auscultation to be less than at other times.

however, extending the arms against the bed on either side, to afford a firmer fulcrum for the muscles of respiration. With eyes widely expanded and starting, eye-brows raised, nostrils dilated, a ghastly and haggard countenance, and the head thrown back at every inspiration, he casts round a hurried, distracted look, expressive at once of fright, agony, and supplication; now imploring, in plaintive moans, or quick, broken accents and half-stifled voice, the assistance already often lavished in vain; now upbraiding the impotency of medicine; and now, in a fit of despair, drooping his head on his chest, and muttering a fervent invocation for death to put a period to his sufferings. For a few hours—perhaps only for a few minutes—he tastes an interval of delicious respite, which cheers him with the hope that the worst is over and that his recovery is at hand. Soon that hope vanishes. From a slumber fraught with the horrors of a hideous dream, he starts up with a wild exclamation that “it is returning.” At length, after reiterated recurrences of the same attacks, the muscles of respiration, subdued by efforts of which the instinct of self-preservation alone renders them capable, participate in the general exhaustion and refuse to perform their function. The patient gasps, sinks, and expires.

Such are the sufferings, in their worst form, of an asthmatic from disease of the heart. We have now to take a more strictly medical view of the nature and progress of the asthmatic paroxysm.

If about to be severe, it is generally preceded by certain premonitory symptoms, which, though not so marked as in ordinary asthma, are much of the same nature—probably because derangement of the circulation and imperfect oxygenation of the blood are present in both. In cardiac asthma, however, many of the nervous symptoms, which characterize the ordinary varieties, are often deficient. One of the most common and efficient exciting causes of cardiac, as of all other asthmas, is derangement of the stomach, the irritation of which extends to the heart, and stimulates it to inordinate action. The irritation, according to the theory of Sir Charles Bell, is propagated through the medium of the *par vagum*, by which nerves the stomach and heart are closely associated as parts of the respiratory system. Accordingly, after a feeling of acidity, flatulence, or a load on the stomach from undigested food, often accompanied with abdominal distension, the patient experiences pain, weight and constriction in the forehead and over the eyes, accompanied (if the case be one of hypertrophy of the left ventricle) with throbbing of the temples and the sound of rushing waters. He feels a sensation, scarcely to be defined, of oppression, tightness and anxiety about the *præcordia*, frequently with slight palpitation. Sometimes the patient is drowsy, listless, restless, irritable, and impatient not only of society but of the attention of friends: these symptoms, however, are, in general, more prevalent in ordinary asthma. The signs described afford the experienced asthmatic well-known assurance of the approaching attack.

They gradually become worse and worse, especially after a meal, and eventually burst into a paroxysm. The time of the accession is less regular than in ordinary asthma, being more

dependent on the state of the heart, which is liable to accidental excitement, from a variety of causes, at any moment. The fit, however, as in ordinary asthma, is, on the whole, more apt to supervene during the evening or early part of the night; and this, as appears to us, for two reasons: 1st. The recumbent position is unfavourable to respiration, the diaphragm being pressed upwards by the abdominal viscera, and the expansion of the chest being opposed by its own weight: 2d. During sleep respiration is not assisted by the will, which, during the wakeful state, from the sensation of want of breath being more acutely felt, is ever ready to maintain the body in the position most favourable to breathing. From the co-operation of these two causes, therefore, the circulation becomes so far embarrassed before the patient is aroused to a sense of his condition, that it can only be relieved by those violent efforts which accompany the asthmatic paroxysm. He accordingly awakes, generally with a start, in a fit of dyspnoea, accompanied either with violent palpitation, or a distressing sense of anxiety in the *præcordia* and great constriction of the chest, as if it were tightly bound. He is compelled to assume a more erect posture, and intensely desires fresh, cool air; the respiration is wheezing and performed with violent efforts of all the muscles of respiration both ordinary and auxiliary. The inspirations are high and accompanied with apparently little descent of the diaphragm, and the expirations are short and imperfect. The surface is chilly, the extremities are cold, and the face is pale and sometimes livid.

In cases in which the pulmonary congestion is only *temporary*, as in hypertrophy, either simple or with dilatation, there is no cough beyond a few slight and ineffectual efforts, producing little or no expectoration; and in such cases the fit subsides as soon as the engorgement of the heart and great vessels is relieved, which nature generally effects in two or three hours or less, by determining the blood to the surface and creating diaphoresis. In some instances we have known this termination to be regularly accompanied with a copious secretion of pale urine and a purging alvine evacuation.

The pulse, though at first full, strong, and bounding, may, during the worst of the paroxysm, become feeble and small, and the sound and impulse of the heart may be diminished; and this in cases even of hypertrophy; for the organ, being gorged to excess, is incapable of adequately contracting on its contents.

Such is the nature of an asthmatic fit when the pulmonary congestion is only temporary: the case is different when it is *permanent*, as in valvular disease and in some extreme cases of dilatation. For, then, there is often violent cough in suffocative paroxysms, accompanied, at first, with difficult and scanty expectoration of viscid mucus, but ending gradually in a copious and free discharge of thin, transparent, frothy fluid, occasionally intermixed with blood. This evacuation by discharging the pulmonary capillaries, affords great relief to the cough and dyspnoea. As, however, the transudation of the matter to be expectorated into the air-passages, and its final elimination, are slow processes, paroxysms of this

description are much more protracted than those of dry asthma from hypertrophy. They frequently last five or six hours, and we have known them persist, with only occasional remissions, for two, three, or more days. During the attack, the pulse is quick, small, and weak, often irregular and intermittent. In other forms of asthma the circulation through the heart is sometimes little disturbed; but this is always incorrect in reference to asthma from disease of the heart.

As the paroxysm subsides, the anxiety and constriction decrease, the respiration becomes less frequent, high, and laborious, and the pulse becomes slower, fuller, and more regular. But some degree of wheezing and tightness of the chest remains, and the paroxysm is very apt to return for two or three nights successively, and sometimes for a much longer period, until the lungs are freely unloaded by copious expectoration. It may, indeed, continue to recur at brief intervals for an indefinite period, or the patient may never be wholly exempt from some degree of asthmatic dyspnoea.

A severe asthmatic attack from disease of the heart is in general far more injurious in its consequences than one from an affection of the lungs.

Treatment of Disease of the Valves.—According to the foregoing principles, the exciting causes of valvular disease are, 1. over-tension of the valves by the force of the circulation; and, 2. inflammation, generally of the chronic kind. If it were possible to ascertain that these causes were in operation before they had actually occasioned an organic change, it would most probably be possible, in many cases at least, to counteract their effects and to prevent the formation of the disease. But, unfortunately, there are no positive signs of the latent mischief but what result from the disease already formed,—from the obstruction itself: and as, in the present state of our knowledge, we are not acquainted with any means of removing a valvular obstruction, the indications of treatment in this disease are, to prevent its increase, to counteract its tendency to induce hypertrophy and dilatation, and to relieve the symptoms of an obstructed circulation.

The remedies calculated to answer these indications are, in general terms, such as diminish the force and activity of the circulation, namely, occasional venesection to a moderate extent, an unstimulating and rather spare, though sufficiently nutritious diet, a tranquil life, with respect both to the body and the mind, and a good state of the digestive organs and alimentary canal.

If there be distinct signs of inflammation of the valves, to the above remedies may be added cupping or leeching on the præcordial region, with counter-irritants, as blisters, setons, issues, and the tartrate of antimony in the form either of ointment, or plaister with the empl. picis comp., and one-fourth of bees'-wax. We have also found digitalis very useful under these circumstances.

The extent to which any remedy must be carried can only be determined by the particular circumstances of each case. If, for instance, the patient be robust and plethoric, depletory measures may be pursued to a greater extent, and *vice versa*. In general, if the valvular obstruction be not very considerable, and there be no hypertrophy

or dilatation, and no tendency to plethora, an abstemious, light diet, and a scrupulously tranquil life, with an open state of the bowels, constitute all the prophylactic treatment that is necessary; and it is satisfactory to know that, by these means, danger may in many instances be completely averted. We have several times known patients with a moderate—even with a rather considerable valvular obstruction, attain the age of sixty, seventy, and even eighty, though the symptoms, judging from their account, had commenced in early life.

On the other hand, if precautionary measures be neglected, and hypertrophy or dilatation be superinduced, there is no organic disease of the heart, except adhesion of the pericardium, which tends more rapidly to its fatal termination. Hence the great importance of detecting and attending to disease of the valves in its earliest stage.

When the obstruction has become very considerable, has produced hypertrophy or dilatation, and is attended with dyspnoea, orthopnoea, and dropsy, the case is one of the most difficult that the practitioner can encounter. The most urgent symptoms, however, generally admit of being removed for a time; and the amelioration which takes place is sometimes truly astonishing. But, unhappily, the complaint seldom fails to return with greater or less promptitude. If the patient be youthful and of a robust constitution, the relapse may not occur for several months, especially if he has not been affected with dropsy, or after the first attack; but if he be of a shattered constitution, and have previously had severe attacks, the symptoms commonly return the moment he resumes any active occupations. In an ulterior degree of the disease, no sooner are the symptoms dispersed than they return, though the patient does not commit any indiscretion. When this is the case, the fatal event is never far remote, and may occur suddenly at any moment.

The remedies suitable for the treatment of the cases described are, abstractions of blood, purgatives, diuretics, sedatives, revulsives, a spare diet, and, what is paramount in importance to all, complete repose. These remedies, however, are not to be employed at random: so used, they might not only be unavailing, but directly destructive. It is only by adapting them to the character of the organic cause of the disease—only, in short, by a sound diagnosis, that they can be administered safely and effectively. It is necessary, therefore, to enter into further particulars relative to their nature and mode of application, and this may be most conveniently done by adverting separately to each.

Bloodletting.—When, with the valvular obstruction, there is hypertrophy or dilatation with dilatation, bleeding is generally necessary and may be repeated in small quantities, two, three, or more times, according to the strength of the patient and the urgency of the palpitation and dyspnoea. Some have recommended that bloodletting be practised in valvular disease in the unsparing manner of Albertini and Valsalva. The results of our own experience lead us to dissent entirely from this doctrine. Excessive bleeding cannot remove the valvular obstruction—cannot, therefore, cure the disease; consequently, its employment

with this object is inappropriate. It is, moreover, directly injurious; as it reduces the patient to a state of debility which renders his circulation more liable to be embarrassed by the valvular obstruction, and his constitution more susceptible of the inroads of the malady. We have always observed bloodletting to be most serviceable in valvular disease when carried only just so far as to relieve the existing urgent symptoms without encroaching on the constitutional powers. It is advantageous to draw from four to eight ounces of blood occasionally during the intervals of the attacks, whenever dyspnoea becomes urgent and the heart's impulse more than ordinarily strong.

If, instead of hypertrophy, dilatation, either simple or attenuated, be conjoined with valvular disease, bloodletting is less necessary, and is more injurious if carried to excess. It should be resorted to reluctantly; only when imperiously demanded by excessive dyspnoea, which other means have failed to relieve; the least quantity that suffices to afford relief should be drawn; and the depletion should not be repeated if it can possibly be avoided. Attention to these rules is still more necessary in the aged. The greater the valvular obstruction, the greater is likely to be the embarrassment of the circulation, if the power of the heart and system be reduced below a certain point. Of this we feel satisfied from reiterated observation.

Diuretics.—When there is dropsy and a scanty secretion of high-coloured urine, remedies of this class are of the greatest utility. In most cases, indeed, the dyspnoea, palpitation, cough, &c. decrease in the same proportion as the urine increases and the dropsy disappears. Nor is it only when dropsy has actually appeared, that diuretics are useful. They are remarkably beneficial in an anterior stage of the disease; for, by drawing off the serous portion of the blood, they diminish the quantity, and thus deteriorating the quality of that fluid, and thus relieve palpitation and dyspnoea and obviate infiltration, without materially reducing the patient.

Diuretics are very variable in their effect, a weaker sometimes answering perfectly after a stronger has failed. When, therefore, one does not speedily produce the effect, another should be tried. The surest way is to employ several at once. A pill consisting of three grains of blue pill, one of pulv. scillæ, and one or half of one of pulv. digitalis, given three or four times a day, seldom fails; or it may be given once or twice a day with a draught of tr. scillæ, mxx. sp. ætheris nit. and sp. junip. C. comp. āā. ℥ss. ad ℥i, in dec. spartii. ℥iss. twice or thrice a day. We have sometimes found all these fail until ℥ii or ℥iii of infusion of digitalis were added to the draught. Its effect, however, must be carefully watched. Supertartrate of potass is always a valuable auxiliary, and may be given to the extent of ℥ii or ℥iii in twenty-four hours, either in the form of a drink, of electuary, or in the above draughts.

Sometimes diuretics cannot be made to produce any effect: it is then necessary to resort to purgatives, as will presently be explained.

In very feeble and reduced patients, dropsy should not be too rapidly evacuated; as the process is attended with a degree of exhaustion,

which is often fatal. The period, indeed, immediately succeeding the disappearance of dropsy is, on this account, one of the most critical. The older physicians were aware of this, and ascribed it to the accumulation of the fluid in the internal cavities. Such, however, is not always the cause; for, in cases terminating fatally at the period alluded to, we have frequently ascertained, both by auscultation, percussion, and post-mortem examination, that the internal and external dropsy disappeared simultaneously.

Purgatives.—When diuretics do not remove dropsy, purgatives will frequently produce that effect. The two classes of remedies may, indeed, be combined with great advantage, when the patient is strong enough to bear them. The drastic hydragogue purgatives are the most efficacious, as tinct. jalapæ, elaterium, &c. The effects of the latter are sometimes truly astonishing. We have seen an extreme universal anasarca removed by it in three or four days. The remedy is apt, however, to be excessively violent in its operation, and should, therefore, only be given to strong subjects. As its effect varies in different individuals, it should be tried at first in small doses, as from one-eighth to one-fourth of a grain. With caution it may be carried to two grains. We generally give it in the form of pills with pulv. capsici, which obviates its griping effect; sometimes we add a grain or two of calomel. A single pill should produce six or eight watery evacuations, and it may be given two or three mornings successively, or every second or third morning, according to the strength of the patient. All the other purgatives may be useful, especially such as produce watery evacuations. A very good one is, the infusion of senna, with tinct. jalapæ ℥i, and tartrat. or acetat. potass. ℥ii.

An occasional purgative is sometimes very beneficial though there be no dropsy; as, for instance, when an attack of palpitation or asthma has appeared to be induced by an excess of bile, by undigested food, or by acrid or long detained feces in the intestines. Under such circumstances a purgative often alleviates, and sometimes terminates the attack. Except with a view of removing dropsy, or plethora in cases where hypertrophy is superadded to valvular disease, frequent, systematic purging should be avoided on the same principle as bloodletting: viz. lest it should too much reduce the system.

Diaphoretics.—When there is anasarca, cutaneous transpiration contributes very powerfully to remove it. A lady, lately under our care, and subject to frequent attacks of anasarca, often found the swelling disappear in twenty-four hours with copious perspiration. Strong stimulating sudorifics, however, should be avoided, as they are both too debilitating and too exciting to the circulation. Gentle saline diaphoretics are the best, and their effect may be promoted by warm clothing, hot diluents, and the occasional use of the warm bath to keep the skin soft and open. When there is no anasarca, and no permanent pulmonary engorgement and expectoration, diaphoretics, beyond warm clothing, are of little use, except occasionally, to relieve asthmatic attacks. For the latter purpose we have generally found them of great utility; but, as internal remedies of this class are

slow in their operation, they should be resisted by fomenting the hands and feet, or immersing them in warm water, at the same time keeping the trunk covered. If perspiration can thus be gently elicited without heating and stimulating the patient, it is one of the most effectual means of curtailing a paroxysm. Nature herself indicates the remedy; as a paroxysm of asthmatic palpitation often terminates with profuse spontaneous diaphoresis.

Emetics.—These are extremely useful or extremely pernicious according as they are judiciously given, or the reverse; and it is only by a sound diagnosis that the practitioner is enabled to judge whether they can be safely administered or not. When there is an undigested, bilious, or acid load on the stomach, exciting a fit of palpitation, its removal by an emetic often affords instantaneous relief. But the medicine should be one which simply evacuates the stomach without much shaking the system, as ipecacuan with sulphate of copper or of zinc, but by no means tartrate of antimony. If the disease of the heart and the embarrassment of the circulation be great, even such an emetic as the above cannot be given without danger of aggravating all the symptoms. We have seen emetics, administered under these circumstances, exasperate and prolong the paroxysm, increase the frequency of its recurrence, and speedily bring the patient to his grave. They may even cause death during the paroxysm. Their dangerous effect consists in their increasing engorgement of the heart and the obstruction of the circulation. For this reason they should not be ventured upon in disease of the heart simply for the object of promoting expectoration—an object which may be much more safely and effectually accomplished by other means. In ordinary varieties of asthma, especially that from pituitary catarrh, they are peculiarly beneficial by promoting the expectoration of the immense accumulations which take place in the lungs. Hence the importance of carefully distinguishing between these two classes of cases. (See ASTHMA.)

Though emetics are objectionable except for the purpose of evacuating the stomach, small doses of ipecacuan or tartrate of antimony are useful as diaphoretics and expectorants. When the obstruction of the circulation is great, they cannot safely be carried to nausea, as this state is apt to bring on a languor of the circulation which leads to the formation of polypi in the heart. In the case of a lady under our care, and affected with extreme contraction of the mitral valve, nausea came on unexpectedly at the moment when she had just been relieved of an excessive dropsy, and was followed by suffocating dyspnoea, an imperceptible pulse, and other symptoms indicating the formation of a polypus in the heart. She died in a week, and the polypus was found.

Puncturing.—When dropsy has failed to be relieved by other means, and the cutaneous tension has become intolerable, the practitioner is compelled to resort to puncturing. We say compelled, because the remedy is a last and dangerous resource. The danger, however, may be considerably diminished by making small punctures with a grooved needle, and allowing the fluid to ooze slowly during four or five days or a week. When incisions are made with a lancet or scalpel and

the fluid is evacuated quickly, as in twelve to forty hours, the patient, according to our observation, generally dies. This event sometimes results from sloughing of the incisions, but more commonly from exhaustion induced by the sudden evacuation of the fluid. In one instance we saw the patient die from hemorrhage. There is less danger of mortification when the incisions are made above the knee.

Setons, issues, and blisters on the præcordial region, are of no use unless there be chronic inflammation of the heart: the pain and irritation which they occasion are often injurious. The emplastr. belladonnæ, however, is often very serviceable in tranquillizing the heart and allaying nervous pain.

Expectorants.—When there is permanent engorgement of the lungs, free expectoration always affords relief; we have seen great dyspnoea result from its suppression by an incipient catarrh, a dry sharp atmosphere, and even a dose of laudanum. Many asthmatic fits dependent on valvular obstruction, terminate with copious expectoration of a thin sero-mucous fluid. This secretion, therefore, should always be maintained when there is a tendency to it.

As the stomach in disease of the heart is extremely fastidious and delicate, oily, sweet, and nauseous expectorants should be carefully avoided. Squill with an acid, as the acetic or nitric, has been found by experience to be the most efficacious remedy of this class. Vinegar of squill has been highly extolled by Floyer, and tinct. scillæ, gtt x—acid. nitrici, gtt vi—extr. hyoscyami, gr. iii—aquæ puræ $\bar{z}$ iss, as a draught every three or four hours during the paroxysm, is the favourite prescription of Dr. Bree for the asthmatic paroxysm of his first species, i. e. "from effused serum in the lungs." Mist. ammoniaci, though in general too heating for the young, is a useful expectorant for the old, when sufficiently diluted. The same may be said of the decoction of seneca. Ipecacuan and tartrate of antimony in small doses, are valuable expectorants as well as diaphoretics. Phlegm accumulates during sleep, and it is for this reason principally, that the patient suffers more on first rising in the morning. The elimination of the phlegm is greatly facilitated by a cup of any hot fluid, especially coffee; and, to allay the nervous irritability of the lungs which generally leads to coughing before the phlegm is sufficiently detached to be thrown off with ease, we have found from half a drachm to a drachm of tinct. camphoræ comp. of great utility.

Expectorants should not be constantly given in disease of the valves, but only to relieve an asthmatic paroxysm, or to restore the pulmonary secretion when accidentally suppressed.

Gases.—The effects of atmosphere on cardiac, as on other asthmatics, are so diversified that they are scarcely reducible to any general rule. When, however, expectoration is habitually copious, a moist warm atmosphere favours it, probably by relaxing the pulmonary vessels. A clear, sharp air, on the contrary, checks it, and thus increases dyspnoea. Again, the latter air relieves dyspnoea when it depends, not on engorgement of the lungs, but on a languid action of the heart as in dilatation with attenuation; and this it does by stimulating and bracing the system, and causing a freer

circulation through the lungs and more perfect arterialization of the blood. Electricity appears to act in the same way when it produces any good effect. We have never tried the inhalation of oxygen, but it is highly commended by Dr. Beddoes and others; and it is rational to think that, in suffocative dyspnoea from retardation of the blood in the lungs, it would relieve the anxiety and straitness by causing a more perfect arterialization.

Smoking tobacco or stramonium sometimes affords extraordinary relief to cardiac, as well as other asthmatics; and this it does partly, perhaps, by increasing the bronchial and salivary secretion, but more especially by its sedative and antispasmodic effect in tranquillizing the nervous system, resolving the bronchial spasm, and allaying the sensation of want of breath. The experience of the patient is the only certain criterion of its utility. In many cases we have certainly seen it prejudicial. Its utility has appeared to us the greatest in those who are of a highly nervous irritable habit, and in whom asthma displays most of the spasmodic character.

Antispasmodics.—While the Cullenian doctrine, that spasmodic constriction of the bronchi was the sole cause of asthma, prevailed, remedies of this class were in great vogue; but experience has not realized the high expectations to which the theory gave rise. Antispasmodics are useful auxiliaries, but cannot be depended upon alone. When they not only resolve bronchial spasm, but contribute to diffuse, equalize, and calm the circulation in disease of the heart, they are beneficial: when they fail to produce the latter effects, they are of little use. In an incipient paroxysm from slight disease of the heart, we have frequently found a draught of *sp. ammoniæ aromat.* or *fœtid.* with *æther* and *laudanum*, promptly restore the colour to the face and warmth with perspiration to the skin, with general relief. In one case of hypertrophy with dilatation and adhesion of the pericardium, a glass of gin and water had always the effect. Sometimes *gr. x* to *xv.* of carbonate of ammonia is more efficacious than any other remedy. The solution of *assafoetida* has also appeared to us to be very powerful, but few patients can be prevailed upon to take it.

In most instances, the antispasmodic, whatever it be, is productive of eructation, and to this, in some cases, we partly attribute its beneficial effect; as flatulence alone suffices to occasion a paroxysm. The eructation sometimes occasioned by the remedies themselves, especially *æther*, must not be mistaken for the extrication of the real flatus.

When the paroxysm is fully established, and is connected with a great degree of organic disease of the heart, antispasmodics alone have little or no effect in affording relief; and large doses of sedatives, as opium, hyoscyamus or conium, or of stimulants, as *æther*, often prolong, rather than curtail the fit. In conjunction with other means, however, moderate doses may be tried, and if the patient feel himself relieved, they may be continued.

Digitalis, according to our experience, is an excellent adjunct to an antispasmodic draught: *gtt xx* or *xxx* of the tincture may be given every three or four hours, with *gtt vi* to *x* of *tinct. opii*,

or if that disagree, of hyoscyamus, in cinnamon water. Care should be taken to intermit the digitalis before its specific poisonous effect is produced.

In suffocative, agonizing orthopnoea, when the restlessness and jactitation of the patient aggravates the distress, we have often found narcotics afford great relief simply by inducing sleep and a diminished sensation of suffering.

Stomachics.—The correction of dyspepsia is of the first importance in organic disease of the heart; as palpitation is often dependent upon it alone. Two gentlemen under our care for hypertrophy, with dilatation, never suffered dilatation, dyspnoea, or headach except when affected with acidity, flatulence, &c. Such cases are often mistaken for "the stomach" alone—a most dangerous mistake: of the individuals alluded to, for instance, one had two fits of apoplexy, and the other was repeatedly rescued from it by prompt cupping. When there is acidity, antacids, of which chalk has appeared to us the most certain, should be freely given every third or fourth hour, its constipating effect being counteracted by the previous or simultaneous exhibition of a few grains of rhubarb. We have already stated that the stomach, if loaded, should, in the first instance, be evacuated by a gentle emetic, copious draughts of tepid water or chamomile tea being taken to insure its full effect. This treatment will generally terminate an attack dependent on dyspepsia, in two or three days and sometimes in as many hours. Towards the close of the attack, sedatives, as opium or hyoscyamus, assist by tranquillizing the nervous system.

Not only antacids, but also acids themselves, have been proved by experience to correct acrimony of the stomach accompanied with flatulence and distension. Their efficacy is the greatest when the acrimony is bilious, and then they act, in all probability, both by neutralizing the alkaline qualities of the bile, and exciting the stomach to an altered and more healthy secretion. That they possess the latter property is to be inferred from their correcting acidity and preventing fermentation even when there is no bile. A sour apple is a popular remedy for heart-burn. The acids to be employed, are, the mineral acids much diluted, and also the acetous. Saccharine acids, as oxymel, acescent fruits, raspberry vinegar, &c. should be avoided, as they are apt to be more injurious by their fermentation, than beneficial by their acid qualities. Acids need not be tried till antacids appear to have failed.

To give tone to the stomach, bitters are very useful. Infusions should be employed during an asthmatic paroxysm, as tinctures are too stimulating; but after the second or third day, when the patient begins to amend, either the one or the other may be used. The bitters may be conveniently conjoined with the antacids, acids, &c. Griffith's mixture is very beneficial in debilitated subjects, in the intervals between the fits.

Tonics.—When disease of the heart is of the hypertrophic kind with increased activity of the circulation, tonics are obviously inappropriate: when it is of the dilated kind, with languor of the circulation and atony of the system, they are remedies of the greatest value, and it is mainly by them that a complete cure can be effected. All

the tonics, of which the preparations of iron are the best, may be used according to the discretion of the practitioner. Of the advantages of bracing air and exercise and of the shower-bath, we have spoken in the article DILATATION. A discreet use of the cold bath also is highly beneficial. (See ASTHMA.)

Such are the remedies to be used in the treatment of organic disease of the heart. It cannot be too strongly inculcated on the practitioner, that the disease, when remediable, is not to be cured by relieving the paroxysm, but by preventing its occurrence. Every attack gives the patient much ground to retrace; a single attack may undo the progress of a year, and death may result from the indiscretion of a day. Great firmness is necessary on the part of the physician to impress this strongly on the mind of the patient; for the latter, when his feelings are easy, can seldom—very seldom—be made to comprehend that the necessity for his rigid adherence to medical, regimenal, and dietetic discipline is equally imperative.

The practitioner, however, is not the less to study the means of relieving the paroxysm; not only because in it he has perhaps the greatest of human sufferings to alleviate, but because by curtailing the attack he increases the chances of an ultimate cure.

HEMIPLEGIA. (See PARALYSIS.)

HEMORRHAGE, (*αιμορραγία*, from *αἷμα*, *sanguis*, and *ῥύσσειν*, *rumpo*,) loss of blood. The purpose of this article is to present a summary view of the knowledge we possess, and of the doctrines now generally received, concerning *internal hemorrhage*. The term is here employed in its most comprehensive sense, as signifying the passage of the blood beyond its natural channels—beyond or out of the vessels that are appointed to contain and convey it in the healthy living body. Under this definition it is indifferent whether the extravasated blood remains pent up within the body or not.

The epithet *internal* is however prefixed, in order to limit the subject to those forms of hemorrhage which fall within the province of the physician, and to exclude all consideration of those cases which, whether they are the result of disease, or of accidental injury, or of surgical operation, are capable of relief by mechanical expedients only. These latter cases are sometimes, though not perhaps with much propriety of language, comprised under the general title of *surgical hemorrhage*, in contradistinction to the former, which are then classed as being *medical*.

In what has been called *surgical hemorrhage* the blood proceeds from some large vessel, situated within the reach of the eye and the finger. The principles upon which the loss of blood in such cases is arrested or prevented are well understood; and in no part of the rapid progress of modern surgery has the union of well-contrived observation with sound reasoning been productive of more

admirable results. With a few remarkable exceptions, such as the protection afforded against small-pox by vaccination, or against sea-scurvy by the use of lemon-juice, there is not perhaps any single improvement in the art of healing by which so many lives are saved, and so much human suffering is relieved or averted, as by the scientific application of the ligature upon the larger blood-vessels.

That kind of hemorrhage which falls to the care of the physician is less perfectly understood, and is controllable with less certainty. It comprehends, however, a large and very formidable class of diseases. In some of these the effusion of blood is an accidental symptom only; of many it forms the principal sign or circumstance; and there are others in which it may be considered, in reference to our united means of investigation, as constituting the whole disease.

The accidental injuries to which the animal frame is continually exposed must have furnished mankind, from the earliest times, with frequent illustrations of the striking fact that the mere loss of blood, when it exceeds a certain amount, implies also the loss of life. They who have seen their fellow-men bleed rapidly to death from external wounds would be strongly impressed with the great importance of the fluid, the removal of which from the body led to an event so appalling; and they would look with interest and alarm upon the rarer instances which might occur of bleeding from internal and unseen parts. A natural but deceptive analogy, uncorrected by pathological knowledge, would almost unavoidably lead them to this further inference, that *all* hemorrhage—hemorrhage, the source of which they could not see, as well as that the source of which they were able to examine and appreciate,—proceeded from an opening in the sides of some one (or more) considerable blood-vessel.

It is true that some hemorrhages, of which the origin is, during life, beyond our vision and means of inquiry, do result from the rupture of vessels of a certain magnitude; but it is no less true that in the greater number of instances of bleeding from the interior of the body, there is no lesion, capable of being detected by dissection, either of the veins or the arteries; but the blood is poured out by what is called exhalation, and proceeds from those ultimate ramifications of the minuter blood-vessels which constitute the capillary system.

This remarkable and important piece of knowledge was ascertained long since by Morgagni; it was more formally and completely demonstrated by Bichat; and it has been so amply illustrated by subsequent observation that it may seem to be a fact almost too trite to dwell upon. Yet, judging from the writings and language even of medical men, it does not appear to be so generally known or acknowledged as it ought to be among *them*; and among unprofessional persons the old errors upon this subject prevail almost universally. To break or burst a blood-vessel, in the most literal meaning of those words, is thought by the public, and by some at least of the profession, to be a misfortune of very common occurrence; yet relatively to the frequency of hemorrhage, it is certainly a very rare one.

Bichat explicitly propounds the doctrine that in certain hemorrhages the blood escapes from the

capillary vessels by a process which, in pursuance of his example and to avoid circumlocution, we shall call that of exhalation. He rests this opinion upon several distinct considerations, some of which are perhaps more curious than conclusive.

Thus he states that if the uterus of a female who has died during the menstrual period, be carefully examined, no erosion of its inner surface or of its blood-vessels can be seen, nor any of those numerous cicatriculæ which, he argues, must have been formed, if each occurrence of the catamenial discharge had resulted from a rupture of those vessels.

The rupture which he here supposes is the simultaneous laceration of numberless capillary blood-vessels. Such laceration, if it took place, would indeed account for the discharge; and it has been assumed in explanation of some morbid hemorrhages. It is by no means certain, however, that it would give occasion, especially on a mucous surface, to visible scars. Punctures, even of the skin, made by fine needles which would wound the blood-vessels, do not, we imagine, however numerous they may be, leave any such traces of their former presence.

He adds, that if we submit the same uterus to pressure, and mark closely what happens, we see minute drops of a red fluid exude from its inner surface; and if we then wipe these drops away, the membrane whence they proceeded appears to be perfectly entire.

Whatever weight this argument may possess is strengthened by the actual observation of the process of menstruation in the living uterus. Dr. James Hamilton of Edinburgh is in the habit of relating, in his lectures, the case of a patient who was once under his care, and whose complaint appeared to him so instructive upon this very point, that he sent her into the clinical wards of the infirmary, that the students might have an opportunity of witnessing it. This woman was afflicted with enlargement and complete prolapsus of the uterus. The professor describes the inverted womb as having hung down between her thighs like a quart bottle; it could not be replaced; and it was tense and hard, except during the period of menstruation, which took place regularly. At those times it became soft and flexible, and the menstrual discharge was seen, by numbers of medical men and of students, to issue *guttatim* from the exposed surface.

As, however, the process of menstruation cannot be looked upon as a morbid process; as, in the unpregnant female, during a certain portion of her life, it is not only consistent with perfect health but actually essential to it; and as the fluid so poured out is not strictly blood; the analogical argument drawn from the preceding facts in favour of hemorrhage by exhalation, though it may afford a strong presumption, is not decisive.

But the deficiency here noticed is supplied by what is observed in those cases (rare indeed, yet well authenticated) of actual cutaneous hemorrhage, where a dew of blood appears upon some portion of the skin, is wiped away, and re-appears, with no perceptible alteration of the affected surface beyond some occasional variation in its colour.

Another of the arguments advanced against the possibility of rupture or laceration in such cases is

drawn from the well-known fact that the flow of blood, or of the catamenia, will sometimes continue for a few moments, then cease, and again recur; and that these alternate changes may happen several times in the course of a single day; so that, upon the supposition against which Bichat is contending, the wounds of vessels must heal and reopen at every change.

This reasoning is obviously both inconclusive and erroneous. We know that the cessation of hemorrhage from a *torn* vessel may and often does result from other causes than cicatrization; that even when the vessel is of considerable size, and the laceration extensive, the bleeding may occur, and pause, and occur again, and that repeatedly, within a short space of time.

Bichat did not overlook that species of evidence by which alone, after all, the existence of hemorrhage, independent of any rupture of vessels, can be satisfactorily established. He states that he had frequently dissected the bodies of persons who had died from hemorrhage; that he had examined, according to the nature of the case, the surfaces of the bronchi, the stomach, the intestines, or the uterus; and that, although he took the precaution of washing them clean, and even of submitting them to maceration before he inspected them with a microscope, he never could detect the slightest appearance of erosion.

Numerous and conclusive observations of the same kind have been accumulated by the zealous pursuit of morbid anatomy for which the present age is so remarkable; and in this way direct proof has been obtained, not only that internal hemorrhage may take place from the surfaces of membranes by exhalation, but that this is the mode in which it most commonly happens; that the effusion of blood by any of the natural outlets of the body can seldom, excepting in the cases of aneurismal disease, be explained by the detection of a broken blood-vessel.

Where hemorrhage, for example, has occurred so profusely from the stomach or bowels that the death which ensued has been sufficiently accounted for by the mere loss of blood, the whole tract of the alimentary canal has been diligently scrutinized, and has exhibited no breach of surface, nor any perceptible alteration of texture. Sometimes its mucous membrane appears, here and there, of a red colour, and as it were charged with blood; sometimes it is pale and transparent, while the vascular network visible immediately beneath it is gorged and turgid; sometimes the whole is colourless, the same network of vessels having been completely emptied by the previous hemorrhage; and sometimes again (and this is very illustrative of the mode by which the blood has issued) vast numbers of small dark coloured masses, like grains of fine sand, can be made to start from the surface of the membrane by slight pressure. There can be no doubt that these are minute portions of blood, which had remained and coagulated in the vessels or apertures forming the ultimate channels of the hemorrhage.

These views receive an indirect but strong support and illustration from the well-known circumstance, that certain hemorrhages are preceded and followed by an increased efflux of the fluids which belong to the surface concerned. In hemorrhages

from the mucous membranes this succession of events is in some persons habitual. First, there is an augmented flow of mucus alone, then of mucus tinged with blood, then of blood alone; and the hemorrhage ceases by a similar but inverse gradation towards a mucous drain, which itself at length decreases and disappears. In such cases (there being no manifest erosion or organic change) it is apparent that the blood proceeds from the same vessels or apertures, which in health pour out the natural fluids of the part—mucus, serum, or sweat. There seems no more necessity, under the action of disease, for a rupture of vessels to give exit to the blood than to give exit to these fluids. What the vessels or outlets to which we give the name of exhalants really are—how they are distributed and arranged—in what manner they are connected with the ordinary capillary circulation of red blood—or under what influences they are placed—are points concerning which we have little or no certain knowledge. We know, indeed, that such channels must exist, though we cannot demonstrate or see them; and that, whilst the health is entire, they do not allow the blood, as such, to pass through them.

Several kinds of hemorrhage by exhalation have been enumerated by pathologists, according to the different morbid conditions with which the efflux of blood is associated. The chief distinctions of any importance may, however, be almost all comprised within the two general classes of *idiopathic* and *symptomatic* hemorrhage.

Idiopathic hemorrhage is that which occurs without any discoverable change of texture, either in the part from which the blood proceeds, or in any other part capable of influencing the circulation in the former, by reason of some intelligible connection of structure, or function, or mutual relation. The epistaxis of young persons affords an example of this kind of hemorrhage, to which the terms *spontaneous* and *essential* are also sometimes applied.

Symptomatic hemorrhage, on the other hand, is that which depends upon some notable organic disease. It comprehends all cases of hemorrhage by exhalation not embraced by the definition just given of idiopathic hemorrhage. It may be said to be *primary* when the organic disease upon which it depends is situated in the very part which gives issue to the blood; *secondary*, when the organic disease is situated in some other part more or less distant from the former.

We have instances of the primary species in hemorrhage from the stomach, or from the uterus, dependent upon incipient scirrhus of those organs; from the pleuræ or peritoneum, under violent inflammation; from the mucous membrane of the air-passages in intense bronchitis.

Examples of the secondary species occur in hemorrhages from the bronchial membrane in consequence of the presence of crude tubercles in the lungs, or of organic disease of the heart; and in hemorrhages from the mucous membrane of the stomach and bowels in consequence of disease obstructing the circulation through the spleen or liver.

The proximate cause (as it is called) of idiopathic hemorrhage—or the essential condition of

the facts concerned in its production—is involved in much obscurity. There appears good reason for believing that it is different in different cases. It is certain that in very many instances the hemorrhage is preceded and accompanied by an unusual accumulation of blood in the capillary vessels of the part. In the secondary species of symptomatic hemorrhage this kind of sanguine congestion is also almost always present, and is then owing to some mechanical impediment of the venous circulation. The causes of such congestion antecedent to idiopathic hemorrhage are less obvious, especially when the congestion is partial.

Since the time of Stahl and his disciples, the existence of local plethora has been fully recognised as constituting a frequent element of disease. Some of the distinctions introduced by him were doubtless fanciful: it is certain, however, not only that local congestion is of common occurrence, but also that this unequal distribution of the blood in the capillary vessels may happen in several ways, and from various causes, easily distinguishable from each other. M. Andral, the most recent, and probably the most able writer on this subject, describes three different conditions under which local plethora (or, to use his own convenient though somewhat uncouth phraseology, *hyperæmia*) may occur in the living body.

One of these conditions has been already adverted to, that, namely, in which the return of the blood from the capillary vessels towards the heart is impeded by some mechanical obstacle. *Hyperæmia* of this kind may be strictly local. It may be confined to a single limb when the principal venous trunk belonging to that limb is compressed, or otherwise diminished in size. If there be disease of the liver, of such a nature as to prevent a free passage of the blood through that organ, congestion will take place in all those parts of the capillary system from which the blood is conveyed by the veins that ultimately combine to form the vena portæ. The force of gravity alone will be sufficient to induce venous congestion in parts of the body in which, under ordinary circumstances, the circulation through the veins is aided instead of being opposed by that force. If the head, for instance, be suffered to hang downwards for a certain time, we see the unequivocal signs of such congestion in the tumid condition and the purplish colour of the lips, cheeks, and eyelids. When an impediment to the free transmission of blood exists in the heart itself, a tendency to stagnation is produced, first in the venæ cavæ, then in the smaller ramifications by which these veins are fed, and at length in the general system of capillary vessels; and thus general hyperæmia from a physical cause will ensue, the parts which are the most vascular being also the most readily and the most completely gorged.

The two other forms in which local plethora or hyperæmia may present itself are called respectively active or sthenic hyperæmia, and passive or asthenic.

The first of these proceeds from some irritation or stimulus, either applied to the part itself, or influencing that portion of the nervous system, by which the vital actions of the part are regulated.

The irregular distributions of blood which fall under this head are not always morbid. In a

certain degree and for a certain time they may consist with the most perfect health. The deep flushing of the cheeks and forehead under strong mental emotion, and the general redness of the skin produced by violent exercise, are familiar illustrations of this healthy congestion of capillary vessels. A similar congestion may be produced at will upon the surface of the body by mechanical or chemical stimuli—by friction for example, or the application of heat. If these causes of the local accumulation of blood be intense in degree, or continue to be applied for a certain time, the congestion is accompanied by disturbance of the functions of the part—by pain, or by other well-known changes.

But local congestion of this active kind, and essentially morbid in its character, is of frequent occurrence in various organs of the body; and in many of these cases there is no obvious exciting cause of such an unequal distribution of the blood. We have evidence, indeed, in the blush of shame or anger, and in the paleness of fear, that the capillary blood-vessels may be filled to excess, or completely emptied, by causes operating through the brain and nerves; and it seems probable that morbid congestions, which are sometimes separated from those consistent with health by shades of difference not easily discriminated, may also be occasioned through the agency of the same nervous system.

Local hyperæmia of the active kind seems in many instances to form a part, or rather to be an effect, of a plethoric condition of the whole body. To understand precisely what is meant by a state of general plethora, it is necessary to remember the physiological doctrine that the whole vascular system is constantly distended beyond the size of the vessels when free from any distending force. When the arteries are in any way emptied of their contents, their diameter diminishes, and frequently they become even impervious. The general notion of plethora is that this state of distension is greater than what is ordinary or natural. It is easy to conceive that in persons who live fully, lead an inactive life, and sleep much, there should be a greater quantity of blood formed, and consequently a preternatural distension of the vessels. Fulness of habit and a florid complexion are marks of the existence of general plethora; of superfluous blood being partly expended in the formation of that substance which is the least necessary in the animal economy, namely, fat, the capillary vessels of the face partaking of the general fulness or vascular distension present in all parts of the system. We trace the existence of general plethora also in the character of the diseases most prevalent in those who are the subjects of it, in the tendency especially which they evince to hemorrhage and to inflammation.

A state of general plethora is, however, by no means essential to the production of local congestion, which, on the contrary, is of frequent occurrence in persons who are pale, spare, and deficient in blood. Nay, a remarkable proclivity to an unequal distribution of blood in the capillaries, has been observed in those who, from accident or disease, have already lost large quantities of that fluid. The general symptoms, however, which accompany local hyperæmia in these two opposite

conditions of the system, undergo proportional modifications.

The simple existence of local congestion of the active kind, and independent of any mechanical impediment, is sufficient to show that the blood, after it has entered the capillary system, is no longer under the sole influence of the heart's impulse; but that its subsequent motion is mainly determined by a power of contraction belonging to the smaller blood-vessels themselves. It is upon a supposed defect of such power—a diminished tonicity of the vessels, that the doctrine of asthenic or passive hyperæmia is founded.

The efficacy of the assigned cause in the production of hyperæmia is perhaps less obvious here than in the cases which have just been considered. The following are some of the observed facts from which its actual operation has been presumed.

In persons enfeebled by age or by disease, the lower parts of the legs, the ankles, and insteps, and the skin which forms the surface of old scars, are often habitually purplish or violet-coloured. This cannot be owing to the mere influence of gravity, because that remains constant at all ages and in all conditions of the system. The peculiar colour, denoting a sanguine congestion of the part in which it is visible, may indeed be diminished sometimes by placing the limb in the horizontal position, whereby the weight of the blood in opposing its own return from the capillary vessels being removed, the action of the vessels themselves again suffices for its propulsion. But the congestion in these cases often disappears upon the employment of friction, or of stimulating application, which would be powerless against any mechanical obstacle in the larger veins, and which would tend to increase the afflux and accumulation of blood in active hyperæmia.

In the same way, the large, flabby, and livid granulations which often appear on the surface of indolent ulcers, are made to contract, and to assume a more healthy and florid hue by local stimulants, which quicken the previously languid circulation by exciting (it is supposed) the vital action of the minute blood-vessels.

There is no part of the body which affords more striking and unquestionable evidence that blood may accumulate unequally in the smaller vessels, than the eye. The conjunctiva and sclerotica, through which, while healthy, colourless fluids alone circulate, are traversed, under various forms of disease, by innumerable vessels bearing red blood. It is notorious that in certain cases the application of any stimulant to the surface of the organ will increase the existing redness, multiply the number of visible vessels, and aggravate the disease. These are cases of active hyperæmia, dependent upon irritation which is still subsisting. It is equally well known that the same vessels are liable to congestion under very opposite circumstances. They are then seen to be distended with blood, tortuous, and varicose; and the redness is browner, and less vivid than before. In this kind or stage of vascular fulness, emollient applications do harm rather than good; while strongly astringent and even highly irritant substances will often promptly dissipate the vascularity. There are, again, cases illustrative of hyperæmia of the asthenic kind. The strong topical irritants restore the feeble and

relaxed vessels to their natural elasticity, stimulate them to contract upon their contents, and to force onwards the blood, which they cease to admit from the arteries, and the redness disappears.

In the examples here touched upon, the asthenic character of the local congestion is denoted by the peculiar aspect of the altered parts; by the circumstances under which the congestion happens; and, above all, by the nature of the measures which conduce to its removal. The doctrine of asthenic hyperæmia admits of extensive and most important application, in regard to various internal morbid conditions of the body. But any further prosecution of this part of the subject would be irrelevant to the present inquiry. The preceding observations have been made with the view of demonstrating or of rendering probable certain differences in respect to the manner in which the capillary blood-vessels may become unequally loaded, and of elucidating thereby some of the modes of hemorrhage; of showing in particular, that a predisposition to hemorrhage may arise under very different conditions; that it is far from being always of one and the same character, or susceptible of relief by the same kind of treatment. The fact, then, which is beyond dispute, of the frequent pre-existence of local engorgement and distension in the capillary circulation, gives support to the hypothesis that (in certain cases at least) the issue of blood results from pressure, whereby the blood in substance is urged through passages naturally impermeable by its red particles, but now mechanically dilated in consequence of the *vis a tergo*. Although the dilatation cannot be made sensible to the eye, this seems the simplest and most obvious explanation applicable to some forms of idiopathic hemorrhage, and to the secondary species of that which is symptomatic. That blood may be thus exhaled, independently of any disease in the vessels themselves, we know from experiments made on animals, and from the observation of what sometimes occurs in the healthy human body. Boerhaave produced hemorrhage into the intestinal canal of a living dog, by placing a ligature on the vena portæ. An extreme turgescence of the whole venous system is one of the results of sudden strangulation. Dr. Yelloly accordingly found such turgescence conspicuous in the bodies of five criminals who had recently suffered death by hanging; and in two of these instances, blood in considerable quantity had exuded from, and coagulated upon, the mucous membrane of the stomach.

Hemorrhage has been ascribed also to some alteration (other than that which we may conceive to be produced by the distension of plethora) in the vessels or apertures through which the healthy exhalations are transmitted. The change is considered as being of the nature of morbid debility or relaxation. That such a state may sometimes exist is not unlikely; but as we are altogether ignorant of the natural condition of these outlets, it is difficult to reason about the alterations to which they may be liable in disease. This hypothesis derives its principal support from the occasional efficacy of astringent substances (either locally applied, or taken into the system) in checking the effusion of blood, when artificial bleeding has failed.

Another mode in which the occurrence of hemorrhage has been explained, supposes an alteration in the consistence or composition of the blood itself, which thus becomes attenuated, and capable of passing through channels or orifices that healthy blood cannot penetrate. In defence of this supposition are adduced the facts that hemorrhages are known to occur where the blood is obviously more thin, pale, and serous than common; and still more remarkably where that fluid has undergone a demonstrable change in its chemical nature, or is even visibly altered in its sensible qualities; as, for example, in certain cases of purpura and of sea-scurvy.

These hypothetical attempts to explain the processes by which hemorrhage may take place deserve, perhaps, more attention than has sometimes been paid to them. The views which they involve can scarcely be regarded as mere speculative refinements; for they often exercise a real, though perhaps an unacknowledged influence upon our practice. At any rate, if they do not, prior to experience, justify certain modes of treatment, they accord wonderfully with what experience has taught concerning the means by which hemorrhage may sometimes be stayed or prevented. In some cases we succeed by measures which tend to abate the general force of the heart and arteries and to lessen general plethora, or by diverting partial plethora and restoring the disturbed balance of the circulation, or by directly emptying the turgid capillary vessels. In other cases we rely chiefly upon expedients which we believed to have the effect of constringing the extreme vessels; styptics to the bleeding part, cold to the surface of the body, producing a sympathetic shrinking in other related membranes; or internal medicines, which use has shown to have the property of restraining the natural exhalations when in excess. And, finally, there are cases where we seek, and not in vain, to repair the blood, to restore it to its natural condition by improvements in diet, or by food of a peculiar kind, such as the juice of lemons; and *thus* the tendency to hemorrhage is cured.

Whether the hypotheses originated from a contemplation of symptoms, or whether they were suggested by the apparent effects of remedies, may be doubted; but it is well worthy of remark how in the several cases they accord with both these classes of observed facts. Certainly hemorrhage is a prominent symptom in several morbid conditions, differing greatly from each other; and there is nothing inconsistent in sometimes attempting its explanation in one way, and sometimes in another.

One observation yet remains, in regard to this doctrine of a preceding turgescence of the minute blood-vessels; namely, that it applies not only to certain kinds of hemorrhage, but also to inflammation, of which indeed it appears to be a *constant* and necessary element. Why, in one instance, the congestion terminates in that complex and variable process, or why, in another, it is relieved by an effusion of blood, we hitherto know not; but the fact that the same condition of capillary plethora is inceptive sometimes of the one form of disease, and sometimes of the other, supplies a rational ground for the analogy which has often

been traced between hemorrhage and inflammation; and, what is of no less importance, it points out also the boundaries within which that analogy should be limited.

There is a very ancient division of hemorrhage (into active and passive) drawn, not so much from the nature of supposed proximate causes, as from the assemblage of circumstances in connection with which the efflux of blood takes place.

The distinctive characters of these two forms of hemorrhage are, in well-marked cases, sufficiently broad and decided.

Active hemorrhage occurs in persons who are young and robust, who live fully, and lead indolent lives, and are subject to the influence of those causes which tend to generate plethora. Occasionally the hemorrhage can be traced to some exciting cause, such as exposure to heat, strong mental emotion, or violent exercise. More frequently, however, it seems to be the consequence of the predisposing causes merely. It is sometimes announced by a set of symptoms expressive of what has been called the *molimen hemorrhagicum*. The patient experiences a general feeling of indisposition, with wandering and obscure pains that gradually settle in the part from which the blood is about to be discharged. A series of local symptoms, such as a sensation of weight, or of tension, or of heat and tingling, sometimes a slight degree of turgescence and redness, and a visible fulness of the larger veins, indicate the afflux of blood towards the labouring organ and the parts in its vicinity; while chilliness, paleness, and shrinking of distant parts, and especially of the feet and hands, denote an opposite state of the circulation in them.

The blood commonly escapes with rapidity, is of a florid colour, proceeds from a single organ, and readily coagulates, though it seldom separates distinctly into serum and crassamentum. While it is flowing, the signs of local hyperæmia diminish and disappear, warmth returns to the extremities, and the pulse regains its natural strength and frequency. The patient becomes conscious of a sensible relief, and feels stronger and more lively than before. This kind of hemorrhage is in some sort its own remedy; it ceases in virtue of the discharge of a certain quantity of blood, and it is followed by morbid consequences only when that quantity has been excessive.

Passive hemorrhage is characterized by circumstances of an exactly contrary nature. It occurs in those who are naturally feeble, or who have been debilitated by disease, fatigue, insufficient nourishment, great evacuations, or the depressing passions. It is not, in general, announced by any precursory symptoms, nor attended by any reaction. The effused blood is of a dark colour, serous, and but little disposed to coagulate; and it often is poured forth from several parts of the body at the same time. If the quantity lost be at all considerable, the natural debility of the patient is rapidly augmented; his face becomes pale, and his body loses its heat. The hemorrhage leaves him in a worse condition than that in which it found him. The flow of a certain quantity of blood is not, as in the cases of active hemorrhage, suspensive of its further effusion; frequently, indeed, passive hemorrhage resists the means op-

posed to it the more in proportion as it has continued longer, or been more profuse.

If every case of hemorrhage could be accurately referred to the one or the other of these forms, this distinction would be of the greatest importance and value. The truth is, however, that the majority of cases cannot be said to possess decidedly either an active or a passive character. The flow of blood is not preceded by any notable excitement or exhaustion, is not announced by any precursory symptoms, and is neither followed by any sensible improvement, nor (unless it exceed a certain limit as to quantity) by any marked debility.

May not this indefinite character of the majority of cases be accounted for by the consideration that most hemorrhages are in fact merely symptoms, and derive their character from that of the disease of which they form a part? Does it not appear that the distinction of active and passive applies chiefly to the smaller class of idiopathic hemorrhages, those that are active being allied to the active form of hyperæmia, and bearing a close analogy to inflammation, both as regards the symptoms which accompany them, the description of persons in whom they principally happen, and their remarkable tendency to recur? whilst the passive belong to that condition of the body which is attended with some morbid change in the blood; a circumstance which would of itself go far, perhaps, towards explaining their simultaneous occurrence from various organs?

However this may be, that hemorrhages are sometimes what is called active, and sometimes what is called passive, is a valuable fact, apart from all hypothesis.

And concerning these morbid effusions of blood, there are several other well-ascertained general facts, with which it imports the physician to be acquainted, but of which the limits of this work will allow of a cursory enumeration only.

In the first place, hemorrhage by exhalation, of whatever kind, takes place much more frequently and readily from some tissues of the body than from others, and most especially of all, from the mucous membranes.

Upon this important fact have arisen questions which, although not without interest in themselves, do not admit, in the present state of our knowledge, of positive solution. Has it any relation to the manner in which these membranes, and the tissues subjacent to them, are supplied with a capillary circulation? or to their laxity of attachment, which facilitates and favours the accumulation of blood therein? Again, has the density or consistence of their natural exhalations any thing to do with this disposition to hemorrhage in the mucous membranes? May we suppose that the vessels or orifices appointed to exhale mucus afford a more ready passage to the blood than those which give egress to thinner fluids—serum for example, or the cutaneous perspiration?

Hemorrhage is also liable to occur, but much more rarely, from the serous membranes; from the skin; into the cellular tissue of various parts of the body; and into the substance of the several viscera.

Another important fact in regard to these hemorrhages is, that they proceed more frequently

from certain parts of the body than others, according to differences of age. Thus, in *childhood* they are most common from the membrane that lines the nasal cavities; in *youth* from the mucous membrane of the lungs and bronchi; in the *middle years* of life, and towards its decline, from the rectum, uterus, and urinary passages; and in *old age* from the blood-vessels of the brain.

There are persons (and the case is far from being an uncommon one) who are subject, during the greater part of their lives, to certain hemorrhages, which occur again and again, without any notable detriment of the general health, independently of any obvious exciting cause, and (as it would seem) from some inherent necessity of the system. Habitual hemorrhage of this kind is said to be *constitutional*: it takes place more commonly from the rectum than from any other part, although cases are recorded of its occurrence from the mucous membrane of the bladder, of the bronchi, and of the nasal cavities. Linked, in some inexplicable manner, with the original constitution of the body, this disposition to hemorrhage, as might be expected, is sometimes observed to be hereditary. It differs from ordinary hemorrhage of the active kind, by affecting, indiscriminately, those who are feeble and those who are robust, but most remarkably by its recurrence at periods more or less regular.

The celebrated Gall used strenuously to maintain the doctrine of a periodic movement in the male system analogous to that which returns monthly in the female, and marked by signs which all might observe who would take the pains to look for them. That the analogy really obtains in many points, and more distinctly in some individuals than in others, there can be no doubt. It has been incidentally noticed indeed by several writers; and Chomel has given the following clear summary of the principal features of the resemblance.

"The primary appearance of these constitutional hemorrhages is sometimes preceded by a state of general indisposition, more rarely by slight febrile disturbance, and even, according to some observers, by a sort of chlorosis analogous to that which affects young girls in whom the menstrual evacuation is delayed or suspended. The hemorrhage sometimes recurs at precisely regular intervals, and by *monthly* periods more commonly than any other; being announced, on each occasion, by the same preludes, proceeding from the same part, continuing for the same space of time, and furnishing always about the same quantity of blood. Its accidental interruption is almost uniformly the cause or the effect of some derangement of the health. It is furthermore remarkable that these habitual hemorrhages, like the catamenia, do not ordinarily occupy the whole course of life; in most individuals they do not commence before the period of adolescence or youth, and they cease altogether, or recur at distant intervals only, in declining age. When they become excessive, they also (like hemorrhage from the uterus) enter the exclusive domain of pathology."

One of the most singular facts relating to hemorrhages is that they are, not unfrequently, vicarious or supplemental—sometimes of each other—but more often, in the female, of the men-

strual discharge, between which and the constitutional hemorrhages of men there has just been shown to be some degree of analogy. Bleedings from the bladder and from the mouth sometimes follow upon the suppression of constitutional hemorrhoids; from the lungs, stomach, or rectum, upon the suspension of the menses. These hemorrhagic deviations, as they are sometimes called, take place commonly by the same organ on each occasion, sometimes by different organs in succession. It is almost always in this supplementary manner that the rarer forms of hemorrhage occur, and those of the skin in particular.

This peculiarity in regard to hemorrhage seems calculated to throw some light upon the obscure doctrine of *revulsion*; a doctrine which, though very imperfectly understood, is of continual avail in the practice of physic.

The *symptoms* which accompany internal hemorrhage are modified by various circumstances; and the degree of certainty which they impart to the diagnosis differs much in different cases.

If the part into which the blood is directly extravasated communicates with the exterior of the body, the expulsion of some of that fluid sooner or later demonstrates the case to be one of hemorrhage. The particular symptoms will have some relation to the functions of the organ that furnishes the blood, and to the time that intervenes between its extravasation and its ultimate expulsion; and certain characters will often be derived from the parts traversed by the blood before it reaches the surface. It is even difficult sometimes to determine whether the blood proceeds from a certain organ, or from those parts that lie between it and the natural outlet by which it ultimately escapes.

The blood itself will be generally more fluid and brighter in proportion as it is effused in greater quantity, and near the surface; more in clots and darker in colour, in proportion to the length of time that it has remained within the body after its escape from its proper vessels: and this length of time may depend upon the smallness of the quantity of blood effused, and the consequent tolerance of the organs through which it may have passed; or upon the actual space traversed.

If the locus of the hemorrhage does not communicate with the external air, we are without that certainty which results from the actual spectacle of the blood. But we are then assisted by *local* signs, which spring from the pressure on, or the laceration or distension of the suffering viscus, or of the parts contiguous to it; and by *general* signs, many of which are the same whether the extravasated blood reach the exterior or not. These general signs again are modified according to several circumstances. They principally vary according to the quantity of blood poured out, and to the *rapidity* of its effusion; something also will depend upon the particular organ, and much (when the quantity is the same) upon the age and strength of the patient.

Besides the symptoms which are observable at the very time of the bleeding, there are others, of much interest, which occur more remotely. These may sometimes result from a single profuse hemorrhage, but more commonly they are owing,

not so much to one large bleeding, as to a repetition of such as have scarcely any immediate perceptible influence on the system.

Some of the general symptoms,—such as paleness of the face, feebleness of the pulse, coldness of the extremities, and a tendency to syncope, which have been observed to ensue upon the eruption of the blood, have been ascribed to the alarm and sense of danger which the sight of that fluid is calculated to produce in the mind of the patient. This is probably true to a certain extent; but the explanation does not apply to those cases in which the hemorrhage is strictly confined to the interior of the body, yet in which the symptoms just alluded to are often strongly marked.

For the method of **treatment** applicable to internal hemorrhages, the reader is referred to the several articles in which the different forms and varieties of hemorrhage are practically discussed. A very cursory notice only can here be taken of the general means which are found most effectual in restraining the actual efflux of the blood.

A preliminary question, however, of some importance, here presents itself. Is it in all cases of hemorrhage proper or safe to attempt to stop the bleeding?

Without going into detail, it may be stated as a rule that *constitutional* hemorrhages ought not to be interfered with, so long as they have no perceptible injurious influence upon the health, and proceed (as they mostly do) from parts of which the structure is not likely to be spoiled, nor the function impaired, by the passage of the blood. The most common seat of these constitutional hemorrhages is the rectum, to which the conditions just mentioned are, fortunately, both of them applicable. Epistaxis supplies a less frequent example of the same kind. When these habitual hemorrhages deviate from their usual channel, and are (as it were) transferred to some more important organ, it will generally be right, among other remedial measures, to endeavour to recall the original hemorrhage. It is very seldom that the metastasis takes place *for the better*, from a part where the bleeding is attended with danger, to one where it is comparatively harmless.

Again, it will seldom be proper to employ direct expedients for stanching the flow of blood in the small class of idiopathic and active hemorrhages, unless the quantity lost is so great as to endanger the safety of the patient. Such hemorrhages have commonly a tendency to cure themselves, by relieving the local or general plethora on which they depend.

Nor may we venture to use *direct* means for checking most of those hemorrhages which result from present inflammation.

With these exceptions, it will generally be right to arrest the effusion of blood as speedily as may be; though in some of the symptomatic hemorrhages this may even be of secondary importance.

To this end the patient is to be surrounded as much as possible with cool fresh air, and kept in a state of absolute quiet. All motion of the body, and emotion of the mind, all kinds of stimulating food or drink—every thing in short which has a tendency to hurry the circulation, should be diligently avoided; and that position of the body

should be chosen which is the least favourable to the afflux of blood towards the part affected. The horizontal posture will be proper in hemorrhage from the bowels, the uterus, or the urinary organs. In epistaxis and in cerebral hemorrhage, the head should be raised.

Of the actual remedies used for checking the further escape of the blood, one of the most important is venesection. The objects of artificial bloodletting are, to diminish the force of the heart and arteries, to lessen general plethora, to remove local congestion, and to divert the current of the blood from the suffering organ. The method, and the amount, and the repetition of the bloodletting must of course be regulated by the circumstances of each particular case. The same objects may sometimes be effected by other modes of general depletion, and especially by the use of purgative medicines.

Next to bloodletting, astringents constitute the great resource against hemorrhage; and of these *cold* is one of the chief. It may be placed in direct contact with the bleeding surface, as when ice is swallowed to restrain hæmatemesis; or cold water injected into the rectum in hemorrhoids, or into the vagina in flooding from the uterus; or it may be applied to the surface of the body, as near as possible to the seat of the hemorrhage, as to the nose and forehead in epistaxis; to the epigastrium in hemorrhage from the stomach; to the lower part of the abdomen, or to the perineum, in hemorrhage from the intestines, uterus, or urinary organs. But the influence of cold in constricting the smaller vessels is not confined to the part with which it is in contact: it will stop hemorrhage by the sympathetic shrinking which it produces in distant parts. Epistaxis, for example, has often been arrested by the sudden apposition of cold water to the neck, back, or genital organs. Of its even mischievous power in this way we have continual illustration in the suppression of the catamenia by cold applied to the feet.

There is a long catalogue of medicinal substances, which are esteemed to possess more or less of a specific virtue, when taken internally, in arresting the flow of blood. Most of these are of an astringent nature, and some of them are essentially useful. The binacetate of lead enjoys in this country a higher character perhaps than any other of these substances.

Many vegetable matters, and some artificial compounds, frequently employed in internal hemorrhages, seem to owe their astringent and styptic properties to the gallic acid [and the tannic acid] which enters into their composition. Such are the rhatany root, uva ursi, bistort, tormentil, the pomegranate, kino, catechu, the several preparations of gall-nuts, [oak bark, maneria, &c.] and the nostrum called Ruspini's styptic [creasote].

The power of arresting internal hemorrhage has also been confidently ascribed by different persons to nitre given in large doses, to the mineral acids, to the muriated tincture of iron, to alum, to the oil of turpentine, [See ASTRINGENTS,] to the secale cornutum, and to various other substances; a more particular account of which may be found in other parts of this work, under the head of the individual hemorrhages.

THOMAS WATSON.

HEMORRHOIDS, hæmorrhoids.—The term hemorrhoids, from the Greek, *αἷμα, sanguis*, and *πῶς, fluxo*, signifying simply a blood-flux, is not adapted to convey any correct idea of the nature of the various affections to be treated of under this head, some of which are not even attended with a discharge of blood.

Custom, however, has sanctioned and established its use in a particular sense, viz. as synonymous with piles, and to custom we think it right to conform, it being our duty to furnish practical information rather than to enter into an etymological disquisition.

The meaning of the word hemorrhoids is now, by common consent, so entirely limited to certain affections of the rectum that no inconvenience can arise from its adoption. But this has not been the case always, for we find that very many authors, modern as well as ancient, have employed it in its literal sense, and under the epithet hemorrhoids have described discharges of blood from the bladder, the uterus, and other organs, as well as from the rectum. Among others, Celsus, in treating hemorrhoids, says — “*Idque (vitium) etiam in ore vulvæ feminarum incidere consuevit.*” (Lib. vi. cap. xviii.)

Notwithstanding this and the many other exceptions alluded to, the majority of authors, beginning with Hippocrates, have restricted the meaning of hemorrhoids to those diseases of the rectum which form the subject of the present article.

By hemorrhoids, then, are to be understood, first, a flux of blood from the rectum without any tumours internal or external; secondly, a flux of blood from the rectum with internal or external tumours; thirdly, tumours internal or external without flux of blood. The distinctive characters of these tumours and of the blood-flux will be described hereafter.

When it is remembered how very common hemorrhoidal affections are, how great the sufferings they occasion, and how frequently they fall under our observation and treatment, we naturally conclude that every particular relating to them has been fully investigated and satisfactorily made out; yet the reverse is the fact; and, innumerable as are the dissertations and other publications on hemorrhoids, we have sought in vain for accurate information of their anatomical characters and pathology; nor have we been able to find it in the museums of morbid anatomy of this metropolis preparations illustrative of the various kinds of hemorrhoids.

The deficiency of information on this subject may in part be ascribed to the few deaths which occur absolutely from hemorrhoids; for, excepting the cases which prove fatal after an operation, the individuals affected with hemorrhoids die usually of some other complaint, which, being urgent and prominent, while perhaps the hemorrhoids have ceased to be troublesome, engrosses the attention during life and at the post-mortem examination. That this is the case at our large hospitals, all who are in the habit of witnessing the post-mortem examinations will acknowledge, the condition of the rectum seldom forming a part of the investigations; an omission not to be ascribed to negligence, but arising from the attention not having

been attracted to this organ during the latter part of the patient's life.

1. *State of the rectum.*—The anatomical characters of the rectum, which we have discovered by dissection, independent of the hemorrhoidal tumours, are an enlargement of the hemorrhoidal veins and hypertrophy of the submucous tissue. The enlarged veins are seen through and lying immediately under the mucous membrane, taking a perpendicular course almost parallel to each other for seven or eight inches, their trunks being as large as a crow-quill, and formed from innumerable small arborescent veins at the anal extremity of the rectum, which render the bowel intensely vascular. The same vascularity and lesion of these veins have been described by Dr. Colles; (Dublin Hospital Reports, vol. v. p. 152,) and Morgagni mentions an instance of extraordinary enlargement of the hemorrhoidal vein, “*interna hæmorrhoidalis vena sub coli intestini fine et tota recti longitudine pollicis fere crassitiem æquaret.*” (De Sedibus et Causis Morborum, lib. iii. p. 38.)

2. *Anatomical characters of the hemorrhoidal tumours.*—These tumours are generally regarded as arising from a varicose state of the hemorrhoidal veins: “*hæmorrhoides autem nihil aliud esse quam varices venarum ani.*” (Morgagni, De Sedibus et Causis, lib. iii. p. 38.) By Sir Astley Cooper they are described as being found in two states; “*a varicose enlargement of a vein; or an excrescence arising from its adhesion and organization,*” a description not very intelligible. (Lectures, by Tyrrell, vol. ii. p. 335.) By others they are distinguished into such as discharge blood, *bleeding piles*; and into such as are not attended with hemorrhage, *blind piles*: “*hemorrhoidum verò aliæ sunt cæcæ, aliæ apertæ: cæcæ sunt quæ omni tempore inflatæ sunt, et nihil excernunt: apertæ verò sunt quæ per tempora sanguinem effundunt.*” (Aetii Tetr. Sermo ii. cap. v.) By Sauvages it is proposed to call the bleeding tumours, *hæmorrhoids*; and the blind, *mariscæ*; “*tumores illi (sine ullo sanguinis effluxu) mariscæ vocari debent, et fluxus cruoris, hæmorrhoids multo aptius vocatur.*” (Nosologia Methodica, vol. ii. p. 323.)

Such are the notions usually entertained of these tumours, notions which give us very little insight into their exact nature, seeing, as we shall presently do, that they differ so materially in their structure as to justify the division of them into the several following kinds.

The first kind (which may be called *varicose*) is that which arises from a varicose state of the hemorrhoidal veins, or from the accidental dilatation of a small vein at a particular point, by which a cyst distended with venous blood is formed without rupture of the coats of the vessel, and is covered only by the mucous membrane of the bowel; a manner of formation which appears to have struck Celsus, who describes hemorrhoids as “*ora venarum tanquam ex capitalibus quibus sergentia quæ sæpe sanguinem effundunt.*” (Lib. vi. cap. xviii.)

These tumours form within the gut, and are eventually extruded from causes hereafter to be described. They may be recognised when external, as consisting of a rounded tense elastic nucleus, the size of a pea, covered by the intestinal mucous membrane which moves easily upon it,

and may be pinched up separately, its adhesion to the distended or varicose vein, the nucleus, being by the submucous cellular tissue in its natural state of tenuity. Should this tumour remain extruded, the blood in the distended or varicose vein, being as it were out of the circulation, coagulates, thus converting the nucleus into a solid clot, still covered by the original mucous membrane of the rectum, which after exposure becomes transformed more or less perfectly into skin. This coagulum sometimes becomes organized, and the exterior covering strongly adherent from attacks of inflammation, in consequence of which the whole tumour is rendered solid and vascular. These tumours constitute one variety of bleeding piles.

The second kind of hemorrhoidal tumours, which may be called *erectile*, present all the characters of an erectile tissue: they are cellular, spongy, full of blood, intensely vascular, and bleed profusely from innumerable points on their surface; a fine example of which is furnished by Sir James Earle, in the case of a young lady, in whom "the tumour was about nine inches in circumference, separable into several lobes, and altogether like a piece of sponge, bleeding from every pore. It was, however, of a healthy appearance, soft, and compressible." (*Observations on Hemorrhoidal Excrescences*, p. 23.)

The vascular character of this kind of tumour has been ascertained by dissection. "I had an opportunity," says Dr. Colles, "of examining the structure of these tumours in a patient who died of another disease. On slitting up the rectum I saw three bloodvessels, each as large as a crow-quill, running for some way down the intestine, and then dividing into a number of branches; these vessels ramified very profusely, and each seemed by interweaving of its branches to form one of these tumours. The trunks and branches were covered only by the lining membrane of the intestine." (*Dublin Hospital Reports*, vol. i. p. 152.) The supply of blood to these tumours is not therefore by one large trunk, but by numerous minute vessels. Tumours of this description commence within the gut, afterwards descend; and they constitute another variety of bleeding piles.

The third kind of hemorrhoidal tumours consist wholly of dense, thickened, or hypertrophied cellular tissue covered by the intestinal mucous membrane, and are from their earliest formation *external*. At their origin each is merely a small fold of mucous membrane, which with its submucous tissue has been forced through the anus by efforts at the closet or other causes, and being pinched by the contraction of the sphincter is prevented from returning within the bowel. Exposed thus to friction and other sources of irritation, these tumours are liable to inflammation and consequent thickening and induration of the submucous tissue above described; while the mucous membrane continuing to be exposed gradually changes its character, is transformed into skin, and its organic sensibility being in this manner diminished, the whole tumour becomes a chronic pile more or less flaccid and insensible until inflammation is again excited in it, when it tumefies, grows red, hard, and extremely painful, but does not bleed. By continued irritation from friction and want of cleanliness, these tumours often increase

to a large size, become excessively indurated, and assume, from the pressure of the nates, a flattened oblong form with a thick rounded irregular edge; and from the same causes the opposing surfaces of these piles become abraded, ulcerated; and fissures and rhagades are produced from which a thin purulent discharge takes place. Tumours of this description constitute the *mariscæ* or blind piles.

All the kinds of hemorrhoidal tumours above described vary much in form and colour. When inflamed or highly congested they will be red or purple, and tense and hard; and when in an indolent condition they will be more or less pale and flaccid. Generally they have a broad base; sometimes they are pedunculated.

The hemorrhoidal flux.—Nothing is more various than this hemorrhage, either as relates to quantity or to the circumstances under which it takes place. The most simple form occurs without any sign or premonition, without hemorrhoidal tumour, without lesion of any kind, if we except a determination of blood to the rectum; and here the hemorrhage, it may reasonably be conjectured, is the product of a vital exhalation from the capillaries of the mucous membrane. Several ounces of pure red blood may be lost at the closet from the rectum, the patient having experienced no uneasiness, no pain either previous or subsequent to the discharge, and without previous or subsequent hemorrhage; or patients subject to bleeding piles at intervals of a week, a month, or longer, may lose blood unconsciously, and in place of stool, to the amount sometimes of half a pint.

On some occasions the hemorrhage will recur so frequently and in such quantity as to induce an alarming debility and anæmia, without any attendant local symptoms; while at other times the excessive discharge will be accompanied with signs of internal hemorrhoids and of great determination of blood to the bowel. It may occur in quantities to endanger life from external tumours of the erectile kind, as happened in the example quoted from Sir James Earle's *Observations*: or the hemorrhage may be small in quantity, not exceeding a tea or table-spoonful, taking place after every dejection and for many days, then ceasing, and returning at uncertain and rather distant periods, attended always with internal or external hemorrhoidal tumours: or the hemorrhage may assume a periodical character, more or less irregular nevertheless, but occurring once in six or seven weeks, or in three or four months, preceded by an abdominal congestion, which is immediately relieved by the discharge. Very many persons who live freely are liable to this kind of flux, a happy resource of nature to unload the system when too plethoric, and so to preserve their health. Experience teaches them that this periodical loss of blood, when not too copious, is beneficial, and they regard its return with satisfaction. If this accustomed discharge ceases, a determination of blood to another organ will ensue, and apoplexy, diseased liver, or some other very serious organic affection be the result. There are instances in which the hemorrhoidal flux will go on without the individual being aware of its extent or of its effects on the system, the loss not being great at any one time, but continuing day after day and

week after week, until it exhausts the strength, blanches the face, and, if he is advanced in years, brings about debility under which he sinks, or from which he recovers slowly and with difficulty.

The source of the hemorrhoidal flux is unquestionably various; yet it is the prevailing opinion that it issues from a rupture or bursting of the varicose hemorrhoidal veins. That this opinion is well founded, and that the varicose or dilated veins are the true source of the blood in the majority of cases, there can, we think, be little doubt. The facts that the hemorrhage occurs very frequently in a stream, while the patient is straining at the closet, the stream being interrupted as the straining is suspended, and returning as the efforts are repeated, form strong presumptive evidence, consistent with the anatomical peculiarities of these veins. It has been stated that the hemorrhoidal veins take a perpendicular course from the anus up the rectum, and as they, like nearly all the veins of the portal system, are not provided with valves, hemorrhage from a rupture of one of these veins when varicose or dilated, in a stream interrupted, as the efforts at the closet are continued or suspended, is probable and intelligible; and it may take place to a prodigious amount.

Another source of the hemorrhoidal flux is from the capillaries of the rectum by vital exhalation or exudation, in cases of determination of blood to the mucous lining, a form of hemorrhage similar in every respect to that which is known to proceed from the mucous membrane of the small intestines in hepatic obstructions.

A third source is by exudation from the surface of the erectile tumours, internal or external, where the blood may be seen to issue from every pore, as stated by Sir James Earle in the case already quoted.

A fourth source of hemorrhage may be laceration of the congested mucous membrane by hard scybala forced through the sphincter by great effort, the body being much constipated. Here the hemorrhage is exceedingly trifling, and attended with pain, such as might be supposed to occur under the circumstances related.

The **Diagnosis** of the hemorrhoidal flux has been explicitly pointed out by Actuarius; "*Verrum ille (sanguis) qui ab altioribus locis emanat et aliquamdiu in corpore est moratus, nigrior est: hic vero purus, sincerus, et qualis ex jam cœcis hostiis profluit.*" (Med. sive de Meth. Med. lib. i. cap. 20.) The blood from piles is fluid and florid, may be discharged before or after a dejection, may cover, but is never mixed with the feces; whereas hemorrhage from the intestines higher up is manifest by the blood being black and coagulated. Where the hemorrhage arises from dysentery, it is mixed with mucus, which gives it the characteristic appearance of portions of flesh; and where it is produced by various kinds of ulceration, it is confounded with the feces.

The **Causes** of hemorrhoids are hereditary predisposition, habitual constipation, free living, obesity, a sedentary mode of life, and aloetic and other irritating purgatives. Hereditary predisposition to hemorrhoids is marked in many persons, but of all the causes which operate in the produc-

tion of piles, habitual constipation is the most frequent. By habitual constipation the residual alimentary matter is delayed in the colon, becomes hard and knotty, and a source of great irritation to the large intestines, particularly to the rectum. This irritation induces a determination of blood to the lower bowel, this again congestion and gradual dilatation and varicose lesion of the hemorrhoidal veins, which eventually form tumours, burst or rupture, and give rise to hemorrhage; consequences all favoured by the anatomical peculiarities of the portal system, and accelerated by the efforts at the closet:—thus are bleeding piles formed. Habitual constipation is perhaps also the only cause of the blind piles or *mariscæ*. When the bowels are costive, the sphincter is always tight and rigid, so that by its contraction the protruded membrane is prevented from returning, and being in some degree strangulated and exposed to irritation from friction, it inflames, indurates, and constitutes piles which do not bleed.

By free living as a cause of hemorrhage, we do not mean gluttony and drunkenness merely, but also that generous system of diet and indulgence at the table which prevails throughout society. The habitual liberal use of fermented liquors and of animal food produces a plethoric state not only of the whole system, but especially of the abdominal viscera concerned in digestion, the veins of which viscera constitute the portal system, and concur to form the *vena portæ* itself. A fulness of the portal system, unprovided as it is with valves, must necessarily determine a congestion of the hemorrhoidal veins; and congestion of these veins from any cause will, as we have seen, produce the hemorrhoidal flux and tumors. It is in persons who have hemorrhoids from living freely, that we have observed the flux to be most regular and periodical, and most decidedly salutary; and there can be no doubt that it proves a great preventive of visceral disease, to which these persons would otherwise be very liable. The suppression of the periodical flux is always attended with inconvenience.

A sedentary mode of life tends to produce hemorrhoids, by favouring a sluggish circulation in the portal system, which leads to hemorrhoidal congestion and its consequences: the pressure accruing from obesity leads to the same results.

Symptoms.—The symptoms are such as arise from the determination of blood to the rectum and congestion of blood in the hemorrhoidal vessels, and such as arise from the tumours whether indolent or in a state of irritation and inflammation.

The hemorrhoidal flux is not always rendered cognizable by symptoms, examples of which have been already mentioned. On the other hand, the determination of blood to the rectum, which precedes the hemorrhage, will be marked by dull pain about the back and loins, a sense of weight and heat about the sacrum and rectum, scanty and high-coloured urine, heaviness of the head, and disturbance of the digestive functions; signs which persist for several days, when the flux supervenes and entirely relieves the patient. These symptoms are most manifest where the flux is periodical. In those who have hemorrhoids from habitual constipation, there will be weight and heat, and a sense of fulness about the rectum very constantly,

an obscure tenesmus, frequent micturition from sympathetic irritation of the bladder, and leucorrhæa, from a similar irritation of the vagina and uterus; all of which are temporarily alleviated by the discharge of blood, but are never entirely removed, the cause remaining.

The symptoms arising from the hemorrhoidal tumours are those of irritation and inflammation. Tumours situated without the sphincter are perpetually irritated by the friction of the parts in the ordinary motion and erect position of the body, and moreover they are irritated to a painful degree during the period of the evacuation of the bowels. The irritation is much aggravated by want of cleanliness, and soothed by regular ablution. Many persons affected by hemorrhoidal tumours experience pain from sitting, aggravated to a great degree when they travel in a carriage or take horse exercise. The irritation will frequently produce accessions of inflammation, in which the tumours will become congested, swollen, red or purple, and excessively painful, so as to oblige the patient to keep his bed for many days.

The **Treatment** of hemorrhoids must be considered in reference to the flux and to the tumours.

In considering the treatment of bleeding piles, the first step should be an inquiry into the influence of the flux on the health; next into the cause and the practicability of removing it.

If the cause of hemorrhoids is free living, and the flux salutary, and if the individual subject to the flux will persist in his mode of life, it would be unwise to interfere. It is only in the event of the flux being profuse that means to restrain it should be contemplated. It may happen, however, that a person subject to a salutary periodical flux may be so harassed by hemorrhoidal tumours as to render their extirpation unavoidable; and should their removal suppress the flux, either the patient must change his habits to those of great temperance, or must lose blood from time to time by an artificial outlet in order to guard against disease; for pathological congestions will otherwise most assuredly occur. It was proposed by the older writers to leave one pile as a safety-valve; "*Quare quum plures sint hæmorrhoides unam relinquere oportet, purgationis gratia.*" (Pauli *Æginatæ de Re Medica*, lib. iii. cap. lix.) a suggestion not to be altogether slighted. The hemorrhage, however, may proceed within the bowel, and, therefore, not be suppressed by the removal of the outward tumours, in which case there can be no hesitation in deciding upon the operation.

In all persons affected with hemorrhoids, except those above mentioned who are sensible of deriving benefit from the flux, there is an anxiety to be free from the hemorrhage and from the tumours; and if sufficient attention is given to the various causes operating in the production of the flux and tumours, there can be no reason why measures to restrain the one and remove the other should not be put in practice. The influence of habitual constipation in the production, aggravation and continuance of hemorrhoids, should never be overlooked; the obviating this cause by regulating the bowels by suitable aperients, will frequently cure the patient either of the bleeding or of the blind piles; and the restoration of the natural action of the bowels is certainly essential to prevent a re-

currence of the hemorrhoids, however effectually they have been suppressed by medicine or removed by operation.

In the treatment of hemorrhoids of all descriptions, the regulating the bowels by suitable aperients is a most essential point: all irritating and drastic purgatives, as aloes and colocynth, are inadmissible, our choice must be directed to those which act efficiently but mildly and without irritation of the lower bowel. Of these, senna, sulphur, castor-oil, and the neutral salts are the most eligible, and should be prescribed in doses adapted to the constitution of the patient. The confection of senna combined with sulphur and magnesia, is in general use, and is perhaps the most desirable form of aperient that can be employed. A point of immense consequence to be insisted on is that the aperient should be so administered as to act upon the bowels in the evening.

Persons afflicted with hemorrhoids will be distressed through the day if their bowels are acted upon in the morning, because of the erect position which they are obliged to sustain in their ordinary avocations, all which distress is obviated if their bowels are not evacuated till the evening, the horizontal position of the night removing all inconvenience, and allowing the day to be passed in comparative comfort. Again, the seat of the closet being inclined instead of horizontal is a means of rendering the excretion of the bowels less painful; and where prolapsus of the gut co-exists with piles, the observance of the horizontal position during the action of the bowels, is a great preventive of suffering as it is a great aid in the cure.

Injections of warm water and other ingredients daily administered with a view to regulate the bowels and to relieve hemorrhoids, are very objectionable; they give a momentary relief, but they aggravate the symptoms they are intended to remove. An injection of half-a-pint of cold water daily has, however, been found highly serviceable. In order to restrain the hemorrhage where it is profuse or its continuance is injurious, we can confidently recommend turpentine, half-a-drachm of which may be mixed with yolk of egg, or given in a table-spoonful of gruel once or twice a day. The hemorrhage is often effectually arrested by the first dose; and where the body is already exsanguineous, and the discharges of blood are frequent and great, the turpentine is an invaluable remedy.

We have been informed by a patient who suffered and was seriously debilitated from bleeding piles, that, after having tried almost every other remedy, the copaiba was successfully administered, and at once and permanently cured the hemorrhage. And although our own experience does not furnish us with facts in favour of the *secale cornutum*, we have every reason to believe from the testimony of others and from the influence which the *secale* exerts on hemorrhage from the womb, that it would prove a very efficacious remedy in the hemorrhoidal flux. It may be administered in the dose of ten grains twice or thrice a day, in the form of decoction or infusion.

[When the hemorrhage becomes dangerous from quantity, the most efficacious of the mineral and vegetable astringents may be prescribed,—care being taken that they are not used of such strength

as to condense and corrugate the parts so much as to endanger the supervention of inflammation. The iodide of iron and creasote form valuable hæmstatic injections. When the discharge is very copious and colligative, the rectum must be examined carefully, in order, if possible, to ascertain the spot whence the hæmorrhage proceeds. In such cases, powdered alum, or tincture of creasote, or the tampon, or caustic, or even the actual cautery may be demanded. The case then becomes one of surgery.]

However objectionable aloetic and other irritating aperients may be in the treatment of hæmorrhoids, stimulants of certain kinds given internally are notoriously beneficial; Ward's paste, which is justly celebrated for the cure of piles, is highly stimulating; as also is a similar preparation, the *confectio piperis nigri*.

Great assistance is afforded in the cure of piles by external applications whenever the condition of the tumours admits of relief without an operation. The application in common use is an ointment composed of the *pulvis gallæ* and *adepts*: we ourselves employ an ointment of black hellebore in preference, and find it a remarkably efficacious, though a painful remedy. The proportions are *pulv. hellebori nigri* ʒi, *adipis* ʒi M., with which the tumours and anus are to be anointed night and morning. The pain caused by the hellebore is intense for half an hour, but it then subsides, and proportionate relief follows. We are in the habit of prescribing it when patients complain of blind or bleeding piles, which are painful, and which do not yield to the senna and sulphur.

The use of the bougie in the treatment of hæmorrhoids is too much overlooked and neglected. Judiciously employed, we believe it would obviate the necessity of an operation in many instances. Its influence in relaxing the rigid sphincter muscle, facilitating the return of blood from the tumours, as well as the replacement of the extruded mucous membrane, is greater than might be supposed; besides, it is found to be a means of inducing a natural action of the bowel and of procuring solid figured dejections; objects very desirable, and which, when attained, facilitate and often effect a perfect cure.

Removal of the Hæmorrhoidal Tumours.—The actual cautery was a favourite remedy with Hippocrates: "Urere enim oportet; et nullam hæmorrhoidem sine ustione sinere, sed omnes exurere. (De Hæmorrhoidibus.)" The moderns have relinquished the use of the cautery in this and in almost every operation, perhaps indeed too universally, it being a less painful and less barbarous remedy than at first sight is supposed, while undoubtedly it is a safe and valuable one in many states of disease.

In the removal of hæmorrhoids, surgeons are in general agreed on the superior advantage of the ligature over excision; excision being frequently followed by dangerous and in some instances fatal hæmorrhage. "For excision," says Sir Astley Cooper, "in the early part of my surgical career I was a strong advocate, for I found it a less painful operation than ligature, and it appeared to me not dangerous; but as my experience increased I was induced to change my opinion, and to consider excision as not divested of danger."

(Lectures, by Tyrrell, vol. ii. p. 342.) Besides disastrous hæmorrhage, the excision of piles has been succeeded by a fatal inflammation of the peritoneum. To the authority of Sir Astley Cooper in favour of the ligature, may be added that of Mr. Copeland and of very many others.

Excision may be practised in some of the hæmorrhoidal tumours, as the *mariscæ* or blind piles, for these are exempt from danger of hæmorrhage; but all internal piles and the external tumours of the erectile character should certainly be removed by ligature.

The mode of applying the ligature to internal hæmorrhoids recommended by Sir Astley Cooper, is "to draw down the pile with forceps or a tenaculum, and tie a piece of waxed silk around it, draw the knot until the patient complains severely, then tie a second, cut off the ligature a little way from the knot, and return the intestine and pile." (The Lectures by Tyrrell, vol. ii. p. 345.) Some precaution and judgment should be exercised in drawing the ligature where the base of the tumour is small or pedunculated, lest it should be cut through and hæmorrhage supervene. Mr. Mayo, operating on a child having a small internal pile upon a long narrow pedicle, drew the ligature too tightly, the thread cut through the part, and the pile came away at once. "No disposition to bleed showed itself at the time; but the following night the child lost a profuse quantity of blood." (On Diseases of the Rectum, p. 75.) This conveys a warning not to make use of too fine a ligature. In cases where the pile to be removed is very large, it should be transfixed at its base with a needle armed with a double ligature; the needle being cut off, leaves the two ligatures, each of which should be tied round the corresponding half of the pile.

The operation, then, for the removal of hæmorrhoidal tumours, whether by excision or by ligature, is simple and easily accomplished; but a point of no mean importance is to determine when the patient, both as regards the state of the tumours and of his constitution, is in a favourable condition to undergo the operation. We have seen a person die of sympathetic adynamic fever in four days after the removal of piles by a most accomplished surgeon; the nervous system of this patient, prior to the operation, was disturbed, and the shock of the operation itself excited delirium and high febrile movement, which soon terminated in dissolution. In proportion as the mucous membrane covering the tumour to be removed retains its natural organic sensibility and structure, so should precaution be observed; and this remark applies, of course, in an especial manner to internal piles. In proportion as the mucous covering has been transformed into skin, which can be the case only with external tumours, so is the operation free from the risk of tetanus, of depression of the vital powers, of inflammation and other consequences which are known to follow injury of this tissue.

The treatment of the patient preparatory to an operation should have for its objects the diminishing the determination of blood to the rectum, the appeasing any irritable state of the tumours, and the removal of any inflammatory disposition in the constitution. Moreover, the natural temperament should not be altogether overlooked, the

hazard of an operation being greater in nervous and irritable persons. To effect these objects, abstinence from all fermented liquors and a moderate diet should be enjoined for some weeks; the bowels should be most carefully regulated, and the determination of blood to the rectum diminished by cupping over the sacrum once or twice to the amount of six or eight ounces; and the irritable condition of the tumours will be much appeased by ablutions and fomentations. We would insist strongly on the propriety and necessity of these preparatory measures, believing as we do that they would disarm the operation, simple in itself, of the disastrous consequences which too frequently ensue.

There is another consequence of this operation which, although it does not affect the life of the individual, affects his comfort materially; it is the incomplete healing of the wound. We have known the trifling wound caused by snipping off a small pedunculated tumour in the rectum, or a small pile from the verge of the anus, remain open for many months, and cause such acute suffering whenever the bowels acted as to render life miserable.

[In the form of hemorrhoids to which the term *vascular tumour* has been applied, and which Dr. Houston, of Dublin, (*Dublin Journ. of Med. Science*, March 1823; or Braithwaite's *Retrospect of Practical Medicine and Surgery*, vol. 7, Jan. to June, 1843,) regards as an affection of the mucous membrane and submucous tissues exclusively, having for its base a knuckle or bunch of varicose veins, or else as being a distinct and independent growth, the result of some other irritation in that region, but giving rise ultimately to the formation of a varicose condition of the diseased part, that gentleman has recently found great benefit from the application of nitric acid, of the specific gravity of 1.500. He directs the patient to strain, as at the night-chair, so as to bring the tumours full into view; and whilst they are down, he lets him either lean over the back of a chair, or lie down, in the bent posture, on the side on which the disease exists, with the nates over the edge of the bed. When the patient is thus placed, a piece of wood, cut into the shape of a dressing-case spatula, is dipped in the acid, and then, with as much of the acid adhering to it as it will carry without dripping, it is rubbed on the tumour to the extent desired,—its effects being exhibited by the colour of the part being changed to a grayish white. One or more applications of the acid are needed, according to the depth of the slough required, after which the whole is smeared with olive oil, which destroys the farther escharotic action. The prolapsed parts are then pushed back within the sphincter, the patient is put to bed, and an opiate administered; the pain is at first sharp and burning, but it goes off in two or three hours, and does not return in the same form. A general uneasiness about the anus, on motion, together with a slight sense of heat, fulness, and throbbing, are felt for a few days, and there may be some feverishness; but the symptoms following the application are usually so mild as not absolutely to require confinement to bed for more than a few hours, although such confinement may often be desirable. On the third or fourth day, Dr.

Houston prescribes a cathartic draught, which is found to act generally without either pain or prolapsus of the rectum. After this the improvement is rapid, and free from any dangerous accompaniments.]

JOHN BURNE.

HEPATITIS. (See LIVER, INFLAMMATION or)

HEREDITARY TRANSMISSION OF DISEASE.—The cases are rare in which a disease under which the patient labours displays itself in the offspring at birth, or so recently after it, that it can be supposed to be directly transmitted. Small-pox and syphilis are the diseases most frequently referred to as furnishing examples of direct transmission. Small-pox has been discovered in infants at birth, as was proved by Mr. John Hunter, and instances of marks of this disease on still-born infants are not infrequent; but those who attend scrupulously to the niceties of language consider these as examples rather of communication by contagion than of transmission by inheritance. The same distinction, if not in any case over-refined, may be drawn in cases of the communication of infantile syphilis; but as a good deal of controversy has arisen on this especial case of hereditary reception, we shall bestow a few remarks upon it.

Until the period when Mr. Hunter endeavoured to give greater precision to our ideas respecting lues, many diseases, particularly scrofula, were ascribed to a syphilitic taint. This opinion was certainly too vague, and was adopted on very insufficient evidence, or rather on no evidence at all. Since the period mentioned, there has existed an unwillingness to admit the possibility of the communication of this disease to the fœtus in utero; and the nature of any indications of it which appear soon after birth is either questioned, or the disease is supposed to have been communicated by direct contagion from ulcers existing in the genitals of the mother. Many persons have questioned the validity of these objections, and among others the late Mr. Hey of Leeds, whose accuracy will not be doubted. This gentleman relates cases of infantile syphilis which could not have occurred in the manner adverted to, the disease never having existed in the genitals of the mother, but having been communicated to the nipples whilst the breasts were drawn in a previous confinement by a person habitually employed in this way, and who had contracted it by the mouth in performing the same operation on an infected female. (*Medico-Chirurgical Transactions*, vol. vii. part ii.) The writer can add his experience to that of Mr. Hey on this point, having seen many cases of what appeared to be infantile syphilis occurring speedily after birth, though at the time of delivery the mother was entirely exempt from ulcers of the pudenda. If the identity of the disease is questioned, it may be urged that the eruption is of the characteristic copper colour, the throat is very generally affected, in some cases ulceration of the genitals exists; in short that it has all the symptoms of syphilis, and is speedily remediable by mercury. A singular circumstance connected with these cases is, that they occasionally occur in infants whose parents do not labour under manifest symptoms of the disease, either at the time of generation or during

pregnancy; but they are never observed in the offspring of those who have not, either one or both, more commonly both, previously laboured under it.

These two diseases and tubercles, which have been discovered in the lungs of still-born infants, furnish perhaps the only examples of direct hereditary transmission. Other diseases, for instance deafness and blindness, are connate, and are frequently observed to occur in members of the same family; but these individuals will generally be found to have sprung from parents who did not labour under the same privation. It is true that persons born deaf or blind rarely marry, so that much opportunity is not afforded of observing how far this family peculiarity, however acquired, is transmissible: but the same fact may be adduced as an argument that it is not received by inheritance. Of one hundred and forty-eight scholars at one time on the foundation of the Deaf and Dumb Institution in London, one was of a family in which there were five deaf and dumb; one in which there were four; eleven in which there were three; and nineteen in which there were two. Of the scholars, fifty-seven were girls, and the rest boys; and none of them were the children of deaf and dumb parents. The gentleman who superintended the manufactories, and who consequently had the best opportunity of tracing the subsequent history of his scholars, stated that some of them were married and had children, all of whom were perfect in the organ of hearing. One instance occurred in which both parents had been born deaf, yet the children possessed the faculty of hearing. (A Treatise on the supposed hereditary properties of Diseases, by Joseph Adams, M. D. &c. p. 66.)

Cataract is frequently observed as a congenital disease in members of the same family; but in this case it is found not to appear in successive generations as if it were at once connate and hereditary. Hydrocephalus, too, is connate, and members of the same family are born with it; but being in the adult a rapidly fatal disease, it cannot of course be received by inheritance.

Though nature is thus sparing of the direct transmission of disease from parents to offspring, she is not equally so of morbid tendencies; and what are commonly called hereditary diseases are so merely by predisposition. That children inherit the outward bodily configuration and manifest peculiarities of one or other of their parents, is well known; and that they likewise derive from them that more hidden weakness of certain organs by which these are prone to take on diseased action, is proved by the experience of ages. The hereditary predisposition to scrofula, consumption, gout, and insanity, is so essentially a part of the medical creed, that a professional man called to a case supposed to belong to any of these disorders immediately endeavours to strengthen his diagnosis by information gathered from the family history. But besides these very common examples, various other diseases, such as asthma, angina pectoris, a general hemorrhagic disposition, apoplexy, epilepsy, and various nervous disorders, blindness and deafness, not congenital, and, according to Dr. Adams, elephantiasis, are transmitted in predisposition from generation to generation. To this sufficiently formidable list, some persons are disposed to add

goitre and cretinism, though this can be regarded as a mere speculative opinion; but an affection closely allied to the latter, idiocy, is unquestionably hereditary. Of this Haller presents us striking examples in two noble families, into which it had been introduced above a century before the time he wrote, and where it was still manifesting itself in some individuals of the fourth and fifth generations. Certain idiosyncrasies too, which, like idiocy, cannot be regarded as diseases, are observable in successive generations of the same family; for instance, a peculiar susceptibility to the effect of certain remedies, such as mercury and opium.

Of transmissible diseases, some have appeared in several individuals at a certain period of life, and such members of the family as have escaped at this critical period have remained exempt from the affection. All the members of the family of the *Le Comptes* saw clearly till about the age of sixteen or eighteen; at that age some of them, without any apparent cause, became dim-sighted, and grew gradually more so till total blindness ensued: such has been the case for three generations with a certain number in each race; but such as have escaped at that critical age have retained their sight through life. (Baltimore Med. and Phys. Reg. 1809.) In the family of Mr. Bass, at Peterborough, deafness has observed a similar course. (*Adams*, ubi supra, p. 19.) Hydrocephalus, the disposition to which exists in certain families, though it cannot be regarded as an hereditary disease, has often attacked individuals of the same race at the same age; and those who have then escaped have continued free from the complaint. The same observation has been made of elephantiasis, angina pectoris, and other diseases.

Like other family peculiarities, hereditary predisposition to disease may cease in one generation to appear in a subsequent one; or, though manifesting itself in each generation, it may pass to the subsequent one through an individual who has escaped it. Of this mode of transmission an extraordinary example occurs in the relation of cases of hereditary hemorrhage by Dr. Riecken. (*Medicinische-Chirurgische Zeitung*, Nov. 1830, and *Edinburgh Med. and Surg. Journal*, No. 108.) These cases occurred in the principality of Birkenfeld in Oldenburg. The parents had never been subject to hemorrhage, and the father, Ernest P., was living in good health in his eighty-sixth year at the time of the publication of the narrative. The couple had twelve children, five sons and seven daughters, of whom three boys and one girl died of hemorrhage. Their youngest daughter, who never suffered from the disease, married a stout healthy man and had six children, four boys and two girls, of whom three boys died of hemorrhage. There is no trace of any member of the family, either on the male or female side, anterior to the children of Ernest P., being affected with the disease.

How the hemorrhagic disposition arose in the second generation of Ernest P.'s family we know not; but in certain cases the first appearance of an hereditary disease in an individual can be traced to an assignable cause. The natives of the warmer regions of the earth become affected in colder latitudes with scrofula and consumption; and the latter disease manifests itself under such circum-

stances even in inferior animals, as in the monkey tribe. Certain modes of living engender gout; and elephantiasis appears to be produced by a peculiar climatorial influence.

It has never been observed that these diseases, when introduced by manifest causes, have not partaken of the property of transmission to succeeding generations. If they do indeed possess this property, (and there seems no reason at present to doubt it,) nature would appear to have instituted laws for the transmission of disease on two points, the opposite of those established regarding hereditary varieties in manifest structure. The laws in the latter case are, as illustrated in Dr. Prichard's very elaborate and ingenious work, that connate varieties are apt to appear in the progeny; but that changes produced by external causes terminate with the individual, and have no influence on his descendants. (Researches into the Physical History of Man. 2d edit. vol. ii. p. 536, et seq.) It will have been remarked that congenital blindness and deafness, though family diseases, or apt to prevail in members of the same generation of the same family, are rarely if ever hereditary. Dr. Adams suggests, that though congenital peculiarities and redundancies are hereditary, connate privations are not so, and that deafness and blindness belong to the latter class; and in this way, provided it is ascertained that connate privations do not descend to offspring, the discrepancy in the law may be reconciled. Dr. Prichard endeavours to adjust the other difference by supposing that the exciting causes of diseases act upon an existing predisposition laid by nature in the original stamina and habit of the body, and that the occurrence of a malady from their application is no proof that it is engendered by them, but that they are the mere occasion on which a congenital weakness previously hidden is rendered manifest. This view he illustrates by the example of gout; but were other instances chosen, such as those of scrofula and consumption occurring in the natives of warm when removed to cold climates, it appears questionable whether the doctrine would be found to apply invariably; whether it would not rather be proved that a morbid peculiarity may be strictly engendered by an external cause, and, being thus engendered, may be transmissible to posterity. Perhaps, too, the rule that acquired peculiarities in general are not hereditary is laid down too absolutely. The writer has in many instances observed in the case of individuals whose complexion and general appearance has been modified by residence in hot climates, that children born to them subsequently to such residence have resembled them rather in their acquired than primary mien.

It is natural to inquire whether we derive any useful inference from our knowledge of the hereditary property of certain diseases? The most important and practical inference that can be deduced is, that the descendants of those who labour under any hereditary disease should be shielded as far as possible from its exciting causes; for the predisposition is of various degrees, in some so intense that at a certain period the disease occurs by the spontaneous act of the constitution; but in others so slight, that the co-operation of noxious agents is required to render it manifest.

Hence the descendants of the gouty should observe the most rigid temperance; certain climates should be selected, if possible, till a certain period of life, for those of the consumptive; the offspring of the maniacal should be guarded as much as possible from mental irritation, and from all habits of life calculated to call their inherent tendency into action; whilst a nutritious and invigorating regimen and warmth should be appropriated to those who, there is reason to think, have derived the scrofulous diathesis from their ancestors.

Another practical inference which might be deduced is, the propriety of avoiding matrimonial alliances between families possessing the same hereditary taint; and, generally, of forbidding all such alliances between kindred families, for few are perhaps free from some congenital weakness or susceptibility, and, to use the phrase of the cattle-breeders, all predispositions to disease are rendered more intense in families by breeding *in and in*.

JOSEPH BROWN.

[HERMAPHRODISM.—See SEX, (DOUBTFUL.)]

HERPES, from the Greek *ἑρπεν*, to creep. *Syn.* Cytisma herpes (*Young*); Lepidosis herpes (*Good*); Neshr (*Arabic*); Zittermahl; die Flechte (*German*); Dartre (*French*); Vesicular tetter.

Herpes is an inflammatory disease of the skin, terminating in the discharge of a quantity of thin fluid sufficient to elevate the cuticle into small irregular vesicles, which appear in groups or circumscribed patches of various forms, on an inflamed base, the skin in the intervals retaining its healthy aspect. The disease, which is non-contagious, generally passes through a regular course "of increase, maturation, and decline, and terminates in about ten, twelve, or fourteen days." (Bateman's Practical Synopsis; 7th edit. p. 319.) Bielt and Rayer assert that it is rarely preceded by fever, and unless when it proves critical of some other disease, that it cannot be referred to any appreciable cause. Our own experience, however, accords with that of Bateman, that it is frequently preceded by considerable constitutional disorder. At first the vesicles are filled with a colourless pellucid fluid, which gradually becomes opaque and of a yellowish hue, but not purulent; after which it forms crusts, which droop off, except when ulceration occurs. The eruption is attended with tingling; sometimes with lancinating pains, as if hot needles were run into the part. In some of the forms of the disease, as the vesicles concrete and the crusts fall off in one part, fresh patches arise in the immediate vicinity, and thus the disease creeps over a considerable portion of the skin.

Herpes is distinguished from pompholyx by the vesicles appearing in groups or patches on an inflamed base; and from erysipelas, by the vesicles not being preceded by redness and tumefaction; by their distinct yet clustered character, and the state of the skin between the clusters. It is scarcely possible to confound it with eczema or impetigo, neither of which assume the purely vesicular form, nor run the same regular progress within a limited period; and both of which form

thin plates or semi-pellucid crusts, from under which a thin acrid fluid exudes, instead of the dry harsh scab which characterizes herpes.

In Bateman's synopsis we find the various appearances of herpes constituting six distinct species; and in this view of the subject he is followed by Rayer. (*Traité Théorique et Pratique des Maladies de la Peau*, tome i. p. 226.) Bielt, on the contrary, considers every form of herpes a variety of one species, *phlyctænodes*, differing only in the seat of the eruption, or in the figure of the clusters of vesicles. Thus he regards herpes *labialis* and herpes *præputialis* as varieties of herpes *phlyctænodes*, distinguished from it only by having a determined site; while herpes *zoster*, herpes *circinatus*, and herpes *iris*, are regarded equally as varieties, differing merely in the form of the vesicular patches. In the view which an extensive experience has led us to take of the generic disease, we feel authorized in dividing it into two distinct species, herpes *phlyctænodes* and herpes *iris*, the characteristics of which are well defined: all the other forms, generally regarded as species, will be found to be mere varieties of herpes *phlyctænodes*, however they may differ in the figure of the clusters, or in the parts on which they appear: indeed the modifications which both herpes *labialis* and herpes *præputialis* display depend on circumstances connected altogether with the parts on which they appear. Taking this view of the general disease, we are of opinion that all its forms are comprehended in the following arrangement:—

Species 1. *H. phlyctænodes*.

Var. a. *H. zoster*.

— b. *H. circinatus*.

— c. *H. labialis*.

— d. *H. præputialis*.

— 2. *H. iris*.

Species 1. HERPES PHLYCTÆNODES.—This species appears in irregular agglomerated groups of small, transparent, globular vesicles, not larger than a millet-seed. It is usually preceded by one or more slight febrile attacks, accompanied by thirst, heat of stomach, and flatulence, which are not immediately relieved by the appearance of the eruption, but on the contrary are sometimes aggravated by the heat and tingling in the patches of vesicles as they continue successively to appear. The clusters rise in various parts of the body; the cheeks, the forehead, the neck, the trunk, and the extremities being indiscriminately the seat of the eruption. The vesicles differ greatly in size, but the smaller are comparatively the most numerous; and when the disease spreads extensively, the clusters are chiefly made up of small vesicles.

On the spot where each cluster appears, a sensation of heat and tingling is felt; at which time, says Bielt, minute red points may be detected, very closely grouped, and over these on the following day the vesicles display themselves on an inflamed base, resisting compression, and varying in size, from that of a small millet-seed to that of a pea. We have never observed the previous state here described, although its existence is highly probable: in general we have seen the spots, which afterwards became groups of vesicles, appearing as simple red blotches, which feel

rough when the finger is passed over them. Rayer states that the number of vesicles in each group varies from twelve to fifteen or more. (*Op. cit.* p. 227.) Several of these groups rise together, forming clusters, in which the intervening skin retains its natural colour; although within, and for a small space beyond each group, it is red. The fluid in the vesicles is at first generally colourless, but occasionally of a brownish hue; it gradually thickens, probably owing to the absorption of the watery part, and in ten or twelve hours acquires opacity and looks milky or pus-like; sometimes in the larger vesicles it appears bloody. About the fourth day the larger vesicles break and discharge their fluid; the inflamed surface acquires a dull purple hue; and while many of the smaller vesicles flatten and disappear, the larger dry and change into irregular yellow or brownish crusts, which fall off about the eighth or tenth day, although sometimes not until the fifteenth or twentieth. The skin for a considerable time retains a reddish hue, indicating the seat of the previous eruption. In this manner the successive clusters run their course.

Authors agree that the causes of herpes *phlyctænodes* are very obscure. In almost every instance which we have seen, the immediate or exciting cause appears to be derangement of the digestive organs accompanied by a highly irritable state of the system. It has appeared also occasionally to proceed from catarrhal or other inflammatory febrile affections, in which the eruption may be regarded as a translation of diseased action from the mucous membrane of the skin.

The continental writers have laboured to mark the symptoms which distinguish herpes *phlyctænodes* from pemphigus. In our opinion it is scarcely possible to confound them; in the one the eruption consists of distinct solitary bullæ, in the other of clusters of vesicles upon isolated surfaces.

With respect to the treatment of herpes *phlyctænodes*, as this differs little from that which is requisite in the varieties, the notice of it may be deferred until these shall have been described.

Var. a. Herpes Zoster (shingles) differs from herpes *phlyctænodes* chiefly in the size of the vesicles forming the groups, in the seat of the disease, and the manner in which the clusters successively appear and extend over the body. The vesicles, however closely agglomerated, are from the first distinct: they generally enlarge in twenty-four hours to the size of pearls; are perfectly transparent and filled with a limpid fluid: the inflamed base of the pustules, which are considerably larger and more irregular than those of herpes *phlyctænodes*, extends some distance beyond the vesicles. The most frequent seat of this variety is the trunk of the body, and as the patches of vesicles successively appear, they extend either round the waist in an oblique direction, like a sword belt, or across the shoulders, or from the shoulder they extend to the arms, or from the nates down the thighs, in an oblique direction to the knee. A perpendicular position of the clusters is very rare: Rayer mentions having seen it on the thigh: he also describes a case in which it extended from the face into the mouth. “La moitié gauche de la langue est tuméfiée, épaisse, rouge, et couverte de plaques

blanches, molles, irrégulières. Les unes ont les volumes des vésicules de la peau, les autres se rapprochent des bulles par leur grande dimension. L'épaisseur de ces plaques est égale à celle d'une feuille de papier, &c. La salive, sécrétée en abondance, est filante; l'haleine est fétide, mais n'a point l'odeur particulière qui s'exhale de la bouche chez les personnes qui ont abusé des préparations mercurielles." (Traité des Maladies de la Peau, tome i. p. 230.) The most frequent seat of the clusters is the lower part of the thorax; the right side is more frequently attacked than the left: the eruption never appears on both sides at the same time.

Rayer has placed this variety among the bullæ, although he regards it as holding an intermediate place between bullæ and vesicular inflammation.* The eruption of shingles appears to be an affection solely of the reticular web of the cuticle, and never extends, like erysipelas, to the subcutaneous cellular tissue.

The premonitory symptoms in shingles are languor, loss of appetite, febrile rigors, headach, a quickened but small pulse, sometimes sickness, pains darting across the chest and epigastrium, and a sensation of scalding heat or deep-seated pain in the spot where the first patches of eruption are likely to appear. In old persons, and in those of delicate habits, this feeling of local heat and pain often continues for a week or more previous to the appearance of the eruption, by the coming out of which it is almost instantly relieved. It is sometimes so severe, that it has been mistaken for pleurisy, and treated by venesection and other depletory means. At other times the precursory fever is so slight, that the first notice which the patient receives of the presence of the disease is a sensation of heat and tingling on some part of the trunk, where he finds on examination patches of shining, pearly, or silvery vesicles, already formed. Sometimes the patches appear at the opposite extremities of the zone, and join by the successive patches extending towards the centre. The vesicles in the separate clusters attain their greatest size, which seldom exceeds that of a pea, in three or four days; and at this time the inflammation of the base of the patch is at its height, of a vivid redness, becoming fainter as it extends beyond the limits of the cluster of vesicles. Generally before the fourth day, while the new clusters begin to appear, the lymph in the first set of vesicles becomes opaque, acquires a milky or yellowish hue, and approaches in some instances almost to the state of pus. The inflammation of the base now changes to a bluish or livid hue, and the vesicles flatten or subside: some, however, break, and either spontaneously or from friction discharge their fluid, which concretes in dark-coloured scabs. These crusts harden and adhere firmly for ten or twelve days, and then fall off, leaving the skin red and tender; and when the vesicles have been rubbed and become ulcerated, cicatrices or pits sometimes remain. These symptoms vary according to circumstances; thus in old people, or those enfeebled by want, the vesicles enlarge almost into bullæ, break soon,

and almost always ulcerate; and even, according to Bielt, occasionally have been followed by gangrene. Yet the same physician has never seen the disease attended with much fever or general derangement of the system.

The febrile symptoms which we have observed, generally subsided when the eruption was complete, but not always; and we have seen cases in which the uncomfortable feelings seemed rather augmented than diminished during the whole progress of the eruption; and more especially the deep-seated pain described by Bateman, which, he says, "continues to the latter stages of the disease, and is not easily allayed by anodynes."

Shingles is not a contagious disorder, and may occur several times in the same individual. In the greater number of instances it appears towards the termination of some acute disease. It occurs most frequently in persons between twelve and twenty-five years of age, although occasionally the aged suffer severely from it. Those who have a delicate and irritable skin are most liable to its attacks. It prevails more in summer and autumn than in spring and winter.

It is scarcely possible to mistake shingles for any other vesicular disease, unless in its early stage, when it resembles in some degree herpes *phlyctenodes*; but it may be distinguished by the appearance of the red patches on which new clusters of vesicles are about to appear. The absence of swelling of the skin, and of the disappearance of redness on pressure, readily distinguish it from erysipelas.

The general treatment of shingles is the same as that of the other varieties of herpes *phlyctenodes*, and therefore need not be detailed here. With respect to local applications, a gently stimulant spirituous lotion to the inflamed clusters, to which a portion of tincture of opium may be added when the pain and irritation are severe, may be employed. By these means the vesicles are prevented from breaking; but when this occurs, nothing is so serviceable as the oxide of zinc ointment.

Var. b. Herpes Circinatus. Ringworm.—This variety of herpes *phlyctenodes* is of very frequent occurrence; and being unaccompanied with any constitutional affection, is of little moment. The vesicles are small, and form in a circle, inclosing a portion of the skin seemingly unaffected, while a red inflammatory blush extends to some distance around the cuticle of the circle of vesicles. The fluid contained in the vesicles is generally discharged in a few days; after which dark prominent crusts concrete over them; and at this time the centre, which seemed free from disease, becomes rough and exfoliates.

The eruption of the vesicle is preceded by a red spot of various sizes, from half an inch to two inches in diameter: it is generally circular, but occasionally oval. In a very short time after the redness appears, the vesicles, minute and globular, can be traced by the aid of a glass, filled with a transparent fluid, which becomes opaque before they burst. Sometimes the fluid is absorbed; in which case the vesicles shrink, and exfoliate almost imperceptibly. The period in which each circle runs its course is from eight to ten days; but the circles appear in succession, and as each

* Cette maladie forme réellement l'anneau intermédiaire entre les inflammations bulleuses et les inflammations vésiculeuses. Tome i. p. 202.

requires a period of eight or ten days to be perfected and desquamate, the disease is thus protracted to two or three weeks or longer. When the crusts fall off, they leave a redness which remains for some time; but no other inconvenience attends the eruption. In some instances, instead of the regular circle, the whole central spot is covered with minute vesicles, which enlarge sometimes to a considerable size, and are accompanied with much heat, pain, and irritation. When this form of disease occurs, the clusters rapidly spread and pass over the great part of the arms, the places on which this variety generally shows itself. The feverish state does not at once abate after the eruption appears; it continues to increase for five or six days; and about the ninth day the vesicles break, and the fever suddenly ceases.

The vesicular circles most commonly appear on the arms, the shoulders, the chest, the neck, and the face; and in young girls of a delicate frame of body, with a thin and irritable skin, the circles frequently display themselves on the chin.

The disease is very frequent among children, and is commonly but erroneously supposed to be contagious. Its exciting causes are obscure; and it is ushered in merely by a sensation of slight tingling and itching.

This variety of herpes, if it appear on the forehead and at the roots of the hair, may be mistaken for *porrigo scutulata*; but the vesicular character of the eruption, the regular course which it runs, and the hair not falling off, very easily enable us to distinguish it from the contagious ringworm of the scalp, as *porrigo scutulata* is termed.

No internal treatment is required: lotions containing either of the mineral alkalies, or sulphate of zinc, or alum, may be applied with advantage. Black writing-ink is a domestic application which has proved as beneficial as any that has been suggested.

Var. c. Herpes Labialis. *Herpes of the Lips.*—This variety differs only in the situation which it occupies. It sometimes extends round the whole mouth, sometimes its seat is the upper, sometimes only the lower lip. When it does not surround the mouth, it is not unusually confined to the angles: wherever it appears it rarely attacks the true lips, but frequently impinges upon the line of union between these and the skin, and at the same time patches of the eruption rise on the cheeks and ala of the nose. The vesicles, like those of the other varieties, at first contain a transparent lymph, which in twenty-four hours assumes a purulent aspect, and in three or four days becomes more yellow than that usually found in pustules, few crusts forming. The lips, as the disease advances, swell, become hard, sore, stiff, and painful, with a sensation of great heat in the affected parts. After the crusts fall, the surface remains red, harsh, and painful; cracking every time the patient laughs or opens the mouth wider than usual.

Herpes labialis is more decidedly the sequel of a distinct febrile state of the system than any of the other varieties. This febrile state is often of a catarrhal kind, and not unfrequently results from sudden alternations of heat and cold, particularly sudden exposure to damp cold air, after having

been confined in a hot or crowded room. The febrile affection is manifested by rigors, headach, pains in the limbs, anorexia, lassitude, and languor. This variety of herpes is often a critical eruption, appearing on the decline of acute diseases, which rapidly disappear as soon as the vesicles, or the inflamed bases on which they rise, show themselves. Severe catarrhs often terminate in this manner; and the appearance of this vesicular disease is considered a favourable symptom in affections of the bowels, and in the latter stages of remittent and low malignant fevers. It occasionally becomes chronic.

In general this variety requires no particular treatment; successive crops of the eruption rarely appearing, so that it runs its course in three or four days, and spontaneously disappears. To allay the heat and itching, diluted alcohol or a solution of zinc proves serviceable. When it becomes chronic, (and in this state it is almost always symptomatic of some deranged state of the digestive organs,) the hydrargyrum cum creta, combined with James's powder in the proportion of ten grains of the former and four of the latter, may be administered every night at bed-time; and during the day the liquor potassæ, in full doses, taken in the decoction of the root of the *rumex acutus* or *obtusifolius*, rarely fails in affording relief. The decoction should be made at first with not more than an ounce of the sliced root to a quart of water, and reduced by boiling to a third; but if the disease do not soon yield, double this strength will be required. The diet should be light, and consist chiefly of milk and farinaceous matters. The diluted ointment of nitrate of mercury is the best topical application in this chronic form of *herpes labialis*.

Var. d. Herpes præputialis. *Herpes of the prepuce.*—Although this variety of herpes is not uncommon, yet until Dr. Willan pointed it out as an herpetic eruption, and Bateman accurately described it, it was often confounded with syphilis and treated as such. It more nearly resembles the last variety, *herpes labialis*, than any of the others. It appears on both the external and internal surface of the prepuce, and not unfrequently on the glans penis. The eruption of vesicles is preceded by a teasing itching and tingling in the prepuce, which appears slightly swollen and inflamed, and covered with two or three red patches, on which, when closely examined, minute vesicles may be observed rising nearly in a circle. These rapidly increase in size; the lymph loses its transparency and assumes a milky hue; and in another day they are coherent and almost pustular. If the vesicles be not disturbed, they sometimes do not break, but the lymph is absorbed, and the shrunk vesicles desquamate; but at other times they break, and form ulcers covered with a whitish fur, and having an elevated base, not unlike the aspect which chancre assumes; and when they are rubbed, or improperly managed by caustic or acrid applications, a tedious state of ulceration sometimes supervenes. When the vesicular patches are situated on the internal surface of the prepuce and on the glans penis, the inflammation is more severe than when the exterior of the organ is the seat of the disease. In some instances the itching and tingling which accompany

the eruption are so severe as to prevent sleep. On the exterior, the vesicles terminate about the fifth or sixth day, forming small, hard, acuminate scabs, under which the healing process is carried on; and about the ninth or tenth day the scabs fall and leave the surface slightly indented. In many instances the disease does not run this regular course, but yields to very simple means in forty-eight hours.

This variety of herpes is rarely observed in young men; on the contrary, persons in the decline of life are most subject to it, and it not unfrequently accompanies stricture of the urethra, or an irritable state of this canal. It is also sometimes produced by an acrid state of the secretion at the root of the glans; and we have seen its approach checked by keeping the part between the glans and the prepuce clean with soap and hot water, and afterwards introducing a small piece of clean dry lint to absorb the acrid fluid. Dr. Bateman properly rejects the idea of Mr. Pearson, that it is caused by mercury. The most severe case of the disease which we have seen occurred in a gentleman who had never taken mercury. We cannot, however, agree with the opinion that it is altogether independent of stricture, or at least of irritable urethra: we think that we have also observed it sympathizing with derangements of the chylopoietic viscera. It is more liable to recur than any of the other forms of herpes.

As all these different descriptions of herpetic eruptions are mere varieties of one genus, the general treatment required is nearly the same in all; and this is regulated chiefly by the nature and degree of the fever which precedes and accompanies the eruption. This is seldom so severe as to require the use of the lancet, unless the patient labours under some acute disease of which the herpetic affection may be regarded as symptomatic. More frequently herpes about the mouth and occasionally on the ears occurs as a salutary crisis of fevers, and ought not to be interfered with. If the digestive organs be much deranged, and the eruption can be traced to that source, an emetic will prove useful in clearing away the superabounding acid which generally prevails, and is undoubtedly one cause of the irritation of the intestinal membrane with which the skin sympathizes.

No class of medicines so effectually fulfil the indication to be answered in herpes as mild purgatives, especially those containing magnesia, as they carry off a large portion of the existing acid, whilst the magnesia allays the morbid irritability of the gastric surface. Neither calomel nor any of the very active cathartics are in general required. Diaphoretics are not indicated; and even when much heat of skin exists, more advantage is derived from the free use of diluents than from antimonials or any medicines of that class.

One of the most distressing symptoms in severe cases of shingles is the deep-seated pain which often occurs about the thorax, and when the pulse is at the same time quick and hard, it has, as already stated, led to the supposition that pleurisy is present. The lancet brings no relief in this case; but much comfort is afforded, and sleep secured, by a combination of colchicum, magnesia, and an opiate. The following form is that which we have found most serviceable:

R Magnesiæ ʒi.

Vini colchici seminum m xlviij.

Tincturæ opii m xxx.

Misturæ camphoræ fʒxi. M.

Sit haustus horâ somni sumendus.

In the chronic state of herpes *labialis* the treatment we have already described is commonly successful; but when the disease is obstinate, it is necessary to place the patient under a course of hydrargyrum cum creta, with decoction of sarsaparilla or of elm bark. Upon the whole, although we cannot refuse to accord with the opinions of most writers on affections of the skin, that herpes requires less of the medici diligentia than almost any other of the numerous list of cutaneous eruptions, yet the young practitioner will feel frequent disappointments if he expects all cases of herpes to run so favourable a course. It is only when they are critical of some acute disease that he may altogether disregard them: on the contrary he will sometimes find the most acute suffering precede the eruption, and a degree of general derangement of the system often so obscure as to complicate and restrain the efforts of the physician. In such cases the first object is to gain an accurate knowledge of the state of the stomach and bowels, that of the liver and the chest; and if the nervous system which is often the case, be involved in the general derangement, to ascertain how far this depends on mental causes, as many cases of herpes, in all its varieties, may be clearly traced to grief, anxiety, and other mental sources.

Species 2. HERPES IRIS.—This species differs materially in all its characteristics from the former. It was first announced as a herpetic affection by Dr. Willan, and afterwards accurately described by Bateman. Its usual seat is on the back of the hands; but it has appeared on all parts of the body; most commonly, however, where there is little fleshy substance. It first displays itself in small red spots, which, as they change colour, are surrounded by fresh circles of inflammation, which become vesicular. The patches gradually extend until they attain the size of a shilling, the circumference assuming a radiated or star-like appearance. In the description of Bateman we are told that the first circle, surrounding the central vesicle which is yellowish, "is of a dark or brownish red colour; the second is nearly of the same colour as the centre; the third, which is narrower than the rest, is of a dark red colour; the fourth and outer ring, or areola, does not appear until the seventh, eighth, or ninth day, and is of a light red hue, which is gradually lost in the ordinary colour of the skin." (Bateman's Synop. p. 340.) The variously coloured rings so well defined in this description are, however, rarely observed.

This species of herpes most frequently appears in children and fair women; but neither the predisposing nor the exciting causes are very obvious. Like some of the varieties of herpes *phlyctænodes*, it has occasionally occurred as a critical eruption. In some individuals, according to Bateman, it has recurred several times, "occupying the same parts, and going through its course in the same periods of time."

It is scarcely possible to confound herpes *iris* with any other disease. There is one species of roseola which extends in successive circles, but it

wants the vesicles, which are sufficient to characterize the herpetic disease.

With regard to the treatment of this species of herpes little requires to be said: no internal medicines are required; nor do we know any local applications likely to prove serviceable in shortening the disease. The warm bath employed only for twenty minutes, and exercise taken immediately after it, has appeared to be useful. Rayer recommends decoctions of linseed to be employed as fomentations: we have had no experience of their use, so that we are not authorised to give an opinion on the subject. Moderate bloodletting, gentle aperient medicines, and a combination of the solution of arsenic and of pure potassa, with the decoction of the *rumex obtusifolius*, have been productive of more benefit than any other means which we have employed. A small piece of soap-plaster laid over the parts affected, has occasionally been productive of much benefit.

[It may be proper to add, that in regard to the local treatment of the different varieties of herpes, difference of opinion has existed. Whilst some restrict it to washing the parts with tepid milk and water, or with mucilage, others recommend oleaginous and other applications, possessed more or less of astringent or excitant properties. Chlorinated lime; chlorine; hydrocyanic acid; creasote, in solution or ointment; soot; cyanuret of mercury; red iodide of mercury; tincture of iodine pencilled over the parts, especially in herpes circinatus; iodide of potassium; cod-liver oil, used externally and internally, have all been employed. Very obstinate cases may require, also, the external use of the preparations of iodine, combined with syrup, to modify the condition of the circulating fluid, and through it that of the system of nutrition.

It has been recommended to open the vesicles early, and apply an emollient cataplasm over them; and it is affirmed, that in herpes *zoster*, where the pain is very severe, the best effects result from the application of a dozen leeches to the inflamed part. If done early, before many vesicles have appeared, the farther progress of the disease, according to Dr. Mackintosh, (*Principles of Pathology and Practice of Physic*, 2d Amer. edit. ii. 286, Philad. 1837.) may be stopped. Small blisters, applied to the inflamed skin, in the vicinity of the vesicles, it is said, check their extension, and produce a shrivelling of those already formed.]

A. T. THOMSON.

HICCUP.—Hiccup or *hiccup*, sometimes written *hiccough*, apparently from a mistaken notion of the etymology of the word. It may have been immediately derived to us from the Danish; but its origin in that as well as in some other languages was most probably an attempt to imitate the peculiar sound which it denotes. It corresponds with the French *hoquet*, and the German *schlucken*; but the Greek *λῆξι* or *λυγρὸς*, and the Latin *singultus*, though applied to this affection, seem also to have designated the somewhat analogous one which we call *sobbing*.

The phenomena of hiccup, as observed by a by-stander, may be described to consist in a sudden, rapid, and brief inspiration (such as may properly be called convulsive), instantly followed by expiration; each of these movements being ac-

companied by a noise not heard in common respiration, and these noises following each other in quick succession, produce that peculiar dissyllabic sound by which the affection is characterized. The convulsive movements return at short intervals, commonly varying from half a minute to a minute, but sometimes of longer duration, and are attended by an uneasy sensation at the præcordia, which, when the hiccup is violent and often repeated, amounts even to pain.

Such are the phenomena presented by this affection, apart from any attempt to explain its mechanism. What this is has been the subject of much conjecture. The oldest opinion seems to have been that it consisted in a convulsive movement of the stomach; an opinion which, in the then very imperfect state of physiology, was not an unnatural inference from the well-known fact that the exciting cause is commonly some impression directly made upon that organ. Since, however, the functions of the stomach and neighbouring parts have been more accurately investigated, most authors have concurred in referring the motions which constitute hiccup chiefly to the muscles employed in respiration, and particularly to the diaphragm. That causes acting upon the stomach are adequate to excite these muscles to violent and irregular contractions is familiarly known. Fits of coughing (especially in the whooping-cough) and of spasmodic asthma are often produced in this way; and whatever difference of opinion may still exist as to the particular combination of muscular actions by which vomiting is effected, it can scarcely be doubtful, especially since the experiments of Magendie, that the expulsion of the contents of the stomach is ordinarily in great measure produced by the agency of some of the respiratory muscles. If, however, two phenomena, so widely differing in their results as vomiting and hiccup, are referred chiefly to the same mechanical powers, some other cause of their difference must exist. It is probably owing to an inverted action of the muscular fibres of the stomach and gullet co-operating with the other agents in the former, and not in the latter, that the rejection of the contents of the stomach takes place in the one, but does not happen in the other.

The modern opinion, which ascribes hiccup chiefly to the respiratory muscles, rests upon the following among other arguments.—1. The phenomena of the affection, as above described, appear to consist chiefly in a convulsive act of respiration. 2. The researches of physiologists have clearly shown that the muscles in question, or at least some of them, are capable of movements corresponding with those of hiccup in rapidity and violence. 3. We are without any satisfactory evidence that such motions are ever performed by the muscular fibres of the stomach. 4. A consideration of two popular methods of preventing the recurrence of hiccup, namely, holding in the breath for a considerable time, and making a protracted deglutition by sipping liquids; both of which seem to owe their efficacy to the power of the will over the respiratory muscles.

Some writers, while they admit the agency of the diaphragm in producing hiccup, have supposed the œsophagus to co-operate with it. Thus Mahon (*Encyclopédie Méthodique*) explains the

affection as consisting in "a convulsive movement of the œsophagus, which draws the stomach and diaphragm upwards, whilst at the same time the diaphragm itself experiences a convulsion which draws it downwards."* It is, however, very questionable whether the œsophagus ever executes movements of the kind here supposed. With regard to the peculiar noise which accompanies hiccup, there can be little doubt that it is caused by a convulsive or spasmodic action of the muscles about the glottis.

There are two convulsive affections which, without being absolutely identical with ordinary hiccup, so nearly resemble it, that they are designated by the same word, at least in some languages, and must apparently be referred to nearly the same muscular powers. Thus, what is properly called the *hiccup of death*, although owing its name to a similarity to the true hiccup, in some respects differs from it. According to Double, it consists of two quick and forcible inspirations preceding a feeble and protracted expiration. The affection which we call *sobbing* is so analogous to hiccup, that, as has been before observed, the Greeks and Romans designated both by the same words. Indeed, not only do they nearly resemble one another, but sobbing in children often passes into perfect hiccup.

Having considered the mechanism of the affection, we may next advert to its *causes*, and the circumstances under which it occurs. In relation to these points, all the cases which are met with may be referred to two general heads, according as the hiccup is or is not preceded or accompanied by some other recognised morbid affection, of which it may be considered a symptom or consequence. It will be convenient to designate these two divisions by the terms symptomatic and idiopathic, although the strict propriety of such words is questionable.

By far the most frequent cause of *idiopathic hiccup* is some impression directly made upon the stomach; as, for example, by very hot or highly seasoned food, especially in a liquid form; by alcoholic and other stimulant liquors; and by food swallowed hastily, or in too great quantity, especially after long fasting. As the affection, when produced by causes of this kind, generally occurs almost immediately after the irritating matter is taken into the stomach, it may be reasonably inferred that the impression upon that organ, which calls forth the muscular efforts by which the hiccup is affected, is chiefly made upon its cardiac extremity; and we shall hereafter see that one mode of explaining the final cause of the affection is by a deduction from this opinion.

The occasional causes just enumerated evidently act upon the sensibility of the lining membrane of the stomach; but there are others which seem to operate by a mechanical impulse communicated to the whole organ. Thus, in children more particularly, any vehement or convulsive movement of the respiratory muscles, as violent crying and sobbing, or a fit of coughing, is apt to end in hiccup. The same occasionally happens with vomit-

ing, as was observed by Hippocrates, who noted it as an unfavourable occurrence.

A cause of a very different description from the above is fasting. It implies a prolonged absence of the proper and accustomed stimulus of the stomach; and the influence of this negative impression seems to afford a more probable explanation of the occurrence than the hypothesis which has referred it to the supposed irritation of the gastric juice.

Idiopathic hiccup, though generally, is by no means exclusively produced by causes directly influencing the stomach, emotions of the mind, copious evacuations, as bleeding and purging; cold applied to the surface of the body, as the epigastrium, feet, &c.; and in fact, where there is a predisposition to it, almost any impression, external or internal, may call it forth. John Hunter observes that it often accompanies local irritation after operations of various kinds. To inquire whether such causes determine the muscular movements by which hiccup is effected, through the medium of an intervening impression upon the stomach, would be a fruitless indulgence in speculation.

The tendency of occasional causes, of whatever kind, to induce this affection, is of course very much dependent upon the degree of predisposition in the individual. This may perhaps be stated in general terms to arise from the same circumstances as those which appear to favour the occurrence of other convulsive movements, and especially from that condition of the system which is expressed by the common but indefinite terms of debility and irritability, or mobility. Thus it is familiar that childhood and old age are more liable to the affection than the middle periods of life; and that the female sex, especially in the puerperal state, is more subject to it than the male. There seems, however, to be ground for a more definite view of the matter, and for referring the predisposition, at least, in a majority of cases, to a preternatural sensibility of the stomach, or to a tendency in that organ to functional derangement. Such a condition or tendency is well known to exist in the earlier and later periods of life, and during gestation; and it is probably owing to its presence in an unusual degree that, in some individuals, even a moderate quantity of the mildest food will often cause a fit of hiccup. Indeed in such persons it not unfrequently occurs without the intervention of any known cause.

The predisposition, in whatever it consists, may be either original or acquired. In the latter case it can sometimes be traced to debilitating circumstances, as excessive evacuations; but it is much more commonly attributable to causes which directly impair the digestive powers, as the abuse of ardent spirits, excesses in diet, &c.; and such an impaired state of the function of digestion is probably one principal cause of the peculiar liability of old people.

Idiopathic hiccup is commonly too slight and transient an affection to merit the name of disease. Sometimes, however, by its violence, but more often by its duration, it assumes a graver character, and has even appeared to be fatal, as will be more particularly stated when the terminations of the affection come to be considered. It has

* "Un mouvement convulsif de l'œsophage, qui tire en haut l'estomac et le diaphragme, tandis qu'en même temps le diaphragme lui-même éprouve une convulsion qui le tire en bas."

occasionally been observed to recur periodically, at regular intervals, as, for example, annually, and at the same period of the year. Thus Heberden speaks of cases, some of them unaccompanied by any other appreciable morbid affection, in which it lasted for many months, and even for years, being in some constant, in others intermitting. Dr. Good also refers to cases in which it returned at irregular intervals, for periods of from four to twenty-four years; in others in which it continued incessant, or nearly so, for eight and twelve days, and even three months.

The second division of cases of hiccup includes those in which it co-exists with, and appears to depend on, some other disease as its cause: being then what we call a *symptomatic* affection. It has been noted by authors as occurring principally in the following diseases:—fevers, both continued and intermitting, especially the latter; a complication which seems to have been formerly not uncommon, as the epithet *singultuosa* was applied to fevers accompanied by hiccup throughout their course; inflammation of the stomach, bowels, and liver; peritonitis, perhaps more particularly when the peritoneal coat of the diaphragm is involved; strangulated hernia; irritation of the mucous membrane of the alimentary canal, including worms, dentition, and the operation of poisons; disorders of the digestive function generally, especially when attended by the acid eructations which cause heart-burn; jaundice; uterine irritation, whether connected with gestation or not. Thus severe and protracted hiccup has been sometimes observed as one of the attendants of hysteria. It is also enumerated by some authors among the symptoms of inflammation of the spinal cord or its membranes; and Heberden states that it sometimes accompanies paralysis, and precedes epileptic fits. Of more uncommon instances, one deserves to be mentioned, because the hiccup is said to have been fatal. It is a case related by Bobe-Moreau, and cited by De Lens, (*Art. Hoquet*, *Dict. des Sc. Méd.*) in which a severe hiccup accompanied an abscess in the upper part of the pharynx: and the death of the patient is ascribed to the symptomatic rather than to the primary affection. Some accidents affecting the diaphragm and neighbouring parts are also stated to be more or less commonly followed by hiccup: such are penetrating wounds of the abdomen, the passage of any of the abdominal viscera through the diaphragm into the thorax, fracture of the ribs, and depression of the ensiform cartilage.

As the most frequent cause of idiopathic hiccup is some direct irritation of the gastric mucous membrane, so by far the most common morbid affection on which the symptomatic variety depends, is functional or organic derangement of the stomach, and of those organs which are associated with it in the digestive process; a derangement of which habitual excess, particularly in the use of ardent spirits, is undoubtedly the principal origin. With regard to the mode in which the other diseases and accidents above enumerated give rise to hiccup, we seem to have no adequate data on which to reason, and mere speculation would be worse than useless. It will, however, be seen that most of them either directly involve the digestive organs, or others which are known

to have a close sympathy with them. The occurrence of hiccup in some of these cases can scarcely be accounted for except by supposing a considerable predisposition to exist; and the same may be said of its appearance under certain circumstances in which it is not strictly referable either to the symptomatic or idiopathic form, but immediately follows the disappearance of some previously existing disease. The most common case of this kind is the sudden cessation of ague, of which numerous examples are found in the older writers. Among others, Fred. Hoffmann mentions instances in which the hiccup assumed both a continuous and periodical form. It has also been observed to ensue upon the disappearance of continued fever, gout, rheumatism, and cutaneous diseases, and upon the cessation of a natural or accidental evacuation, as the menses, hemorrhoids, and diarrhoea. When originating in this way, it is sometimes very tedious and obstinate; as, for example, when connected with amenorrhoea, not ceasing till the menstrual evacuation is re-established.

Among the circumstances which determine the occurrence, or rather the continuance of hiccup, we must include the force of habit. The influence of this cause is seen in most if not all of the convulsive movements to which the body is liable; and in none more so than in the one now under consideration.

Of the *terminations* of this affection little need be said. When unconnected with any other severe malady, it almost invariably disappears sooner or later, though its duration is, as we have seen, sometimes very protracted. Cases are, however, reported to have occurred, in which the hiccup itself was the cause of death. One has been already adverted to, in which it was symptomatic. The same author (Bobe-Moreau) relates another, also complicated with difficult deglutition, and speedily fatal; but no cause of the hiccup was discovered by dissection; nor have we any thing beyond conjecture to explain the fatal termination. De Lens, apparently following some preceding authority, states that prolonged hiccup produces swelling and redness of the face; thus implying the possible occurrence of cerebral congestion or of suffocation.

It has been before stated that hiccup sometimes follows and takes the place of other convulsive movements, in the production of which the respiratory muscles are chiefly concerned. In like manner it occasionally terminates in them. The most common instances appears to be that of sneezing: thus Hippocrates says, if hiccup be restrained, sneezing comes on, and the hiccup ceases; and Lanzoni and Bartholin met with hiccup alternating with violent sneezing after tertian ague.

Having thus mentioned most of the facts relating to this affection which seem worthy of notice, it will be proper to make a few remarks on what may be called its *final cause*. In many of the convulsive movements of the body, such as coughing, sneezing, and vomiting, this is in general sufficiently obvious, being either the expulsion of offending matter, or the protection of the irritated part by exciting secretion, or the restoration of its interrupted circulation and functions. In others, as epilepsy and often asthma, the existence of such a cause, though not admitting of demonstra-

tion, seems deducible from a just analogy; and the same may be said of hiccup, at least when excited by some direct irritation of the stomach. In such cases, the final cause is evidently not the rejection of the offending matter; for this would be effected by the act of vomiting, which hiccup has little or no tendency to induce. It is conceivable that one end to which it is directed is the propulsion of the irritating matter towards the duodenum; and thus the final cause has been conjectured to be the removal of such matter from the cardiac extremity to a less sensitive part of the stomach. However this may be, it seems probable that the hiccup subserves another and perhaps more important purpose,—that of determining so much of vital energy to the organs of digestion, especially the stomach, as shall counteract the morbid influence exerted upon them, and induce a vigorous performance of their functions. Such a view well accords with that pleasurable sensation, referred to the epigastric region, which is stated often to follow a fit of hiccup. The same may be said of a fact already mentioned, the occurrence of hiccup as a termination (sometimes apparently a critical one) of continued and intermittent fevers, and also of its occasional appearance at the commencement of eruptive fevers. To these may be added another, mentioned in the first report made by Drs. Russell and Barry, on the cholera at St. Petersburg. These gentlemen observe it is “singular enough to say, hiccough coming on in the intermediate moments between the threatening of death and the beginning of reaction, is a favourable sign, and generally announces the return of circulation.”

Undoubtedly the above view of the final cause is most obviously applicable to those cases in which the hiccup appears as the effect and remedy of a temporary irritation; but it is by no means incongruous with others in which the affection is symptomatic of some grave or fatal lesion. The parts of our frame are so associated by that inexplicable bond which we call sympathy, that irritation in one organ commonly gives rise to a morbid condition or movement in others. This association is governed by certain general laws, often very imperfectly known to us, but the great end of which is manifestly the preservation of the whole body; and the operation of these laws continues, not only when it cannot produce any beneficial effect, but even when it becomes absolutely pernicious. Thus the hiccup which ushers in death is a fruitless effort of nature; while that which results from abdominal wounds, inflammation, or herniæ, may not only be inadequate to accomplish any good purpose, but may even aggravate the existing evil by a repeated concussion of parts which stand in need of perfect rest.

In relation to **diagnosis** generally, the presence or absence of hiccup does not appear to be a guide of much value, since it is pathognomonic of no one morbid affection, but appears under widely different circumstances, from an inconsiderable and temporary irritation to the most formidable and fatal lesions. In cases which present general indications of severe abdominal disease, but not such as enable us to localize it, hiccup may indeed point to some two or three organs more particularly, but it cannot justify us in allo-

cating the disease in any one of them rather than in the others.

As a ground of **prognosis** it may be more valuable; though, for the reasons just stated, scarcely so much so as has been generally represented. Conjoined with other symptoms which portend death, it of course strengthens the evidence of its approach; and when it occurs in affections which have produced great prostration of the vital powers, it no doubt generally implies an expiring and ineffectual struggle of nature. Thus Hippocrates speaks of it as an alarming symptom after hemorrhage, vomiting and purging; and Sydenham appears to have verified the observation, especially with reference to the aged. It is, however, to be borne in mind that even in such circumstances it sometimes indicates (as already stated of cholera) a successful effort of nature to bring about a salutary reaction.

It is not necessary to say much about the **treatment** of an affection which is mostly either too inconsiderable and temporary to call for medical aid, or else a mere symptom of some more formidable malady. In the slighter cases of idiopathic hiccup in which its recurrence seems chiefly the effect of habit, impressions of various kinds, made either upon the organs more immediately concerned, or upon the body generally, are adequate to remove it. Such are the emotions of surprise and fear, a forcible suspension of the act of respiration, sneezing, vomiting, protracted deglutition by sipping liquids, the administration of what are called antispasmodic medicines, including opium; of stimulants, as oil of anise, mint, &c.; of mineral acids, alkalies, and bitter tonics, especially quinine; cold aspersion of the body, &c. The efficacy of many of these remedies is no doubt partly or principally owing to their removing those disorders of the digestive function of which hiccup is so often a symptom.

In cases of a more severe or obstinate nature, cupping at the epigastric region, the application of blisters, sinapisms, and warm plasters to the same parts, and opiate friction, have been resorted to with success. Borrichius relates a case in which the affection returned annually at the same period, and each time yielded to a copious bleeding; a fact which illustrates the remark of Hippocrates, that hiccup, like spasm, may result from repletion (*πληρωσις*), as well as evacuation (*κρίωσις*). When it depends upon causes of the latter class, opium is undoubtedly, as Sydenham has told us, the best remedy; and the same may be said of those cases of visceral disease or lesion, in which, supposing recovery to be hopeless, we must still attempt to remove, or at least to mitigate, a distressing symptom.

EDWARD ASH.

[HOMŒOPATHY. (See DISEASE.)]

HOOPING-COUGH.—Hooping-cough has been described under a variety of names, many of which, as chin-cough, kink-cough, &c. refer to its prominent symptom. In France it is usually termed *coqueluche*; in Germany, *keuchhusten*, *stichhusten*, &c.; in Scotland, *kinkhoast*. It was called *tussis convulsiva* by Willis, *tussis ferina* by Hoffman.

The nosological term at present most generally employed to express the disease is *pertussis*, first

given to it by Sydenham, and afterwards adopted by Cullen, who arranges it under the class Neurosis, order Spasmi. His definition of the disease is the following:—"Morbus contagiosus, tussis convulsiva, strangulans, cum inspiratione sonora, iterata, sæpe vomitus."

In the above definition may be found Cullen's opinion as to the contagious nature of the disease. Doubts have, however, been raised upon this point by Laennec, Desruelles, and others, though not supported in such a way as to invalidate the common notions upon the subject.

The disease appears to have two distinct stages. The first lasts generally from ten days to a fortnight, or even three weeks, and is not different from an ordinary catarrh; there is cough and coryza often with very little fever. At the end of a period varying from one to two or three weeks, the second stage commences, and is distinguished by the peculiar convulsive cough. In this cough a number of expirations are made with such violence, and repeated in such a quick succession, that the patient seems to be almost in danger of suffocation. The face and neck are swollen and livid, the eyes protruded and full of tears; at length one or two inspirations are made with similar violence, and by them the peculiar *whooping* sound is produced: a little rest probably follows, and is succeeded by another fit of coughing and another whoop; until, after a succession of these actions, the paroxysm is terminated by vomiting, or a discharge of mucus from the lungs, or perhaps by both. [In very young children, as properly remarked by M. Constant (*Gazette Médicale*, 1836, p. 53,) the expectoration is an important element of diagnosis, as it is the only affection at an early age in which it is met with. (Bell, art. *Coqueluche*, in *Dict. des Etudes Médicales*, Paris, 1839.)] Sometimes when the *kink* is unusually severe, blood is forced from the nose, ears, and even from the eye-lids; and occasionally it ends, without producing any discharge, in the complete exhaustion of the patient.

The number of paroxysms occurring during a day varies much in different cases, according to the severity of the disease; and the violence of each is diminished in proportion to the freeness of the expectoration. After the disease has continued at its height for two or three weeks, it begins naturally to decline; the paroxysms become less frequent and violent, the expectoration increases, the cough soon loses its peculiar characteristics, and finally wears away altogether, leaving the patient in perfect health. It is to be observed, however, that occasionally, several weeks after the cough has entirely subsided, it may return; and for a long time, if the patient accidentally catch cold, the cough will often assume the spasmodic character, and be accompanied with the "whoop."

We may safely assert, notwithstanding a contrary surmise advanced by some of the French writers, that hooping-cough rarely if ever affects the same individual twice; and as its usual period of occurrence is during childhood, we shall of course seldom meet the disease among adults.

It is also supposed to be very uncommon in early infancy (for the first two months)—an opinion which is generally true, although we have seen more than one instance of an attack in chil-

dren three weeks old. When the disease attacks an adult, it generally wants the peculiar whooping inspiration, and the same thing is usually, but not constantly, observed in the cases of very young children.

Nature and seat.—A great variety of opinions have been advanced by different authors respecting the nature of hooping-cough; all, however, that have any bearing on practice may be reduced to the three following:—

1. It was considered to be essentially spasmodic, and to arise from irritation affecting either the brain or some parts of the nervous system, a theory advanced and variously modified by Cullen, Leroy, Löbenstein, Jahn, and Webster.

Dr. Webster's opinion is "that the actual seat of hooping-cough is in the head, and that the affection of the respiratory organs is only to be considered as the secondary effect, or as an effort of nature to relieve herself by expanding the lungs to an unusual degree, and thereby allowing a greater quantity of blood to flow into them, which may in some degree diminish the fulness and congestion in the head." (*Med. and Phys. Journal*, Dec. 1822.)

Löbenstein and Breschet favoured the idea of the disease having its origin in the phrenic and pneumogastric nerves.

2. A great number of celebrated names may be enumerated in support of the opinion that it is always an inflammatory affection of the bronchial membrane; amongst these are Guersent, Watt, Marcus, Laennec, Dewees, &c.

As the attention of Dr. Watt was particularly directed to hooping-cough attended with bronchial inflammation, in consequence of the death of two of his children from this cause, we shall here give an abstract of his general conclusions on the subject. According to him, "it is in all cases an inflammatory disease of the mucous membrane of the larynx, trachea, bronchi, and air-cells;" and when mild, he says, it may run its course without materially disturbing the other functions of the body, or even the functions of that very membrane where it is seated; and that, whenever it proves dangerous or fatal, it does so by the degree of inflammation in the natural seat of the disease, or by that inflammation extending or being translated to other parts. (*Treatise of Chincough*, Glasg. 1815.) Dr. Dawson differs from the other writers who support the inflammatory origin of hooping-cough, in confining its first seat to the membrane of the larynx, or, strictly speaking, of the glottis. (*Nosological Practice of Physic*, London, 1824.)

3. Some consider the disease to be at first inflammatory, afterwards spasmodic. Desruelles advanced this opinion, and proposes to designate hooping-cough by the term "broncho-cephalite." According to him the disease consists of an inflammation of the bronchi complicated with irritation of the brain, the bronchitis being always primitive, the cerebral irritation always consecutive. So long as the bronchitis is simple, the cough has nothing peculiar; but as soon as the cerebral irritation occurs, the diaphragm and respiratory muscles, and those of the glottis and larynx, are drawn into spasmodic action, and the cough changes its character and becomes convulsive.

This theory has the great recommendation of being in accordance with the practice which is found most beneficial in the treatment of the disease; and it has been justly remarked that the effects of remedies, if accurately observed, are like chemical tests, frequently the means of detecting important differences in objects which otherwise could not have been distinguished from each other.

Amongst so many different opinions respecting the nature of the disease, and the sources from which danger most frequently arises, the young practitioner is left without any steady guide to regulate either his prognosis or his practice.

There can be little doubt that much of this confusion has arisen from the attention of practitioners having been directed so particularly to certain complications as to lead them to overlook the simple disease itself. In order to avoid this error, and to give (as it is hoped) a clearer view of the subject, we shall consider whooping-cough under the four following divisions:—

1. Simple whooping-cough.
2. Whooping-cough complicated with bronchitis or peripneumony.
3. Whooping-cough complicated with disordered bowels or infantile remittent fever.
4. Whooping-cough complicated with convulsions or hydrocephalus.

1. *Simple Whooping-cough.*—The disease may be called *simple*, where after it is fully formed, the fits are neither frequent nor violent, the expectoration is moderate, and the child during the intervals of the cough is quiet, retains his appetite, sleeps well and without fever or difficulty of breathing. A child will be playing apparently in good health, when suddenly he drops his playthings, rushes out of the room, and is heard to cough, whoop, and discharge the contents of his stomach; immediately after which he returns calling out loudly for something to eat. In a few minutes after the paroxysm, his pulse will be quite tranquil; and if the stethoscope be applied to the chest, the respiration will be heard perfectly natural, without any mixture of wheezing.

In such a case the disease must be considered almost, if not altogether, free from danger, and it is scarcely reasonable to suppose the existence of bronchial inflammation.

It may be said that cases of this description are rarely to be met with, and this must be admitted; but if children always lived in pure air, and were in perfect health when attacked by the disease, and if it occurred during the summer season, such cases would be much more frequent.

As this combination of favourable circumstances, however, rarely occurs, so we seldom meet the disease in this simple form; but its occurrence even in a single instance decides the question that the disease, in the second stage at least, is not necessarily inflammatory, as we can hardly presume an inflammation to exist without any symptoms of inflammation being present.

2. *Whooping-cough complicated with Bronchitis or Peripneumony.*—The symptoms of this complication, though sometimes obscure, are generally well marked. According to Cullen, whooping-cough hardly ever proves fatal without considerable dyspnoea having existed for some time. It would appear that in older children, when the dis-

ease proves fatal, it is most commonly in consequence of inflammation supervening in the mucous membrane of the lungs. In very many instances where the state of the lungs was ascertained by dissection, the most remarkable phenomenon that presented itself was an inflamed condition of the bronchi, which were almost entirely plugged up with frothy mucus and sero-purulent fluid.

[Of thirty-eight cases of complications, reported by M. Blache, (*Archiv. Général. de Médecine*, 1833, tome 3,) twelve were of pneumonia; and of twenty-eight cases, observed by M. Constant, in the *Hôpital des Enfants* of Paris, ten were of the same affection. (*Gazette Médicale*, 1836, p. 528.)]

A point of the greatest importance in the treatment of the disease is to watch the earliest symptoms of bronchitis, as upon their speedy removal will principally depend the safety of the patient.

We are warned of the occurrence of bronchitis when the pulse becomes permanently quick, small, and hard; the fits of coughing become more frequent and more distressing, and the breathing is hurried in the intervals of the paroxysms; when any exertion or speaking causes increased difficulty of breathing or panting; the lips acquire a livid hue, and the extremities show a great tendency to become cold.

As the disease advances, the pulse becomes more frequent, the difficulty of breathing increases, the *alæ nasi* are alternately contracted and dilated, and there is great prostration of strength; in many cases the cough is nearly suspended, and when it does occur, it is not accompanied by the usual whoop, and the difficulty of getting up the mucus is greatly increased.

The respirations vary from 60 to 100 in a minute; and if, after having maintained this frequency for twenty-four or thirty-six hours, they come down to 40 or 50, the change generally indicates recovery.

There is considerable and permanent wheezing for the two first days, not audible unless by aid of the stethoscope or by applying the ear to the chest, after which it increases and becomes quite perceptible by laying one hand on the chest and the other on the back. The wheezing is greatest after sleep, or immediately before a paroxysm of coughing.

When the bronchial inflammation cannot be checked, the breathing becomes more hurried and laboured; the wheezing increases; stupor and prostration succeed; the cough is suspended; the pulse becomes nearly imperceptible; the extremities cold; and in the course of eight or ten days from its commencement death ensues from the accumulation of mucus, which apparently produces suffocation.

When the attack terminates favourably, the breathing becomes less hurried, the wheezing diminishes, the cough after a temporary suspension returns, the fever subsides, the countenance assumes a more healthy appearance, and quiet sleep succeeds to distressing restlessness.

On examination after death, the most usual morbid appearance is inflammation of the mucous membrane. The lungs collapse imperfectly, and when cut into, an abundance of frothy and puri-

form mucus exudes from the bronchi and air-cells. Increased solidity of the lung has often been found, and by some it is said to be constantly observable. When it does occur, it would appear that the inflammation had extended from the mucous membrane to the substance of the lung, or attacked both its textures.

3. *Hooping-cough complicated with disordered Bowels or Infantile Remittent Fever.*—These, though present, are much less formidable combinations than the last, but still they render the disease very intractable.

If we find a child in this disease breathing heavily, with foul tongue, loss of appetite, tumefied belly, and the discharges from the bowels unnatural in colour, consistence, or smell, we may rest assured that, unless these symptoms are removed by the prompt use of medicine calculated to effect that purpose, much distress will eventually ensue. Infantile remittent fever will next arise, and this may itself prove fatal, or lead to hydrocephalus.

A great number of the long-protracted cases of hooping-cough are complicated with remittent fever. After the symptoms just enumerated have continued for a longer or shorter time, the fever makes its appearance, sometimes commencing with a rigor; more frequently, however, it comes on so gradually, that we do not know precisely when to date its commencement. The paroxysms of coughing become more frequent, and the breathing is quickened and oppressed; but still it may be with a little care distinguished from the attack of bronchial inflammation. The stethoscope affords us useful though negative evidence. The usual symptoms of bronchial inflammation are absent. The frequency and force of the respiration are found increased, but this increase is not accompanied by any r le indicative of bronchial inflammation; while the daily remissions, the loaded tongue, the nature of the alvine discharges, the aspect of the child constantly picking his nose and lips, all serve to determine the true character of the disease.

4. *Hooping-cough complicated with Convulsions or Hydrocephalus.*—Every one who has seen much of hooping-cough is aware that when it occurs during the period of dentition, it is frequently accompanied by convulsions, and that they were among the principal sources of danger at that age.

This complication may be accounted for in like manner as the bleeding from the nose, ears, &c.—namely, by the interruption given by the violence of the cough to the free return of blood from the head, and also by the circumstance of children being so liable to convulsions at this period of their lives.

It is said that the child may be carried off by one of the convulsions: this, however, very rarely happens. After their frequent return, the case may pass into hydrocephalus.

In a child from seven months to two years of age who has the hooping-cough, if we observe that the paroxysms become suddenly increased in violence, that the thumbs are drawn into the palms of the hands, while there is no accession of bronchial inflammation to account for the increase of cough, we may apprehend convulsions. If, however, in addition to these symptoms, the child,

after each fit of coughing, instead of whooping becomes livid, we may calculate to a certainty on convulsions, if suitable means be not employed to ward them off. If the child has ever had the swelling of the top of the fingers and toes, noticed by Dr. Kellie of Leith, or that peculiar spasmodic affection described by Dr. Clarke and more recently by Dr. Marsh, under the title of Spasm of the Glottis, (see *GLOTTIS, SPASM OF*.) we can scarcely expect that it will pass through the hooping-cough without an attack of convulsions.

It is sometimes important and always desirable to be able to say if the convulsions in these cases depend upon disease in the head; and rules have been laid down for ascertaining this point, but they are not altogether unobjectionable. It is said, that in hydrocephalus one side of the body is more affected than the other, but in convulsions which are independent of organic disease of the brain, that both sides are equally affected. If the convulsions are distinctly confined to one side of the body, there is every reason to fear the existence of hydrocephalus; but it certainly does not follow, because the convulsions are general, that the brain is unaffected. In the latter case we must wait until the convulsions subside before we can discover their cause, and then we must form our opinion from the general state of the child and the history of the case, rather than from any peculiarity in the convulsion itself.

When hydrocephalus supervenes upon hooping-cough in a child under two years of age, it is almost uniformly preceded or accompanied by convulsions; occasionally, however, it creeps on more insidiously, and we have several times been called upon to see a child in a state of stupor, with one arm sawing the air, whilst the other side was paralysed: and yet neither the parents nor medical attendant were aware of the nature of the case, but were solely occupied in attending to the cough.

Where hydrocephalus prevails in the family, we must, whenever the children are attacked by hooping-cough, be on the look-out for the earliest symptoms. If there are fits of drowsiness and languor, aversion to light or noise, occasional headach, screaming out during sleep, grinding the teeth, frequent sighing; after more or fewer of these symptoms, if the child is attacked with fever, accompanied by greater irritability of stomach than we can account for or than is natural in hooping-cough, and if, to use the words of Dr. Cheyne, "purgatives produce mucous rather than feculent stools," we may safely consider that our most strenuous exertions will be required for the averting of this formidable malady.

The approach of hydrocephalus in these cases has been occasionally overlooked in consequence of mistaking the laborious respiration arising from oppressed brain, and considering it to be the effect of bronchial inflammation. The assistance of the stethoscope would be here most valuable, but unfortunately the restlessness and crying of young children renders its application in many cases difficult if not altogether impossible, and we are often obliged to form our opinion from the character of the breathing. In hydrocephalus the breathing is not permanently quick; it is irregular and sobbing; occasionally the child sighs heavily,

expanding the chest in a manner that never takes place in inflammatory affections of that cavity.

[*Causes.*—Of the causes of hooping-cough, as of every other epidemic disease, we know but little. It occurs sporadically, and often epidemically, and prevails at all seasons, and in all climates, attacking every age and condition; but children under the age of the second dentition are most liable to it. It is generally considered to be contagious; (M. Blache, art. *Coqueluche*, in *Diet. de Méd.* tom. ix. Paris, 1835,) and the writer is rather disposed to be of this opinion, although he finds it difficult to come to any positive conclusion on the subject, (*Practice of Medicine*, 2d edit. i. 281, Philad. 1844.) and such appears to be the case with others, (Rilliet & Barthez, *Traité des Maladies des Enfants*, ii. 231, Paris, 1843.)

Prognosis.—It is generally supposed that hooping-cough is more dangerous in proportion to the youth of the child, and it is certainly true that the majority of its victims are under two years of age. It is, however, equally true, that a healthy child under six months, who has a good nurse, will get through the disease better than one a few months older, who has been recently weaned, or in whom dentition has commenced. The following circumstances would lead us to give a favourable prognosis: dentition being completed, and the head, bowels, and lungs not being subject to determinations or irritations; the season of the year being mild and dry; the patient not suffering or not having recently suffered from any other of the diseases of childhood, and having a sound, healthy constitution; finally, the accessions being at long intervals, the remissions complete, and the night, during which the symptoms are usually most severe, well spent. In adults, owing to their greater strength of constitution, and lesser liability to the diseases which usually produce a fatal result in hooping-cough, the prognosis will be more favourable.

[When hooping-cough prevails extensively, the mortality is occasionally considerable. In Glasgow, according to Dr. Watt, (*Treatise on the Nature &c. of Chincough*, Glasgow, 1843,) the deaths were pretty nearly $5\frac{1}{2}$ per cent. of the whole number; and in one year, they amounted to $11\frac{1}{2}$ per cent.]

General Treatment.—The treatment of hooping-cough has always been considered as difficult; indeed, it is generally admitted that, even in the mildest form, it will run its course without much interruption or abbreviation from medicine. From this consideration it would appear that in the simple hooping-cough very little medical interference is required; and judicious practitioners content themselves with giving every night a few grains of rhubarb and ipecacuan proportioned to the age of the patient, with an occasional emetic; confining the child to a milk and vegetable diet, and, during the existence of the catarrhal symptoms, to an equable temperature. The latter advice leads us to speak of the popular error, too often countenanced by practitioners, of unguardedly exposing the child to cold and open air. We shall shortly find that change of air is often very beneficial in a later stage: but when the first or catarrhal stage exists, we should adopt the practice now recommended. Mr. Pearson's plan of

treatment is applicable to the simple disease. He prescribes in the first instance an antimonial emetic, and afterwards, for a child of one or two years old, a draught containing a drop of tincture of opium, five drops of ipecacuan wine, and two grains carbonate of soda, to be repeated every fourth hour for several days. When purgatives are required, he gives rhubarb and calomel. As the cough subsides he diminishes the opiate, and substitutes gum myrrh in place of the ipecacuan wine. It is important to hold in mind that to patients labouring under hooping-cough, the great danger is from the complication with bronchitis; and in the treatment of the simple disease, our attention will be chiefly required to obviate this predisposition. The state of the lungs must be watched, and any approach to inflammatory symptoms met early by bleeding and purgatives, and (if the age of the child does not forbid) by tartar emetic. The latter medicine will also be found of use by facilitating the unloading of the stomach, which usually terminates a fit. Should the weather be cold, it will be well to have the child warmly clad, and to direct the use of flannel next the skin. When, under treatment of this kind, the disease gets through its course without any unpleasant events, and reaches the period of decline, we often find that although the patient be otherwise quite well, the cough will still continue. In such a case, when our interference appears to be necessary rather to break a habit than cure a disease, we shall often find change of air to be the very best remedy. [A change even from a better to a worse air, and even from one room of a house to another, is often serviceable. See AIR, CHANGE OF.] At this period, also, antispasmodics and sedatives may occasionally be employed with advantage. The oxide of zinc has been recommended by Guersent in doses of a grain every hour for a child of six months old; and in a case of the disease with some threatenings of convulsions, we on one occasion found benefit from musk. The latter medicine has also been highly recommended to us by a practitioner of considerable experience.

[Of late, iodide of silver has been advised in the dose of one-eighth to one one-fourth of a grain, three times a day. (Dr. C. Patterson, *Dublin Med. Press*, April 19, 1843, or Braithwaite's *Retrospect*, viii. 110, Lond. 1843.) It is said to have afforded decided relief.

Subcarbonate of iron has also been extolled by recent observers. Dr. Lombard (*La Lancette Française*, 9 Juin, 1838,) gave it in the quantity of 24 and even of 36 grains in the day to young children, either in water or syrup, or mixed with a cough mixture. It was found by Dr. Steyermann to be especially advantageous after the first stage of the disease. (*Gazette Méd. de Paris*, Juin 20, 1838.)]

A cough mixture, containing a small quantity of tincture of opium or syrup of poppies, will sometimes be of use, as will also the laurel water, or, in adults, prussic acid itself, administered with due caution. In cases where considerable debility exists, or the disease, towards its close, becomes manifestly intermittent, the tonic plan may be required, and sulphate of quinine will be found to act most beneficially in conjunction with change of air and diet.

[Hydrocyanic acid, according to some, (Dr. A. T. Thomson, *Elements of Mat. Med. and Therap.* i. 435, Lond. 1832; and Dr. Roe, *A Treatise on the Nature and Treatment of Hooping-cough*, Lond. 1838,) is the sheet-anchor of the practitioner in simple hooping-cough. (*New Remedies*, 4th edit. p. 25, Philad. 1843.)]

Various external applications are popular in the treatment of hooping-cough, as the patent medicine called "*Roche's embrocation*;" and the "*pon-made d'Autenrieth*," composed of a part and a half of tartar emetic with eight parts of lard. [(W. Horn, *Encyclop. Wörterb. der Medicin. Wissenschaft.* xxvi. 606, Berlin, 1841; and Copland, *Dict. of Practical Medicine*, Pt. V. p. 250.)] These, however, are means very secondary indeed, in the treatment of any of the complications of the hooping-cough. In the simple disease embrocations which merely redden the surface can do no harm, and are sometimes useful, but applications containing tartar emetic or other violently stimulating substances, in addition to being unnecessary, very often produce pustules and ulcerations, which materially augment the sufferings of the patient.

Treatment of Complications.—The first complications of which we have spoken are inflammation of the bronchial mucous membrane, or of the substance of the lungs itself,—bronchitis and peripneumonia. And in truth it is to the guarding against these affections that much of our attention and remedial measures must be directed in the treatment of the simple disease. When from the occurrence of the symptoms mentioned above, we have reason to suppose the existence of one or both of these inflammations, we must at once take decided steps to cut short the disease, if possible; or should that not be practicable, to promote the speedy expectoration or absorption of the fluids effused into the bronchi and air-cells. The means of effecting the first of these indications are obviously those applicable to similar inflammations under ordinary circumstances, in which we do not propose at present to enter. A few peculiarities, however, are to be attended to in their use, to which we shall briefly advert. In the first place, we must observe that in bronchitis supervening upon hooping-cough, a more free use of the lancet is warranted and required than would be advisable in other cases, and for the reasons already mentioned that it is proved both by the symptoms and appearances after death, that the substance of the lung is almost always affected. With respect to the employment of purgatives, we would also remark, that although it is very necessary to attend to the state of the bowels, still continued purging will be found to produce a degree of flatulence, which by exerting pressure upon the diaphragm will considerably increase the dyspnoea, irritate the mucous membrane, and needlessly debilitate. We shall occasionally meet cases attended with so much irritability of the stomach and bowels as to prevent altogether the use of either ipecacuan or antimonial medicines. In these instances, of course, our reliance must be chiefly upon the lancet, aided by blistering, the warm bath, and small doses of nitre. In following up the second indication, after effusion into the bronchi and air-cells has taken place to any extent, we must be very cautious about the further abstraction of blood;

this stage being attended with considerable debility, and our object being to prevent such exhaustion as would interfere with the process of expectoration. It is at this period we may expect most benefit from blistering, both by arresting inflammation and preventing further effusion.* To promote expectoration in older children, we may employ antimonials or a combination of calomel and ipecacuan in repeated doses. In very young infants, when the use of antimonials is not advisable, we may give an occasional emetic of ipecacuan wine and syrup of squills, and in place of calomel substitute hydrarg. cum cretâ in combination with pulv. ipecac.

We shall now turn our attention to the next train of morbid actions which we have mentioned as being occasionally attendant upon hooping-cough—a disordered state of the bowels and infantile remittent fever; and as these complications are rarely met with except in children, our observations principally apply to them. In speaking of the treatment of the simple form of hooping-cough, we alluded to the frequent occurrence of derangement of the bowels. This tendency exists in all acute diseases of children, and in practice it will be found that the most marked improvements in the symptoms of the original disease will attend the correction of the alvine discharges. It is important, therefore, to meet the symptoms indicating derangement of the bowels, by keeping up their regular action. If actual constipation exists, active purgatives will be required. Nothing is better for children than a combination of scammony, rhubarb, and calomel in divided doses, repeated until a full effect be produced. For patients more advanced, one or two grains of calomel, or three or four of blue pill, followed by any mild purgative mixture, may be administered. When the secretions are merely altered in quality without constipation, mild laxatives only will be required, as rhubarb and hydrarg. cum cretâ in the younger, and blue pill and rhubarb in older patients. The state of disease we are speaking of has been accurately described by Dr. Hamilton as the first stage of marasmus, and some very judicious observations are made by him upon its treatment. Unfortunately, however, the fatal facility of the purgative system has led to its adoption in this affection to an extent that has been very injurious, and was certainly never authorized by that able physician. Where the purging has been carried to excess, tenesmus, scanty mucous stools, tenderness of the belly, and a degree of tympanitic fulness succeed, which greatly aggravate the cough. Our object must then be to allay irritation by warm fomentation to the abdomen, soothing enemata, and sometimes, when the tenesmus is very distressing, by the employment of opiate glysters. When the bowels are so irritable as to be acted upon by the force of each cough with fetid depraved stools, a state which sometimes occurs in hooping-cough, small doses of hydrarg. cum cretâ and Dover's powder, followed by castor-oil, usually gives relief. When the symptoms become decidedly those of remittent fever, it is to them we must direct our treatment rather than to the original disease, as we shall always find the cough to become more distressing in a ratio with

* The practitioner must, of course, hold in mind the danger of incautiously applying blisters to children.

the increase of the fever, and on the other hand to be proportionately relieved by its decline. For the management of this form of fever we must refer to the article upon that subject. (See FEVER, INFANTILE REMITTENT.) We may remark, however, that the observations offered above upon the administration of purgatives are even more particularly applicable here. A torpor of the intestines often exists to so remarkable a degree, as to render doses of purgative medicine quite inert that would at other times be amply sufficient. This we have been in the habit of accounting for by the congestion that exists in the head, and accordingly have found in practice that when strong purgatives have had no action by themselves, abundant effect was produced by a much milder one employed after a general bleeding, or, if the strength of the child did not permit this, after the application of leeches to the temples or epigastrium.

The last formidable complications of hooping-cough we have noticed are convulsions and hydrocephalus. When any of the symptoms already mentioned as premonitory of convulsions occur, our treatment must be guided by what we can learn of their causes and tendencies in each particular case. The convulsions of children, whether they are idiopathic or complicated with hooping-cough, generally depend upon the irritation of teething, irritation of the alimentary canal, or disease of the brain itself; and the tendency most to be dreaded is the hydrocephalic.

The indications, therefore, are to remove these irritations by attending to the state of the gums, by regulating the action of the bowels, and obviating local determinations, particularly to the head. When, in spite of our best directed efforts, convulsions, as will be frequently the case, do supervene, they must be treated according to the general principles laid down for their management under ordinary circumstances. When the attacks recur frequently and baffle the usual means of cure, there are two plans by which we shall often be able to prevent their return: one is, a total alteration of the child's diet, the other a complete change of air. When the child affected is at the breast, defectiveness of quantity or quality will usually be detected in the nurse's milk. Often it will be found that she has menstruated, or, as sometimes happens, that, without the discharge actually occurring, she has experienced sensations similar to those which attend the accession of the catamenia. In such cases the milk almost uniformly disagrees, and here it is a good rule, whenever the convulsive attacks withstand ordinary treatment, to inquire closely into the state of the nurse, and if there be any grounds for suspicion, to have a young and healthy one procured.—Change of air often in the most remarkable manner puts a stop to the recurrence of convulsions, and will be found particularly beneficial in those cases of spasm of the glottis to which we have already alluded.

Both these means will also act most usefully in protracted attacks of hooping-cough, even where there is no tendency to convulsions.

For the treatment of hydrocephalus, when it supervenes upon hooping-cough, we must refer to the article upon that disease. With respect to its prevention, the remarks made upon deranged

bowels and convulsions are equally applicable as to those complications. One thing is to be remembered, that in conjunction with hooping-cough hydrocephalus is more than usually fatal, and requires our whole attention to its management.

Specific remedies.—An immense variety of these has been brought into notice, but if the views above offered be correct, their value will be less estimated. From what we have said of the simple disease, it will be seen that such medicines must be superfluous. Some of them from their violence are dangerous, and in the various complications it must be evident that no specifics are admissible. However, as some are strongly recommended, and may perhaps occasionally be of use in the decline of the disease, when the cough has become habitual, we shall give a list of the most remarkable, adding the names of those who brought them into notice.

Opium,	recommended by Dr. Kirkland.
Cicuta,	 Dr. Butter.
Belladonna,	 Dr. Buckham.
Digitalis,	 Various authors.
[Hydrocyanic acid,	Dr. A. T. Thomson and Dr. Roe.]
Bark,	 Dr. Cullen.
Cup Moss,	 Mr. Hayes.
Arsenical solution,	Mr. Simmons.
Nitrate of silver,	Mr. Jones.
Assafoetida,	 Dr. Millar.
Castor,	 Dr. Morris.
Musk,	 Mr. Hayes.
Artificial Musk,	 Dr. Hufeland.
Camphor,	 Popularly.
Oil of amber,	 Dr. Underwood,
Meadow narcissus,	Mr. Dufresnay.
Alkalies,	 Dr. Stutz.
Antimonials,	 Dr. Fothergill.
Cantharides,	 Dr. Burton.
Acetate of lead,	 Sauvages.
Cochineal,	 Popularly.

C. JOHNSON.

[See Dr. Cowan's abstract of the remedies prescribed by different observers in hooping-cough, in *Provincial Med. Journ.*, May 13, 1843, and in Braithwaite's *Retrospect*, Pt. viii. Lond., 1844, also, Rilliet & Barthez, op. cit. ii. 234, and Condie, *Practical Treatise on the Diseases of Children*, p. 525, Philad. 1844.)]

HYDATIDS.—This word (derived from *hdaris*, *vesicula*, *hdop*, *aqua*.) has in descriptive pathology been indiscriminately applied to pellucid cysts, containing a transparent fluid, developed either in the cavities, or in various tissues of the human body, as well as in those of the inferior animals. These cysts, on minute examination, having been found to vary considerably in structure, and in some instances to possess the characteristics of animal life, an extended signification has been attached to the term, and it has been adopted as the name of an order of animals or animalcules, consisting of several genera and species.

It may be presumed that animal bodies have been subject to such vesicular formations from the earliest period, and the records of medicine abundantly testify that their occurrence has been com-

monly noticed from the time of Hippocrates to the present day, though, until a recent date, their real nature seems to have been little investigated. It must, however, be acknowledged that even up to the present time the term hydatid has a very indefinite meaning.

The general appearance of these bodies has probably had an influence in limiting the opinion entertained by medical men of their morbid effects to mechanical action, and experience has hitherto afforded no reason which invalidates it: it is to this cause probably that we must attribute the common notice of their occurrence by the early writers on medicine, without further description than that which the etymology of the word hydatid conveys; and as we find little in their observations which can serve to elucidate the subject, we shall endeavour to be very brief in showing how far they attracted their notice.

Hippocrates has adverted to them in his general application of the word growth, *φύμα*, particularizing this kind by the nature of the contents; and he seems to have been well aware of their occurrence in some of the inferior animals as well as in man. It is remarkable, however, that he has only noticed their presence in the chest, a part of the body in which they are not most frequently observed, and where they are in general acknowledged to be only simple cysts.

Such were probably the nature of those to which he has alluded as the precursors of anasarca and hydrothorax, and as occurring frequently in the ox, the dog, and in swine, quadrupeds in which, he says, growths on the lung, containing water, were most frequently found, as dissection testified: "and such things (he adds) seem to be formed in man more than in cattle, inasmuch as our diet is more conducive to disease." (*Περὶ τῶν ἐν τῇ πλάτῃ*, sect. v. p. 544.)

Areteus alludes to a species of dropsy in the abdomen, occasioned by several small bladders, in proof of which he says, if the abdomen be pierced, a very small quantity of water escapes, these bladders including it; but their origin and nature he confesses were unknown to him, and adds that there were some who affirmed that bubbles of this kind passed through the intestines into the belly. (Lib. ii. cap. i. 51.) Celsus probably alludes to dropsy from the same cause in the observation, "*modo corpus inæquale est tumoribus aliter aliterque per totum id orientibus*;" but makes no direct mention of hydatids, or other reference to them. (Lib. iii. s. xxi.) Galen noticed the aptitude of the liver to generate them, and their frequent presence in this organ in animals killed without disease, (Comment in Aph. 55;) they are referred to also by Ætius, (Serm. x. cap. 20, p. 234;) and in the compilations of Bonetus, Morgagni, and Van Swieten, are introduced, from various sources, numerous observations on hydatids in man as well as in the inferior animals. The idea of the animalcular nature of hydatids, which appears to have first excited attention to the difference of bodies referred to under this name, was broached by Hartmann (Misc. Nat. cur. Dec. 2 A. 4to.) in the year 1685, and was the result of a more particular examination than had been before instituted on some taken from the inferior animals; it was par-

ticularly suggested by his witnessing their motions when immersed in warm water: his observations, however, seem to have been unknown to our countryman Dr. Tyson, when in the year 1691 he published in the Philosophical Transactions (No 193) a paper entitled "*Lumbricus Hydropicus*, or an essay to prove that hydatids often met with in morbid animal bodies are a species of worms or imperfect animals." It should be particularly borne in mind that Tyson's observations were made from hydatids found in the dissection of a gazelle or antelope, and were consistent with a preconceived suspicion (by what circumstances suggested he does not inform us) that such hydatids were of the insect tribe, or at least their embryos or eggs. His reasons for this supposition, he states, were, first, that he observed them to be included in an outward membrane like a matrix, so loosely that, by opening it with his fingers or a knife, the inward bladder containing the lymph or serum seemed no where to have any connection or hold to it, but very readily dropped out, still perfectly retaining its contents:—secondly, from observing with the naked eye, that to the inward bladder there was attached a neck or white body more opaque than the rest of the bladder and protuberant from it, with an orifice observable at the extremity, which seemed to be occasioned by the retraction of some part of it inwards, serving, as he conjectured, the purpose of a mouth to suck the serum from the outward membrane, and so to supply its bladder or stomach, organs with which his imagination had also supplied it: thirdly, by finding with the testimony of another observer, that this neck, on being approached to the flame of a candle, did really move, at first protruding, and then retracting itself. On further examination, two small strings or pipes were observed proceeding from the neck, and floating in the liquor, the object of which Dr. Tyson conceived was to convey from the mouth the pabulum of the animal, derived by suction from the outer involving membrane. "Perhaps some," he adds, "may be more inclined to think that the whole is but an egg or embryo of another insect formation, and that this bladder is as it were the amnion, and the outer coat that includes it the chorion;" but having observed the same peculiarity of construction in every one of several hydatids taken from a rotten sheep, he considered such a supposition void of probability. The hydatids of the human body Tyson seems also to have minutely examined, and the circumstances in which he found them to differ he has noted in the record of a case so illustrative of the subject and fortunate in its termination, that we deem it well worth transcribing in this place:—"Thus in a patient still living, and enjoying her health better than all her lifetime before, about ten years of age, I caused her right side to be opened a little below her short ribs, whence issued out abundance of limpid water; but what was most surprising, together with it a great many hydatids, that first and last we guessed there might come out about five hundred of these bladders: most were entire and filled with limpid water, of others that were too large for the orifice the films were broken, but in none of them could I observe the neck, though I was inquisitive to find it, which makes me think

them to be different from our present subject; as are also those I have frequently met with in the ovaria of women who have died hydropical, which I take to be only the eggs contained there, which by an extravagant flux of humours into them are often swelled to that prodigious size that I have taken several gallons of liquor out of them." Dr. Tyson further adverts to hydatids without necks, which he had found in the bladder of a human subject. "I shall only add," he says, "that the lumbrici hydropici I have always found hanging to the membranous parts rather than included in the body of any of the viscera, as to the omentum peritoneum or the outward membranes that cover the stomach, liver, colon, or other intestines." Hydatids of this kind were afterwards examined by Pallas, (Miscel. Zool. Ed. Hagæ Comitum, 1766, p. 157,) and named by him *tæniæ hydatigenæ*, from the resemblance of their heads to those of the common worm of that genus. They have been further recognised as animalcules and adopted as such in the classifications of Linnæus, Fontana, Muller, Bloch, Werner, Cuvier, Lamarck, Zeder, Rudolphi, and Laennec. With regard to hydatids of the human body, Pallas has noted that those which came under his examination were void of neck and head, but that they evinced considerable contractility, as was exemplified by the retraction of their coats on division with a knife, "and with such force as to be turned almost inside outwards." The insect nature of the former having been acknowledged, the property just noticed was considered a title to the credit of distinct animalcular life in the latter, which had hitherto been regarded as morbid products endowed with the mere organic life of the parts with which they were found in contact. The new hypothesis seems to have been generally received with little further examination, and to have gained additional confirmation by the observations of Dr. John Hunter, published in the first volume of the Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge for the year 1793. In this paper are detailed the case and dissection of a subject, with the result of an examination of some hydatids, taken from a collection found between the neck of the bladder and the rectum, compared with others which presented themselves in the abdomen of a rotten sheep. The just estimation of Dr. Hunter's evidence will induce us to draw largely on the information he has left on record; we cannot, however, but remark with regard to hydatids of the human body, that he has expressed himself in language presumptive of data acknowledged by him to rest only on probability, assuming the endowment of the highest functions demonstrative of animal life, for bodies in which the existence of the lowest order was a question yet undetermined. It is worthy of remark that the hydatids of the gazella, examined as we have already stated by Tyson, were found in a situation in that animal corresponding to that of the human subject from which Dr. Hunter's specimens were taken.

From the period at which animalcular life became a distinctive characteristic of certain hydatids in the inferior animals, and that this property, though on more slender evidence, was assigned to some others which were found in man, the pre-

vailing inclination among medical writers and in oral communication has been to appropriate the term hydatid to those apparently so endowed; hence they have been denominated true hydatids; and to other pellucid cysts, formerly so considered, the epithet false has been applied in contradistinction.

From the preceding remarks it will be obvious that things most diversified in nature have been incongruously confounded under one name, and that to view them in their clear light as well as to see their pathological bearings with any profit or advantage, they must be severally considered with the definite signification proper to the classes in which nature presents them. These appear to us to be three in number, the *first* of which comprehends those hydatids which evince in their structure and properties the unquestionable endowment of distinct animalcular life. The *second* consists of such as have no evidence of animalcular life either in their construction or properties; but which has been assigned to them from certain phenomena, presently to be noticed, connected with their situation and growth. The *third* division embraces such as are universally admitted to have no place in the animal kingdom, but which may be regarded as excrescences or morbid formations, arising out of the natural tissues and organs of animal bodies.

The animalcular hydatids to which our first division refers have been observed to vary considerably in their structure, and have been ranged by naturalists in four distinct genera placed in the order *Vermes*, and thus designated, *H. cysticercus*, *H. polycephalus*, *H. ditrachyceros*, and *H. echinococcus*: to these a fifth genus has been added, constituted by the hydatids of our second division, the real nature of which, to say the least, is questionable, though they are commonly considered to belong to the insect tribe, and described as such under the name of *H. accephalocystis*.

The occurrence in the human body of the first four genera, and their specific consequences, have been little if at all investigated by the pathologists of our own country, and we find recorded by them only a single case in which any of them are particularly referred to. This case appears in the tenth volume of the London Medical Journal, but contains merely the statement that the patient had voided a number of *tæniæ hydatigenæ*, a name synonymous with the *cysticercus* of the above classification, and with the *lumbricus hydropicus* of Dr. Tyson, which, as we have already stated, was described by him and also by Dr. Hunter from specimens taken from the inferior animals. That their occurrence in the human body is not frequent, we infer from their having been rarely noticed by writers on pathology or medicine; but as minuteness of structure may have been more frequently overlooked than we have reason to suppose, and as they have been particularly adverted to on high authority, the following description, for which we are indebted to the labours of Cloquet, (Dict. des Sciences Méd. Art. *Hydatid*. Paris, 1818,) will, we conceive, be an acceptable guide for future comparison and inquiry.

Genus. 1. *Hydatid cysticercus*, Rudolphi; from *κύστις*, vesica, and *κόπος*, cauda. Body nearly cylindrical or slightly depressed, wrinkled,

terminated by a caudal vesicle; head furnished at its base with four parts or suckers.

Sp. 1. *Cysticercus tenuicollis*, *Rudolphi*. *Syn.* *vermis vesicularis*, *Hartmann*; *hydra hydratula*, *Linnaeus*; *tænia hydatigena*, *Pallas*; *vermis vesicularis eremita*, *Bloch*; *hydatigena orbicularis*, *Goeze*; *hydatigena globosa*, *Batsch*; *vesicaria orbicularis*, *Schrank*; *tænia globosa*, *Gmelin*; *hydatis globosa*, *Lamarck*, *Bosc*, *Brugnières*; *cysticercus lineatus*, *Laennec*; *cysticercus globosus*, *Zeder*.

Character.—Head almost tetragonal, snout cylindrical, a little crooked, neck short, body small, caudal bladder nearly spherical. *Habitat.*—The peritoneum and plura of ruminating animals, and of swine, especially in sheep, oxen, and goats, in the stag, the roebuck, and gazella. A single instance is cited by Goeze of this species of hydatid having been found in the plexus choroides of an apoplectic human subject.

Sp. 2. *Cysticercus cellulosus*, *Rudolphi*. *Syn.* *finna humana*, *Werner*; *tænia hydatigena ovilla*, *Fischer*; *tænia cellulosa v. finna*, *Gmelin*; *vesicaria hygroma v. finna*, *Schrank*; *hydatis finna*, *Blumenbach*; *vermis vesicularis*, *Brera*; *cysticercus finna*, *pyriformis*, *albo punctatus*, *Zeder*; *tænia hydatigena anomala*, *Steinbach*; *cysticercus finnus*, *Laennec*.

Character.—Body conoid, from four to ten lines in length, caudal bladder ovoid, formed by a thin membrane, equal, transparent, without fibres; head tetragonal, furnished with four suckers, and thirty-two hooks divided into two rows. *Habitat.*—The hog, in which animal it causes the disease commonly known under the name of leprosy.

The word *finna* applied to this species of hydatid is of German extraction, from *finnen*, the name of this disgusting affection. *Werner* is reported to have found this species of hydatid in man.

Sp. 3.—*Cysticercus fischerianus*, *Laennec*. Body round, very slender, annulated; head larger than the neck, furnished with suckers and crooks; caudal bladder pyriform, three or four lines in length, united to the body by its large extremity, and terminating in a point which adheres to the viscous which this worm inhabits. No cyst. *Habitat.*—This hydatid has been found twice in the plexus choroides of the human subject, by *M. Fischer* of *Leipsic*. It is yet but little known.

Sp. 4.—*Cysticercus dicystus*. This worm has been observed but once, and then by *Laennec*; he met with it in the ventricles of the brain of a man who died of apoplexy. It presents two pretty large bladders; one of these is caudal, whilst the other encloses the body anteriorly. This, which consequently is only developed in a bag which forms part of the animal itself, is conical, annulated, composed of an outer membrane of a yellowish colour, rather transparent, and of an anterior substance, white and rather bluish, and almost opaque. It is crossed by a large canal, terminating in a cul-de-sac at the side of the head, but which at the other extremity communicates with the caudal bladder. The number of hooks of the head is undetermined. It has only four suckers.

Sp. 5.—*Cysticercus albo punctatus*. *M. Treutler* is the only person up to the present time who has observed this hydatid; he found it in the

plexus choroides of a woman who died at twenty-two years of age.

The body of this hydatid is three times longer than the caudal bladder. *M. Treutler* thought that he distinguished, with the aid of a magnifying-glass, one sucker and six hooks. The caudal bladder is spherical and sprinkled irregularly with small white points.

Genus 2.—*H. polycephalus*, *Reder*; *cænurus*, *Rudolphi*, from *πολύς*, *multus*, and *κεφαλή*, *caput*. The derivation of the name of this genus explains its principal character. There are two species of it, viz. the *P. cerebralis*, and the *P. granulatus*; but as neither of them has been found in the human species, we shall pass on to

Genus 3.—*H. ditrachyceros*, from *δύς*, *bis*, *τραχὺς*, *scaber*, and *κέρας*, *cornu*. Only one species of this vesicular worm has been noticed, viz. the *D. rudis*. The following is its character: Body oval, a line and a half long, flattened, terminated in a point posteriorly, enclosed in a membranous bladder, furnished anteriorly with a bifurcated horn, which appears rough to the naked eye, and, seen through a microscope, to be thick-set with straight and long scales. In which particular organ is the usual nidus of this hydatid is unknown. The specimens which *Sultz* had an opportunity of observing had been expelled by stool from a young woman after having taken a purgative.

Genus 4.—*H. echinococcus*, from *ἐχῖνος*, *echinus*, and *κόκκος*, signifying a body of a round form with asperities, which characterise this genus.

Sp. 1.—*E. hominis*.—*Character.* Body pyriform, retracted towards the part where it adheres to the common bladder, one row of hooks on the head.

This species of hydatid was first found by *M. Meckel*, and afterwards by *Zeder* in the brain of a young woman. They were about twelve in number, and occupied the third and fourth ventricles.

Of the nature and effects of these hydatids in the human body little is yet known, their characteristic distinctions having been more an object of inquiry amongst naturalists than pathologists. *Dr. Hunter* has remarked, as *Hartmann*, *Tyson*, and *Pallas* had done before, that hydatids taken from a sheep (the *cysticercus tenuicollis*) even twelve and fourteen hours after the animal had been killed, moved briskly with a kind of peristaltic motion over the whole body, on immersion in hot water; and *Sir Everard Home* states that in a similar experiment made by himself, he witnessed a very evident contraction and relaxation of their bodies, with a brisk undulation of the circumambient fluid, which continued for half an hour, and exactly resembled the action of muscles in more perfect animals. (*Croonian Lect. Lond. 1795.*) The author last named submitted animalcules of the same kind to examinations with microscopical glasses of a high magnifying power, but was unable to detect any appearance of muscular structure: he remarked, however, that their coats resembled paper made upon a wire frame, and, as this structure does not belong to membranes in general, considered it to be the organization upon which their motions depend. (*Ibid.*)

Observations are wholly wanting as to the particular effects on the human body of those hyda-

tids already described, and stated to have been occasionally found in it; but it is probable that their morbid agency must nearly correspond to that of any foreign body situated in the same cavity or structure. During life, unless when they are evacuated either naturally or artificially, there appear to be no means of ascertaining that their particular presence is the cause of constitutional disorder, even though, as when they occur within the cranium, it may be severe and irremediable. Under such circumstances therapeutic attention can be directed only on general principles to the relief of sympathetic disorder, and to the maintenance, as far as possible, of the due functions of the abdominal viscera.

Some of the inferior animals, particularly sheep, often become the subjects of disease in which the *H. cysticerci* are generated. A cachectic state of the body, followed by abdominal dropsy, commonly described under the vague and indefinite term *rot*, are the conditions with which their occurrence is most usually observed. Co-existent with them are frequently found pervading the liver and in its ducts great numbers of the flat vesicular worm named *fluke*, *fasciola hepatica*: the small intestines are at the same time blackish, and easily lacerable, and the glands of the mesentery enlarged and indurated; purulent tubercles and cysts containing transparent fluid are also observed to pervade the lungs. Hydatids of the same kind are apt also to be generated within the crania of these animals, giving rise to that singular affection commonly called *gid* or *staggers*, from the particular effect produced on their locomotive powers: their precise situation in this cavity has been frequently discovered by the effects produced on particular nerves and the action of those parts under their influence, indications which have sometimes led to their extraction, to the perfect relief of the suffering animals. Wet seasons, variable temperatures, and watery pasturage, are the causes to which the occurrence of *rot* in sheep, and consequently hydatids, are usually attributed; and Dr. Jenner has proved, by direct experiments made upon rabbits, that the same animalcules could be produced at will by feeding them solely on green succulent food. (See Inquiry into the Nature of tuberculated Accretions. By John Baron, M.D., 8vo. 1819, p. 96.) The production of hydatids in these instances is probably consequent to the general disease induced in the constitution, and its restoration to a healthy state in sheep is often successfully attempted by removing them to a dry and sheltered pasturage, with the exhibition at the same time of muriate of soda, considered the safest and most effectual of all the remedies of this distemper. To relieve the hydropic state of the body which accompanies it, diuretics are given, and it is from their diuretic action, we presume, that fox-glove and spirits of turpentine have been much extolled. Broom, heather, elecampane, and coltsfoot are also popular: and tonic medicines, such as the preparations of iron, have been highly recommended by those who have had the care of sheep thus diseased. How far medicines of the same kind may be useful in the human subject under circumstances apparently similar, we shall not pretend to determine; but direct experience having failed to sup-

ply the requisite information, some hints of practical advantage may be derived from analogy.

The second division of our subject refers to one distinct kind of hydatid which very commonly occurs in the human body, and is a simple bladder, more or less transparent, without any visible fibres or other traces in its organization of animalcular life. It has been considered, however, from some phenomena presently to be noticed, of the same nature as the hydatids already described, and has been classed with them under a name proposed by Laennec, viz. *hydatid acephalocystis*, derived from the Greek words *a*, *priv.* κεφαλή, *caput*, and κύστις, *vesica*.

The shape of the acephalocyst is uniformly round or oval, and in size they vary from the smallest perceptible through every gradation to that of several inches in circumference. Their coats are translucent and composed of a white semi-opaque pulpy matter, separable into two layers of variable thickness, in the same as well as in different specimens. The fluid they contain is clear and transparent like water, but occasionally of a yellowish or amber hue; but their most distinguishing characteristics are, that they are always found unattached to each other or to the cyst in which they are included, together with a fluid very variable in its nature, sometimes consisting of serum, at others of serum mixed with blood, or pus, or both; occasionally of pus only, and now and then of a fluid which has the appearance of dirty water with chalk diffused through it; and it is remarkable that, whatever it may be, it does not affect the contents of the acephalocysts, a fact which has been considered indicative of an assimilative function proper to their tunics, and hence to favour the hypothesis of their animalcular nature. The acephalocyst is sometimes solitary, but in most instances a great number of them are found in the same cyst or sac: the latter is usually of a firm texture, formed of condensed cellular membrane, and consisting of two laminae, the outer of which is strongest and thickest; the inner tender, soft, and pulpy; but together they have a strong contractile power, and have been observed on incision forcibly to protrude their contents. These sacs are sometimes fibrous in their texture, fibro-cartilaginous, cartilaginous, and even occasionally osseous. When acephalocysts, immediately after removal from the body, have been partially divided with a knife, the cut edges have been observed to be immediately incurvated,—a circumstance which has been considered indicative of animal contractility. Adhering to the inner surface of a small proportion of them, several minute vesicles are to be seen, which have the appearance of so many pearls or studs; but examined with a microscope, they were noticed by Hunter to be merely sessile on the tunic, and to be covered by a thin transparent membrane, so as to be interposed as it were between the two. These he considered to be young hydatids, an opinion which Laennec amongst other pathologists also entertains; and that the numerous vesicles, observable with a microscope diffused throughout the fluid of acephalocysts, are of the same nature. They have been noticed in every variety of size, from the two-hundredth part of an inch in diameter to that of a red globule of blood, and

even less: and the coats of the largest to be a little rough, with numerous filaments or villi, which, examined with a deeper magnifier, presented somewhat of a mulberry appearance. "It is not improbable," says Hunter, "that the small globules attach themselves by the villi to the side of the hydatid and to each other, and thereby give the appearance of being covered by a thin membrane. However that may be, the globules being found of various sizes floating in the liquor, seems to prove that they are originally formed there, and not in the coats of the hydatid upon which they are afterwards deposited."

To proceed with the graphic description of the same writer: "The hydatids in their growth and decay appear to pass through various stages; they are first found floating in the fluid that fills the hydatid, and afterwards attached to its coats. The hydatid thus pregnant with young, if the expression may be allowed, adheres to the neighbouring parts, increases in size, and becomes itself a sac, containing numerous small hydatids. These after a certain time decay, and the skins or empty bags are squeezed together into a substance like isinglass. It is probable they still undergo a further change; two small bodies of the size of a common bean, of a cheese-like consistence, and covered with a skin, were taken notice of adhering to the bladder near its neck," in a human subject, in whom the bodies now described were found between the rectum and the organ just mentioned. "It may be a question whether those were not the remains of hydatids; but that must be determined by future observations. It is to be observed that the young hydatids are found in two very different stages; in the one they are attached to the coats of an hydatid that floats loose in the parent bag or sac; in the other extremely small globules adhere slightly to the inner surface of a bag or sac, which is firmly attached to the neighbouring parts, and covered with a strong outer coat. It is obvious that the progress of growth is very unequal in these two, and, indeed, inverted; for in the first the young ones are as large as the heads of pins, while the parent bag is not larger than a walnut, and floats unattached; but, on the contrary, in the second there is a larger sac, with a strong outer coat, and a more tender inner one, adhering strongly to the surrounding parts, while the young ones that are very slightly attached to its sides are not of a larger diameter than a two hundredth part of an inch." Besides the small transparent vesicles already described, Laennec has remarked that on the exterior as well as interior surfaces of acephalocysts, some small prominences (*bourgeons*) of irregular form and variable size are presented to notice. These, we presume, correspond to the mulberry appearance adverted to by Hunter, and are considered by the former distinguished pathologist as nascent hydatids, which in a certain state of growth are detached, the interior increasing the number in the fluid of the acephalocyst, and those from the outside forming so many distinct and separate hydatids in the surrounding fluid. In some instances hydatids (probably of this kind) are stated to have been included in succession to the number of three or four, with the fluid proper to them interposed between the several layers, the last being distended

in the usual manner of single hydatids. An illustrative specimen in a state of transformation, that appeared in the examination of a human body which came under his notice, has been described by Dr. Baron; at least such is our inference from the statement that its section exhibited a series of concentric laminae, resembling very much the appearance of a urinary calculus. (See Dr. Baron's Inquiry, p. 95.) Another instance of the same kind is related by Sir Astley Cooper in his valuable work on Diseases of the Breast, page 41. Their appearance is thus described: when opened, they were found to be composed of numerous lamellae, like the crystalline humour of the eye, or like the layers in the onion, which could be readily peeled from each other.

Acephalocysts have been found in almost every structure and cavity of the human body, but particularly in the liver, the uterus, the kidneys, and cellular tissue; they have been ejected in considerable numbers from the stomach by vomiting, and downwards from the intestines; brought up from the lungs by coughing, voided with the urine, and discharged from tumours in various parts of the body. Pallas seems to allude to their occurrence in the lungs and liver of the ox tribe and other ruminating animals, and Laennec has noticed their presence in sheep.

From the period of Tyson's publication already alluded to, it has been a question which refers particularly to the hydatids we are now considering, whether they are distinct members of the animal kingdom. We have cited pathologists of the highest repute who have supported this hypothesis, and it must be acknowledged that it has obtained an extensive credit; it behoves us, however, to examine the ground on which it is founded, believing, as we have reason to do, that the greatest misconception exists as to the nature of these bodies. Our knowledge of the structure of the acephalocyst has afforded no inference favourable to the conclusion, nor can we recognise any evidence of it in the retraction which is said to take place in its cut edges when divided, such being a phenomenon of mere organic life, and their incurvation an effect which would be mechanically caused in any spherical membranous bag distended with fluid under similar circumstances. Proof has been further sought, but found wanting, on the immersion of acephalocysts in hot water, no contraction having been evinced in obedience to this stimulus, which, as already stated, has occurred most obviously when the *H. cysticerci* have been the subjects of the same experiment. Baillie (*Morbid Anat.* vol. ii. p. 205) and Monro, (*Morbid Anat. of the Gullet*, p. 256.) as well as Hunter, (*Medico-Chir. Trans.* vol. i.) contend that this failure in the anticipated result may depend on the hydatids (acephalocysts) having been allowed to remain a longer time in the dead body before examination, than would be compatible with their vitality, supposing them to be possessed of it. Dr. Monro has also stated that purulent matter proves fatal to hydatids, but if applied to acephalocysts, the assertion involves a *petitio principii* unsupported by facts. It must be admitted that there are phenomena in their economy difficult to be accounted for, from which arguments in favour of their animalcular nature have been advanced;

these we shall mention *seriatim*. 1. Their original production; 2. their growth and increase, without any vascular continuation with surrounding structures; 3. the unvarying identity of their fluid contents under the diversified media of that by which they are found surrounded; lastly, their inclusion, or, as it has been termed, the generation, of others often found in considerable numbers and different sizes within them.

The earliest hypothesis which appears to us to refer to the origin of the particular kind of hydatids now under discussion, ascribes their formation to an altered state of the lymphatics, suggested probably by a resemblance of the fluid proper to them to the usual contents of these bodies. It was supposed that on any accidental impediment to the transit of the lymph, the valvular structure of these vessels would prevent its reflux, and necessarily occasion a distension of its parietes between the obstructed portion and the valve immediately above it; and that, from their natural approximation to each other, a successive distension would ensue, giving rise to an adhesive apposition, or to a complete separation of them in the spherical form of the hydatids now called *acephalocysts*. This view of their formation seems to have originated with the celebrated anatomist Bartholine, afterwards to have been disseminated by Wharton and Nuck, and to have been generally adopted until their promotion, on the score of analogy, from the rank of inanimate to that of animated bodies.

If it be admitted that *acephalocysts* are animalcules, their origin must necessarily be involved in all the obscurity which envelopes the subject of generation in the lowest grade of insects, rendered still more incomprehensible by their natural localities in the bodies of men as well as of the inferior animals, unless, indeed, it be accounted for by the following general explanation, given us by Andral, which, to say the least, deserves considerable attention. "Besides the clot of extravasated blood which, by the experiments of Hunter and Home, has been proved susceptible of organization, it not unfrequently happens," says Andral, "that under the influence of causes more or less appreciable, the fibrine, either alone or accompanied with a considerable proportion of colouring matter, abandons the blood, and escaping from the vessels by some morbid process, finds its way into the adjacent tissues, as is proved to demonstration in the cavities lined by serous membranes. The fluid containing these is not unfrequently found to exhibit certain fibrinous concretions presenting evident marks of incipient organization; and of the same nature, though in a more advanced stage, may the transparent cysts now under discussion be considered, the formation taking place just in the same manner as the coagulum of fibrine, at first an amorphous mass, becomes vascular and organized." As successive links in the chain are placed—the cysticerci and other hydatids in their progressively complicated forms, and next to these the flattened worms, in which the characters of animal life, become much better marked, by the manifestation of unequivocal movements, and by the appearance of different organs as distinct and as well formed as those of the vertebrate animals. In this way we pass by

regular and almost insensible gradations from the simple clot of fibrine deposited in the serous cavity, to the *strongylus* or the *ascaris lumbricoides*; just as during the formation of the embryo we observe it gradually advancing from the state in which it exists as a homogeneous mass, devoid of form or texture, until it acquires all the organs of a perfect animal; and as in the series of animated nature we can trace the development and progress of life and organization from the green matter of vegetables up to man. It appears to me perfectly futile to attempt fixing the point in this series of transformations where what is called animal life commences. If we give the name of animal to the cyst which floats loose in a serous cavity, and is moreover provided with vessels, and if we consent to admit the animal existence of this clot of fibrine, where are we to stop, or where draw the line of demarcation? If we admit to the rank of animal every aggregate of matter which, being developed in the interior of a being endowed with life, is capable of supporting itself, and of increasing in size without having any connection with that being, the serous cysts already described must then be considered as animals, and accordingly they have been described as such by Laennec. But if we only recognise as animals those bodies which present some trace of sensibility or mobility, these cysts then forfeit all claims to that title: so that, in fact, this much agitated question turns out to be a mere dispute of words, which can never be finally adjusted until the contending parties shall agree in their definition of what it is which essentially constitutes an animal." (*Vide Treatise on Pathol. Anat. Trans. vol. i. p. 477.*)

The growth of the *acephalocyst*, it is evident, depends on some property inherent in its membranous portion, whereby it is fitted to appropriate to itself from the surrounding medium the particular fluid proper to it. The process appears to be analogous to that of secretion in serous membranes; but in the latter it must be remembered that red blood is the immediate pabulum of the secretions, whereas in the present instance it is a fluid which has already been eliminated from it; a circumstance certainly favourable to the hypothesis of the parasitic nature of *acephalocysts*, but which nevertheless may be referred to the mechanical process of imbibition, a property belonging, there can be little doubt, to the serous as well as other membranes of animal bodies.

The third division of our subject embraces the simple pellucid vesicles commonly called false hydatids, which are found either partially or wholly in contact with the adjacent tissues, and are supplied directly through them with the fluid by which they are sustained and their growths increased. As they have been usually adverted to in medical writings, they consist either of perfect bladders, capable of being detached without lesion of structure, or else are, as it were, diverticula from the subjacent membranous expansions, from which they could not be separated at their bases without laceration of a part essential to the integrity of one or the other. The manner in which the former are produced is a question yet undetermined, but the following explanation seems to us to be consistent with the knowledge we possess on the subject—that under particular condi-

tions of the system, either general or local, there takes place a deposition of serous fluid, which accumulates in proportion to the distensible nature of the part; but according as the latter is more resistant, an increase of pressure ensues, serving to condense the surrounding cellular membrane into a corresponding envelope, and thus to present an entire cyst. Bichat, however, contends that the formation of the cyst takes place prior to the deposit of the fluid, which, though scanty at first, increases with its growth, and that it is first developed in the filamentous tissue, according to laws analogous to those of the growth of parts in general, to be referred, in his view, to unknown aberrations or unnatural application of those laws. He argues thus against the explanation previously advanced: "1. That cysts are analogous in all respects to serous membranes, and should therefore have the same origin; 2. that the mechanical hypothesis of their origin, in which all the vessels ought to be obliterated, does not accord with the exhaling and absorbing function of cysts, nor with the mode of inflammation; 3. that if these sacs are formed by the mutual application and agglutination or adhesion of cells, (that is, of the filaments,) the contiguous tissue ought to be diminished, or to disappear when they are bulky, which is not observed to take place; 4. that if cysts are formed by condensation of the filamentous tissue, and if their fluid is effused by exhalation, this fluid ought to exist in the organ which separates them from the blood." (Elements of Pathol. Anat. by David Craigie, M.D., 8vo edit. p. 52.)

The second kind are produced by the distension of the interstices of the particular structures or of natural cavities with effused deposits of fluid, and vary, therefore, in nature, according to the texture of the parts in which they are situated, the quality of the fluid being determined anterior to its separation from its depositing vessels. It is, we presume to cysts of this kind, under the denomination of hydatids, that Boerhaave and Haller have ascribed an origin in the follicles of glandular structures; which Monro has treated of as an alteration of the cellular membrane; and in like manner Portal and Broussais as the result of a chronic inflammation of the capillaries which convey the blood deprived of its colouring matter to the cellular membrane interposed between the serous and other textures. Single cysts of this kind are sometimes met with, but frequently they grow in clusters, and resemble bunches of grapes; sometimes they are thickly set on a broad surface, and present a honey-comb appearance; occasionally they are found adhering to each other at their sides, and when crowded on the superficies of an organ having a cavity, or when produced in the same manner from the internal surface of another cyst, they occasionally lose their organic vitality in consequence of pressure at their pedunculated extremities. When single, they sometimes have broad bases, not unlike the vesications produced by a blister plaster, or boiling water, which might with as much reason be called hydatids as the cysts to which we now refer. The contents of these cysts as to quantity vary in every gradation from a single drop even to several pints of fluid, and are found also to differ in nature, being frequently clear, like water, often resembling serum

mixed with blood, and occasionally purulent. To cysts of this kind recent pathologists have applied the term *hydroma*. Examples of it are often found in the female ovary, in which they vary much in size, and also in the colour and consistence of their contents from mere serum, with more or less of albumen, to reddish, bloody, or even tar-like fluid. Their appearance, it is probable, may depend on an altered condition of a particular part, as they have been frequently witnessed in bodies free from disease; but they are often the result of a hydropic state, which is general, when they appear to be produced under circumstances precisely corresponding to those of dropsy. Hence from an early period after the discovery of the lymphatics, their occurrence has been attributed to a morbid condition of this system of vessels; and though the links in the chain of their causes have never been distinctly traced, experience seems to prove that a cachectic state most commonly predisposes to their formation. Although frequently connected with disease which is irremediable, they are in themselves void of all malignant tendency; and their influential action on the organic function seems to be limited to the degree of pressure occasioned by their presence and the nature of the organ in which they are situated.

An hypothesis has been promulgated by Dr. Baron, that the hydatid or vesicular form is the primitive state of the tuberculous and other morbid formations, as the strumous, scirrhus, sarcomatous, steatomatous, and fungous. The period at which these transformations take place he states is very uncertain; that they may commence in a few days after the hydatid is brought into existence, or that they may not occur at all, the original structure continuing for many years. The occasional co-existence of hydatids with such morbid changes is consistent with general observation, and is confirmed by the undoubted testimony of several pathologists cited by Dr. Baron. Proof, however, is wanting that the one state is commonly consequent to the other; and supposing the elementary particles of such morbid growths to be deposited in a state of fluidity, we see no reason why they should be regarded as hydatids. On the same principles, we conceive, might every globule of blood or every collection of fluid be similarly classed, and thus the real nature of the product be lost sight of in the extension of a term already too vague and indefinite. Moreover it seems very improbable that morbid products arising under a diversity of constitutional circumstances, and manifested by appearances as well as producing effects as different, should at any intermediate stage evince a perfect identity of character.

To Dr. Baron's work, however, we refer for the full elucidation of his views, which could not be transferred to this place without obliging us unreasonably to exceed the necessary limits of this article; and we do so with the less reluctance, because, whatever may be the reader's conclusion, he cannot fail to benefit by the consideration of the facts and reasoning with which Dr. Baron has supported his positions.

It has been already stated that hydatids have been found in most of the structures of the human

body:* we shall now proceed to the practical consideration of them according to their several localities.

Hydatids in the brain.—The presence of animalcular hydatids in the human brain has been rarely noticed, but the occurrence of cysts under this denomination has been very frequently referred to by medical writers. Their real nature it is impossible to determine during life, but their effects are found to be similar to those from any other foreign bodies in the same structures, passing on from those of nervous irritations to the partial impediment and abolition of the functions of the parts under their influence, and ultimately in most instances, it is to be feared, to death.

An instructive illustration has been given to us by Dr. Abercrombie, in the following case submitted to him by Mr. Headington:—A boy, aged eleven, was suddenly attacked with dimness of sight, amounting to blindness. It went off in a few minutes; but from that time his sight was gradually impaired, and after a year nearly lost. He then had an affection resembling chorea, and after a short time suffered an attack in which he lay speechless for three days. This was followed by hemiplegia of the right side. He complained much of his head, which appeared to his friends to enlarge, and he sometimes lost his speech for two or three days. His intellect was not affected, but at times extremely acute. He died, after coma of five weeks' continuance, about a year after the attack of hemiplegia, and two years from the commencement of the disease.

Dissection.—On the surface of the left hemisphere, the membranes adhered firmly to the surface of the brain for some extent on the middle lobe. On raising them at this place fluid escaped in great quantity, and on further examination it was found to have been discharged from the cyst of an immense *hydatid*, which was seated in the left lateral ventricle, and had gradually advanced to the circumference of the brain. It contained about sixteen ounces of limpid fluid, and besides these there were several ounces in the proper cavity of the ventricle. (Researches on the Pathology of the Brain, by John Abercrombie, M.D. Part iv. Case 29.)

* Experiments on the nature of the fluid constituent of hydatids have not been sufficiently numerous and diversified to determine how far our knowledge of the subject may be advanced by the aid of chemistry. Dr. Marcet, in "an account of various dropsical fluids," (Med. Chir. Trans. vol. ii. p. 373.) has thus described his analysis. "A quantity of this fluid was procured from a hydatid attached to the kidney of a woman, whose body was opened by Mr. Cooper and myself at Guy's Hospital. It was clear and transparent, though of a yellowish colour. No coagulum or turbidity appeared on adding dilute sulphuric or muriatic acid, but concentrated muriatic acid produced a milkiness. Infusion of galls and oxy muriate of mercury occasioned precipitates. Heat did not produce any coagulation except after very considerable concentration. The specific gravity of this fluid was not ascertained, but a thousand grains of it being evaporated to dryness, at a temperature not exceeding 180°, the residue weighed thirty-six grains, and yielded by incineration a saline mass weighing 8.7 grains. This saline mass contained the usual ingredients; namely, muriate of soda crystallized chiefly in octahedrons, phosphate of iron and of lime, and a small portion of sulphuric acid. Upon the whole, this fluid, which was examined long since, and with much less minuteness than the other, appears to resemble much in its chemical composition that of hydrocephalus and spina bifida, only containing a larger proportion of animal matter, which appeared to be chiefly of the mucus-extractive kind, since it did not coagulate by heat or gelatinize by cold or concentration."

In an examination of the brain of a man who died on the fifteenth day of synochus, we discovered not long since a pellucid cyst, full of transparent, yellowish, limpid fluid, lying close to the base of the brain at the side of the tuber annulare. Its size was that of a plover's egg, but during life there were no particular symptoms to indicate the presence of such a body. It would be to little purpose to go on enumerating similar instances of morbid formation. We refer, therefore, to the several works on general pathology, especially to those of Bonetus and Morgagni, and to the very valuable work entitled Elements of Pathology, recently published by Dr. Craigie, in which (page 477) references are given to several remarkable instances of similar encysted bodies found within the cavity of the cranium, and imbedded in the substance or cavities of the brain.

It is obvious that medical treatment under such circumstances must be limited to the relief of the organ oppressed, and to the suitable regulation of the functions of those which, primarily influenced by external agents, exert a corresponding action upon it. The means of effecting these objects could not be defined for general application, even if the cause of the existent disease were ascertained; but latent as it must be, alleviation of the consequent symptoms can be rationally attempted only by a reference to the general principles of therapeutics.

Hydatids in the thorax.—The lungs, though not often the nidus of hydatids, have occasionally been found to contain them; and instances are related of acephalocysts having been ejected from this organ by coughing. Their presence usually excites considerable irritation, and gives rise to cough, pain, dyspnoea, and quickness of pulse; but we are unacquainted with any particular symptoms by which their existence here could be positively ascertained. A case in which their expulsion from the lungs was followed by complete recovery has been recorded by Dr. Doubleday, in the fifth volume of the Medical Observations and Enquiries, by a Society of Physicians in London, 1779; and another by Dr. Monro, unattended with any pulmonary symptoms except that of pain on the right side of the chest behind the mamma, and which was not relieved by bleeding or the application of a blister. In this particular instance there was no sense of oppression nor difficulty of breathing, nor any alteration in the state of the pulse, and the patient could sleep on either side or on his back. By coughing he was relieved of portions of hydatids, and also of some entire, varying from the size of a hazel to that of a walnut, and in quantities amounting at times to as much as would fill a pint measure. The larger hydatids contained a fluid which was clear and viscid; in the smaller it was of a yellow hue and reported to have been bitter to the taste. A few days before their ejection the patient suffered very acute pain in the breast, which he compared to that of the penetration of a pointed instrument. The previous fits of coughing were violent and attended with paroxysms threatening suffocation which continued for two or three minutes. These effects were first manifested when the patient was fourteen years of age, and occurred at intervals for seventeen years, when at length he was attended

by the present Dr. Monro and his father. Having been recommended to smoke tobacco and to inhale the fumes as deep as he could into the chest, the symptoms appeared to be arrested, and for the following eight years he was known to have remained free from any return of the disorder. (See *Morbid Anatomy of the Human Gullet*, by Alexander Monro, M.D. 8vo. edit. 1811, p. 279.)

Instances are on record of hydatids having occasionally passed through morbid perforations in the diaphragm into the thorax. In the first volume of the *London Medical Communications*, we read an account of a post-mortem examination in which "a common cyst found to contain a quantity of them, and attached to the liver, omentum, mesentery, and peritoneum, passed through a perforation in the diaphragm; from thence expanding again, it adhered to the plura and mediastinum, filled almost the whole of the left cavity of the thorax, and communicated in several places with the lungs, which were ulcerated. Had the patient lived long enough, it is possible that hydatids would have been coughed up, as one of the openings from the cyst into the lungs was large enough to admit a goose-quill." In the substance of the liver, which weighed sixteen pounds and a half, another large cyst was found. A similar case is related in the *Edinburgh Medical and Surgical Journal*, vol. ii. p. 170, in which, "an immense cyst occupying the whole cavity of the abdomen" was found after death connected to the mesentery. It was distended to the utmost, and contained thirty-five pints of hydatids, many of them exceeding the largest oranges in size. In both these cases the disease was supposed to be common ascites during life, and in both a fruitless attempt was made to draw off the fluid by tapping. An instance somewhat analogous has been recorded by Dr. Collet, (*Transactions of the College of Physicians*, Lond. vol. ii.) in which hydatids originally lodged within the liver, were discharged by coughing: the patient, a female, aged thirty-seven, "first complained of lowness of spirits and of an oppression on her breath," followed by some œdema of the ancles, which, however, soon disappeared. A violent cough, attended with great dyspnoea, and the occasional expectoration of tough viscid phlegm, soon followed, and the subsequent ejection by coughing of hydatids at different periods in the course of six months, amounting to the number of one hundred and thirty-five: these varied from the size of a pea to that of a pullet's egg, and were in their ruptured state, no water either accompanying or following them: there had been a swelling at the umbilicus evidently containing fluid, and distension of the whole abdomen, which in parts communicated to the hand of the examiner the sensation of lumps; these, however, had disappeared, and the case promised a favourable issue. Another instance of the same kind is related in the *London Medical Journal*, vol. vi. p. 593, 1785. A lady, during an illness which continued more or less for three years, "coughed up several hundred of hydatids, most of which were burst, and of these many must have been as large as a pullet's egg: those which were not burst were only about the size of a nutmeg." This patient was considered dropsical, and to have disease of the liver; she, however, recovered her health.

It is probable that the bronchi are very rarely if ever the original seat of hydatids, but that they are passed into their ramifications from the parenchyma of the lungs and the pleura, or from other structures, as in the cases above related; but, under whatever circumstances, we may generally anticipate recovery if their expulsion through this channel has commenced, provided that other diseases be not co-existent, when of course the probabilities of the issue must depend on the nature and circumstances of the latter, and the remedial means be applied accordingly.

"Although," says Andral, "instances are not uncommon of animalculæ having been found in the vascular system of quadrupeds, I know only of a single occurrence of this nature in the human body." The subject was examined by himself at La Charité. "I found both lungs," he writes, "filled with hydatids, and thought that these *entozoaires* were lodged in the parenchyma of the lungs; but a more close examination disclosed the existence of hydatids in the pulmonary veins of both lungs. They had all the characters of acphalocysts. Around them the pulmonary tissue was in some cases sound and crepitating; in others obstructed and hepatized. An hydatiferous cyst, with cartilaginous parietes as large as an orange, existed in the middle of the liver, and contained from eight to ten hydatids. The individual who was the subject of this case was fifty-five years of age, for a year previously had been ill-fed, and often experienced considerable distress. The symptoms of an aneurism of the aorta under which he laboured were the object of therapeutic attention during life; and from the post-mortem examination, the latter appeared to be the effect of impeded circulation, consequent to the presence of hydatids in the pulmonary veins." (*Andral's Pathol. Anat. Trans.* vol. ii. p. 424; and *Med. Repos.* vol. xix. p. 347.)

Hydatids in the Abdomen.—Hydatids have been frequently found in the several viscera of the abdomen, occasionally attached to the peritoneum, and sometimes loose, either between it and the abdominal muscles, or amongst the viscera themselves.

Except the kidneys, the liver is more frequently affected with hydatids than any other organ, and in sheep as well as in some other quadrupeds, under the particular circumstances of wet seasons and marshy pasturage, this appearance of disease is apt to prevail very extensively. In the human species corresponding causes have not been observed to influence their formation, although there is reason to believe that a cachectic state of body has been conducive to it. Symptoms of a disordered liver to a greater or less extent are usually present; occasionally the same effect is produced as when a calculus is passing through the gall ducts, viz. violent spasmodic pain at the epigastrium, frequent vomiting, with an unaccelerated pulse, and sometimes jaundice alternating with intervals of good health.

When hydatids are confined within the substance of the liver, there appear to be no means of ascertaining their existence; but when formed on its outer surface near its lower edge, it is probable that they may be detected by examination. When, however, the parietes of the abdomen are

thick, and hydatids or their cysts not distinct, but lying in contact with each other and making an irregular tumour, it will hardly be possible to form an accurate opinion of their nature. If the tumour be gradually formed, and the general health little affected, it is probable that hydatids may be the cause. Close attention to the sensation which the tumour yields on pressure or on striking it gently with the hand, may also assist in enabling the examiner to form a probable idea as to its nature. If it should consist of hydatids, it will generally feel to a certain degree soft; and if the hydatids should be very large, there may be an obscure sense of fluctuation on striking the tumour with one hand while the other is applied to the opposite side of it. If, moreover, it should occupy a great part of the cavity of the abdomen, and can be clearly traced from the liver as the source of its growth, there can be little doubt of hydatids being the cause. (See Works of Matthew Baillie, M.D. vol. ii. p. 212.)

Some instances have already been referred to in which hydatids had passed through a perforation in the diaphragm from the abdomen, and were ejected by coughing from the lungs: they have occasionally also been evacuated from abscesses, and sometimes from the abdomen with the fluid discharged by tapping; in the former most frequently to the complete relief of the patient. The circumstances under which they thus occur being variable, preclude any specific character being given of them, and therefore must be illustrated by example. A female was treated with mercury under the supposition that hepatitis and consequent suppuration in the liver had taken place. In about ten days the mercury began to affect her mouth, and at the same time she voided an incredible quantity of the *tæniæ hydatigenæ*, or hydatids, by stool and vomiting, calculated by her attendants to amount to a thousand, varying in size from that of a small pea to an inch and a half in diameter. An hepatic abscess afterwards opened externally, a gall-stone was discharged from it, and she ultimately recovered. (Lond. Med. Journ. vol. x. p. 7. 1789.)

An instructive case of the same kind is related by Mr. Gaitskell, of Rotherhithe, in the fourth volume of the London Medical Repository. The patient, a married female, aged thirty-eight, had been under treatment for hepatic disorder with inflammatory symptoms, and, a short time after ptyalism was induced, began to void biliary calculi, which in three months amounted to forty-seven in number, and with them hydatids not less than a thousand, varying from the size of a grape to that of a peach. At the date of the report the patient was convalescent.

An example of fatality occasioned by a sac of hydatids situated in the porta or the liver, which by its pressure on the vessels produced complete obstruction and jaundice, is related by Dr. Duncan, Sen., in the Edinburgh Medical and Surgical Journal, vol. iv. p. 137.

Hydatids which are ejected from the stomach or discharged from the alvine canal, have in most instances been generated in the liver, but occasionally it is probable that they have passed from their common sac in consequence of its adhesions

to, and resulting communication with, some part of this tube: they may be transferred in the same manner, we conceive, from the other abdominal viscera, but having found an exit through this channel, recovery so commonly ensues, that the opportunity of proving the truth of the remark by ocular inspection can rarely occur, nor can we adduce any such positive testimony in support of it.

From the co-existent disease, rather than from the presence of hydatids in the liver, the judgement of the practitioner must be formed as to the issue; and the requisite treatment of the patient must necessarily be influenced by the same circumstances. The hepatic disorder will generally be such as to render the exhibition of mercury necessary, and the stimulating effect of this remedy on the absorbent system renders its use, at all events externally, of considerable importance in the removal of hydatids, whether situated in the liver or in any other of the abdominal viscera.

The presence of hydatids in the spleen is an occurrence which has not often been noticed: during life the symptoms occasioned by them in this organ are too obscure to be recognised, and can never become the specific object of medical treatment. We shall subjoin a remarkable case of this kind in preference to any discussion which we cannot found on experience.

"A labourer, thirty years of age, of a phlegmatic habit, after lifting a heavy load, complained of pain in the chest, accompanied with cough and much debility. Two months afterwards his legs began to swell; he spat blood twice, a little at a time, which degenerated into a purulent expectoration of a bitter taste. He now applied for medical assistance, under the idea of his disorder being the first stage of pulmonary consumption. His pectoral sufferings abated, but the œdema increased, and the parts became erysipelatous, but soon changed their colour again on the application of dry aromatic fomentations; and the œdema subsiding on using twice anti-hydrotic medicines, the patient thought himself cured. A short time after, however, when he had been at hard labour, the spitting of blood returned, and he complained of stitching pains in the chest; the scrotum was swelled, the pulse very slow, and digestion disturbed. These symptoms were also attended with headach. The pectoral sufferings were again soon removed, but the dropsical swelling remained, and a painful, hard, circumscribed tumour, beginning in the left hypochondrium, and extending upwards to the xiphoid cartilage, now made its appearance, which, with the obstinacy of the dropsical swelling, induced Dr. R. to make use of drastic medicines. An abscess now formed over the right knee, which effused a considerable deal of ichor; but the dropsy increased, and the patient at last died suddenly after a long ambiguous state of health.

"Dissection.—The greatest mark of disease was found in the spleen, which was unusually distended, and weighed about nine pounds; and a tendinous place was found in its centre, about the size of a hand, from which, on being cut open, a great quantity of water escaped, with a number of globular vesicles, varying in size from that of a millet-grain to that of a duck-egg, containing

partly a clear liquid and partly a friable substance, which by the help of a magnifying-glass exhibited other small vesicles. Many of them were burst asunder and dried away. The bag containing these bladders divided the disorganized spleen into two halves, formed by an aponeuritic membrane, from half a line to two lines in thickness, interwoven with the substance of the viscus, and furnished with very swollen blood-vessels. It ran obliquely through the spleen, so that its larger half lay to the left and upwards, and the smaller to the right and downwards. All the other viscera were healthy, except that some water was contained in cavities caused by serous membranes." (Lond. Med. Repos. vol. vi. 1816, p. 332. Extracted from Horn's Journal, 1815.)

The pancreas is still more rarely the seat of hydatids than the spleen, and it is probable that their occurrence in this organ can only be ascertained by post-mortem examination.

Of the various organs of the body, the kidneys are more frequently than any other affected with hydatids: these for the most part are simple cysts produced in their peritoneal covering, and on inspection present an appearance resembling bunches of grapes: they may exist to a very considerable extent without manifesting any distinguishing characteristics of their presence during life, and without at all affecting the quantity or sensible qualities of the urine. Sometimes, however, though rarely, acephalocysts have been found to pervade these organs, but no particular symptoms have been evinced to render their presence recognisable during life. Pain is commonly felt in the loins during their formation; there has also been remarked symptomatic fever, nausea, and vomiting, but these are symptoms which belong also to other diseases: they have occasionally, however, been passed through the urethra, and in such instances have sometimes occasioned dysuria from interruption to the passage of the urine, either in the ureters, the neck of the bladder, or in some part of the urethra. (Works of Matthew Baillie, M.D. vol. ii. p. 257.)

One or more acephalocysts having been passed with the urine, a continuance or repetition of the precursory symptoms, or the subsequent occurrence of dysuria, will be almost certain indications that others are in their transit; and even if the same symptoms should have been caused by the passage of renal calculi in a subject prone to the latter formation, the treatment during the paroxysm consequent to the obstruction will alike be directed to the relief of an organic channel thrown into a state of spastic contraction in consequence of unnatural distention. The symptoms of acephalocysts in these as in other organs will be variously modified by other disease with which they are almost always connected, particularly, and most frequently perhaps, abscesses following blows or other injuries. On this account, therefore, it seems to us that examples are essential to an intelligible description of the morbid states in which their presence is evinced. We subjoin the following as particularly illustrative of renal acephalocysts.

"A gentleman, aged 32, was thrown from his horse in February 1780, by which he received an injury on the loins, and had considerable hematuria in consequence. After the first fortnight he

experienced no further inconvenience until the June following, when he complained of cough attended with bloody expectoration, which he ascribed to the previous accident; but from a little attention he recovered, nor experienced any symptom of his late disorder until about three years afterwards. In December 1783, he was attacked with rigor, and felt a return of severe pain in the loins, extending to the region of the left kidney: in a few days he perceived an enlargement in the hypochondrium, which continued gradually increasing until the latter end of February 1784, a space of nine weeks: after the first month, the tumour was so little painful that the patient was enabled to travel to London, a distance of one hundred and thirty miles, to consult Dr. Lettsom, by whom the case is detailed. Upon examination the tumour, which was as large as an infant's head, was found to contain fluid: it extended from the vertebræ of the back along the left hypochondrium to the umbilical region, and occupied the whole space from the ribs to the *os innominatum*. The pain increased with the swelling, and was aggravated by exercise or motion, but was relieved by an anodyne, "till at length some difficulty of making water came on, and for many hours a total obstruction: in this situation surgeons of the first eminence were consulted, to determine how far it would be advisable to make any incision in the side and perforate the cyst, in order to take off the pressure on the bladder, and obviate the fatal event which the retention of urine threatened: this was on the 20th of February; the result was, that, from the uncertainty of the situation of the tumour with respect to the intestines, which were suspected to take a curve over its anterior surface, as well as from the risk of exposing such parts to the external air, the operation was protracted, and the usual opiate of the patient was ordered to be increased in the evening, which was the chief remedy besides the use of cicuta and anodyne clysters. He passed a painful night, suffering frequent and violent rigors, but early in the morning experienced the most happy relief by a discharge of a large quantity of thick pus with the urine, which was followed the next day by that of pus and numerous hydatids.

"In a few days the tumour subsided, and the purulent discharge ceased; after this he continued recruiting in strength for nearly a fortnight, when his side enlarged again after exercise in a coach, probably by a large hydatid stopping up the ureter; rigors and strangury succeeded as before, and the tumour became as large as in the first instance, till the latter end of March, when he experienced a second discharge in every respect like the former, except that the hydatids were much larger. His health and strength again returned, until his side filled a third time after exercise on horseback, and continued swelling until the 25th of April, when he was again relieved by a third discharge of hydatids, and these were considerably larger than those of the preceding attack. The passages now became so open that he frequently discharged the hydatids, after walking or riding, without enlargement or pain of side; or, if he felt uneasy, or perceived a tendency to tumescence, by pressing his hand upon the side he could squeeze them into the bladder, where

they would remain some time before they were discharged; but the hydatids became at length so considerable in size that it was with great difficulty they passed the urethra. The last that he voided was on the 12th day of July, which was so very large that it stopped up the urethra, and remained in it for a considerable time, until the weight of the accumulated urine forced its way. The earliest hydatids burst in their exit; they gradually increased in magnitude in every successive discharge, the first being not larger than a pea, and the last about the size of a pullet's egg. After the last mentioned discharge his health gradually recovered, and the patient enjoyed, without the least inconvenience, the chase and every other species of exercise as well as ever he did.

"During the whole progress and termination of the disease very little medicine was administered, except cicuta, gum arabic, clysters, and anodynes. He once took an emetic when the tumour became uneasy, previous to the second discharge, and which seemed to hasten the eruption of hydatids. Bark was tried, but with manifest inconvenience, between the eruptions, and was left off. After the last discharge it seemed beneficial, as well as asses' milk." (Memoirs of the Medical Society of London, vol. ii. p. 33. 1789.)

From the history of the disease there remains very little doubt but that it originated in the kidney, where the suppuration was extended to an amazing degree, till at length the pus, breaking through the cyst in which it was contained, passed into the ureter, and was thereby conveyed into the bladder.

A temperate man had been for some years subject to paroxysms of pain in the region of the right kidney, which appeared to descend in the course of the ureter of the same side, and ceased after discharging by the urethra some membranous bags (acephalocysts) of different sizes, some whole, but others broken and empty; there were considerable intervals between the paroxysms, during which the patient enjoyed perfect health; but the latter, from recurring every four or five months, had now increased in frequency, and the hydatids in size. The patient had suffered thus for ten years previous to the date of the above report, but at first their discharge was attended with a sense of weight or pressure rather than of pain, preceded sometimes with slight rigors. These discharges, together with purulent matter, at length recurred as often as five times within a twelvemonth, accompanied with increasing pain preceded by a sense of fulness in the region of the right kidney; for three years there was a cessation of the above symptoms, reasonably attributed to continued attention for four months to the following prescription of Dr. Lettsom:—

R Extr. cicutæ et pilulæ sapon. āā ℥i. fiant pil. xxiv. cap. ii. omni nocte.

R Elect. lenitiv. ℥i.

Æthiop. mineral. ℥ss.

Syrupi simpl. q. s. ut fiat elect. de quo cap. magn. nucis mosch. prout venter postulat verit.

R Uvæ ursi ℥iiss. coque ex aq. font. ℥ix ad ℥vi. sub finem coctionis addendo rad. glycyrrh. ℥ss. et cola.

R Liq. colati ℥iiss.

Tinct. stomach. ℥i. fiat haustus bis per diem sumendus.

Three years having elapsed, the report states that after some considerable pain in the back, he voided again several more hydatids, of a longer size than formerly, to the basis of which, or that part which appeared to have been attached to the kidney, some sabulous matter adhered; he discharged several more at different periods, but had experienced such amendment from the use of the same prescription, the powder of uva ursi only having been substituted for the decoction, as to give a fair promise of perfect recovery. (Memoirs of the Medical Society of London, vol. ii. p. 43. 1789.)

For another instructive case of the same kind, related by Dr. Alexander Russel, the reader is referred to the third volume of the Medical Observer and Enquirer, published by a Society of Physicians in London, 1767. In this instance the patient retained his health, though at intervals he discharged hydatids with his urine occasionally mixed with purulent matter and streaked with blood; these at first are stated to have been round, "of the size of a common garden pea, with a small stalk." The patient about ten years before, when at school, had experienced "some violent complaints in the urinary passages, when he voided dark coffee-coloured urine with great pain." Dr. Baillie has given us an account of the dissection of a case in which the right kidney of the body of a man who had been a soldier was converted into a bag, capable of containing at least three pints of fluid, full of hydatids (acephalocysts) differing from a pin's head in size to that of an orange, and only a small part of the kidney retained its natural structure. (Morbid Anatomy.)

When hydatids have been passed into the bladder, irritation to a greater or less degree is excited to propel them with the urine, and it is probable that the exceedingly thickened state of the parietes of this organ in those in whom they have existed has been occasioned by increase of action, as was suggested by Dr. Baillie in the above-mentioned instance. In another related by Tyson the same effect was observed to have been produced: in the latter the cysts or sacs (acephalocysts) were twelve in number, varying from the size of a goose's to that of hen's eggs, and distended the bladder to the size of a child's head, though little or no urine was contained in it: the ureters are stated to have been impervious at their vesical extremities, but distended to the calibre of the intestines of a child, and at their renal extremities to the size of a hen's egg, the kidneys themselves being of their natural size and figure, but resembling rather large bags than fleshy substances: the cavity of the pelvis (whether of one or both kidneys is not stated) contained above three ounces of fluid. The liver, lungs, and heart of this individual were considerably diseased, and polypi were observed in the aorta and pulmonary vein. (Philosophical Transactions, No. 188, p. 332. 1687.)

Hydatids have occasionally been found between the bladder and the rectum, as in the case already referred to, which came under the observation of

Dr. Hunter,* and had occasioned only the particular symptoms of dysuria and distension of the abdomen: the patient, a man forty-six years of age, died suddenly, and on post-mortem examination the bladder was found to be enormously distended, reaching full eight inches above the pubis, its fundus having risen to within two inches of the arch of the colon; it contained between five and six pints of urine, and the hydatidous tumour was found between the neck of the bladder and rectum, completely filling the pelvis, and thrusting the former forwards and upwards. (*Medical and Chirurgical Transactions*, vol. i. p. 35. 1793.) It was remarked by Dr. Hunter that the prejudicial effects of the hydatids in this case were limited to those of mechanical pressure, and that of the numerous cases related by writers hardly any had proved fatal when an outlet for them was procured.

The peritoneum and its various duplicatures are occasionally the nidus of hydatids, i. e. of acephalocysts and those of the simple encysted kind, but rarely if ever without implication of disease of one or more of the subjacent viscera: it is probable that the development of the hydatids takes place under the different states of cachexy arising from a depressed condition of the vital powers, from the combined circumstances of constitutional diathesis and chronic disease, and not unfrequently are the consequence of inflammation of this membrane taking place under the same circumstances as ascites, with which they are commonly co-existent: the pathognomonic symptoms are thereby rendered extremely obscure, and there appear to be no other means of detecting this morbid process than by manual exploration of the abdomen, and thus only when there is an inequality in the surface, and a partial fluctuation can be perceived on altering the positions of the patient.

The constitutional symptoms complicated with those of the local disease are generally such as to betoken a fatal issue in the human subject, should the real nature of the distension of the abdomen from this cause be ascertained during life; but when the hydatiferous sac is situated between the peritoneum and muscular parietes, adhering to and distending the latter into a tumour, or, in fact, an abscess, as most frequently happens, an artificial opening will be the principal means of relieving the patient; and if this be the only disease, a favourable issue may almost always be anticipated. A sense of unequal fluctuation communicated to the hand of the examiner will be the only method of distinguishing the general nature of this from other tumours; and if the fluid of the common cyst is purulent, it will have the common characteristics of an abscess, the presence of hydatids being concealed until the latter be emptied of its contents, as will generally be the case also, whatever may be the particular nature of the contained fluid. The same observations will apply also to any part of the muscular structure with which formations of this kind may be connected.

Cysts commonly denominated hydatids sometimes constitute the bulk of tumefied ovaria, and

are probably formed by the progressive enlargement of the small vesicles which belong to their natural structure; they often acquire an immense size in this organ as well as in the uterus, and vary frequently in their construction, some of the larger cysts enveloping smaller ones, and thus resembling acephalocysts, with which they have not unfrequently been confounded. The inner, however, will be found to be reflected from the outer cysts, like the serous membranes when they are reflected off from the internal parietes of cavities upon the organs contained in them, and to receive from them a continuation of vascular structure; in this respect differing essentially from the isolated state of acephalocysts, and always sufficiently distinctive of the latter kind of vesicular bodies. Though there appears to be no reason why acephalocysts should not constitute ovarian disease, we are not aware of any instances of the kind being on record; and as the preceding morbid condition more properly belongs to ovarian dropsy, and will be discussed under that head, it is not requisite to enlarge upon it here: we have to notice, however, that the suspicion of such an instance in a female forty years of age, who had the symptoms of ovarian dropsy, but attended with more pain than is common in that disease, has been recorded by the present Dr. Monro as occurring within the observation of his father: about a fortnight after the patient had been seen by him, the tumour subsided in the night, and the patient told him "that she had passed several watery stools with skins in them."†

Hydatids of the uterus constitute a morbid condition of this organ, very frequently referred to in medical writings, but it is probable that they are invariably attached cysts, and never acephalocysts. They are described by Baillie (*Morbid Anat.*) as vesicles of a round or oval shape, with a narrow stalk to each, by which they adhere on the outside to one another. A large one has generally a number of small hydatids adhering to it by narrow processes, and in the same manner to the uterus, by small filaments; and portions of a substance resembling blood and coagulating lymph are frequently mixed with them. A similar substance is attached to the internal part of the uterus, from which the footstalks of the hydatids grow. As these increase in number, they distend the uterus in proportion, and at length by their quantity stimulate it to contract upon them. "The cause of this complaint has not been ascertained; it sometimes appears as a morbid condition of the opaque membranes of the ovum; and in such cases, interfering with its functions, it destroys the vitality of that body, and thus produces abortion.

"It is probable that the existence of pregnancy is not necessary for the production of this disease; and perhaps a morbid condition of organized coagulating lymph may, under certain circumstances, have the power of originating it, but what these circumstances are is not known. It may admit of a doubt whether, in consequence of the morbid condition of the ovaria, some separation of the corpora Graffiani may not induce the complaint." Hydatids of the uterus, when arising

* Dr. Hunter has suggested that they may have escaped from a ruptured orifice of a sac originally formed in the spleen, and passed by simple gravitation into the pelvis.

† *Morbid Anatomy of the Gullet, &c.*, by Alexander Monro, M.D., 8vo. Edin. 1811, p. 273.

from the destruction of an ovum, are preceded by the symptoms of pregnancy common to the period before this change takes place, and the time when it happens is marked by the breasts becoming flaccid, and the sickness and symptomatic effects of pregnancy going off; but of themselves they do not appear to produce any peculiar symptoms, with the exception of one to be mentioned hereafter. The greater number of inconveniences attending the disease arise out of the pressure made by the enlarged uterus upon the subjacent parts, such as retention of urine from compression of the urethra, constipation of the bowels from compression of the rectum, œdema, and cramp of the lower extremities. These symptoms, however, are not necessarily present, and instances have occurred in which they have been altogether wanting.—When the pelvis can no longer contain the enlarged uterus, that viscus will rise into the abdomen, and may be felt as a circumscribed tumour through the parietes.

The function of menstruation is usually interrupted as in pregnancy: on examination the body of the uterus will be found enlarged, and suddenly bulging out from the upper part of the cervix. All these symptoms, however, attend other enlarged states of this organ; but besides the absence of the movements of a fetus, usually felt by a pregnant woman, the size of the belly and state of the womb rarely correspond with the supposed period of pregnancy, and from this condition as well as other diseases, it is especially characterized by the discharge of an almost colourless watery fluid. "This watery discharge is to be distinguished from that which attends the cauliflower excrescence, by the irregularity and suddenness of its appearance and cessation; being produced by a rupture of one or more of the coats of these hydatids, in consequence of the occasional contraction of the uterus upon them, or of any sudden violence, as in the act of coughing or sneezing; whereas the discharge from the cauliflower excrescence being a secretion from its surface, is constantly escaping. It may be distinguished also from those splashes of urine which sometimes come away from pregnant women, by being wholly inodorous."

When the uterus is excited to contraction upon hydatids, the process resembles that of incipient labour, for which it has unfortunately been mistaken even by experienced practitioners: "the os uteri is dilated; the hydatids are expelled by periodical pains; and then for the first time danger presents itself in the form of alarming hemorrhage. This hemorrhage is more frightful than that which follows the removal of the placenta from an uncontracted uterus; and the reason is obvious—the placenta covered only a limited space of the internal surface of the uterus, whereas the hydatids spring from every portion of the cavity. (Observations on Diseases of Females, by Charles Mansfield Clarke, part ii. p. 116.) In some cases milk is secreted after the hydatids are expelled, and occasionally pain in the hypogastrium with febrile symptoms follow.

The uterus is sometimes distended by a single hydatid or cyst to an enormous size, but this variety is very rare, for the very experienced author above cited, to whose invaluable work we are most largely indebted for our information on this part of

the subject, has stated that such an instance has never come under his observation, and concludes, from the accounts given of it, that its effects are purely mechanical. From the equality and size of the enlargement "it would be difficult to determine whether it were produced by a single hydatid, or by a deposit of solid matter in the substance of the uterus. The fluidity of the contents of the tumour does not necessarily cause a sensible fluctuation of these contents. A full bladder felt above the pubis does not give to the hand the sensation of a fluid being contained within it. The discharge of a watery fluid in large quantities is in this variety of the disease the first announcement of its existence and the presage of its speedy removal.

"The water having escaped, the cyst is expelled, and the disease terminated without the occurrence of those distressing symptoms which threaten the patient's life in the disease first described.

"This last variety being very uncommon, the practitioner will hardly be prepared for its occurrence, and the patient expecting it to be of long continuance, will be agreeably surprised by an expeditious and favourable termination of her complaints.

"Examination by the finger will enable the practitioner readily to distinguish the single hydatid from the more formidable disease, fleshy tubercle; a discrimination of importance in forming the necessary prognosis, though symptoms arising from both forms of disease demand similar modes of relief."

It is probable that distention of this organ by hydatids is the particular condition to which some writers have referred under the term *hydrops uteri*; for it seems impossible from its natural position with respect to its aperture and fundus, that any large accumulation of fluid could take place, and continue for a length of time in it, unless enclosed in a cyst. Such is the expressed opinion of the writer above cited, and that neither he nor Dr. Denman should have witnessed such an instance appears to us evidence almost conclusive.

The presence of a tumour consisting, as suspected, of a bag of hydatids situated between the neck of the uterus and the rectum, has occasionally been found to interfere considerably with the process of parturition, but the nature of its contents it would appear impossible precisely to determine either before or after delivery, unless an opportunity were afforded by a post-mortem examination. A tumour of this kind would occasion little pain in its growth other than that arising from pressure on the surrounding parts, the nature of which would materially depend on its size; but the greatest inconvenience would consist during pregnancy, by its adding to the mechanical impediment to the passage of the urine.

As the occurrence of hydatids in the female breast, in the tunica vaginalis testis, the thyroid gland, and between the muscles and integuments, constitutes the morbid structure of local diseases especially belonging to surgery, their present discussion would be irrelevant to the particular objects of this work.

Having no reason to suppose that hydatids have any inherent malignancy, the variety of morbid actions resulting from their presence are to be

ascribed to mechanical irritation and compression: these are seen to be modified by their size and number, their locality, and the predisposing circumstances of the constitution in which they may occur. As mechanical irritants, the effects they produce, whether inflammatory or spasmodic, must be treated entirely on general principles adapted to the age and habit of the patient, and other circumstances, either morbid or natural, under which their occurrence is observed. When a tendency has been evinced to their expulsion by natural processes, through either of the outlets of the alvine canal, art may take advantage of the suggestion thus afforded, and by an emetic or purgative, according to the operation already induced, expedite the accomplishment of the object to be effected. When they have had their seat in the chest, or have passed into this cavity from the abdomen, so as to be ejected through the lungs by coughing, nature may be allowed uninterruptedly to continue its purpose, but any morbid action that may result from the effort must be counteracted by the method of treatment its peculiarity may point out. When impacted in either of the biliary ducts, and giving rise to spasmodic pains and other symptoms resembling those which arise from biliary calculi similarly situated, an emetic, unless particular circumstances should contra-indicate its use, ought to be given, and if its action fail to procure the relief desired, the same kind of treatment will be required as for the analogous condition just referred to, viz. a full dose of the tincture or wine of opium, or Battley's sedative, or tincture of henbane with compound spirit of sulphuric ether in camphor mixture, to be repeated or not according to its effects: if the bowels should be in a constipated state, a combination of castor-oil and laudanum may be preferred, or if great irritability of stomach should prevail, opium combined with calomel, or with calomel and compound extract of colocynth, may be advantageously substituted: a hot bath, a blister to the epigastrium, and injections per anum of hot water with laudanum, or, if need be, purgative injections, are remedies one or all of which may be had recourse to as the necessities of the case may indicate.

When a cyst within the abdomen, containing acephalocysts, can be detected, and is adherent to its muscular parietes, distending them and producing great disorder of the system, an artificial aperture will be the readiest and perhaps the only method of cure. If contained within an abscess, the latter will be the prominent object of consideration, and the evacuation of its contents may prove a cure to the patient, and give the earliest manifestation of their presence. If not acephalocysts, however, but the attached hydatids which grow as it were from the organic structures or tissues, the disease with which they are complicated will form the more prominent object of consideration: it will be obvious that any distension of the abdomen from this cause cannot be relieved, as in ascites, from tapping, an operation to which, in the want of other means of relieving a patient, a practitioner may be urged: should the hydatids be numerous, little relief could follow, and even if the evacuation of a large hydatid were to promise greater advantage, the too common issue of such cases should warn him, except under particu-

larly advantageous circumstances, against a step by which his reputation might suffer, and the expectation of the patient be disappointed.

When it has been ascertained that the liver is affected with hydatids, the removal of the hepatic disorder which must at the same time exist, should be the prescriber's aim; and the process will comprehend the only rational method of relieving the organ, and the rest of the system which sympathizes with it. It has been suggested that mercury in its various forms may possess a specific quality adapted to the destruction of the vitality of animalcular hydatids, particularly acephalocysts; and on this principle has its use as well as that of some other medicines been resorted to when their presence has been recognised or suspected. How far the idea may be founded on fact, time and particular attention to the subject must determine, but experience has sufficiently shown that its influence in such cases of disease has been most salutary, and is indispensable to restoring the natural secretion of the liver, and thereby communicating to the whole of the assimilative organs that degree of vigour which is the main defence of the system against noxious influences from without and morbid depositions within the body, and still further to the removal of various products of disease which a contrary state has engendered. The specific stimulus also of mercury to the absorbents is an additional reason for its prescription when the more direct removal of hydatids cannot be effected, whether situated in the liver, spleen, pancreas, kidneys, peritoneum, or other structures.

When productive of great inconvenience from their situation between the rectum and bladder, or, as in pregnancies, between the vagina and the rectum, and the nature of the resulting tumour can fortunately be determined, an incision into its most prominent part it is probable will speedily and effectually relieve the patient. The circumstance, however, being rare, and the records of medicine affording no general guide for practice on this point, the writer feels it incumbent upon him to state that the above recommendation has been suggested by the perusal of a valuable paper on tumours within the pelvis occasioning difficult parturition, by Mr. Park of Liverpool, inserted in the second volume of the *Medico-Chirurgical Transactions*, p. 296, and particularly by a successful example of the practice therein recorded, and of another in which the tumour disappeared in consequence of the pressure occasioned by the act of parturition. If hydatids have been voided with the urine, and symptoms should arise indicative of the passage of more of these bodies from the kidneys to the bladder, relief should be sought by the immersion of the patient in a hot bath, and by the administration of antispasmodics, as advised for the corresponding effects produced by their impaction in the biliary ducts. If checked in their passage through the urethra, the impediment we conceive might easily be overcome by rupturing the enveloping bag with the point of a bougie. When the uterus has been the seat of hydatids, we are told by the highest authority that "all attempts to cure the disease artificially, and to arrest its progress otherwise than through the natural efforts of the organ, have been of no avail. The patient is to be informed of its nature, and

the result is to be patiently waited for. As symptoms arise they are to be treated accordingly, and the practitioner will best perform his duty by watching over the complaint, and by doing no more than is absolutely required. But when the period arrives at which the uterus is excited by distension to unload itself of its contents, then all his skill and energy will be wanting, and all his efforts will be called forth to control the hemorrhage and to sustain the powers of the constitution." "Two or three fingers or the whole hand should be covered with pomatum, and carefully introduced into the uterus, and carried up between its sides and the hydatids, which are to be detached from the part to which they adhere by the most gentle efforts. The mass being now included in the hand of the operator is to be brought out of the uterus, it being remembered, in the performance of this operation, that the degree to which the os uteri is dilatable without laceration is in proportion to the size of the whole uterus both in pregnancy as well as in this disease. So that, supposing it to be enlarged by hydatids to the size of the viscus in the sixth or seventh month of pregnancy, the whole hand may be, if necessary, introduced through the cervix; whereas, in smaller dimensions of the uterus, if any attempt is made to introduce it through the cervix, however carefully it may be attempted, a laceration of it may ensue, and thus the patient be involved in a new danger. The contents of the uterus having been naturally expelled or artificially removed, and the hemorrhage restrained, the strength is to be restored by allowing the patient a nutritive diet, and by the exhibition of such medicines as tend to increase the tone of the system, amongst which the mineral acids and preparations of cinchona may be accounted the most serviceable: these or other medicines, possessing similar properties, should be from time to time exhibited until the vigour of the system shall have been entirely restored.

"The usual cautions given to women after delivery should be here impressed upon the patient, such as confinement to the horizontal posture until the parts shall have acquired their usual size and tone." (See *Observations on Diseases of Females*, by [Sir] C. M. Clarke, M. R. C. S. &c. part ii. p. 120. Lond. 1821.)

"The acknowledged efficacy of the ergot of rye in stimulating the pregnant uterus to contraction, suggests the idea that it may in the same manner be administered with advantage as soon as it is known that the distention of the uterus is occasioned by hydatids: the writer, however, is not aware that it has ever been used under such circumstances, but as there is some reason to believe that it possesses to a considerable extent the additional property of restraining the hemorrhagic tendency of bleeding vessels, it appears probable that it may prove an eligible medicine for the purpose above specified."*

* "In the fourth number of the *Glasgow Medical Journal*, Dr. Macfarlane, in his observations on *polypus* of the uterus, gives a case where the ergot appeared to act by promoting the expulsion of the polypus. One drachm was infused in four ounces of water, and one ounce given every two hours. The whole was given before the effect was produced. In the course of a few hours the tumour was discovered to be in the vagina. Four days after the exhibition of the ergot the polypus fell

The single hydatid of the uterus by its growth effects its own cure, and thus affords a hint which may, under other circumstances of the disease, be usefully applied; when arrived at a considerable size, a rupture of it suddenly takes place, its fluid escapes, and the cyst is expelled; the patient being in a moment relieved of her sufferings and the cause of her fears, in most instances requiring nothing more than a bandage round the abdomen to give support to the organ which has so long been distended and consequently relaxed.

In all cases of hydatids the condition of the body and the specific nature of the co-existent disease, be it either predisponent or consequent, must be special objects of remedial attention; hence the treatment connected with these morbid formations involves also that of cachexia, of the various disorders of the digestive organs, of dropsy, &c., each of which having a proper place in this work, it is necessary only to refer to them here; and it would be further a waste of time to dwell on means to be adopted for the removal of a morbid deposit under circumstances in which its presence could only be discovered by post-mortem examination.

Abstractedly considered, the removal of hydatids may be contemplated by three different methods: first, by their direct expulsion from the body, either naturally or artificially, as already explained; secondly, when their expulsion cannot reasonably be anticipated, by re-invigorating the relaxed habit of the body, and thus communicating to the absorbent system its lost power, an indication which will also be required to be attended to for the prevention of their recurrence when already got rid of; thirdly, by exciting the absorbents to extraordinary action, when the exercise of their natural function is inadequate to the end in view.

To reinvigorate the relaxed habit of body it will be necessary to avoid the influence of the external causes by which it has been reduced to this state; to select a dry and healthy residence; to use a nutritious diet adapted to the powers of the organs of digestion, improving the condition of the latter by promoting, in the first place, the due secretion of the liver, by the exhibition of such of the preparations of mercury and to such an extent as the occasion may demand. The irritative fever induced by such disorder having been allayed, the tone of the stomach must be invigorated by corresponding medicines, as, for instance, by some of the preparations of cinchona, especially the sulphate of quinine, or by quassia, rhubarb, gentian, or cascarilla, combined either with the alkalies or sulphuric acid, according to the condition of the stomach and alimentary canal: the preparations of iron and sulphate of zinc are also medicines which will generally be adapted to constitutions thus affected.

When these or similar means are found unavailing, and the inconvenience resulting from the presence of hydatids is so considerable as to render it expedient to attempt their removal by exciting the absorbents to extraordinary exertion, a process which requires more discrimination and

off."—From Dr. Young's *Observations on the use of Scabellum Cornutum*, in the *Transactions of the Medico-Chirurgical Society of Edinburgh*, vol. iii. p. 578.

care perhaps than any other in medicine, it will be necessary either to have recourse to the free use of mercury in one or other of its forms, or by persevering in the use of evacuates of the alvine canal or kidneys, or by maintaining a continued state of nausea with repeated doses of tartrate of antimony to effect the same end; but of all the excitants of the absorbent system none appear to have so direct and powerful an influence upon it as iodine: we have, however, no experience of its use in disease resulting from hydatids, and rest our anticipations of its efficacy in such cases on the great advantage stated to have been derived from it in scrofula as well as from the particular actions observed to have been produced by it in the treatment of this disease. (Lugol on Iodine, by Dr. O'Shaughnessy. 1832.)

In the article BRONCHOCELE will be found an excellent account of the medicine in question, which renders it unnecessary for us to enter into any further discussion upon it here; we shall, therefore, merely state, as the result of our own experience of iodine and the hydriodate of potash, that the evidence of their effects on the system in medicinal doses becomes very gradually perceptible, but that these remain so long after their use has been discontinued, as to be prejudiced by their excess, and, as far as we know, the means have not been discovered for regulating them when the necessity has been indicated.

[From a brief article in the *Medico-Chirurgical Review* for April 1844, p. 473, it appears that Professor Klencke, of Brunswick, has instituted some researches on the transmission of hydatids by contagion. The writer has not seen the original paper, but the following are stated in the Review to be Professor Klencke's general conclusions. *First*. That in all species of hydatidic animals, the mode of generation is twofold—fissiparous and oviparous. *Secondly*. That there are false or spurious hydatids, which are propagated by *blastidia*. *Thirdly*. That all the different sorts of hydatids are communicable from one organism to another; and as they are found to exist in fluid food and in the flesh of different animals, they may be readily transmitted by infection. *Fourthly*. That the acephalocysts are not distinct from the echinococci; the former are only the ova of the latter, with or without the parent envelope. *Fifthly*. That the current of the circulation serves to diffuse the hydatidic animalcules, whatever be the mode in which they have been introduced into the system. *Sixthly*. That there exist agents in the living organism, as well as numerous substances in the *Materia Medica*, which are capable of acting as poisons to these parasitic productions.]

WILLIAM KERR.

HYDROCEPHALUS, from ὕδωρ, water, and κεφαλή, the head. Under this term was formerly comprehended every preternatural effusion of serous fluid in the region of the head, whether external to the cranium or contained within it. In process of time, however, it became limited to effusion occurring within the cavity of the skull. Systematic writers have laid it down that such effusion may take place either between the cranium and dura mater, into the great cavity of the arachnoid, in the subarachnoid cellular

membrane, or finally into the cavity of the ventricles. But hydrocephalus, in the more limited sense in which it is usually understood in this country, means a serous effusion taking place into the ventricles, or (which is a much rarer occurrence) into the sac of the arachnoid.

The disease is divisible into acute and chronic. Hufeland, Coindet, and many other late writers, have restricted the use of the name hydrocephalus to the chronic effusion, and have employed the term hydrancephalus to designate the acute variety: a species of nomenclature which is objectionable, as it proceeds on the erroneous assumption that the water in the latter case, and in it only, is always confined within the cavities of the brain.

1. **ACUTE HYDROCEPHALUS**.—This species has been defined by Cullen—a disease which affects chiefly infants and young persons under the age of puberty, arising gradually, and manifesting itself at first by lassitude, feverishness, and pain in the head, and subsequently by slowness of the pulse, dilatation of the pupil, and somnolence. In addition to several of the above symptoms, Hufeland (*Conspectus Morborum—Hydrancephalon*) has noticed in his definition the tendency to convulsions and paralysis, vomiting and constipation.

Though the chronic species is plainly alluded to by several of the older writers, it has usually been supposed that the symptoms of the acute had, till the beginning of the last century, when it was imperfectly described by Petit, escaped the observation of practitioners. This, however, is a mistake, as Hippocrates was certainly acquainted with it, as appears from a passage in the treatise *De Morbis*, (lib. ii. cap. 6,) where he distinctly notices this species of water in the brain, and says that it gives rise to acute headach, pain in the eyes, double vision, blindness, vomiting, and fever;—thus clearly enumerating some of the most characteristic features of the disease, whilst at the same time he recommends purgatives, emetics, and errhines, as the means best suited for its removal.

The first accurate account of acute hydrocephalus which appeared, was that by Dr. Whytt, in a posthumous work published in 1768, entitled *Observations on the Dropsy of the Brain*. His history of the symptoms and progress of the affection is so full and accurate, that a late French writer asserts that little of any importance has been since added to it. So much cannot, however, be said for his hypothesis as to the nature of the disease. He considered it a kind of passive dropsy, and all its symptoms merely the effect of the pressure made on the brain by the effused fluid. The disposition to vomit is attributed to the sympathy of the stomach with the brain; the slow, irregular pulse of the second stage, to the cardiac nerves receiving an imperfect supply of nervous energy; the quick pulse of the third stage, to the injury now done to the cerebral fibres, and the irritation thence arising in the whole system; and, finally, the dilatation of the pupil and stertorous breathing, to the compression of the brain. But neither his theory of this affection, nor his despondence as to the possibility of its ever being cured, have been justified by later and more extensive observation. Dr Fothergill's remarks on the hydrocephalus internus, and Dr.

Watson's observations on the same subject, appeared soon after, and the latter contained one of the first instances on record where the disease terminated in recovery. A valuable addition to the usual mode of treatment was made known in 1775 by Dr. Dobson, who, with a view to increasing the activity of the absorbents in the brain, was led to the employment of mercury, and had the satisfaction to find it successful. The first approach to a correct theory of the disease was contained in the thesis of Dr. Quin, of Dublin, published in 1799, in which he pointed out its affinity to the inflammatory diseases, and supported his views by a reference to the appearances which are found on dissection in those who have fallen victims to it. This manner of considering the disorder necessarily led to a great improvement in the mode of treating it. A similar view of hydrocephalus was taken about the same time by Dr. Rush of Philadelphia, who believed it to be closely allied to phrenitis, and pushed the antiphlogistic method of treating it still further than Quin had done. Dr. Withering held a similar opinion as to its inflammatory nature, and, like Quin and Rush, considered the effluvia here, as in many other instances, a mere result of inflammation, and not as constituting the essence of the disease. His introduction of digitalis into its treatment likewise entitles him to a place in the literary history of this affection. Dr. Percival of Manchester strongly advocated the use of calomel and opium in hydrocephalus, and strove to give precision to the mode of employing the various remedies previously in use. Amongst the writers who have most contributed to throw light on the nature and treatment of hydrocephalus, we may place, in addition to those already mentioned, the names of Cheyne and Abercrombie in this country; Odier and Coindet in Geneva; Guersent and Lallemand in France; Formey, Portenschlag, and above all Gölis, in Germany. Besides these, we shall have occasion to allude, in the course of this article, to several others who have made important additions to our knowledge of the disease.

Precursory Symptoms.—In a great majority of cases premonitory symptoms may be detected; and of these the greater number and the most striking are connected with derangement of the digestive organs. The appetite is either capricious or defective; the tongue slightly furred, and the breath heavy; the epigastrium and hypochondria are occasionally tumid and tender on pressure; the biliary secretion is deficient or vitiated, as is evident from the torpor and irregularity of the bowels, and the unnatural appearance of the stools; the urine is high-coloured and diminished in quantity; the cutaneous circulation loses much of its vigour, as is evident from the faded and unhealthy complexion and harshness of the skin. To the attentive observer slight indications of the derangement of the cerebral functions may even at this early period be discovered, in the languid manner and frequent drowsiness; the disturbed and restless sleep, from which the child awakens unrefreshed; in the occasional complaints of giddiness or confusion, of noise or slight pain in the head, or of pains like those of rheumatism in various parts of the body and limbs. The pulse as yet deviates little from its natural condi-

tion, but on attentive examination some of its beats are found weaker than others, and an occasional intermission may sometimes be detected. The child becomes silent and irritable, indifferent to such persons and things as it formerly took an interest in, frequently assumes a grave and thoughtful appearance, or falls into a reverie, from which it awakens with a sigh. Notwithstanding all this evidence of deranged function, the patient often makes little complaint, even when closely questioned. When the disease is about to manifest itself in a more unquestionable shape, flushings and chills frequently alternate; the gait becomes laborious and unsteady. "In stepping forward," says Gölis, "they raise the foot as if they were stepping over a threshold—they totter and stagger as if drunk."

Dr. Yeats, who has made the earlier stages of the disease his peculiar study, places amongst the premonitory symptoms occasionally present, tenderness in the scalp, stiffness of the neck, increased sensibility of the eyes to light, and in some rare cases severe ear-ach. He also draws attention to the remarkable change from the healthy appearance which the countenance undergoes, the transient paleness and occasional collapse of the features, the dulness and loss of expression in the eyes, and the dark line under them. A teasing cough is sometimes present; there is an unusual tendency to constipation. If aperient medicines be given, the consequent evacuations are both harder and less abundant than they were wont to be from a similar dose; in colour they are sometimes lighter than natural, and at others tinged of a dark greenish hue, and accompanied with slimy matter.

It must be confessed that there is nothing essentially characteristic in the above symptoms, and that even when all are taken together, they rather indicate a derangement in the functions generally, than point in an unequivocal manner to incipient disease of the brain. Still they are sufficient to justify much watchfulness on the part of the friends and of the medical attendant, and particularly so when the child discovers an unusual precocity of intellect, or is one of a family which has already suffered from hydrocephalus, or from scrofula in any of its forms. The mere occasional exhibition of a purgative will in such cases, as Dr. Yeats very truly observes, usually prove quite inadequate to the removal of the symptoms; nothing less than the systematic employment of a combination of alteratives and aperients, continued for some time, being capable of producing this effect.

Dr. Cheyne has the merit of having been one of the first writers who strongly directed the attention of the profession to the derangement in the functions of the liver and of the alimentary canal, which so often precedes, and not unfrequently seems to excite, this affection of the brain. The proportion of cases in which the diseased action commences in the abdominal viscera is, he thinks, very considerable. He was led to this belief partly by having observed how usually derangement of the above-named organs precedes hydrocephalus, and partly from the remarkable benefit which, in the early stages of the affection, so often ensues upon the use of active purgatives,

and finally, from the frequency with which unequivocal marks of disease are discovered in the liver or intestines on dissection. In the incipient stage, or while the disease of the brain is as yet only forming, the colour of the stools indicates an inactive state of the liver, whilst at a subsequent period, when hydrocephalus has become fully established, the bile seems to be both vitiated and in excess. The intimate sympathy which exists between the brain and the liver is well known to surgeons, and that between the brain and the stomach and intestines is familiar to every one.

There is, we think, a general aversion amongst French pathologists to admit the sympathetic or secondary origin of diseases, and accordingly most of them, in treating of hydrocephalus, have looked upon the morbid appearances found in the abdomen as a mere casual complication, and by no means the cause of the cerebral affection. M. Brachet of Lyons has, however, departed from the general rule, and admitted a gastric variety of hydrocephalus, (*hydrocephalite gastrique*), in which the disorder of the digestive organs evidently precedes that of the brain, and in which subsequently, during the progress of the cerebral affection, the violence of the gastric symptoms seems clearly to indicate that the irritability of the stomach is not the mere effect of sympathy, but the result of inflammation in the mucous membrane itself.

Less importance has been attributed by Dr. Abercrombie than by most other late British writers, to derangement of the chylopoietic viscera as a cause of hydrocephalus. Disease of the brain in unhealthy children, he admits, may appear in connection with that of the liver or other abdominal organs; but the latter, he thinks, cannot correctly be said to be the cause of the former; on the contrary, he looks upon both as a common result of a tendency to chronic or scrofulous inflammation. When we consider, however, the close and unquestionable sympathy which exists between the head and the digestive organs, and take along with this the greater exposure of the latter to irritating causes and consequent functional derangement, we are disposed to think that the now very generally received opinion as to the frequent origin of hydrocephalus in abdominal disorder is well founded. Dr. Abercrombie, indeed, himself admits that the more acute affections of the bowels have some pretensions to be considered an occasional cause of the disease, though even here the connection is, he thinks, very obscure: and the secondary affection in some of them arises, perhaps, merely out of the general febrile excitement. In admitting the precedence of the derangement of the digestive organs and its occasional connection with disease of the brain, all that is of any practical importance is conceded. How this connection is to be explained matters little. The comatose state in which inflammation of the mucous membrane of the bowels in infants about the period of weaning often terminates, is a striking instance of this origin of cerebral derangement. A remarkable diminution of the urinary secretion frequently precedes the oppression of the brain, and may possibly sometimes, as Dr. Abercrombie has suggested, be in some degree connected with it.

Under the title of "Erethysm or Irritation of the Brain in infants," Dr. Whitlock Nichol has described a state which, as it is accompanied by no increased determination of blood to the head, is distinct from inflammation, though, it may, if neglected, terminate in it. It seems, consequently, to be one of the forms in which the precursory symptoms of hydrocephalus occasionally present themselves, and in which they appear to depend on a peculiarly irritable state of the nervous system. "It is a state," says Dr. Nichol, "in which inordinate effects arise from ordinary impressions upon different parts of the nervous system." The child is wakeful, irritable, and attentive to every sound and every object of sight, and is easily startled; the eye is very sensible to light; there is frequent sneezing; and repeated winking or a firm spasmodic closing of the eyes is occasionally observed. A frequent, sudden cry, without any obvious cause: clenching of the fist, with the thumb laid across the palm; throwing back of the head, and a degree of opisthotonos, are amongst its occasional symptoms. The temperature and pulse may be sometimes raised, but are for the most part natural. Scrofulous children are the most prone to this affection. It may be called into existence by any irritation of the extremities of the nerves, as by painful dentition, by disorder of the liver or alimentary canal, by surgical operations, ulcers, burns, or suppressed discharges. Great wakefulness in infants should always excite attention, as it is very apt to terminate in inflammation of the brain. Children in whom this alarming symptom appears should be carried out much in the open air, and have the head sponged daily with cold water, and the bowels kept in a free state. If it still persist, and we can detect any evidence of undue determination of blood to the head, leeches must be employed. If, on the other hand, the watchfulness and increased sensibility of the nervous system exist simply, small doses of Dover's powder are recommended by Dr. Nichol, and should be repeated at intervals of five or six hours, so as to procure a sufficiency of sleep. We believe, however, that when the bowels are duly attended to, and care is taken to give the child the advantage of air and exercise, the aid of narcotics need rarely be had recourse to; and till every other method of inducing sleep has been tried and failed, we should certainly not advise their exhibition.

Though hydrocephalus in its advanced stages presents considerable uniformity in its symptoms, yet so great a variety is there in its manner of commencement, as fully to justify Quin in styling it a truly proteiform affection. These varieties have been reduced by Dr. Cheyne to three principal ones, which may be respectively entitled the gradual, the rapid, or violent, and the secondary, under one or other of which most of the cases met with in practice are reducible.*

First or gradual form of Attack.—It is in

* Hopfengärtner has made a division of hydrocephalus into three varieties, which coincides very nearly with that of Cheyne, viz. into, 1st, the *nervous*, which at its commencement strongly resembles a low nervous fever; 2d, the *inflammatory*, characterized by high fever and evident congestion of the head; 3d, that which succeeds to *scarlatina* several days or weeks after the disappearance of the eruption.

this form that the precursory symptoms, into which we have entered with so much detail, are the most obvious. The disease here comes on by slow degrees, and at its commencement its true nature is involved in considerable obscurity. The child is indisposed for many days or even weeks, complaining from time to time of slight pain in the head or belly, together with which there is anorexia or capricious appetite, and evident derangement in the functions of the abdominal viscera. It is all this while somewhat feverish and dispirited; its colour fades, and the eye becomes dim. A dragging of one of the legs, or a painful stiffness in the back of the neck, has sometimes been observed from the very commencement. The pain in the head soon becomes severe, returns at shorter intervals, and is complicated with vomiting, which, as well as the headach, is much aggravated by motion. By these symptoms the fears of the friends are at length awakened. The child now seems unable to support the weight of the head, sighs frequently, and looks dejected: the eyes are pained by a strong light, the pupils much contracted, and flashes of light are occasionally complained of. The derangement of the abdominal functions is indicated by the white tongue, by costiveness, or the unnatural appearance of the stools, which are at first of a clay colour, but gradually become gelatinous and of a dark-green hue, and have a peculiar heavy smell. The pulse becomes rapid, and frequent exacerbations take place, characterized by increased heat and irritability, with flying pains in various parts of the body, in the nape of the neck or limbs, the chest or abdomen. This first stage usually lasts for ten days or a fortnight, the patient gradually becoming weaker and much altered in appearance, unsteady in his motions, and fretful.

Second or rapid form of the Attack.—The disease here assumes a more acute and turbulent form. After a brief period of indisposition, which has possibly been overlooked, the fever appears suddenly and violently, with only short and irregular intermissions. There are frequent flushings, severe headach, occasional brilliancy of the eye, with increased sensibility of the retina, and indeed of the whole nervous system, and frequently pain in the abdomen, and tenderness on pressure.

It is this form of hydrocephalus which bears so strong a resemblance to fever as often to have been confounded with it. With proper care they may, however, be usually distinguished. "We are led to suspect," says Cheyne, "some deeply seated evil from the frantic screams and complaints of the head and belly, alternating with stupor, or rather lowness and unwillingness to be roused; and we are struck with the great irritability of the stomach, which exists in a degree beyond what we generally find it in the fevers of this country, retching and vomiting being brought on by a change of posture, and certainly by every attempt to sit up in bed; and the disordered state of the bowels which attends this irritability of the stomach is also remarkable. And when at any time the child has a little respite from the violence of these symptoms, we find our suspicions confirmed by his look; for when the features do not

express pain or terror, there is not unfrequently a vacancy of look, the eyes being set with an expression of dejection which is peculiar to certain diseases of the brain."

Third form of Attack.—When hydrocephalus supervenes upon other diseases, as upon scrofula or painful dentition, the exanthemata, remittent fever, or hooping-cough, it is called metastatic or secondary. When it ensues in the course of an acute disease, its approach is most insidious. The symptoms of the early stage are almost all absent, and palsy and convulsions often afford the first evidence of the brain having become implicated. Even pain in the head is occasionally never complained of; and Dr. Quin alludes to a case in which not one characteristic symptom of hydrocephalus had occurred, and yet a large quantity of fluid was discovered in the ventricles.

Of these three modes of commencement, the first is the most frequent. The second occurs perhaps seldomer than either of the other two, but is the most regular in its progress, and presents the different stages the most distinctly marked. It answers to what Gölis has called the *tumultuous* form of hydrocephalus; and to Guersent's *hydrocephale ataxique*. It is the most acute variety, and Gölis thinks it the most amenable to the influence of medicine, both because it occurs in the healthiest children, and because, being often ushered in by sudden fever and severe convulsions, it is apt to excite attention in its commencement, and thus has more frequently the benefit of early treatment. But if the critical moment for the employment of active measures be lost, in a few days, or sometimes even in a few hours, effusion and palsy ensue. Recoveries from the third form are very rare, which is ascribed partly to the progress which the affection of the brain has usually made before there is any suspicion of its existence, and partly to the debility produced by the previous disease often rendering active treatment inadmissible.

Stages of Hydrocephalus.—The great variety and complexity of the symptoms of hydrocephalus have led most writers on the subject to attempt their simplification by distributing them into separate groups characteristic of successive periods of the disease. Dr. Whytt, struck by the remarkable differences which the pulse presents in the progress of this affection, has assumed it as the ground-work of a division into three stages, in the first of which the pulse is quick, in the second slow and irregular, whilst in the third it rises again, and becomes rapid and feeble. By Gölis four stages have been described, founded on the presumed pathological condition of the brain at successive periods of the disorder. These are, first, the period of turgescence, which answers nearly to what we have called the precursory symptoms; second, the period of inflammation; third, that of effusion; and, lastly, that of palsy. But two stages, on the other hand, have been admitted by Frank and by Conradi; what Gölis calls the stage of turgescence being by them considered as merely indicative of the approach of the disease, whilst the two last stages of Gölis and of Whytt, not appearing to them to be really distinct, have been consolidated into one. The three-

fold division of Whytt appears, however, to have practical advantages sufficient to justify us in retaining it. It is that which has been adopted by Cheyne in his valuable essay: but in naming these stages, he has proceeded on a different principle from Whytt, characterizing them by the state of the nervous system instead of that of the circulation. Thus, the first he calls the period of increased sensibility, the second that of diminished sensibility, and the third that of palsy or convulsions. "In the first stage," says he, "every stimulus produces an impression more than proportioned to its common effects. There is generally a great aversion to light and to sounds; there is watching, sickness, pain, and a quick pulse. In the second stage, the child is not easily roused, his pupil is dilated, his pulse slow; he is lethargic, with obstinately costive bowels. In the third stage, which perhaps might be considered as a continuation of the second, there is squinting, rolling of the head, raving, stupor, convulsions, with a rapid thready pulse."

Many cases do, it must be confessed, present themselves which set these and all other artificial divisions at defiance, cases in which the most careful observers fail in detecting any thing like a succession of regular stages. Thus convulsions, in place of first occurring near the end, occasionally usher in the disease; and as to the pulse, we have ourselves found it keep high during the whole course of the illness; whilst others have met with cases where it never exceeded the natural standard; and others, again, instances of its being remarkably slow at the very commencement of the attack.

First Stage.—The morbid phenomena of this period are so variable, that it would perhaps be impossible to give any description of it answering accurately to all cases. Amongst the symptoms most frequently present are pain in the head and eyes, occasionally alternating with pain in the abdomen, in the limbs, or in the nape of the neck. There is usually a certain degree of fever, with great restlessness and total inability to sit up for any length of time. During the sleep, which is very disturbed, there is frequent grinding of the teeth, and the child often awakens with a scream of terror. The head feels hotter than natural, the conjunctiva is occasionally slightly injected, and the pupil usually closely contracted. There is a manifest aversion to light and noise, with other indications of increased sensibility of the nervous system. The intellect is often but little impaired, for replies, though unwillingly made, are usually correct. The symptoms of disorder in the digestive organs are numerous. The nostrils are always dry, and the lips cracked. The tongue is for the most part slightly furred, and the breath has a faint sickly smell. There is usually complete anorexia, but often less thirst than would seem consistent with the degree of feverishness present. Vomiting very frequently occurs, and is aggravated extremely by the erect posture, or by carrying the child out of bed. The epigastrium and hypochondria are often tumid and slightly tender on pressure, but in the progress of the disease the belly usually falls in, and becomes flaccid, though no proportional increase in the stools has taken place. There is commonly

a great tendency to constipation; and evacuations, when procured by medicines, are generally of a dark greenish spinach-like appearance. The occurrence of such discharges does not depend, as many persons have asserted, on the employment of calomel, as they often exist before a single dose of this medicine has been given, and are frequently procured also by other purgatives. We have not, however, by any means found them invariably present. Their peculiar colour has been attributed to morbid bile, but there is reason, as we shall afterwards see, to doubt whether this be universally the cause. The urine is deficient in quantity and turbid, with a whitish sediment; it is often retained or suppressed for a great many hours, and dysuria is not unfrequently complained of.

The functional derangement of the respiratory organs is manifested by the occasional cough, the irregular breathing and moaning, and by that deep sighing which is almost pathognomonic of affections of the head. The pulse is considerably accelerated, and is very excitable. An occasional irregularity and slight inequality in the force of succeeding strokes may be discovered as the second stage approaches. The skin is dry and of an unhealthy colour. An eruption of almost imperceptible vesicles, which become, however, more obvious towards the latter part of the disease, now occasionally manifests itself. They occur chiefly about the mouth, cheeks, and forehead, the outside of the humerus, and the upper part of the chest. They were first pointed out by Forney of Berlin, and have been subsequently noticed by Gölis, Raimann, Schmalz, and other German pathologists. Though these writers speak of this eruption as an almost invariable occurrence in hydrocephalus, it has attracted little attention in this country, where almost the only mention of it that we have met with is that by an anonymous writer in the second volume of the Edinburgh Medical and Surgical Journal, who says that it has been considered as a certain sign of approaching death. Whilst on the subject of the skin, we may mention that ecchymosed and gangrenous spots have been observed near the close of fatal cases, and we have at the same period remarked a few large-sized vesicles scattered over the body at distant intervals.

The duration of the first stage varies according to the acuteness of the attack, from a few hours to a week or more.

Second Stage.—The pulse, which had been gradually getting weaker, now becomes irregular, of unequal force, very variable, and unnaturally slow; yet it is still liable to be greatly accelerated on the slightest exertion, or when the patient is taken out of bed, or even placed in the sitting posture. The slow pulse is accompanied with a gradually increasing heaviness and torpor, and the head is now generally less complained of, though this is by no means universally the case. Squinting and impaired or double vision now occur along with dilatation and immobility of the pupil, an oscillatory state of the iris occasionally preceding its permanent retraction. The child lies with the eyes half closed, in a soporose state, which is interrupted from time to time by exclamations of suffering extorted by the momentary increase of pain. The sickness and vomiting often now

diminish; appetite occasionally seems to return, the child greedily swallowing any food which is presented to it; but the bowels still continue obstinately bound, except while under the influence of powerful purgatives. The stools as well as the urine are passed unconsciously. The hands, which are tremulous and unsteady, are frequently raised to the head and back of the neck; and the child is almost incessantly picking at its nostrils, lips, or hair. Spasmodic winking or a fixed stare, a stern or a desponding expression, often rapidly succeed each other. There is great emaciation, and frequent partial suspirations indicative of extreme debility and of irregularity in the distribution of the blood.

The soporose state is now often suddenly and unexpectedly dispelled, the child recovering the use of its senses, and noticing and even taking an interest in surrounding objects. But this deceitful calm is usually of short duration, and is followed within one, or at most two days, by a deeper state of coma than before. The shrill piercing scream, which is so characteristic of hydrocephalus, occurs chiefly in this stage; and during its continuance the pulse becomes almost innumerable, and the cheeks suffused. The duration of the second stage may be variously stated at from one to two weeks.

Third stage.—A feeble attempt at re-action now manifests itself, the pulse again rising and attaining to a height which is scarcely equalled in any other disease. We have counted it as high as two hundred in a minute, and Whytt once found it it even so high as two hundred and ten. Convulsions in every degree, from slight spasmodic twitching of the face and vibratory motion of the eye-balls up to violent contractions of the muscles of the trunk and extremities, take place, and are usually soon followed by paralysis of one side, the opposite side continuing to be convulsed at intervals. The child lies raving and insensible; moaning and sighing, waving the unpalsied hand through the air, and rolling its head from side to side on the pillow. The cheeks are alternately flushed or pale; the eye half closed, as if from partial paralysis of the levator palpebrarum; the conjunctiva bloodshot, and the cornea dim and covered over with a slimy secretion; the pupil is dilated, the teeth grind violently together, or there is a frequent smacking of the tongue and lips. The balance of the circulation is lost, the skin being dry and burning in some parts, and drenched with partial but profuse perspiration in others. The feet grow cold, the pulse gets weaker and weaker, the respiration unequal and stertorous, and a violent convulsion often closes the scene.

The length of the third stage is even more uncertain than that of the two preceding, varying from a few hours to one or even two weeks.

The duration of the whole disease, where the elements of which it is made up are so variable, is necessarily very uncertain. It may be stated approximatively at from two to three weeks, but it is generally nearer to the latter than the former. There has, however, been the greatest difference of opinion as to the time the disease lasts, arising partly from the variety which actually exists in different cases, and partly from the difficulty, in those cases where hydrocephalus is grafted on a

previous disease, of ascertaining precisely the period at which it originated. Fothergill, Cheyne, Gölis, and the majority of writers think it usually runs its course in less than twenty-one days; whilst Whytt, on the other hand, has attributed to it a period of from four to six weeks, and Frank has mentioned a case which lasted the longest of these periods. It seems to be considerably influenced in this respect by age, as in very young infants it is often over within a week; and Coindet has mentioned one instance which terminated fatally within three days. A still more rapid species, in which effusion and death take place within a few hours from the commencement of the attack, has been described by Gölis under the name of the water-stroke, (*wasserschlag*), or hyperacute hydrocephalus, which may, according to this writer, be either an idiopathic affection, or else the consequence of the repulsion of some of the exanthemata, or of the suppression of some cutaneous discharge, (as that from *crusta lactea*, *tinea*, sore ears, &c.) or of the sudden and imprudent checking of a diarrhoea, dysentery, or perspiration. The precursory symptoms in this variety are either absent or so slight as to escape notice; and the stages of inflammation and effusion seem to be almost coincident, the fluid being poured out at the very onset of the disease. Such a disorder rarely leaves any time for treatment, and it terminates almost invariably in death. On dissection, a fluid more turbid than that usually found in hydrocephalus is detected in the ventricles. Of the cases of hydrocephalus appended to Gölis's work, the most rapid was one which terminated fatally in twelve hours; in the majority death seems to have occurred about the seventeenth or eighteenth day. Springel has assumed fourteen days as the average duration. When the disease makes its attack in a very violent form, infants may be cut off by convulsions in its very commencement.

Prognosis.—Hydrocephalus has always, and with too much reason, been considered a very fatal disorder. It does not, however, as some would have us believe, universally and necessarily terminate in death. Since its diagnosis in the earlier stages has become more accurate, and its inflammatory nature in the majority of cases been generally recognized, patients have been saved much more frequently than formerly. Recovery has been known to take place after the occurrence of all the most decided symptoms of the disease; slow pulse and stupor, strabismus, dilatation of the pupil and blindness, convulsions and paralysis. In Dr. Cheyne's essay numerous instances of recovery under the influence of judicious and energetic treatment are detailed. At Geneva, according to Odier, about eighteen children on an average are attacked by it yearly, and of these about six, or one-third, recovered. Of the eleven cases recorded by M. Brichteau, four recovered; of Dr. Mill's twenty-eight cases, seven; and of the thirty-seven given in Gölis's work, five had a similar termination. In the whole practice of the latter physician, which has been unusually extensive in the diseases of children, forty-one cases of recovery from hydrocephalus have been met with, these were, however, very early seen, and being subdued in the inflammatory stage, have been thrown in his tables under the head of inflammation of the

brain. These results are very gratifying to those who feel an interest in the progress of medical science, and form a pleasing contrast to the desponding views of Whytt and Fothergill, and the other early writers on the disease. "So long," says Dr. Cheyne, "as the pulse continues steady and the breathing natural, we are not to be prevented by the most alarming symptoms from an employment of active remedies." A very few instances of what may almost be called spontaneous recovery, so inefficient was the treatment employed, are to be met with in medical writings, and must still farther encourage our exertions on the behalf of those labouring under the disease. Willan speaks of an infant which recovered in the fifth week of its illness, though its case had been abandoned by the medical attendants as hopeless. No medical man who has a due regard for his own character or for the feelings of the friends of a hydrocephalic patient, should desert a case of this kind at any stage, however unpromising it may be. Under circumstances apparently desperate, a temporary or even permanent amendment will sometimes most unexpectedly take place; and if a new medical attendant has been called in, what is perhaps only the effect of an effort of nature will be set down to the credit of his superior penetration and more judicious measures. After effusion has occurred, the disease is generally supposed to be utterly hopeless; but such a dogma should be allowed to exert no influence on our practice, both because it seems unwarrantably to limit the powers of nature, and because we possess no unequivocal signs from which we can certainly conclude that such effusion has actually taken place; for all the symptoms usually attributed to it may, it is now well known, be produced by inflammation alone.

In forming our prognosis, much attention must be paid to the state of the pulse and of the excretions. If the pulse, from being very quick, falls slowly and moderately, the prognosis must be more favourable than where it comes suddenly down; the former showing a diminution of fever, whilst the latter might imply that the second stage of hydrocephalus was about to establish itself. Inattention to this point in suspicious febrile cases has often led practitioners into disagreeable mistakes; the fall of the pulse inducing them to give a very favourable prognosis, and pronounce the disease at an end at the very moment it was about to assume a new and fatal aspect. Where the pulse, on the other hand, has already become unnaturally slow, a slight increase of frequency may be considered a favourable circumstance; whilst a rapid and very considerable rise would point to the commencement of the final stage.

An increased facility in procuring stools, an improvement in their appearance, a plentiful secretion of urine, a profuse warm perspiration, or a running from the nose, are to be considered promising circumstances. It is on the latter of these evacuations that the vulgar reckon most, and empirics often take advantage of their credulity to exhibit powerful emetics, a practice which is said, we know not how truly, in some rare instances to have been successful. We must beware, however, of attributing too much importance to any single symptom: thus we have known a profuse perspiration about the head and neck occur though the

disease was rapidly hastening to a fatal conclusion. Indeed partial perspirations here, as in most other cases, are generally to be looked on with a suspicious eye: in the stage of palsy they are the usual forerunners of death.

If under the influence of powerful medicines or otherwise, an intermission of symptoms for two or three entire days takes place, we may entertain good hopes of recovery; but unfortunately this cessation is rarely so prolonged. In the great majority of cases the truce is a brief and fallacious one, the irregularity of pulse, headach, vomiting, &c., recurring in a few hours, and the disease proceeding rapidly to its fatal termination. Even in cases of apparent recovery we must not be too sanguine as long as the pupil continues dilated, or contracts but sluggishly on exposure of the eye to a strong light.

Where the acute disease supervenes on the chronic, the prognosis is very unfavourable; not indeed on account of any irritating or corroding quality which the effused fluid has, as some of the German writers fancy, contracted, but on account of the almost irremediable nature of the exciting cause and the debilitated state of the constitution generally. Where it occurs during the slow and imperfect convalescence from an acute disease, or develops itself in the course of whooping-cough, infantile remittent, or painful dentition, or succeeds to some scrofulous affection or other tedious disease by which the powers of the constitution have been greatly reduced, recovery very rarely takes place. This is attributable in some of these instances, partly to the extreme difficulty of detecting the disease of the head in its incipient stage, and partly to the debilitated state of the patient not admitting of the employment of those active measures which the nature of the local disease requires. That variety which occasionally occurs as a sequela to scarlet fever is generally more within the influence of medicine than the other kinds alluded to above. On the other hand, that which occurs in the early stage of this disease or of the measles usually assumes a very violent form, and is, as we have already stated, almost always rapidly fatal.

Amongst the possible terminations of acute hydrocephalus is its passage in the chronic form; but this is extremely rare, and is scarcely to be desired, being very liable to be accompanied with blindness or deafness, idiocy, epilepsy or paralysis, or some other lamentable impairment of the functions of the nervous system, arising from the serious injury which the brain has undergone. Such consequences are, however, not universal. Guersent mentions a case which, having become chronic, got completely well on the spontaneous occurrence of a cutaneous eruption, and that too after all the ordinary means of treatment had proved ineffectual.

It has appeared to Dr. Cheyne that hydrocephalus is more frequently cured when it occurs in such constitutions as have a decided predisposition to it, which may always be presumed when several individuals of the same family have been successively attacked. This apparent paradox is perhaps only explicable on the supposition that previous losses dispose and enable parents more early to detect the incipient symptoms of the disease, and thus lead to the employment of an ap-

propriate treatment at that period when medicine is most likely to be of any avail. Success has by some been thought most probable in those cases which come on slowly and gradually, and thus afford ample time for treatment. According to Abercrombie and Gölis, on the contrary, those are the most favourable in which the symptoms indicate very active inflammation, and admit of energetic treatment: whilst the least promising cases are those where the inflammation is of the low or scrofulous kind. "In all," says the first of these writers, "the period for active practice is short, the irremediable mischief being probably done at an early period of the disease."

Diagnosis.—There is perhaps nothing more characteristic of this affection of the brain than the rapid fluctuations which the several functions of the body undergo, and that often within a very brief space of time. This mutable condition is indicated in the cerebral functions by the state of the intellect and senses, now unnaturally acute, again dull, and at times altogether obliterated. The muscular system is at one moment unaffected save by debility, and the next moment perhaps convulsed or paralysed. The pulse and capillary circulation are constantly varying under the influence of slight or inappreciable causes, the face being at one moment flushed and at the next deadly pale, whilst heats and chills, perspiration and dryness of the surface, rapidly alternate. The respiration likewise undergoes endless changes in force and frequency. The functions of the digestive organs are equally variable, anorexia and incessant vomiting being succeeded by an apparent insensibility of stomach, or a ravenous and indiscriminating appetite.

Of effusion having actually taken place, there is, as we have already stated, no symptom, nor even set of symptoms, which can afford us *certain* evidence. Somnolence, strabismus, convulsions, and partial paralysis, which were once so much confided in, have lost much of their credit since pathological anatomy has been more diligently cultivated; and numerous cases are now on record where they all existed though no water was found on dissection. Coma, immobility and dilatation of the pupil, and blindness, and sundry other symptoms which have been supposed by later authorities to be more worthy of reliance, will also frequently deceive us as far as effusion is concerned: their true value consists in fixing attention on the state of the brain itself. When we recollect that the effusion is a mere result or consequence of the disease, and reflect on the complicated state of cerebral derangement which often precedes or coexists with it, the difficulty of recognising it with certainty during life will cease to surprise us. In a practical point of view, moreover, it is of less importance than is generally imagined. It is not the effusion, so much as the morbid state of the parts within the cranium which leads to it, which is the legitimate object of treatment: over the former, when it already exists, many doubt whether medicine can exert any influence.

The difficulty of distinguishing hydrocephalus in its earlier stages from many of the febrile affections to which children are liable is often very considerable. We may generally avoid confound-

ing it with the infantile remittent fever by attending to the extreme irritability of stomach, and its aggravation by the erect posture and by motion—the greater severity and constancy of the headache—the disposition to somnolency, the child often falling asleep the moment after it has been replaced in bed, or after it has been answering our questions—the knitting of the brows and aversion to light and noise, the pupil being at first contracted and subsequently unnaturally dilated—the caution in moving the head, and the frequent raising of the hands to it—the thrusting back of the neck—the variability and extreme excitability of the pulse—the green stools or obstinate costiveness. The morning remissions moreover, if they occur at all, are much less marked in hydrocephalus than in the infantile remittent. Amidst our efforts to establish a diagnosis in any particular case, we must not forget that diseases are at times, in the language of the older writers, convertible into each other; or that, to use the more moderate phrase, complications may arise in their course, and the secondary affection eventually predominate over the original. It is thus that in the course of infantile fevers hydrocephalus frequently comes on, and often with such insidious advances as altogether to elude observation almost up to the very moment of its fatal termination; we confess we have even remained doubtful as to the existence of the disease within the head till the scalpel revealed its presence. Where infantile remittent is about to pass into hydrocephalus, the remissions become gradually less and less distinct. Pain is in some cases never complained of.

Fevers of a typhoid type are comparatively rare in children, and when they do occur can scarcely, with ordinary attention to the symptoms, be confounded with hydrocephalus. Gölis has, with a truly German patience, been at the pains of drawing a long parallel between the two diseases. The more equable pulse, the diarrhoea with dark and fetid stools, the trembling tongue, petechiae, and low muttering delirium, the tumid belly, supine posture, and sliding to the bottom of the bed, to say nothing of the absence of all the more striking symptoms of hydrocephalus, will scarcely suffer us to confound a case of typhus with even the obscurer examples of the former disease.

In connection with low and protracted fever, symptoms frequently occur, as has been remarked by Abercrombie, which seem to indicate serious affection of the brain, and yet these shall all disappear as the fever subsides. Thus he gives a case of a child labouring under a tedious disorder of this kind, accompanied with stupor, blindness, dilated pupil, and squinting. After lying speechless for near a month, it gradually recovered after a copious discharge of matter from one of the ears. We think it probable, however, that the essential part of hydrocephalus, namely, inflammation in the central parts or at the base of the brain, was present here, and that the fever was throughout only symptomatic, and its cessation attributable to the escape of pus from the external meatus.

A want of correspondence in the symptoms has been pointed out as one of the marks of this disease of the brain. Thus, when the headach is

greater or more permanent than accords with the degree of fever, and especially if the pain increases in intensity as the pulse falls, our suspicions should be awakened. Brichteau dwells on the slightness of the thirst and its total disproportion to the fever. This, however, is by no means invariably the case. Many children labouring under hydrocephalus drink largely, so that M. Brachet, another French writer, has even considered the extreme avidity with which they seize the vessel containing their drink as one of the most remarkable symptoms of the disease.

The frequent and deep sighing and the peculiar scream, such as might be uttered under the agonies of a severe surgical operation, are also very characteristic of the disease.

Severe pains appearing successively in different parts of the body, and for which we cannot in any way account, should in children as well as in adults always excite suspicion, and make us turn our attention to the nervous system, and especially to the state of the organs contained within the cranium and spine.

The diagnosis is peculiarly difficult in feeble children who have been exhausted by long previous illnesses, as scrofula, painful dentition, or chronic disorders of the digestive organs already attended with vomiting. Quin met with a case of acute hydrocephalus which proved fatal in seven days, in which there was no evident division into stages, no dislike of light, nothing characteristic in the pulse, no dilatation of the pupils, nor any violence of headach; and Rush alludes to similar cases.

In very young infants the detection of the disease in its early stage requires the closest observation. Long-continued wakefulness, or starting from sleep with a cry of alarm, or prolonged screaming without any obvious cause, should always awaken our apprehensions; and when the infant subsequently lies moaning and drowsy, and rolling the head from side to side on the nurse's arm, or thrusting it back against the pillow; when there is frowning and aversion to light, a contracted state of the pupil, and unusually frequent vomiting, our suspicions are almost converted into certainty. The negative indications also, or the absence of well-marked disease in the chest or abdomen, will frequently throw additional light on the nature of the case. The face, as has been remarked by Cheyne, is expressive rather of uneasiness than of acute pain; nor is there the extreme violence of temper, or the alternate throwing out and drawing up of the legs which accompanies colic and griping pains in the bowels. "In no other infantile complaint do we observe the same knitting of the eye-brows unaccompanied with crying. The head hanging over the nurse's shoulder, and the half-closed eye-lids, are also alarming symptoms." Where convulsions, together with strabismus, dilated pupil, blindness, and a comatose state, have already taken place, the nature of the case is but too evident. Convulsions, as we have already stated, sometimes occur even at the commencement of the disease; no one, we believe, at the present day considers them ever to be a purely idiopathic affection; whatever may be their exciting cause, they indicate serious functional derangement of the nervous

system, and what was originally perhaps only sympathetic disorder, may, if neglected, terminate in organic disease. When convulsions or spasm of the glottis, which may be considered as a modification or local species of them, resist the ordinary means for correcting disordered states of the digestive organs and improving the general health, we should suspect a tendency to disease of the brain, and take our measures accordingly.

A readiness in detecting that species of hydrocephalus which occurs some days or weeks after an attack of scarlatina, is peculiarly desirable, both because it is an affection by no means of rare occurrence, and because, if taken early, it is the most manageable perhaps of all the forms of dropsical effusion within the head. The first symptom which warns us of its existence is severe headach; and if this be neglected, convulsion, loss of sight, and a comatose state soon follow. Like the general anasarca which usually accompanies it, it is a truly inflammatory affection, and may be often speedily arrested by the use of active antiphlogistic measures. It is most to be dreaded when it makes its advances in a slow and insidious manner. The sudden disappearance of the anasarca, when unaccompanied by any increase in the evacuations, occasionally gives rise to this affection of the head.

A lethargic state, with irregularity of the pulse and dilatation of the pupil, occurring with or without fever, occasionally depends on constipated bowels, and vanishes rapidly on the exhibition of an active purgative; but it is highly probable that such cases, if neglected, would often pass into confirmed hydrocephalus; for we cannot agree in opinion with Willan and Underwood in thinking that cases, though they possess all the characteristic symptoms of hydrocephalus, yet are not really allied to that disease, provided they yield to the free use of purgative medicines. Dilatation of the pupils has sometimes seemed to depend on the presence of worms in the intestines.

In all cases of doubt it is safer to lean to the supposition of the disease being hydrocephalus, and to treat it as such. From this, even though we should be in error, little inconvenience can arise; whilst, on the other hand, if we wait until unequivocal symptoms of the disease in its confirmed state have developed themselves, all our efforts at checking its further and fatal progress will too often be of no avail.

Dr. Gooch has described a peculiar state of the brain occurring in infants which has usually, but erroneously, been attributed to congestion of this organ; whereas it seems really to depend on the very opposite state, or a deficiency of blood in it. It is in children of from two months to two or three years old that it usually makes its appearance, and generally in such as are small and delicate, and have been exposed to some previous debilitating cause. The leading symptoms consist in heaviness of the head, drowsiness, and languor. There is an absence of heat and of all the symptoms of fever, the skin being occasionally even colder than natural. The tongue is slightly white, and a transient flush at times passes over the cheek. There are no signs of pain. Under the antiphlogistic treatment usually pursued in acute hydrocephalus, consisting of leeches, cold applica-

tions, purgatives, and especially calomel, all the symptoms become aggravated, the child growing colder and more languid, the pulse quicker and weaker, and death by exhaustion takes place after a few days; whilst, on the contrary, several have recovered under the use of an abundant supply of light nourishment, and the cautious employment of ammonia and other stimulants. In two cases only did he observe symptoms of oppressed brain, coma, stertor, dilated and motionless pupils; and this was only for the last few hours before the fatal termination. On dissection, the brain is found pale and bloodless, with no other morbid appearance than perhaps an increased quantity of serum in the ventricles. The late Dr. Armstrong has applied to an affection in many respects very like that just described, the name of "hydrocephalus from venous congestion;" whilst by Dr. Darwall it has been called asthenic hydrocephalus.

The disease, however, to which the term hydrocephalus is, by the majority of writers of the present day, conventionally restricted, is so different from this passive effusion, as well in most of its symptoms as in the treatment which it requires, and in the morbid condition of the brain discovered after death, that no benefit, we think, can arise from comprising both under the same name. The term, in regard to its derivation, is, we admit, equally applicable to each; but this only shows the impropriety of having named them, not from any thing essential, but from an effusion which may be present or absent in both, and is consequently characteristic of neither.

The above described morbid condition in infants has also been noticed by Dr. Marshall Hall, who was generally able to trace it to the diarrhoea of weaning, or to leeching from some previous complaint, or some other cause of exhaustion. He too, like Gooch, believes that it is often mistaken for "hydrocephalus, or inflammation of the brain." There is at first, according to his observation, great restlessness with irritability of temper, pale and anxious countenance, and frequent pulse; dozing and deceptive appearances of amendment succeed; but the pulse continues to rise, the cheeks and the extremities grow cold, the voice and cough husky, and the patient soon sinks exhausted;—a termination which may, however, be often averted by a proper supply of nourishment and a cordial soothing plan of treatment. Dr. Abercrombie, in like manner, in the last stage of diseases of exhaustion has seen both adults and children, but especially the latter, fall into a state resembling coma for a considerable time before death: the pulse still continuing to be distinctly felt, though feeble; the face pale, the pupils dilated, and the eyes open, but insensible. He has known children, after lying for a day or two in this kind of stupor, recover under the use of wine and nourishment. This state, which seems to correspond very nearly to the apoplexia ab inani-tione of the older writers, is supposed by Dr. Gooch to consist in impairment of the nervous energy, or deficient cerebral circulation. Profuse hemorrhage is well known to be capable of producing dilatation of the pupil and blindness; and when animals are bled to death, convulsions very usually occur, and more or less serous effusion takes place

in the brain, as appears from the experiments of Dr. Leeds.

Appearances on Dissection.—There is sometimes, in consequence of previous inflammation and adhesion, considerable difficulty in separating the skull-cap from the dura mater, and the former is occasionally thinner, more transparent, and of a bluer colour than usual. When we come to examine the state of the parts within the cranium after death, we usually find the vessels on the surface of the brain in a state of considerable congestion. A net-work of florid vessels is occasionally observed in the pia mater, and even patches of extravasated blood, indicative of high inflammatory action, are occasionally detected. This membrane at times also adheres more strongly than natural to the brain. An effusion of serum underneath the arachnoid, and filling the space between the convolutions, is very frequently observed. When it is considerable in quantity and of a yellowish hue, it might be mistaken by a superficial observer for a gelatinous effusion. In some instances it has a sero-sanguinolent character. Opacity and thickening of the arachnoid membrane, and depositions of coagulable lymph, or more rarely of puriform matter on its surface, or between it and the pia mater, are amongst the more commonly observed morbid appearances, and prove unequivocally the inflammatory nature of the affection. These occur especially at the base of the brain, about the pons varolii and decussation of the optic nerves. That these and many other characteristic morbid appearances should have escaped observation in the slovenly manner in which the brain used too often to be examined by slicing it from above downwards in situ, is not wonderful. Before commencing the dissection of the brain itself, it ought to be removed altogether from the skull and inverted into a plate, so as to enable us accurately to examine the important parts at its base.

Adhesions between the opposite surfaces of the arachnoid through the medium of false membrane, are sometimes, though rarely, observed. The arachnoid is occasionally covered, especially when it lines the ventricles, with minute granulations, which give it a rough appearance. They are probably one of the many forms which the effused coagulable lymph assumes, and require a good light for their detection. We must not confound with these granulations the bubbles of air which at times exist between the pia mater, and which may be distinguished by their vanishing on raising this membrane.

The mass of the brain itself, in some rare instances, has appeared evidently infiltrated with serosity. Gölis mentions such a case, in which the fluid could be expressed from the cerebral substance as if from a sponge; and Cheyne also has noticed this appearance of increased moisture on making sections of the organ.

A frequent appearance is that of an unusual number of bloody points in the cut surface of the brain, indicating a considerable increase in its vascularity.

The substance of the brain in acute hydrocephalus is generally softer than natural; and this is especially observable towards the central parts. Yet in some cases, and especially in those which

run a very rapid course, it is found to have retained its usual firmness.

In most instances the ventricles contain a considerable quantity of fluid, which is usually more limpid than that found in the other serous cavities. Sometimes, however, it presents a turbid, whey-like, or puriform appearance, with shreds of coagulable lymph floating in it, as well as lining the walls of the ventricles; and this is particularly the case in the most acute and rapid examples of the disease. The existence of a fluid may often be predicted before we have punctured the ventricles, from the feeling of fluctuation communicated to the finger applied to the surface of the hemispheres, as well as from the flattening of the convolutions. The quantity of water varies from a few tea-spoonfuls to seven or eight ounces; four or five ounces may be stated as the average. Of this the greater part is contained in the lateral ventricles, the posterior horns being usually much enlarged, and the anterior portion of the fornix elevated so as to make the opening of communication very free with the third ventricle, in which, as well as in the fourth, and in some very rare instances also between the layers of the septum lucidum, the effused fluid is likewise found. The choroid plexus is very generally remarkably pale. Small vesicles, not unlike hydatids, are occasionally found attached to the pia mater; and we have seen such adhering to the choroid plexus. They seem to owe their origin merely to a circumscribed sub-arachnoid infiltration; the serous membrane being detached by the effusion at a given point, and distended into a small cyst.

The septum lucidum, the fornix, and other parts forming the walls of the ventricles, are often found in a state of softening, being of a pulpy or occasionally even of a creamy consistence, whilst the lining membrane of these cavities displays equal evidence of inflammation by its opacity, as well as by the layers of coagulable lymph with which it is at times overspread. A lacerated opening in the septum lucidum occasionally exists, and forms a new and unnatural communication between the lateral ventricles. We have seen the infundibulum and the cellular membrane in the structure of the pituitary gland distended with serous effusion into the form of a little bladder. This, by its direct pressure on the optic nerves, in addition to that to which they are exposed from the lymph effused at the base of the brain, and from the dilatation of the ventricles, must tend to complete the derangement of the functions of vision.

Laennec has spoken of minute tubercular granulations dispersed through the brain, and discoverable by a careful microscopic examination; but as their existence has not been confirmed by subsequent observers, it is probable they are at most only a casual occurrence.

Other morbid appearances, of a date anterior to the hydrocephalus, and occasionally, no doubt, its cause, such as tubercles or abscesses in the brain, caries of the petrous portion of the temporal bone, &c., not unfrequently co-exist, and should be carefully sought for.

With regard to the nature of the effused fluid, it differs somewhat from that found in the other serous cavities, being for the most part not coagulable by heat or acids; this is, however, by no

means universally the case, a slight coagulation having in some instances been detected by Dr. Baillie, Dr. Blackall, and others. It has been carefully analyzed by Marcet. Of 1000 parts operated on, 990.80 were water; 1.12 mucopurulent matter, with a trace of albumen; 6.64 muriate of soda; 1.24 sub-carbonate of soda, with a vestige of an alkaline sulphate; .20 phosphate of lime, with traces of phosphate of magnesia and of iron. Acids or heat, according to this chemist, did not produce any decided coagulation.

It has been already stated that abdominal affections often complicate hydrocephalus, that they frequently precede it, and are probably not very rarely its exciting cause. On dissection, unequivocal examples of disease in the viscera of the abdomen have been detected in too many cases to be considered a mere casual coincidence. Thus the liver has been found enlarged, and presenting evident traces of inflammation on its surface, and adhering through the medium of organized lymph to the neighbouring parts. Tubercles on its surface or in its substance, as well as in that of the spleen and mesenteric glands, are occasionally observed. We have found the mucous membrane of the stomach and intestines inflamed, the patches of Peyer's gland much developed, and such firm contraction of the intestinal tube as to give it in parts the appearance of a solid chord. This spasmodic state, when existing in the large intestines, enables us to account for the great difficulty which sometimes attends the administration of enemata during the latter part of the disease. We have likewise met with intussusception of the small intestines, an appearance of which has been alluded to by several writers on the disease. The spasmodic state of the intestines which is thus evinced is probably in some degree analogous to the convulsive actions in the voluntary muscles, and takes place like them under the influence of the morbid state of the brain; at least, they do not seem to be attributable solely to the irritation in the mucous membrane, both because such extreme contraction is not usually observed in instances of uncomplicated inflammation of this membrane, and because we have found it greatest in those parts of the intestines which presented least appearance of inflammation. We have noticed a similar constriction of this canal after death by tetanus, where there existed no inflammation of the intestines.

The peculiar green colour of the stools in hydrocephalus has been attributed to their union with the morbid bile. We were first led to entertain doubts of this opinion being universally correct, and to ascribe the appearance in question rather to a morbid secretion from the glands of the intestines themselves, by observing that the peculiar porraceous tinge was not acquired in perfection till the feces had reached the lower part of the small intestines, the contents of the upper portion being of a pale drab colour, whilst the bile in the gall-bladder was of a yellow colour, and without any tinge of green.

The assertions of Dr. Cheyne as to the frequency of disease in the liver and intestines have been corroborated by the subsequent observations of Dr. A. T. Thomson, Mr. Cooke, and others. In eleven dissections of patients dead of this dis-

ease, Dr. Thomson found traces of inflammation of the liver in nine, inflammation of the colon in the tenth, and intussusception of the jejunum in the remaining one; whilst in three out of Mr. Cooke's four cases the liver was found diseased. Dr. Wilson Phillip's experience leads him to the conclusion that five out of six cases of hydrocephalus arise out of the derangement of the digestive organs; and Abernethy has mentioned three cases of hydrocephalus in all of which the liver and bowels were notably diseased.

Though evident traces of inflammation in the brain or its membranes are detected in a very large proportion of cases, yet there are a few in which a trifling effusion of serum in the ventricles or under the arachnoid is the only morbid appearance discoverable; there being neither congestion of the vessels nor effusion of coagulable lymph, nor softening of the central parts of the brain, the whole organ being as firm and perhaps even paler than in its natural state. Such is, as we have already stated, usually found to be the case in infants who have died with the symptoms of passive effusion previously described. M. Bicheteau, in the *Archives Générales* for the year 1824, has described a case where most of the usual symptoms of hydrocephalus had existed; and yet, on dissection, a limpid serous fluid in the ventricles was almost the only thing detected, and was not by him thought to be the result of inflammatory action: by many, however, we believe it would have been considered as an instance of low inflammation in the arachnoid. Of late years, since pathological investigations have been conducted in a more careful and methodical manner, it has been much more rare to hear of cases which, having possessed the whole assemblage of symptoms characteristic of acute hydrocephalus, yet present on dissection no indubitable marks of inflammatory action. Guersent candidly confesses that amongst his earlier dissections he has notes of many such cases in which no allusion to inflammatory appearances is made; but that, as he became more accurate in his mode of examining the brain, the instances in which proofs of their existence could be detected became infinitely rarer.

Theories of the Disease.—The uncertainty which has prevailed as to the true nature of acute hydrocephalus has given rise to a corresponding diversity of opinion as to the appropriate place for it in systems of nosology. It was long confounded with apoplexy, till Whytt, by a closer investigation of its symptoms, became convinced that it was much more nearly allied to chronic hydrocephalus. Cullen, who at first classed it along with chronic hydrocephalus, in a later edition of his nosology made it a species of apoplexy, under the name of *apoplexia hydrocephalica*. By Macbride it was placed along with fevers, under the name of *febris nervosa hydrocephalica*; and a similar view of it was taken by Pinel in the earlier editions of his *Nosographie Philosophique*, in which it bears the name of cerebral fever; but he subsequently restored it to its old place amongst the dropsies: there is, however, usually no evidence of any dropsical diathesis, effusion into the other cavities, or swelling of the face or limbs, scarcely ever co-existing with it. The investigation of the disease by Quin and Rush, proceeding

on the basis of pathological anatomy, the only solid groundwork of nosological arrangement, led to a more correct conception of its nature, and demonstrated its affinity in a great majority of instances to the phlegmasie. Subsequent inquiries, both in this country and on the continent, have tended to confirm the justice of this manner of considering the subject, and have proved that the effusion is almost always a secondary phenomenon occurring in connection with obvious morbid changes in the brain or its membranes, and in a very large proportion of cases demonstrably the results of inflammation. So fully convinced is Rostan of the effusion being always consecutive to cerebral or meningeal lesions, and never constituting an essentially distinct disease, that he proposes that the term hydrocephalus should be altogether expunged from our tables of nosology. As the effusion and other morbid appearances are such as to indicate inflammation of the serous membrane, the disease has been treated of by several foreign writers under the head of arachnitis of the ventricles and base of the brain; whilst others, conceiving that inflammation of the cerebral structure itself often precedes that of the membranes, have referred its symptoms to the head of cephalitis. Thus, by Conradi it is called "*encephalitis exsudatoria infantilis*," and by Coindet, "*cephalite interne hydrencéphalique*."

That the effusion does not constitute the most important feature in the disease, and that it is not indispensable to the production of any of the symptoms which characterize hydrocephalus, we have a double proof; first, in the occasional absence of these symptoms where effusion to a considerable extent is detected on dissection; and secondly, in their being sometimes present, and that in a very marked degree, when an examination of the brain after death has shown that no effusion had yet taken place. There is sometimes even reason to think that the inflammatory tension is temporarily relieved by this increased action of the exhalent vessels: this can, however, be the case in those instances only where the effusion is moderate. Where it takes place rapidly, and to a considerable excess, it cannot fail to add still further to the derangement of the cerebral functions, and to manifest its presence by symptoms indicative of compression under some circumstances, and of irritation under others. We cannot, therefore, concur in opinion with a late writer, who supposes that the increasing fluid, by stimulating the brain, may occasionally answer a beneficial purpose, and give rise to that momentary recovery of the senses and of the intellect which so often takes place before the fatal termination. Such fleeting and fallacious indications of improvement in the state of the cerebral functions should perhaps rather be attributed to a temporary diminution in the quantity of water in the ventricles under a casually increased action of the absorbing vessels. This partial re-absorption of the aqueous effusion, some time previous to death, is rendered probable by the instances of a similar diminution of effused fluid in the extremities and other parts of the body lying open to our observations, being by no means rare in dropsical subjects at this period. It is only to some change in the state of the effused fluids, or of the circulation within the brain, that we can

look for an explanation of this fact; for as to the alterations of structure and consistency which have occurred in any portion of the cerebral mass or its membranes, it is inconceivable that they should undergo any sufficiently rapid modification to account for it. As to the presence of absorbing vessels in the brain, so long a subject of dispute, the changes which are now so well known to take place in the apoplectic coagulum cannot leave a doubt. The occasional diminution of the effused fluid in chronic hydrocephalus under the influence of pressure or other methods of treatment, is also conclusive on the same point. Indeed the analogies in favour of the existence of such vessels within the brain are so strong, that it seems wonderful that there ever should have been any scepticism on the subject. It is altogether inconceivable that the fluid, which even in a state of health always lubricates the serous cavities within the cranium, should, unlike that in the thorax or abdomen, be stagnant and incapable of removal. Cheyne suggests that the effused fluid may answer the usual purpose of supplying the place of the cerebral matter removed by absorption, thus giving support to the brain, and enabling it in some degree to continue its functions; and hence he conceives that any sudden withdrawal of the water, so far from being desirable, might even have a fatal effect.

Morgagni was one of the first pathological anatomists who pointed out the very frequent dependence of effusion on organic disease of the brain; and Portal has likewise long since insisted on the very secondary importance of the latter in determining the indications of cure. The belief in the inflammatory nature of hydrocephalus, since it was first promulgated by Quin and Rush, has been slowly but steadily making its way both in this and all other countries where medical theories are in any degree under the influence of morbid anatomy. Dr. Garnett argued in favour of this view of the disease from the buffy state of the blood, the acuteness of the pain, the character of the pulse, the benefit received from antiphlogistic measures early employed, as well as from the aggravation ensuing upon the use of stimulants, and finally from the appearances found on dissection. Similar views were followed up with great industry and ability by Dr. Cheyne, who showed that the opinion of Fothergill, who attributed the effusion to the rupture of a lymphatic vessel in the brain, as well as that of Whytt, who ascribed it to a watery state of the blood, or to a laxity of the exhalents, and that of Darwin, who thought it consisted in a debility of the absorbent vessels, were all hypothetical and untenable; whilst he proved by numerous carefully made dissections that dropsical effusion here, as in so many other cases, is, to use the language of Heberden, not so much a disease in itself as a symptom of one. The opinion of Cheyne seems to be, that hydrocephalus owes its origin, in the first instance, to inflammation; that this gives rise to a morbid accumulation of blood in the head, or venous congestion; and that effusion is the ultimate result. Occasionally the concatenation of morbid actions can be traced still farther back: thus there is often, first, disease of a distant part, then increased irritability, which is soon attended by increased arterial action, absorp-

tion of the substance of the brain, venous congestion, and finally effusion. "There is no proof whatever," says the above-named writer, "that the effusion into the ventricles is the cause of any of the violent symptoms."

The greater or less quantity of fluid found in the ventricles in acute hydrocephalus seems to depend on the length of time which the patient has continued to live after the commencement of the second stage. Though the state of the disease may undergo some modification by the occurrence of effusion, yet there is much reason to believe that some degree of inflammation exists to the very end. Cheyne, although a strong advocate for the inflammatory nature of hydrocephalus, by no means goes the length of Dr. Rush, so as to believe it merely a modification of phrenitis. He points out, on the contrary, with his usual accuracy, many striking marks of distinction between the two diseases, deduced from their causes and symptoms, from the ages respectively prone to each, as well as from the morbid appearances found after death. "Hydrocephalus," he concludes, "appears to consist in a diseased action of a peculiar kind, but of what kind we can as little explain as we can the nature of the scrofulous or syphilitic action."

According to Abercrombie, hydrocephalus is originally an inflammatory affection; in its most ordinary form seated chiefly in the substance of the central portions of the brain, and terminating generally in ramollissement of those parts, combined with serous effusion into the ventricles. It may, however, prove fatal, and have all the symptoms commonly considered as those of hydrocephalus, without any effusion. Thus we occasionally observe coma of long continuance, though on dissection no such cause of it is detected; and on the other hand, effusion has been unexpectedly found, though coma had never manifested itself. Again, even when the symptom does exist, it may sometimes be entirely removed by purgatives and other antiphlogistic measures, and yet the disease proceed uninterruptedly to its fatal termination. In the cases which have been published by the same able physician, we meet with every variety in the state of the pulse, the vision, and the intellectual functions; so that we can obtain from none of these sources indubitable evidence of effusion having taken place. Though inflammation of the central parts of the brain constitutes the most frequent modification of hydrocephalus, he admits that it may take place in connexion with inflammation of other parts of this organ, or of the membranes which envelope it. He has noted but two instances in which he did not succeed in demonstrating other inflammatory appearances besides the effusion of serum; and in these the disease presented itself in the most insidious and chronic form, and offered a remarkable contrast to the active symptoms of what he considers the usual species of the disease. As to the serum, he believes, that even though it were absorbed, the patient's condition would be little improved, as the softening or disorganization of the brain would remain behind. In a word, the coma and other symptoms of hydrocephalus are the effect, not of the effusion, but of that morbid condition of the brain of which it is itself the consequence.

Lallemand conceives that the inflammation in hydrocephalus may commence either in the cerebral substance, and subsequently extend to the membranes of the brain, and thus induce effusion; or, on the other hand, begin in the arachnoid, and extend, after a longer or shorter period, to the brain; but of these two origins he considers the latter by much the most frequent. In their earlier stages he believes that they may often be distinguished from each other. The possibility of their commencing simultaneously in some cases, in both these parts, under the influence of a common cause, must not, however, be forgotten. Inflammation of the membranes, according to Lallemand, is characterized by restlessness, insensibility, convulsive affections and delirium; whilst that of the cerebral substance itself may be recognised by the gradually extending paralysis, the rigidity and pains in the limbs, together with the impairment of the memory and intellect. Inflammation of the brain itself has a rapid progress, and is speedily mortal. Hence, when the symptoms of hydrocephalus depend on inflammation of the cerebral substance, they are more severe, and the disease runs a shorter course. In several cases such inflammation has existed in the septum lucidum, fornix, and other central parts of the brain, without extending to the arachnoid where it lines the ventricles, and consequently without effusion, and yet all the symptoms of hydrocephalus have been present. Hence, he argues, it is highly probable that even in those other cases where effusion does exist, it has much less concern than the state of the neighbouring parts in producing the characteristic symptoms of the disease. From erroneous views on this subject too little attention has, he thinks, been paid in the treatment to the ramollissement, and the efforts of practitioners have been too exclusively directed to promoting the absorption of the effused fluid.

The investigations of MM. Martinet and Parent-Duchâtelet have shown that inflammation of the arachnoid at the base of the brain is much more common in infancy than in adults. In the latter, inflammation of this membrane occurs more frequently in that portion of it which covers the upper and lateral parts of the hemispheres, and is characterized at first by delirium, to which a soporose state and at length coma succeed; whereas in the arachnitis of infants there is a greater tendency to convulsive affections and less to delirium.

[Dr. D. D. Davis, of the London University, maintains, that acute hydrocephalus is an inflammatory disease, and that it is curable equally and by the same means with other diseases of inflammation. (*Acute Hydrocephalus or Water in the Head, an Inflammatory Disease*. Amer. Med. Lib. edit. Philad. 1840.)]

The inflammatory nature of the great majority of cases of hydrocephalus has also been recognised in its fullest extent by Gölis, Conradi, and almost all of the German pathologists of the present day. Forney, however, a very respectable authority, thinks that the frequency of effusion into the ventricles during childhood depends not on inflammation, but merely on a state of increased activity in the vessels of the brain, which accompanies its rapid and premature development; but Raimann with much reason believes that in addition to this

state, the existence of true inflammation, either of an acute or chronic kind, is indispensable.

[Of late years, by many pathologists the acute hydrocephalus of authors has been regarded as *tubercular meningitis*. According to MM. Barthez and Rilliet, (*Traité Clinique et Pratique des Maladies des Enfants*, i. 550. Paris, 1843,) M. Papavoine is probably the first who established the tubercular nature of this form of meningitis. (*Journal Hebdomadaire*, vi. 113. Paris, 1830.) Afterwards, MM. Fabre and Constant presented a memoir on the same subject, which was "crowned" by the Institute. In 1835, Dr. Gerhard, of Philadelphia, (*American Journal of the Medical Sciences*, Nov. 1835,) and M. Ruz, (*Thèse de Paris*, 1835,) published their observations on the subject. An inaugural dissertation by M. Piet, published in 1836, is highly spoken of by MM. Barthez and Rilliet. These gentlemen regard tubercular meningitis or acute hydrocephalus to be characterized anatomically as follows:—*First*. By a deposition of tubercular matter in the meshes of the pia mater, presenting itself in the form of flattened or round granulations disseminated in different parts of the hemispheres or base of the brain, often not larger than a pin's head, most frequently opaline or white, sometimes grey; semi-transparent; commonly isolated, sometimes congregated;—in very rare cases, the granulations being the sole meningeal lesion. *Secondly*. By inflammation, characterized by a secretion of concrete pus or of false membranes in the pia mater, which is thickened, yellowish or greenish, friable, and sometimes adherent to the cerebral surface. This phlegmasia most commonly coincides with the tubercular granulations of the meninges. In rare cases, it is entirely independent of them. It commonly occupies the base of the brain. In 27 of 33 patients, MM. Barthez and Rilliet found the tubercles or granulations and the phlegmasia of the pia mater associated; in four cases, the meningitis was not accompanied by any tubercular production of the encephalon; in two cases, the granulations or meningeal tubercles had not occasioned any phlegmasia. In all these cases, however, the symptoms were nearly identical. *Thirdly*. By a peculiar state of the arachnoid, which renders it slightly glutinous or fishy to the feel. *Fourthly*. By a white, creamy softening of the central parts of the brain, occupying, in the majority of cases, the septum lucidum and fornix, seldom extending to the inferior parietes of the ventricles. *Fifthly*. By an effusion of serum into the ventricles, varying from two to four fluid ounces, and, at times, in much greater quantity. *Sixthly*. By a deposition in the organs of tubercular matter, generally at a slightly advanced stage, or when it has assumed the acute form.

It may be proper to remark, that patients unquestionably present themselves with all the symptoms that are ascribed to acute hydrocephalus, without any tubercles being present in the brain or its meninges; whilst, on the other hand, it is affirmed by Dr. P. Hennis Green, tubercles may exist without there being any cerebral or other phenomena, that could give occasion to more than a suspicion of their existence, and in some cases not even to that.]

Causes.—Of the predisposing causes, the pe-

riod of life seems to be one of the most influential; hydrocephalus being very much more frequent during infancy and childhood than at any subsequent period. The rapid evolution which the brain is then undergoing, and the great proportion of blood sent to the head, appear to be the causes of the peculiar tendency to cerebral inflammation which characterizes this age. The more early and rapid the development of the cerebral organs, the greater is the risk of hydrocephalus. Its connection with precocity of intellect is indeed matter of daily observation, and large-headed children are generally found to be the most subject to the disease. The latter fact, indeed, is doubted by Underwood, but both Gardien and Guersent confirm the popular opinion. The greatest number of cases appear from the tables of Percival and of Bricheteau to occur between the second and fifth year; but at the same time it is not infrequent in infants at the breast, or, indeed, in children of any age up to the twelfth or fourteenth year: after this period it is less common. A scrofulous habit predisposes strongly to the disease. The greatest number of cases occur in constitutions evidently of this kind. When a strumous tendency exists, all the children of a family have been known to be thus swept off in succession as they approached a certain age. Hydrocephalus and scrofulous affections seem to be mutually convertible into each other, the disappearance of scrofulous disease of the glands or joints being frequently followed by the development of hydrocephalus; while, on the other hand, all the symptoms of confirmed phthisis have been known to vanish on the occurrence of the latter affection. The disease has usually been thought to take place most frequently in children with a fair skin and hair, pink complexion, and blue eyes. Cheyne, however, says that he has seen it oftener in those with dark eyes and dark complexion. As scrofula occurs pretty equally in both these temperaments, it is probable that hydrocephalus also is nearly as frequent in one as in the other.

Disorders of the digestive or respiratory organs, difficult dentition, scarlatina, measles, and other diseases which induce debility or excite febrile action in the system, may, according to the intensity of their action, be placed either amongst the predisposing or the exciting causes. The frequent and indiscriminate use of calomel in children's complaints has been accused by Blackall of predisposing to the disease. This, however, can apply only to the abuse of this remedy; judiciously employed it is of the greatest utility in cutting short such indisposition as might, if neglected, terminate in hydrocephalus. The pernicious habit practised by some unprincipled nurses, of giving narcotics to infants in order to quiet them and render them less troublesome—a practice which cannot fail to derange the functions both of the digestive organs and of the brain, has been noticed as an occasional cause of this affection. Belladonna, which is much and advantageously employed in Germany as a remedy in whooping-cough, and also as a preventive of scarlet fever, has sometimes, in imprudent hands, led to inflammation and effusion within the cranium. We have seen hydrocephalus apparently induced by the abominable custom, unfortunately not very

uncommon amongst the lower classes, of giving spirits to children.

Great terror and anxiety in the mother during the last months of pregnancy has been placed by Gülis in the list of predisposing causes, in support of which he adduces the fact, that a great proportion of the children born soon after the bombardment of Vienna by the French in 1809, were seized with convulsions within a month after their birth, and died of inflammation within the cranium; effusion of coagulable lymph on the membranes, and of serum in the ventricles, being discovered on dissection. The same writer conceives that the frequent exhibition of emetics in catarrhal or other affections may occasionally lead to the disease in scrofulous children. We are not aware, however, that any facts in confirmation of these opinions have been observed in this country.

To the list of exciting causes enumerated above, we may add external injuries, such as falls or blows on the head, the extension of inflammation from the external ear to the brain. The sudden suppression of accustomed discharges, or drying up of sores behind the ears or eruptions about the head, without an appropriate modification of diet, or the simultaneous employment of suitable evacuations, are also amongst its occasional causes. However erroneous may have been the explanation of the facts afforded by the humoral pathology, their reality and importance are indubitable, and will be least questioned by those who have attended the most closely to the powerful influence of counter-irritation in controlling morbid determinations of blood to internal organs, and in subduing their tendency to inflammation.

Treatment.—The chances of success in the treatment of hydrocephalus depend in a great measure on the period at which it is detected. It is during the precursory symptoms, or the commencement of the inflammatory stage alone, that the influence of remedial measures can be reckoned on with any thing like confidence. It may be said that at so early a period we can have no certainty of the disease being actually incipient hydrocephalus: in dubious cases, however, it is infinitely more reasonable to assume the affirmative, and take our measures as if the presence of this formidable affection were fully ascertained, than to remain inactive spectators of its progress till the disease has assumed an unequivocal and comparatively hopeless character. When a family has already lost one or more of its number by this disorder, the recurrence of a precisely similar set of initiatory symptoms in any of the remaining children renders an active mode of proceeding doubly incumbent. Under the head of prognosis it has been already stated that cases in every stage of the disease have, under active and judicious modes of treatment, been brought to a favourable termination; and this is sufficient to show that trifling in the commencement, or despondency and the want of energy and perseverance to which it gives rise in the advanced stages of the complaint, are equally unjustifiable. There is too much reason to apprehend that many children have fallen victims, not so much to the incurable nature of their case, as to the indecision of their medical attendant.

The precursory stage being very commonly

marked by derangement in the action of the intestines, and interruption or perversion of the biliary secretion, the employment of active purgatives, of which mercury should form a part, is almost always indicated; and we should persevere in their use with the double object of rendering the evacuations natural, and relieving the uneasiness in the head.

Where the threatening symptoms have taken their rise soon after an injury of the head, though it may have been of a slight nature, and the effects be as yet trifling, the employment of venesection, or the application of a few leeches to the temples as a precautionary measure, is advisable, in addition to the use of aperients and a reduction of the ordinary diet.

Where the symptoms in the head undergo no favourable change, though the bowels have been freely acted on, the probability of disease having become established within the brain becomes hourly stronger, and more energetic measures must immediately be had recourse to. The chief indications in hydrocephalus are to reduce the force of the cerebral circulation; to obviate all sources of irritation, whether originating in the abdominal organs or elsewhere, which might re-act on the brain, and thus aggravate, if they did not give origin to, the disease: to alleviate pain, vomiting, and convulsions, even where we fail in removing their cause; to support the strength in the advanced period of the disease; and finally, when death seems inevitable, to render its approach as easy as possible. For fulfilling the first and most important of these indications, our chief resources are to be found in the antiphlogistic class of remedies. Bloodletting, active and repeated purgation, cold applications, mercury, and blisters, are amongst the most accredited remedial agents, and are here arranged nearly in the order of their relative efficacy. The mode of employing these, as well as some additional therapeutic means, remains to be considered.

Bloodletting.—The advantage of early bloodletting in hydrocephalus is more generally agreed upon than that of any other measure whatsoever. The importance of the brain to all the functions of life, and the unyielding nature of the parietes of the cavity in which it is contained, show us, when conjointly considered, how the effusion, which in many other situations is the natural cure of inflammation, must, within the cranium, if it proceed to any extent, be attended with extreme danger. The only safe termination to inflammation here is in resolution; and to effect this, free, early, and in some cases repeated abstraction of blood must be had recourse to. Opening the temporal artery, or copious venesection, either in the arm, or, perhaps, better still, in the jugular vein, often affords immediate relief to the headach, reduces the fever, and causes purgatives and mercurials to act with greater readiness and efficacy.

Dr. Rush practised bleeding in this disease at least as largely as in phrenitis; and the activity of his practice has been equalled or surpassed by that of Dr. Maxwell of Dumfries, with the remarkable result of sixty recovering out of ninety cases, or two-thirds of the whole. The child being placed in the horizontal posture, Dr. Maxwell opens the jugular vein, and stops it from

time to time with the finger, so as to prevent syncope taking place, till a very considerable quantity of blood has been obtained; the bleeding is allowed to go on till the pulse altogether disappears: a state of insensibility ensues, and occasionally continues for some hours afterwards. The disease is said to be often immediately arrested by the shock which is thus given to the circulation. But the possibility of death occurring under the very hands of the operator will probably prevent many persons from imitating this bold proceeding; besides, some doubts might be raised even as to the principle on which it is performed being physiologically correct or universally applicable, as excessive losses of blood are known, as already stated, to induce convulsions and effusion even in healthy subjects. The experience of no single individual, however extensive it may be, is sufficient to establish the propriety of such a practice; and certainly the great debility which exists in so many cases of hydrocephalus, seems often strongly to counter-indicate such an extreme measure. Except when the attack is of the very violent kind, with high fever, a strong pulse, and extreme pain and restlessness, the majority of practitioners are satisfied with a single bleeding, and trust subsequently to the repeated application of leeches or to cupping. Cheyne is an advocate for early bloodletting in most infantile fevers of a suspicious character, attended with great irritability of stomach, tumid hypochondria, or suppression of the secretions. He has also adduced evidence of the utility of a moderate bleeding even in the advanced period of hydrocephalus, when pain of the head and vomiting continue to be predominant symptoms; at the same time he is convinced of the inadequacy of this measure singly to subdue the disease at any period of its progress, and believes that its repetition is even at times not unattended with hazard. The pulse must, however, be our guide, as, if it rises in strength, and the symptoms continue or recur, blood may again be abstracted with safety and advantage. By Abercrombie also, venesection is employed in the most decided manner in the acuter forms of the disease; whilst he admits that in those which assume a more chronic character, it has much less control over the disease, and cannot be borne to the same extent. Bloodletting seems to have been practised in some of his cases, and with occasional good effect, even after the occurrence of the slow, varying, and weak pulse of the second stage. The French practitioners generally trust almost exclusively to the free abstraction of blood in the earlier stages of this complaint; and some of them prefer taking it from a vein in the lower extremities, instead of from the arm or jugular vein; but we are not aware that any decisive proofs of the superiority of this mode of bleeding, which is gone into very general disuse in our own country, have been adduced.

Bloodletting has, however, its opponents as well as its advocates, but they are comparatively few in number. Dr. Garnett was averse to the employment of general bloodletting in children labouring under hydrocephalus; and even in adults he usually gave the preference to the local abstraction of blood, both because it appeared to him to exert more influence over the local inflamma-

tion, and because he thought it less likely to add to the debility which comes on in the course of the disease. Similar views of the relative value of local and general bloodletting are entertained also by Dr. Porter of Bristol. Such is not, however, the general opinion of the profession; and on a review of such cases as have fallen under our own observation, we have sometimes seen cause to regret that general bloodletting had not been earlier performed, or carried far enough, but never the reverse. That this as well as every other measure will, in a very great proportion of cases, prove ineffectual, we readily admit, as we do not participate in opinion with those who think that hydrocephalic inflammation is always as capable of being subdued by active antiphlogistic treatment, as that induced by injuries of the head in adults, which usually falls under the care of the surgeon. The predisposition and debility of constitution which often exist in the former, render the cases, in many instances at least, widely different.

As to the quantity of blood which may be taken from infants with safety, the most specific directions are those furnished us by the late Dr. John Clarke: his extensive experience led him to the important conclusion that very young children bear well the loss of blood even to fainting, once or twice repeated; whilst on the other hand their powers are apt to sink if it be more frequently had recourse to. Children of four years old and upwards can, however, support the repeated performance of venesection with impunity. In infants of only a year old the jugular vein may often be opened without difficulty. At this period of life three ounces may be considered a full bleeding, and nearly the same quantity may again be taken away in twelve hours afterwards, if the symptoms seem to demand it, and the weakness is not too great. Where blood could not be obtained from a vein, Dr. Clarke gave cupping from the nape of the neck the preference to leeches. Local and general bloodletting should usually go hand in hand. Where the latter measure is, from the age of the child or any other cause, inapplicable, or has already been carried as far as is prudent, it is to cupping from the nape of the neck or to leeches that we must chiefly trust. For an infant of six months old, from four to six leeches, according to the strength of the child and the violence of the symptoms, may be once or oftener applied either to the temples or behind the ears, to the angle of the jaw, or to the nape of the neck; perhaps the latter situation, from its proximity to the medulla oblongata and base of the brain, may deserve the preference. Kuhn recommends their application to the inner angle of the eye, probably with a view to more directly unloading the cerebral vessels. When there is pain, tenderness on pressure, or fulness in the region of the stomach or liver, the application of leeches to these parts should not be neglected.

Purgatives.—Remedies of this class are exhibited in hydrocephalus with the double view of improving the secretions of the mucous membrane and liver, and thus removing one evident source of irritation, and also of producing derivation from the head, and diminishing the quantity of the circulating fluids. By means of calomel given in

combination with jalap or compound powder of scammony, or, if these are found to irritate too much, with rhubarb, we shall generally succeed in procuring evacuations. At first these medicines may require to be aided by the occasional interposition of saline purgatives with the infusion of senna, which have the additional advantage of producing abundant watery secretions. Purging actively seems to Abercrombie to be the remedy which is of the most importance in all the forms of the disease; and though he sets a due value on the aid of venesection, he believes that more recoveries from head affections take place under the use of very strong purgatives than under any other mode of treatment whatever. He has found the croton oil one of the most convenient and effectual cathartics in diseases of this kind, which are so often accompanied by great obstinacy of the bowels. Whytt never saw even temporary relief of the symptoms produced by any other means than those which increased the evacuations; and Rush was likewise a strenuous advocate for the employment of medicines of this kind. It is chiefly at the commencement of the disease that active purgatives are proper; but even here there are limits and exceptions to their use. Where there is a high degree of irritability of the mucous membrane of the stomach or intestines, they will be useless or even injurious till these states have been subdued by bloodletting in some of its forms. When in a high state of excitement, we shall often attempt in vain to force the secretions of the liver or mucous membrane; and to procure healthy evacuations under such circumstances is quite out of the question. When the usual purgatives seem to aggravate the vomiting without moving the bowels, or when they produce only mucous stools attended with much irritation, a perseverance in their use cannot fail to be prejudicial. When the commoner purgatives have been rejected by the stomach, or proved insufficient, Dr. Cheyne occasionally succeeded in quieting the stomach and procuring evacuations, by giving a drachm or two of magnesia saturated with lemon juice every second or third hour, venesection to an adequate extent having been usually premised. In other cases he postponed the use of aperients till the state of the secreting organs had been first modified, and some appearance of feculent matter could be observed in the stools, under the influence of a combination of calomel, opium, and antimony. Besides, we must always bear in mind that the local irritation which the excessive or untimely employment of cathartics is capable of producing, cannot fail to re-act on the head, and aggravate instead of relieving the hydrocephalic symptoms. So great, however, is the torpor of the intestinal canal in most instances, that such cases are, perhaps, only to be looked upon as the exceptions. We cannot agree with Dr. Porter in condemning active purgation as an inefficient measure, even were his hypothesis granted, namely, that the derangement of the abdominal organs is always secondary, and merely symptomatic of the cerebral disorder.

Purgatives should have a fair trial in conjunction with other antiphlogistic measures during the commencement of the disease; after which, if they do not appear to be making any decided im-

pression on it, the mercurial plan of treatment may be resorted to, a laxative enema or an aperient medicine being still occasionally exhibited. A large glyster of broth, with some of the purgative salts in solution, repeated frequently in the course of the day, has been found a useful palliative by Cheyne, the child lying at ease for a considerable time after its exhibition. Its good effect is attributable partly to its soothing influence, and partly to its protecting the intestines from the irritating qualities of the morbid feces.

Cold Applications.—The increased activity of the circulation within the brain may be controlled in a considerable degree by the long-continued application of cold to the shaven scalp, which may be effected either by means of cloths, kept constantly wet with cold water, or evaporating lotions containing spirits and ether; or more effectually still, by means of a bladder containing pounded ice mixed with water, kept in constant contact with the forehead, temples, and upper part of the head. This measure, in conjunction with an erect position of the head and trunk, persevered in for many days together, has been known to exert a surprising influence over inflammation of the brain both in adults and children. But the most efficient method of all consists in directing a stream of cold water against the crown of the head, and continuing it for some moments, till its full effect is produced. This is so very powerful a means of reducing cerebral action, as to demand much circumspection in its employment; and it is chiefly applicable to the more violent examples of the disease. To Burns it appears a measure of rather doubtful propriety, as it is often followed by alarming collapse: he thinks that it is only in the early part of the disease, when there is much heat, and when adequate evacuations have been already premised, that its employment can be safe. Abercrombie, while he admits that its use requires discretion, is a strenuous advocate for its utility in hydrocephalus, and has likewise employed it with great success in sudden coma connected with congestion of the head, and in the convulsive affections of children, in which last it is more effectual and much more generally applicable than the warm bath. Dr. Darwall has known cases which seemed utterly hopeless recover by letting water drop in a small stream upon the scalp, and continuing it till the head no longer recovered its high temperature on intermitting the stream; and Formey thinks it, when repeated every two hours for several days and nights consecutively, the most effectual remedy we possess both in the inflammatory stage and in that of effusion.

Mercury.—It is now nearly fifty years since the first recommendation of mercurials in hydrocephalus by Dr. Dobson; but though they have formed a part of the standard treatment of the disease during all the intervening period, the mind of the profession is still far from being made up, either as to the principle on which they act, or even as to their utility. Upon an extensive examination of the subject, the preponderance of evidence seems to be decidedly in favour of their employment. To bring the constitution of young children fully under the influence of mercury is often very difficult, and especially so in this dis-

ease; and even when we have succeeded, and the gums and salivary glands have become affected, the case too often runs rapidly on to its fatal termination. A few cases, however, seem unequivocally to have been saved by this remedy; and in many the convulsions and other symptoms have been rendered milder by it, and the senses restored, though the disease has not been eventually arrested, or the patient has been too weak to rally again. The effect of mercury in controlling inflammation and modifying the action of the exhalents in other parts of the body is notorious; and in certain affections of the eye, as every step in the progress of improvement is exposed to view, there can be no doubt as to the reality of its influence. Its first introduction into the treatment of hydrocephalus was grounded on the hope of increasing the activity of the absorbents, and cases have since been recorded where it seems incontrovertibly to have had this effect. Thus in a young child labouring under the disease, where the sutures were not yet closed, Dr. Clarke has seen the fluctuating tumour at the fontanelles gradually disappear under the use of mercury; and numerous instances of recovery by the same means in very advanced periods of the affection, in some of which effusion had in all probability occurred, are favourable to the same hypothesis; as is likewise the influence which it seems occasionally to exert in cases of chronic hydrocephalus.

Considerable embarrassment is often felt as to the precise period at which the mercurial treatment should be commenced. To lay down any invariable rule as to this or any other part of the management of a disorder which appears under so many different forms, is impossible; but to give this practice a fair trial, it must be commenced before the inflammatory stage is very far advanced; and as we are often not called in till the disease has already existed many days, it is frequently necessary, after merely clearing out the bowels and abstracting a due quantity of blood, to proceed immediately to the use of mercury.

Calomel is the preparation usually employed. It may be given in doses of one or two grains, with or without opium, according to the state of the bowels and other symptoms, and is to be repeated every third or fourth hour till the gums become affected, unless griping and diarrhoea be induced by it, in which case the hydrarg. cum cretâ, or the external use of mercury, should be substituted. Gölis, though he has great faith in calomel in the commencement of the inflammatory stage and previously, is averse to the large doses usually given in England, as he thinks he has seen them in some instances produce fatal enteritis, both in this disease and in croup. The dose to which he confines himself is half a grain repeated every two hours, till it produces four or five green slimy stools or colic; and after these effects have ceased, he returns to it again. If the bowels are very hard to move, he combines with it three or four grains of jalap previously toasted, in which state it is less apt to sicken or gripe. Children under one year he finds bear larger doses of calomel without colic, diarrhoea, or salivation, than those several years older. His experience here coincides with that of Dr. Clarke, who never

saw salivation induced in children under three years of age save in three instances, though he employed it largely in a variety of diseases.

The corrosive sublimate in minute doses has been preferred by some practitioners, when it is necessary to produce the specific effects of mercury very rapidly. Dr. Merriman, who has succeeded in curing two cases of the disease with this preparation, employs it in doses of from one-thirtieth to one-sixteenth part of a grain repeated every four or six hours, with the effect of producing copious olive-green stools, and an increase in the urinary secretion.

In very urgent cases both the internal and the external employment of mercury should be combined. From half a drachm to a drachm of mercurial ointment may be rubbed into the thighs, or in very young infants more conveniently into the back three or four times a day; and it may also be used as a dressing to blistered surfaces. If in the case of infants this ointment be objected to, calomel may be rubbed into the gums, three or four grains at a time, and repeated every four or five hours.

In whatever form mercury is employed, it is usually requisite to continue its use for a great number of days uninterruptedly; and when either it or any other medicine has produced a favourable change in the disease, its employment should never be abruptly terminated, but on the contrary very gradually relinquished. The only exception, perhaps, to this rule is in regard to digitalis.

Blisters.—The greatest contrariety of opinions prevails as to the period at which blisters should be used, and the place where they ought to be applied. If employed at all in the commencement of the disease, while the inflammatory symptoms continue high, a practice the propriety of which there is much reason to doubt, it should only be to parts at a distance from the disease, as the legs or arms, or between the shoulders, with a view to producing derivation from the seat of the inflammation. In the acuter cases, where there already exist much restlessness and vascular excitement, they can scarcely fail to be injurious till the activity of the circulation has been reduced by adequate evacuation.

In the second stage of the disease, a remarkable alleviation of the symptoms is frequently produced by the application of large blisters to the head or nape of the neck: a number of these may be applied in rapid succession to the vertex and all round the head; or what is perhaps a still more effectual method, the blistered surface may be kept in a state of suppuration for several days consecutively, by dressing it with ointment of savin or of Spanish flies. The dread of strangury has deterred many practitioners from the use of the latter, though perhaps without sufficient reason, as it is possible that the occurrence of such an effect might occasionally even have a beneficial influence on the disease in the head. Tincture of cantharides has been exhibited with the very intention of inducing this species of irritation in the neck of the bladder by Dr. Merriman, in doses of five or ten drops every four hours, and the occurrence of severe strangury has appeared to him to arrest the cerebral symptoms; thus exemplifying the influence of a new and artificially excited

disease in controlling the morbid action existing in a distant organ.

When tenderness in the epigastric or hypochondriac regions continues even after leeching the part, a blister may be applied here also with advantage. Gölis thinks that from the sympathy of the head with the stomach, a blister over the latter organ exerts a peculiarly marked influence on the cerebral symptoms; but as blisters often rise but slowly in this situation, he generally applies them in preference to the calves of the leg.

We have thus passed in review those remedies which seem most entitled to confidence in attempting the cure of hydrocephalus. Of these, purgatives, bloodletting, and cold applications belong, as we have seen, more peculiarly to the early or most inflammatory period of the disease—mercury and blisters to the more advanced stages. But the stages often run into each other by such insensible steps, or are so completely confounded together, as frequently to render any division of this kind of very little avail in practice. It remains to say a few words of some other modes of more equivocal efficacy, or which are useful only as palliatives.

Digitalis.—This medicine, first used in this disease by Dr. Withering, and very generally employed since, is given in the earlier stages with a view to aid in reducing inflammatory action, and in the later to favour the absorption of the effused fluid. It is in that variety of the disease which succeeds to scarlatina, that it has appeared to be of most use. It is not, however, without difficulty that we can ascertain when it has been carried as far as is consistent with safety; for in consequence of the irregular state of the pulse, the tendency to vomiting, and derangement of the cerebral functions which already exist as a part of the disease, we are deprived of some of the chief signs by which to recognise the influence of the medicine. What we have seen of its use in this disease has not disposed us to value it highly. Dr. Cheyne, however, speaks rather favourably of it, and has given two cases in which it seemed to be of use. He begins with ten drops of the tincture, and to every succeeding dose, which is generally given after an interval of four hours, he adds two or three drops more than was contained in the preceding one; so that in a day or two some part of the system may be affected. He has thus given as many as one hundred and twenty drops a day to a child only four years old. He thinks that the slow irregular pulse from digitalis may be distinguished by its smallness and sharpness from that of hydrocephalus, which is not only unequal, but more soft and full. "The languor from digitalis is attended with vertigo, and sometimes with momentary blindness; that from hydrocephalus has more of coma in its character." Gölis, without appearing to place much faith in its efficacy, gives digitalis both in the inflammatory stage and in that of effusion—in the latter chiefly as a palliative to moderate the violence of the convulsions. He employs it sometimes in the form of infusion, and sometimes in that of the powder, in doses of a quarter of a grain, combined with half a grain of calomel, repeated every second hour. He has not found it exert much influence on the urinary secretion in this disease. Some continental practitioners prefer extensive frictions made with the tincture of digi-

talis (sometimes combined with that of squills) to its internal employment. In whatever form it is used, if the pulse suddenly become very feeble, irregular, and slow, with increase of vomiting, and frequent recurrence of dimness of sight or blindness for a minute or two at a time, its use should be immediately intermitted, and stimulants, wine, soup, &c., substituted.

Antimony.—The late M. Laennec succeeded thrice in curing acute hydrocephalus by means of the tartrate of antimony given after his peculiar method. In two of them the disease supervened in the course of a continued fever. The subject of the third was a young man, who, after having sat up nightly in attendance upon his sick master for nearly four months, was seized with occasional vertigo and other symptoms which excited suspicion of some incipient cerebral affection. Some time after this he suddenly dropped down insensible, and after continuing in this state five days was brought to the hospital, where Laennec found him pale, motionless, and with the pupils greatly dilated. Leeches were applied to the temples, and twelve grains of the tartrate of antimony were given in the course of twenty-four hours. The next day he was able to move, and uttered some incoherent words. Fifteen grains were now ordered, and on the third day he had completely recovered his consciousness and power of motion, and the pupil had nearly regained its natural dimensions. He was still very feeble. As he had had no evacuation, eighteen grains of the tartrate were prescribed, and some nourishment. On the sixth day he was in a state of rapid convalescence; and crying out for food. Subsequent trials of this plan of treatment have not, we believe, tended to confirm the expectations which these cases (which by the way do not appear to have been very well marked examples of the disease) had raised.

The late Dr. Mills was in the habit of giving rather large doses of the tartrate of antimony, with a view to lower the pulse and relieve the headach; combining it, when the stomach was very irritable, with the tincture of opium. James's powder is, however, the preparation which has been most frequently used; small doses being given either alone, or oftener in combination with calomel, or calomel and opium, or with cathartics, with a view both to directly reducing the inflammatory action in the brain, and to assist in restoring the secretions of the abdominal organs and of the skin. This method of giving antimony is favourably spoken of by Dr. Cheyne. It has also been administered empirically in very large doses, so as to induce profuse perspiration, and it is said at times with success: in the hands of regular practitioners, however, this mode of giving it has failed entirely.

Opiates.—In the second and third stage of hydrocephalus considerable benefit has resulted from the use of opium. It has appeared not only to relieve the pain in the head and calm the general irritability, but also to reduce the morbid irritation in the intestines, and thus lead to an improvement in the stools, to render the pulse fuller and less irregular, and the convulsions less frequent; whilst fortunately it seems in no respect to impede, but rather to favour the action of other remedies. From the eighth to the fourth part of a grain of opium,

or three or four grains of Dover's powder, may be given every fourth hour, either alone or in combination with calomel and antimony; or else with hydrarg. cum cretâ if there be great irritability of the mucous membrane. The contraction of the pupil which ensues after the use of opium has been pointed out by Drs. Crampton and Cheyne as affording evidence of the remedy having been carried as far as is safe. Dr. Brooke has recorded a case in the Transactions of the College of Physicians in Ireland, where Dover's powder, in large and repeated doses, proved a very useful palliative. All agree that a moderate employment of opium does not interfere with the action of the bowels. When its use is once commenced, the patient must be kept steadily under its influence; as, if suddenly withdrawn, the symptoms recur with increased violence.

Squills, colchicum, and other diuretics, have been recommended in the advanced periods of the disease. When, however, the stomach is very irritable, we must be cautious in the use of medicines which might aggravate the vomiting, and thus increase the determination of blood to the head. Dr. Warren, indeed, was bold enough to use emetics in hydrocephalus, but in this he has had few imitators. The warm bath, which has in this country been occasionally found a useful auxiliary, is thought by Gölis to determine the blood still more strongly to the head, and thus aggravate the violence of the symptoms. M. Itard is an advocate, in the advanced stages of the disease, for the use of the vapour bath impregnated with vinegar, a powerful means of stimulating the surface and producing an abundant flow of perspiration. At an earlier period, when there is much reaction in the system, M. Recamier, on the other hand, has used the cold bath, and it is said with some benefit. Fomentations to the abdomen when pain is complained of there; stimulating pediluvia, or, what is more convenient and equally efficacious, sinapisms to the extremities, are also frequently had recourse to. Tartar emetic ointment is recommended by Mills, especially in those cases which have succeeded to a repelled eruption.—When applied to the extremities, it has sometimes appeared to produce a very useful derivative action. In a disease in which the unfortunate patient often lingers on for an unexpected length of time in a state of great apparent suffering, a state at all times distressing to friends to witness, and most so when no efforts are made to relieve it, the advantage of a variety of resources during the long and painful attendance is obvious. Recoveries having occasionally taken place under circumstances which seemed utterly hopeless, the medical man who values his own reputation will not resign himself to absolute inactivity at any period of the disease.

Palliatives.—When we fail in subduing the morbid condition of the brain which constitutes the disease, something may still be done in the way of alleviating symptoms, and, even when death seems inevitable, in rendering the steps which lead to it less painful. To enumerate all the measures conducing to these ends would be to repeat much of what has been already detailed. Thus moderate blood-letting, either local or general, according to the degree of strength remain-

ing, will often, even in the advanced stage of the disease, afford considerable relief, without appearing in any degree to accelerate the progress of the disease. Opiates at the same period form an invaluable resource.

Vomiting may sometimes be temporarily stayed by effervescing draughts, to which a few drops of laudanum and ether are occasionally added with advantage. This symptom may also be frequently much relieved by the administration of laxative enemata, to which a nutritive quality may be at the same time imparted.

Convulsions can often be cut short by the affusion of cold water on the head, or even by sprinkling the face and chest plentifully with it; a measure which is at once of easier application, and more frequently successful, than the warm bath. The simultaneous employment of cold to the head and the warm bath is often very efficacious. Musk and zinc in large doses appeared to Odier to have considerable influence in controlling this symptom. When very violent and long continued, the trial of an enema, composed of a very weak solution of tobacco, might perhaps be justifiable. For the mode of employing it, and its utility in an analogous instance, see *GLOTTIS, SPASM OF*. Where coma is the predominating feature of the complaint, strong coffee or tea have been given in the advanced period of the disease with some appearance of benefit. Retention of urine is often relieved by turpentine enemata or the hip-bath.

The diet in the earlier and more inflammatory part of the disease, should be strictly diluent; but when it has already run on for a number of days, with rapidly increasing debility and emaciation, it becomes a very important object to support the strength. This is peculiarly necessary where the urine, perspiration, or any of the evacuations, has, either by a spontaneous effort of nature or under the influence of medicine, become unnaturally increased. Under these circumstances, beef-tea, jelly, asses' milk, &c., should be freely given. Life has sometimes seemed to be considerably prolonged in this disease under the influence of light stimulants and tonics, wine, small doses of ammonia, quinine, &c. Arnica is a favourite remedy with some German physicians: we need not say how reluctantly and with how much caution such remedies should be had recourse to.

When recovery takes place, the convalescence is often very slow, and requires uninterrupted attention to the state of the bowels, and great care in the regulation of the diet. Asses' milk is here an invaluable article of nutriment, as it recruits the strength without exciting the pulse, oppressing the stomach, or confining the bowels.

If hydrocephalus supervene in the course of an infantile fever, or in a child greatly debilitated by diarrhoea or other previous illness, the treatment presents peculiar difficulties. We are here often unable to venture on general bloodletting, and are obliged to trust to leeches, cold applications to the head, blisters, and calomel, to which opium is to be added if there be great irritability of the mucous membrane or nervous system. Such remedies certainly afford a fairer prospect of success than the arnica, serpentaria, and other stimulants

recommended by Kuhn and some other German writers.

Where the head becomes suddenly attacked in a patient labouring under one of the exanthemata, nothing but the most vigorous antiphlogistic measures condensed into the shortest possible space of time can afford even a chance of safety. Venesection or arteriotomy, leeches, ice to the head, or a stream of cold water poured from some height on the vertex, purgatives by the mouth, or if the patient is unable to swallow, active enemata; and stimulating vapour-baths where the eruption has suddenly receded, or sinapisms or blisters to the extremities, should all follow each other in quick succession. The following case from Gölis gives some idea of the rapidly fatal nature of the attack. A child of two years old, on the fourth day from the eruption of scarlet fever, seemed to be going on favourably at eight o'clock in the evening. At midnight it became highly feverish and convulsed; spasms of the muscles of the back and palsy of the right side soon followed, and within ten hours it was dead. We have ourselves seen it fatal on the second day of the attack. Fortunately, however, this may be considered a rare form of the disease. That which occurs in the convalescence from scarlatina is much more frequent. It comes on with giddiness, headach, somnolence, and nausea or vomiting, to which convulsions and all the other symptoms of hydrocephalus are soon added. It demands the prompt employment of bloodletting and purgatives, blisters, and digitalis. Bark has appeared to Dr. Blackall to have much effect in accelerating convalescence.

Prevention.—Where there is reason to suspect a predisposition to hydrocephalus, as is the case with respect to the children of a family which has already suffered by the disease, and perhaps with regard to scrofulous children generally, the earliest attention should be paid to every deviation from the natural state of the functions of the body, and especial care directed to the condition of the digestive organs. To support their tone and that of the whole system by good air, nutritious unirritating diet, and daily exercise, is a point of prime importance. Where costiveness exists, or the stools by their unnatural colour or consistence indicate derangement in the secretions of the liver or mucous membrane of the intestines, appropriate remedies should not be a moment delayed.

An issue or seton in the arm or neck has sometimes seemed to have a remarkable influence in warding off this disease. We know an individual of a family strongly predisposed to it, whose life appeared to have been saved by an issue long kept open in the arm. Though the eighth child of the family, he was the first who survived infancy, the seven older ones in whom this precaution had been neglected having all died of hydrocephalus. Dr. Cheyne, in the work to which we have been so frequently and so largely indebted, mentions some still more remarkable instances of the good effects of establishing an artificial irritation at some distance from the morbidly disposed organ.

The parents and instructors of children of a peculiarly precocious intellect should be made aware of the danger of early and protracted application. In such individuals it should be our object, if possible, rather to retard than to accelerate the deve-

lopment of the brain and of the mental faculties connected with it; and it is only by postponing the interests of their intellectual to those of their physical education, till the constitution has become established and the period of danger is past, that this object can be attained.

II. CHRONIC HYDROCEPHALUS.—This affection may be either congenital or acquired. When congenital, some malformation or defective development of the brain in many cases coexists. When acquired, it may either come on as the sequel to the acute form, which however is rare, or it may originate insensibly, and attract little attention till the functions of the nervous system and of the body generally become perceptibly deranged by the pressure of the effused fluid. In all its forms it is in the earlier stages of existence, while the brain is undergoing the process of evolution, that it chiefly occurs.

When the cranium becomes very much enlarged, as the face retains its ordinary dimensions, or is even smaller than natural, the visage assumes a singular triangular appearance, and the patient being unable to support the immense head, it hangs on one shoulder or on the breast. The sutures and fontanelles continue widely open, and pulsation of the arteries, as well as the fluctuation of the contained fluid, can be distinctly felt through them. Occasionally, from the unequal yielding of the brain and its membranes, a circumscribed tumour presents itself at some of these openings.

That the dimensions of the head are always increased is the popular belief; and Frank has included enlargement of this part in his definition of the disease. Yet this is far from universally taking place, for the head is sometimes of the ordinary size, or occasionally even smaller than natural.

Gölis, the best writer on this disease with whom we are acquainted, and Breschet, who usually copies him closely, have divided the disease into three varieties, having relation to the size of the head. The first variety, or that in which the head is enlarged, is either congenital or commences in early childhood. The second, or that in which it is unnaturally small, is always congenital. The sutures are found closed at birth, and the head is of a conical shape. Such children are usually dead-born, or die in convulsions soon after they come into the world. Should they by chance survive a few months, their intellect is totally defective; they are blind, with the pupils greatly dilated, and the eyeballs in constant convulsive motion. They lie in a state of almost total insensibility, with their legs crossed and drawn up to the belly, their toes contracted and feet distorted. Of this variety Gölis has known but a single instance attain the age of eighteen months. The third variety, or that where the head is of the natural size, is perhaps the commonest of all, as it may take place at any period of life.

In chronic hydrocephalus the intellectual faculties, the senses, and the muscular power all suffer. The patients labouring under it become emaciated, and of a pallid unhealthy complexion, stupid and indifferent to external objects. The countenance is without expression. The senses become successively impaired, the sight being the first to fail.

The gait is unsteady, as the power over the involuntary muscles is in a great degree lost.

The following abstract of the symptoms is chiefly taken from the second volume of Gölis's work, which has not, we believe, hitherto been translated into English.

When the disease comes on at a period subsequent to early infancy, its first approaches are commonly indicated by an unusual excitability of the nervous system. The individual is easily made to laugh or to cry by the slightest causes, is peculiarly irascible, and the temper and dispositions are totally changed. The memory is impaired or lost. The muscular debility is excessive. Epileptic fits, especially at night, are of common occurrence; and on awakening a peculiar piercing cry is often uttered. There is a great degree of sleepiness, together with a dull pain and heaviness of the head. By shaking the head, vertigo or complete stupefaction is brought on. If we make pressure on the fontanelles, a soporose state often accompanied with convulsions is induced. The pupil of the eye becomes larger and larger as the disease advances, and amaurosis usually takes place in the end. Squinting exists in some instances, whilst in others the eyeball oscillates from side to side. The sense of smell becomes perverted or lost. In the former case imaginary odours are complained of; and the nose is at all times itchy and dry. The function of hearing is also impaired. In short, the senses of taste and touch are often the only ones retained, and these occasionally in a very imperfect degree. Violent grinding of the teeth, which are thus worn down to the stumps, is very common. If the patient possess the power of speech, it is for the most part nasal and snuffling, and often interrupted for want of words in consequence of the defective state of the memory. From the mouth, which is usually half open, the saliva is constantly dribbling, either from this secretion taking place in an excessive quantity, or from a diminished power of swallowing. Of the secretions and excretions the saliva and tears are the only ones which do not appear to suffer a decrease.

The functions of the digestive organs are considerably changed from the natural state. The appetite is often voracious; there is frequently a tendency to vomit, and obstinate constipation is rarely absent. The urine is diminished in quantity, and both it and the feces in the advanced stages of the disease are passed involuntarily.

As the disorder advances, the pulse and respiration become affected, the patient sighs much, and is put completely out of breath by the slightest causes, and paroxysms of suffocative cough occasionally take place. Debility and loss of power over the voluntary muscles is one of the earliest symptoms, and is manifested in the unsteadiness of the gait. Automatic motions of the limbs are common. The posture is much influenced by the disease. When it has made some progress, the erect position of the body can often no longer be borne, as it causes pain in the head, with lightness and stupefaction, and inclination to vomit. There is usually a disposition to keep the head lower than the rest of the body, and not unfrequently a preference is manifested for lying on the belly with the face buried in the pillow. When they

lie on the back, the head is often rolled with great regularity from side to side. In the last stage the patient lies gathered up, with the legs crossed and drawn up against the belly, the cervical vertebrae and head being thrown back, whilst the rest of the spine is bent forward. As the disease approaches its fatal termination, the pulse becomes weak, irregular, and intermitting, and the extremities cold and damp. Death takes place either by the supervention of the symptoms of acute hydrocephalus, or by a slow hectic fever, the scene finally closing either with a paroxysm of suffocative cough or with an attack like apoplexy.

Though the impairment of the intellect and senses usually keeps pace with the advancement of the disease, and the subjects of it at length may be said rather to vegetate than to possess an animal existence; yet a few cases are on record, where, though the head had attained a very considerable magnitude, the individual continued perfectly rational and observant of things around him; whilst in other instances again, amidst the general wreck, some one faculty, as the memory for example, has alone escaped uninjured. The moral qualities usually suffer as much as the intellectual, the patient being frequently passionate and revengeful; and every time that a fit of anger is excited, convulsions are apt to follow.

The sexual propensities commonly continue strong, and in several instances, in children of both sexes, a remarkably premature development of the organs of generation has been observed.

Hydrocephalus being a disease of foetal life, and the unnatural-sized head often presenting a great obstacle to delivery, and frequently even requiring an operation destructive of the life of the child, its early detection would be very desirable. Unfortunately, however, till the head actually presents itself in the progress of delivery, we have no means of detecting its existence. The fact of the mother having previously borne hydrocephalic children should excite a suspicion of its existence in cases of difficult parturition.

The disease may take its rise either before birth or very soon after it, or more rarely during the later periods of childhood. Yet even adult age is not altogether exempt from it. Gölis has mentioned three cases where it came on in old age. Two of the individuals in question were about seventy years old. The third, who was a physician in Vienna, likewise died of it at a very advanced period of life, after having suffered from the disease ten years. In such cases, however, it rarely runs on for more than three years. In cases occurring subsequent to early childhood, no change in the external form of the head is appreciable, for the sutures and fontanelles in most children are found already closed in their second or third year. Occasionally, however, as we learn from Ruysch and Van Swieten, they remain open much longer. We know at present of a child of upwards of six years old, in which the posterior fontanelle is still open; it is of a scrofulous habit, but has hitherto manifested no tendency to hydrocephalus. Dr. Baillie met with a singular case in a boy of seven years of age, where the coronal and sagittal sutures, after having been firmly closed, re-opened to the extent of half an inch and upwards from the pressure of the accumulating fluid. The same

author has detailed an instance of chronic hydrocephalus occurring in a man fifty-six years of age, in the ventricles of whose brain six ounces of fluid were discovered. The chief symptoms were pain of the head, and a loss of memory so great that he could recollect but five words, which were continually reiterated to express all his wants. He seemed to retain somewhat of his intelligence. There was no dilatation of the pupils, and the sight was good. The pulse was occasionally rather quick, and never became either slow or irregular. The hemiplegia which existed was accompanied with a permanent rigid flexion of the paralytic limbs, like a fakir. Heberden, on the other hand, has mentioned the case of a man in the ventricles of whose brain, though eight ounces of water were found on dissection, no symptom of hydrocephalus had existed during life.

The **duration** of this disease is very various. When it commences in utero, death almost always occurs very soon after birth; and if it originate in early infancy, the child very rarely survives the third year. Yet the brain in some instances becomes, as it were, reconciled to the pressure of the contained fluid, and existence has thence in a few rare cases been prolonged to adult age. Gölis mentions one in which the patient lived to twenty-seven; Aurivill another which reached forty-five years; and Gall one which attained to fifty-four years of age. In the case of Cardinal, who died in Guy's Hospital a few years ago at the age of thirty-two years, the head was of great magnitude, being thirty-three inches and a half in circumference, and twenty inches and a half from ear to ear. Notwithstanding this immense enlargement, many of the functions of the body were little impaired. The appetite and digestion were natural, and his intellect not remarkably deficient. He was, however, subject to occasional epileptic attacks, especially when costive; and he was unable to walk much, as vertigo was speedily induced by it. For some weeks before his death he was somewhat comatose, though still capable of answering questions when roused: the insensibility gradually increased, and he sunk at length as if apoplectic.

Prognosis.—It is only in the early stage that much can be effected by medicine in this disease. If treatment be deferred till the head has become greatly enlarged, the case is too often hopeless. When it is congenital, or occurs very soon after birth, its termination is, according to the best authorities, invariably fatal. In other cases, Portenschlag, Dreysig, Richter, and Gölis, think it may often be cured, especially if there be no complication, if the disease be early seen, and no great exhaustion has as yet come on. Frank looks upon the disease as very generally incurable. He knew of one case which disappeared on the invasion of a scrofulous affection in another part of the body; and both he and Gölis have seen the breaking out of chronic cutaneous eruptions and sores behind the ears have a very favourable influence over the disease. On the other hand, where any of the exanthemata supervene, speedy death is the usual consequence. Cases originating where there is a scrofulous or syphilitic taint, or after concussion or other accidents by which the texture of the brain may have been injured, have appeared to Gölis particularly unfavourable. Those which

arise as a sequel to acute hydrocephalus are likewise very unpromising, as has been already stated. The same may be said of those cases where there is long-continued coma, furious delirium, or frequent convulsions from very slight causes.

Of the **causes** of this disease little is known with certainty. A strong predisposition to it undoubtedly exists in certain families. Thus Frank mentions the circumstance of a mother bearing seven children, all of which were born with this affection: and Gölis another, in which six of the children were born prematurely in the sixth month of pregnancy, labouring under chronic hydrocephalus; and in the three others, which were carried to the full time, it appeared soon after birth. The father being very old or drunken, is thought by the last-named writer to predispose the offspring to the disease; and perhaps intemperance in either of the parents has a similar tendency. A scrofulous habit, and violence done to the head in birth, may also be numbered amongst the predisposing causes. Mechanical injuries, falls, shocks, and blows, are capable of exciting it; as is likewise the sudden repulsion of cutaneous diseases, the suppression of the menses, over-exertion of mind, and long-continued anxiety.

Appearances on Dissection.—The bones, which are usually remarkably thin and transparent, are frequently separated from each other by a very considerable interval. When the patient has lived for several years after the commencement of the attack, nature often appears to make an effort to close the sutures by the establishment of new points of ossification and the formation of *ossa wormiana*. The thinness of the bones of the skull, though an ordinary, is not an universal appearance. They have sometimes, on the contrary, been observed of unnatural thickness, which, like the supernumerary bones above alluded to, seems to mark an attempt on the part of nature to counteract the effects of disease, and restore to the cranium a proportional thickness. It is supposed that such thick and large skulls on being dug up have been mistaken for those of giants, an error which attention to the comparatively diminutive bones of the face would have prevented. The head of hydrocephalic patients is sometimes of a very irregular form, one side being much more prominent than the other. The effused fluid is found either in the ventricles, or, though much more rarely, in the great sac of the arachnoid. In the former case the ventricles are extremely dilated, the convolutions are unfolded, and the brain converted into a thin membranous-like sac, in which the medullary and cineritious substance can no longer be distinguished. The corpus callosum is much raised, and the septum lucidum occasionally torn or destroyed, so that the brain has sometimes been found forming only one great hemisphere without any central division. The cerebral substance seems denser than usual, and its absolute quantity as compared by weight with that of a healthy individual of the same time of life, in many cases does not present any diminution.

When the water is contained in the sac of the arachnoid, frequently scarcely any appearance of brain can be discovered; or the parts constituting its base, the pons varolii, medulla oblongata, &c., alone exist.

With water in the head and imperfect development of the brain, malformation in other parts of the body frequently coexists. It is now a generally received doctrine that many congenital defects of structure depend upon the continuance of certain states belonging to the earlier periods of foetal existence beyond their proper time. Thus the fluid which naturally occupies the ventricles during the first steps of the formation of the foetal brain, by remaining unabsorbed, may lay the foundation of congenital hydrocephalus.

A rare species of the disease is mentioned by Schmalz, in which the fluid is encysted. In such cases the sudden bursting of the sac has led to a fatal result. Gölis met with a cyst of this kind about the size of a goose's egg, situated between the hemispheres, in a child of six years old, who died suddenly, though the bag was in this instance entire.

The quantity of fluid discovered in the head varies from a few ounces to several pounds. Cases in which upwards of ten quarts have been found are on record. In the case some years ago in Guy's Hospital, to which we have already alluded, the bones of the cranium were found on dissection to be of an ordinary thickness. On cutting through the dura mater water immediately gushed out. This was of a pale yellow colour, and the total quantity contained within the head was found to exceed ten pints. At the bottom of the great cavity formed by the immensely dilated skull, lay the brain much flattened. The corpus callosum was defective, so that the ventricles of the brain communicated directly with the great sac of the arachnoid. This was, by some of those present, thought to be a natural malformation, as the convolutions of the brain were not unfolded and obliterated, as in those cases where the effusion takes place originally into the ventricles.

Dr. Baron, in the eight volume of the *Medico-Chirurgical Transactions*, has given the history of a very interesting case of congenital hydrocephalus. At three months old the head had attained to the enormous magnitude of twenty-nine inches in circumference. About this time a swelling appeared at the posterior fontanelle, and soon acquired the magnitude of a goose's egg. This suddenly became much smaller and soft, and a constant dribbling from the urinary passage was observed, by which the head in three days became so reduced in size, and the integuments were so relaxed, that the skin of the forehead fell in wrinkles over the eyes. The urinary discharge by the end of two months diminishing, the swelling on the top of the head re-appeared. A watery discharge tinged with blood now began to ooze from the nostril and mouth, and flowed most freely when the head was held forward; by this the tumour was again reduced, and the circumference of the head brought down to twenty inches. The child died at eighteen months old. On dissection, the dura mater was found ruptured, a well-defined circular opening nearly an inch in diameter existing in the situation of the tumour, and communicating directly with the interior of the brain. The brain itself, which was expanded into a great sac with very thin parietes, had likewise given way at this part, and thus allowed the fluid from the internal cavity to escape into the

outward swelling. A probe passed easily through the ethmoid bone into the nose.

Treatment.—In this disease the unassisted efforts of nature seem incapable of effecting any thing. The indications consist in the removal of the fluid already contained within the cranium, and in subduing the tendency to its further effusion; but unfortunately the resources which we possess will too often prove utterly unavailing towards the fulfilment of either of these objects. Diuretics, purgatives, and diaphoretics, together with mercury, tonics and a strengthening diet, are the internal measures which, singly or conjointly, have been most confided in; whilst, externally, it has been recommended to keep the head warm, to apply aromatic and slightly stimulating embrocations, or to employ severer but more promising remedies, such as blisters, issues, tartar emetic ointment, and even the actual cautery. Local and general bloodletting have also frequently been had recourse to.

Gölis asserts that he has cured the majority of cases when early seen, provided they were not congenital or occurring very soon after birth, by the long-continued use of calomel internally, by the application of a mercurial ointment to the head, which is kept constantly covered with a woollen cap, and by the daily use of stimulating baths.

In more obstinate cases, he has been obliged, in addition to these measures, to employ issues, blisters, or tartar emetic ointment to the head, and under particular circumstances leeches or cupping. In scrofulous habits a tonic plan of treatment must be carried on simultaneously with the above remedies. He has occasionally, also, called in the aid of mild diuretics or diaphoretics, and such measures as appeared to him best calculated to quiet nervous irritation, and to support the strength.

The remedy which has most frequently appeared useful is, unquestionably, calomel. This he gives in doses of half a grain twice a day; and if it purge too much, he reduces it to a quarter of a grain, or even intermits its use for a short time. Whilst employing calomel, one or two scruples of mercurial ointment, combined with an ointment of juniper berries, are rubbed into the head every night. The woollen cap, in which he has great confidence on account of its keeping up a constant though slight counter-irritation on the closely shaven scalp, and at the same time supporting the insensible perspiration, and preventing the sudden cooling of the head, is worn constantly for many months, and even then only very gradually laid aside. Becoming impregnated with mercurial ointment, it must help to bring the constitution more speedily under the influence of this remedy.

Mildly stimulating baths he conceives likewise to have a very beneficial influence, as they tend to excite an extensively diffused though moderate stimulus over the whole cutaneous surface. Alkaline baths may be employed for this purpose. Baths holding tartar emetic in solution, in the proportion of one ounce of this substance to a pailful of water, and gradually made three or four times stronger, have been found by M. Recamier a very useful remedy in this disease, appearing, whilst it reduced the size of the head, to act as a diuretic, and render the patient thinner.

If in five or six weeks some improvement is observed, or if salivation takes place, the calomel and the ointment are to be used only every second or third day. During the whole continuance of the mercurial course an acescent vegetable diet is to be avoided, as being liable, according to Gölis's experience, to cause colic and gastro-enteritis. Infants require no other nutriment besides good breast-milk, whilst for older patients a moderate quantity of flesh-meat is proper. In mild weather they should both be much in the open air. Under this plan of treatment Gölis has known the circumference of the head decrease by from half an inch to an inch in a period of from six weeks to three months, and has frequently seen a perseverance in it effect a perfect recovery both of the mental and bodily powers. When the automatic motions of the limbs cease, and the patient becomes able to hold up the head, to sit up, and even to walk a little, we have evidence that a beneficial change is going forward.

If within two months, on the contrary, no improvement is visible, mild diuretics, such as the acetate of potass or squills, may be associated with the preceding remedies, together with an issue in the nape of the neck, or in both arms, kept open for many months; or tartar emetic ointment or blisters to the same parts, so as to keep up a steady discharge. The use of these measures is particularly indicated when the disease has supervened on the sudden disappearance of a cutaneous eruption. We have known large blisters, applied alternately to each side of the head for many weeks in succession, productive of much benefit. Convalescence, according to Gölis, may be much accelerated by minute doses of the sulphate of quinine, as a quarter of a grain thrice a day.

If acute inflammation of the brain or its membranes supervenes, the antiphlogistic plan of treatment must be put in practice; leeches, calomel in larger doses, blisters to the calves of the legs, &c. Even in the latter period of the disease, when hectic fever has come on, the symptoms have been moderated, and life prolonged by leeches and calomel.

The palliative treatment recommended by Gölis in the advanced and hopeless stages, consists in such medicines as tend to promote the secretions, and to moderate convulsions, viz. aperients, diuretics, and antispasmodics.

As to the propriety of evacuating the water by means of an operation, where all other means has failed, practitioners have long been divided in opinion. Gölis has given the names of twenty-seven writers who have expressed themselves in favour of it, especially if the fluid be slowly evacuated, and at several repetitions of the operation. Yet he himself, along with seven or eight others, including Boerhaave, Heister, Hecker, and Portenschlag, proscribe it altogether as cruel and useless. Richter thinks, that even where the water is gradually drawn off, death by the disease always sooner or later ensues; and Gölis asserts that the fatal termination is even accelerated by it. It appears to us, however, that he has spoken too decidedly on this point, as there are a few cases on record where it has appeared to effect a cure, and several where it has palliated the symptoms. In cautious hands, and where only a moderate quantity of water is drawn off at a time, it has rarely been

attended with any immediate danger. In cases where all other kinds of treatment have been tried without benefit, this is, perhaps, not altogether to be rejected.

In a case related by Dr. Vose of Liverpool, in the *Medico-Chirurgical Transactions*, this operation was performed with complete success on an infant seven months old, when the head was more than double the natural size. The instrument used the first time was a couching needle, and the quantity of fluid drawn off upwards of three ounces; about as much more was supposed to have dribbled away afterwards, upon which the child became very weak, but revived by means of the moderate administration of slight cordials. About six weeks after, the water having re-accumulated, an opening was made with a bistoury, and eight ounces were again taken away; and by a third operation nine days after the second, twelve ounces were drawn off without any injurious effect on the general health. A copious serous diarrhoea now set in, by which considerable debility was induced, but this was only temporary. The head gradually diminished in size, and the patient completely recovered.

Mr. Lizars has detailed a case in the *Edinburgh Medical and Surgical Journal*, in which he operated about twenty times in the course of three months. The instrument which he usually employed was a delicate trocar, which was introduced at the most lateral part of the anterior fontanelle, so as to avoid the longitudinal sinus, and thrust in to the depth of about one inch below the surface of the integuments. On the reduction of the water the strabismus and dilatation of the pupil ceased immediately. In some of the later operations, the sutures having become in part closed from the progress of ossification, the head was no longer capable of being adequately compressed, and air rushed in to supply the place of the extravasated fluid, but without any ill effects ensuing. The case proves, if not the utility of the operation, at least its safety, when carefully conducted. About the same time with the above case, another was published in the same journal by Dr. Fréckleton, of Liverpool, in which the lateral ventricles were four times punctured with safety; but in the fifth operation, fourteen ounces of fluid being taken away at once, the child became very uneasy and convulsed, and died on the ninth day.

More recently the operation has been repeatedly performed, and with very favourable results, by Dr. Conquest, of London, to whose kindness we are indebted for the following particulars. The total number of children on whom he has operated is nine, and in four of these the operation has been completely successful, the individuals being now quite healthy and free from every symptom of their former complaint. The largest quantity of fluid withdrawn at any one time has been twenty ounces and a half; and the greatest number of operations on one child has been five, performed at intervals varying from two to six weeks. The largest total quantity of water removed was fifty-seven ounces by five successive operations. The trocar was introduced through the coronal suture, below the anterior fontanelle; and pressure on the head was subsequently made by strips of adhesive plaster, with which likewise the wound

in the integuments was carefully closed after each operation.

The first successful case was operated on before a large number of medical men at St. Bartholomew's Hospital in the session of 1829. Of this, and a subsequent one, a short account appeared in the *Lancet* in April and November, 1830, to which we refer the reader for further information.

[See the results of tapping the head in nineteen cases of Hydrocephalus by Dr. Conquest, in *Lond. Med. Gaz.*, Mar. 17, p. 967, or *Amer. Med. Intelligencer*, May 1, 1838, p. 40.]

Punction has likewise been lately had recourse to with complete success by the celebrated Graefe (*Graefe and Walther's Journal für Chirurgie*, &c. 1831, b. xv. p. 3) of Berlin, in the case of an infant whose head, of preternatural dimensions from birth, had attained to a great magnitude at the age of four months, when the first operation was performed; no derangement in the functions of the body had, however, as yet manifested itself. The operation was repeated eleven times within the course of six months. The fluid was each time allowed to escape only slowly and interruptedly; and the canula was altogether withdrawn and the wound closed as soon as the pulse was observed to become weak, the pupil contracted, and the expression of the face altered, symptoms which, under the influence of stimulants, always disappeared within a few hours after the operation. Each operation was followed by a considerable diminution in the size of the head, and after the eleventh and last the sutures closed. The child could walk and speak before it was a year old. At the age of two and a half (upwards of a year and a half after the completion of the cure) it was exhibited at the Medical Society of Berlin.

A still more recent instance of the value of this operation has been put on record by Mr. Russell of Edinburgh. (*Edinburgh Med. and Surg. Journ.*, July, 1832.) At three months old the head of his patient had attained to an enormous size, (twenty-three inches in circumference, and fifteen inches and a half from ear to ear.) There was strabismus and constant rolling of the eyes, irregularity of the bowels, and frequent starting in sleep; but the pupils were neither dilated nor insensible. Compression, blisters, mercury, diuretics, &c., having already been tried without the slightest benefit, recourse was had to punction as the last resource. By four operations performed at intervals of about ten days, the dimensions of the head were considerably reduced. After the fourth operation, the water again threatening to accumulate, calomel was administered in small doses, so as to affect the mouth, by which all the remaining hydrocephalic symptoms were removed, and the cure confirmed. The size of the head at eight months old was found to be less by four inches in circumference and two and a half across the vertex, than it had been previous to the first operation; and the ossification of the sutures was complete.

[Dr. Charles West (*Lond. Med. Gaz.* April 15, 1842) has inquired into the results of puncture of the head in 56 cases of chronic hydrocephalus, from which he infers that the instances in which life was prolonged by the operation appear to be very few, and the cases in which any reasonable pros-

pect of the patient's recovery existed after a week had elapsed from the first performance of the puncture, still fewer. Sometimes the puncture was followed by an almost immediate aggravation of the encephalic symptoms, and by death. Usually, however, a degree of apparent improvement followed the puncture; but the fluid soon collected again, and the second operation was succeeded by less marked relief. The quantity of fluid increased; and whilst the size of the head continued undiminished, or even grew larger, the body became emaciated; and death took place either from exhaustion, or cerebral symptoms came on, and life was terminated by coma or convulsions.]

Storch has mentioned an instance of hydrocephalus where the spontaneous escape of about a pint of serous fluid by the nose was followed by temporary relief; and a singular case has been related by Mr. Greatwood, where a child of fifteen months old was accidentally cured of the disease by falling upon the back of the head upon a nail, above three pints of fluid gradually escaping from the puncture thus made.

When the operation of puncturing the head is followed by extreme faintness and collapse, as is occasionally the case when too much fluid is removed at once, small doses of ammonia, or a few tea-spoonfuls of brandy and water, may be given to revive the patient. Inflammatory reaction sometimes sets in within the course of a day or two. Here leeches, cold applications, aperients, and other antiphlogistic measures must be employed.

Sir Gilbert Blane, conceiving that chronic hydrocephalus might sometimes depend on a want of firmness and due resistance in the bony compages of the skull, tried the effect of compression by means of a roller, with apparent benefit, in a case related in the *Medical and Physical Journal*, for October, 1821. But as leeches and purgatives were simultaneously employed, it is very difficult to say what share the compression had in the amendment which took place. Mr. Barnard has related two cases in the *Medical Repository*, in which pressure on the head made by means of straps and adhesive plaster, along with leeches and the application of cloths wet with cold water constantly to the head, appeared beneficial. [For further cases by the same gentleman see *London Lancet*, Oct. 12, 1839, p. 82.] In other hands, however, compression has failed altogether. [See a similar case cited from Caspar's *Wochenschrift*, in *Provincial Med. Journ.* April 29, 1843.]

W. B. Joy.

HYDROPERICARDIUM.—From ὕδωρ, *aqua*, and τὸ περικάρδιον, (*th. περί et καρδία*), *pericardium*. *Hydrops pericardii*, *dropsy of the pericardium*.—This affection can very rarely require the exclusive attention of the physician, since, although the pericardium is frequently the seat of effusion, it is seldom, probably never, so affected independently of organic disease either of the heart or some other structure. The symptoms consequently are always more or less obscured by the concomitant affections; and even when we are enabled to attain a tolerable certainty of the presence of fluid within the pericardium, its removal

alone would have but little effect in restoring the patient to health. These and some other considerations of a similar nature might almost induce us to exclude hydropericardium from a separate consideration, but as it has usually obtained from nosologists and writers on the diseases of the heart a distinct place, it could scarcely be omitted in a cyclopædia of medicine. The treatment of the subject is, however, a matter of very considerable difficulty, and the information we have to offer must be rather of a negative than a positive kind.

As the pericardium is a serous membrane, and hence always in some degree bedewed with moisture, a preliminary inquiry becomes necessary as to what must be considered its natural state, and what quantity of fluid ought to be regarded as constituting disease. This question has been much discussed by older authors, while the more modern have been usually content to refer to the opinion of Corvisart, without inquiring into the data upon which that opinion was founded.

Among the ancient authors, Vesalius and Lower maintained that the pericardium generally contained some fluid, and the former had observed it in the pericardium of criminals, who had been quartered while yet alive. He was not, however, certain of its existence in every case. Lower says decisively that some fluid is always present, but without any detail of the researches which led him to entertain so positive an opinion. Hoffmann, after referring to these and other authorities, merely observes that he had never been able to detect any fluid in the pericardium of animals which he had opened alive. Haller, after reviewing these and many other writers, intimates that in his opinion some fluid, but in very small quantity, is always to be found, and that it does not usually exceed a few drachms. Littré had decapitated puppies, and had always found some water in the pericardium. Senac, reviewing these contradictions, and remarking that in a number of bodies in which the heart and its envelopes were perfectly natural, the membrane was dry, inclines to the opinion that in the healthy state the pericardium contains no fluid, but at the same time admits that some fluid is occasionally observed which could not properly be referred to disease. Corvisart does not enter at any great length into the dispute, but contents himself with pronouncing, that whenever the fluid exceeds six or eight ounces in quantity, it must be regarded as the effect of disease, and consequently as forming hydropericardium. To this last author Kreysig, Bertin, Testa, and other contemporary writers are satisfied to refer, and in this state the subject still rests. Under these circumstances we have endeavoured in some degree to promote our knowledge of this subject by the result of dissections, and the following tables will show what proportion of one hundred and fifty examinations exhibited fluid in the pericardium. Fifty of these cases are drawn from our case-book; fifty, respectively, are furnished by Mr. Wickenden and Mr. Parsons of Birmingham, who are well qualified for such investigation. Any appreciable quantity of fluid was always noted, that is, whenever it exceeded a couple of drachms; in some cases even less than this was noted. To this we shall add an additional table

of sixty-four cases, for which we are indebted to Mr. Baynham, whose pathological researches have been very extensive, and are most valuable from the accuracy with which they have been conducted.

The largest quantity of fluid was in the case of phlebitis, in which it amounted to sixteen ounces. In the cases of phthisis it never exceeded eight

ounces, and generally not more than four: in some one ounce was the whole quantity. In the other cases it varied from eight ounces to two drachms.

II. *Table of sixty cases in which water was found in the pericardium after death.*

Disease.	No. of Cases.
Phthisis pulmonalis.....	14

Sudden death.....	1

In both these tables it will be seen that tubercular consumption affords the largest proportion of cases in which water is found in the pericardium. Diseases of the heart stand in the next place, and, generally, affections of the chest are much more frequently accompanied with hydropericardium than those of any other cavity. The largest quantity was three pints, and was the consequence of inflammation of the membrane.

The colour of the effused fluid much varied; in most instances being nearly a clear serum, in others being of a chocolate colour. This is in unison with the experience of Kreysig.

Notwithstanding the number of these dissections, they have afforded very little information as to the diagnosis of hydropericardium; nor, if we look at the tables, can we be much surprised at this result. In no single instance did the presence of fluid constitute the only disease when it exceeded a few ounces, and in those cases in which a few drachms only were found, no symptoms existed during life by which attention was attracted to the condition of the pericardium.

Having made these preliminary remarks, we may proceed to state that no very well authenticated case of idiopathic hydropericardium has yet been related. The only instance with which we are acquainted, that is on record, is one mentioned by Morgagni upon the authority of Valsalva; and even of this some doubt may be entertained. The symptoms were dyspnœa increasing to orthopnœa, cough, mucous expectoration, and fever;

and the case proved fatal. The pericardium was distended with water. But as the affections of the mucous membranes were scarcely distinguished in the time of Valsalva, and as many of the symptoms above enumerated were, if not peculiar to, at least such as are usually attendant upon bronchitis, we may be pardoned if we refer the presence of water in the pericardium to the existence of bronchitis. Nor is another case, related by Morgagni, and referred to by Kreysig, Testa, and others, much more illustrative of idiopathic hydropericardium independent of other disease. This case occurred in a nun in whom the over-activity of her physician had produced hypercatharsis, and a series of anomalous symptoms for full a year, soon after which she died. The case, nevertheless, is worthy of notice in connection with this subject, although we can scarcely refer to it as a means of diagnosis.

The patient the day after the purging above alluded to became suddenly very faint upon attempting to rise from her bed, and this faintness recurred whenever she attempted to speak or move much. These symptoms continued with little variation for a considerable time; her countenance still remained healthy, and her sleep undisturbed. The bowels acted regularly, and the catamenia were as usual. Respiration in every position was uneasy. Her pulse was regular. There was no palpitation, and no pain in the chest, nor cough. The only complaint was a sense of weight in the region of the heart, and excessive nervousness. Towards the termination of her life she had sharp pains in the region of the heart; her strength gradually diminished, and at length she died. On dissection the only morbid appearances were the effusion of about nine ounces of water in the pericardium, and ulceration of this membrane. The ulceration Morgagni refers to the acrid nature of the water: modern pathologists would, probably, rather refer the whole appearances to inflammation originally, which had produced equally ulceration and effusion, both common terminations of inflammatory action.

These are the only cases with which we are acquainted, where even a pretence can exist for considering hydropericardium as idiopathic: nor does any author of late years ever regard it in this light. Nevertheless, while the science of medicine remains in its present imperfect state, every effort to forward our knowledge of the diagnosis of disease is worthy of encouragement; for if disease is to be treated successfully, excepting by accident, it must be by an accurate acquaintance with all its phenomena.

Like every other form of dropsy, hydropericardium may be the consequence of some affection of the membrane in which it is seated, or of some organic disease of other parts. In the former case it seems always to result from inflammation of the pericardium; in the latter it may be connected with inflammation, or the simple sequence of the pericardium participating in the atonic state of the general system. Kreysig has attempted to lay down the signs by which we may distinguish effusion in the pericardium succeeding inflammation of the membrane.

According to this author, when the more prominent symptoms of pericarditis subside, a feverish

state with slight exacerbations still remains, and for some time a more marked symptom is present. These exacerbations gradually increase both in severity and frequency, and are soon accompanied by anxiety and great sense of oppression. The patient is unable to lie down, and usually sits with the head and chest leaning forward. The pulse becomes habitually irregular, the appetite uncertain, and the sleep bad. During the exacerbations all these symptoms are worse; the anxiety and restlessness become excessive, and delirium or most painful irritability, one or both, ensue. This state continues for some hours, and then nearly disappears, again, however, to return after a short interval of rest. The disease lasts from seven to fourteen, or even twenty-one days. During the last few days of life the patient is less complaining, and endures positions which had previously been intolerable. A species of drunken sleep is manifested; the patient lies as it were in a dream; the action of the heart becomes weak and more irregular; the extremities are cold; the surface of the body is covered with a clammy perspiration; and death at length ensues as the consequence of a weakened and obstructed circulation.

Such is the account given by Kreysig of this affection; but in it we see nothing to distinguish hydropericardium from hydrothorax. Many of the symptoms are common to this with other diseases of the heart and thoracic organs; none of them are so peculiar as to mark without error the occurrence of effusion in the pericardium. Still the whole relation is excellent; and could we see the symptoms as well developed in every case, it would certainly much facilitate our diagnosis in this difficult disease. Unfortunately, however, this is seldom the case; sometimes one, sometimes another symptom is absent, and sometimes the dropsy of the pericardium is complicated with other diseases, which leave us doubtful to which affection particular symptoms are to be referred. It is at present scarcely possible to afford any certain signs by which an accurate diagnosis may be obtained.

We might here also notice the affection which Testa has named hydropericarditis of child-bed; it is, however, as in truth is the disease above described by Kreysig, a true pericarditis terminating in effusion.

Hydropericardium from Organic Disease.—The signs by which hydropericardium may be distinguished when complicated with organic disease, especially if this disease be seated in the heart, are even, if possible, more obscure than when simply the result of pericarditis. Corvisart, who must still be regarded as the best author on this subject, has enumerated many signs by which the presence of effusion in the pericardium is indicated; yet a very cursory perusal will show us that they are deserving of little confidence. Patients, he observes, who suffer from hydropericardium have usually livid countenance, and black and livid lips; they experience great anxiety and oppression in the region of the heart; dyspnoea is so great as to threaten suffocation, especially when the patient assumes the horizontal position. In applying the hand to the heart, its action is found to be obscure and tumultuous, and the organ appears to beat through a soft body, or

rather through a liquid placed between it and the walls of the thorax. Percussion produces a dull sound over a space commensurate with the extent of the effusion; and in some instances the left side over the region of the heart is more vaulted and elevated than the right. When the disease is of long duration, the strength fails, œdema of the extremities ensues, and, more rarely, a slight puffing over the anterior and left side of the chest.

Vieussens has mentioned œdema of the face and a dark leaden colour round the eye-lids, as more peculiarly indicating hydropericardium, but Testa justly regards these appearances as by no means peculiar to this affection. We have, ourselves, in a former article, remarked that all dropsies which depend upon diseases of the chest for their origin, are usually indicated by œdema of the face; and hence it must be insufficient to mark this form of dropsy alone. On the other hand, Testa remarks, and the remark is worthy of notice, that hydropericardium very rarely exists without œdema of some part of the face; and that this œdema does not disappear before death, as does the œdema of the extremities.

Morgagni, Kreysig, and Testa have discussed at considerable length the value of individual symptoms; and they have all come to the same conclusion, viz. that they are all useless to distinguish hydropericardium from hydrothorax, and often from diseases in which no effusion is present. It would take up more space than ought to be allowed to this article, were we to go over the ground which they have trodden with so much ability; nor, considering that they at last arrive only at a negative conclusion, would any advantage be derived from such a discussion. Modern ingenuity has, however, introduced a new means of diagnosis, as well as revived and improved an old one. These are percussion and stethoscopic auscultation. With regard to the value of the first, no dependence can be placed upon it in this disease. It will indeed inform us, and that with tolerable accuracy, of the extent which the heart and pericardium occupy together when there has been no condensation of the lungs nor any material alteration in the change of parts; but should either of these occur, it would be useless even so far as we have indicated. But again, should no impediment arise from the source now referred to, percussion would do no more than intimate differences of sound without informing us of the causes of such differences; whether, for instance, depending upon enlargement of the heart or effusion into the pericardium. Of this difficulty Corvisart himself was well aware.

The stethoscope may perhaps, in very practised hands, afford some information; and Dr. Hope thinks even eight ounces of fluid in the pericardium might be detected; "the sensation communicated to the hand and the stethoscope being that of an impulse transmitted through a fluid, and not of an organ striking the ribs immediately." We confess that we are not so sanguine in this respect as Dr. Hope; and we are much inclined to think, with Laennec, that less than a pint will scarcely afford any signs cognizable by auscultation.

The mistake made by Desault in tapping the pericardium may seem to corroborate our doubts. This distinguished surgeon made an opening into

the chest between the sixth and seventh ribs of the left side near to the apex of the heart. He introduced his fingers into the chest, and perceived a cavity full of water, which he took for the pericardium. Dubois, Sue, and Dumangin, who were with him, examined the parts, and were of the same opinion; and Desault then enlarging the opening, let nearly a pint of fluid escape. The fluid being discharged, he again introduced his finger into the aperture, and perceived a pointed conical body to strike the finger. The man, however, died in a few days; and the conical body was discovered to be the heart enveloped in the pericardium, which closely adhered to it; and the opening had been made into a cavity formed by a membrane which united the edge of the left lung to the pericardium. Here, then, the union of the pericardium to the heart, and the proximity of the fluid, would probably have obscured even this sensation of the heart beating through a fluid.

There is only one other sign which we feel called upon to consider, and this was proposed by Corvisart; but the suggestion has not been confirmed by any other author. Even this, however, is only applicable to very large collections of water. Corvisart had observed the phenomena now referred to in two instances. To employ his own words, "the beating of the heart is perceived sometimes to the right, sometimes to the left, or, to speak more clearly, in different parts of an extensive circle. Now this could not occur if the heart should be retained, as is natural, by the pericardium, whose cavity, proportioned to the volume of the organ, fixes the extent and direction of its motions. The pericardium must, therefore, be dilated, and this may happen in two ways; by augmentation in the volume of the heart itself, in which case, though the impulse of the heart might be stronger, and occupy a larger space, still it would strike against the same place; or by an accumulation of fluid in the pericardium, and then the heart, not being likewise dilated, would swim, as it were, freely into the fluid, and strike against different parts of the chest."

There can be no doubt that this is a very important observation; but Corvisart himself had only seen two cases in which it occurred: in one there were four pints of fluid, and in the other one pint. We have ourselves in vain endeavoured to detect the phenomenon, but have never yet been able; nor can this excite surprise, when it is remembered how large a quantity of fluid is probably necessary for its exhibition.

Morbid Appearances.—These are seldom peculiar to hydropericardium; the essential circumstance of the disease being merely the presence of fluid in the pericardium. This fluid, we have already stated, varies much in colour; and the membrane itself sometimes exhibits traces of inflammation, increased vascularity, depositions of coagulable lymph, suppuration, and ulceration. A more detailed account of the morbid appearances will properly fall under those diseases of which effusion is the consequence.

Treatment.—Of this we have very little to say in addition to what has been stated under the general head of Dropsy. Hydropericardium is so rarely, perhaps never, a solitary affection, that it cannot be treated upon any exclusive principles

Only one remedy may be proposed which it seems to us necessary to mention, and this is tapping the pericardium. This operation has been very rarely performed on the living subject; nor can we suppose it probable that it will again be proposed till experiments upon animals, and observations of injuries in the human subject, tending to prove that the membrane in question may be wounded with impunity, shall have afforded more justification for such an operation than at present exists. Certainly, however, we have no reason to believe that perfect adhesion of the pericardium is inconsistent with considerable enjoyment of life, although probably not with perfect health.

JOHN DARWALL.

HYDROPHOBIA.—When it becomes our duty to illustrate the nature and history of a disease, our thoughts instinctively turn themselves to the mass of obscurity which hangs over so great a majority of morbid affections; an obscurity which, under every advancement of science, diminishes but slowly, and which keeps almost all those maladies which were unintelligible two thousand years ago unintelligible still. Sometimes it may be doubted whether the disease is truly an original mischief, or merely the symptom of some other primitive disorder; whether it is not frequently confounded with affections happening to coincide with it only in a few occasional symptoms, or is it not daily viewed in the most erroneous light with regard to its pathology and causes; or, in fine, whether proper evidence be not still wanting in these various respects, to enable physicians to establish any conclusion upon a firm and rational foundation. But whatever may have formerly been the case, it is no very common occurrence, at the present day, to have the doubts and hesitation of the writer upon what may be called a disease of extreme notoriety extended to its very existence; such, however, literally happens with *hydrophobia*, of which many intelligent persons of different ages and countries have utterly denied the existence, except as a phrenitic or maniacal affection, deriving its sole origin from the imagination of the patient, (*C. Aurel*, Lib. iii. c. xiii. p. 223.—White on *Hydrophobia*.) or the injudicious treatment of his attendants. It seems necessary, therefore, on the threshold, to lay before the reader the grounds of our belief in the real existence of *hydrophobia*, reserving for future detail any other confirmatory circumstances which may present themselves as we proceed. Having briefly stated the general arguments, we shall be at liberty to carry him along with us to the history and treatment of the malady.

Our first argument is, simply, that numerous persons become affected with the disease, which is essentially characterized by *spasmodic contractions of the pharynx, and a difficulty of drinking*, (the latter generally believed to be a consequence of that spasm,) very soon after having been bitten by an animal labouring under a similar affection; and that these persons *invariably* go on from bad to worse, and finally die before the sixth day; their bodies upon dissection presenting appearances as uniform as can be expected from the great mechanical irritation produced on

the adjacent secreting and circulating organs by the violent convulsions. On the other hand, we rarely observe the same train of symptoms preceded by any other cause. Now, of these victims some are mere infants, and cannot therefore be suffering under any mental impression; others are idiotical, others delirious; in neither of which states are the sources of mental terror long kept steadily in view. But in point of fact, a very large majority of hydrophobic patients, whose cases have been distinctly described in our medical records, are positively stated to have retained an adequate clearness of intellect till long after the terrible spasm and dread of fluids had established themselves, and in very many till the last moment of existence. Not a few of them have happened to be sensible, well-educated persons, of particularly strong minds. And seeing that we have for these facts the moral evidence of the entire faculty, of all ages and countries,—to assert in defiance of it that every hydrophobic patient is the victim of his own insane fears, does really seem to us to be begging the very question or proposition which those who make this assertion are bound to prove, although in direct contradiction to all medical testimony. Besides, if the cause consisted solely in a deep impression of fear, why should the disease, its presumed effect, intermit so frequently and in so many instances, as it is known to do? It cannot be said, therefore, that the proximate succession of the disease to the bite is the effect of mental emotion; and it will be easy to show that in most cases of this special class, not one of the other presumed causes of *hydrophobia* spontaneous, or rather nonrabida, were present. Consequently there is at least one form of *hydrophobia* of which the only constant known antecedent is the bite of a rabid animal; and this, therefore, in the present state of our knowledge, we are compelled to consider the cause till another is shown. Secondly, the wound inflicted is not unfrequently found to hold a manifest relation to the characteristic symptoms. At first, these do not show themselves, and the wound heals up kindly; but just before the time when the characteristic symptoms are about to appear, the cicatrix occupying the place of the wound often undergoes the remarkable alteration which we shall here for convenience technically name *recrudescence*. It swells, becomes red, livid, and painful, and the pain sometimes seems to shoot along the soft parts to a considerable distance from its origin. In other cases the wound opens of itself, and discharges a peculiar matter. Something similar is known to take place in traumatic tetanus; and although in this affection, as well as in *hydrophobia*, we cannot explain why the phenomenon of *recrudescence* does not occur in many fatal examples, yet we ought not therefore to deny that in those cases in which it does appear, the connection between the *recrudescence* and the disease is most remarkable. Neither is it difficult to understand that, although the bite may, yet the *recrudescence* may not be essentially necessary to the appearance of *hydrophobia*; and hence we have full warrant to infer that the wound is the antecedent principally and determinately connected with the disease as an effect. Again, it is abundantly established by observation and experi-

ment, that the bite of a dog produces, in animals of different species, a disease to all appearance hydrophobic; and on the other hand some experiments of M. Magendie, M. Breschet, and Mr. Earle, have led to the inference that the bite, or at least the saliva of man, may produce similar effects on the lower animals. These analogies are so forcible, that notwithstanding all the original differences between the economy of the human body and that of the lower orders of creation, we cannot refuse here to admit its application as an evidence, that upon man also the bite of a rabid dog will probably produce similar effects. Lastly, the universal persuasion and testimony of the people of every country in the world for more than two thousand years, affirming the connection between the bite of mad dogs, and precisely the same characteristic phenomena of spasm in the throat and fear of drinking, is not to be passed over as a trivial or superstitious evidence of the reality of hydrophobia in man. It is not trivial, for the impression is deep; and a dread of pestilence is not more strongly implanted in the minds of men than the fear of hydrophobia; it is not superstitious, for it will be shown in what follows, that mankind came to a knowledge of this direful malady in the enlightened period between the days of Aristotle and the foundation of the great medical school of Alexandria; after Democritus and Hippocrates had long freed the science from all connection with superstition; and when the cities of Greece, Asia, Sicily, and Egypt, abounded with medical schools, and with professors alike distinguished by their cultivation of the healing art and their improvement of general philosophy. A coincidence of belief so universal cannot fairly be ascribed to accident, and is no more to be neutralized by the possible circumstance that other causes also may produce these symptoms, than the operation of marshy miasm in producing ague, from a well-known fact that other causes may also induce that disease, or reproduce it in the system after it has been to all appearance subdued for many years. It is still more illogical to infer, with some authors, that because the bite of a mad dog is not always followed by hydrophobia, it is therefore never succeeded by it. No known cause of disease whatever, not even the exhalations of the pest-house, the inoculation of variola, or the contact of scabies, produces its effect upon every person to whom it is daily applied; many escape, and probably, as in the case of small-pox, after vaccination, from previous changes in the system, which have rendered the body no longer susceptible of its influence. At all events, if we were to admit the conclusion drawn by late authors, we should be obliged to deny the influence of every exciting cause of disease, of which every successive effect, from the point to which it was first applied, to the parts ultimately involved in the affection, could not be fully traced.

Having premised these considerations, we hope we may now crave the attention of the most sceptical of our readers, while we examine in detail the principal circumstances which have come to the knowledge of the profession respecting this terrible affection.

The term *hydrophobia*, from ὕδωρ, *water*, and φόβος, *fear*, has been obviously compounded to ex-

press the principal symptom of the present disease, namely "a dread of swallowing water;" the latter fluid being taken by synecdoche as the most common liquid known then, in order to signify all other drinks as well as water. On a similar principle, the most characteristic symptom, namely, the dread of swallowing liquids, or hydrophobia, seems to have been insensibly assumed as a name for the whole diversified series of phenomena which constitute the disease resulting from the bite of rabid animals. While ignorant of the proximate cause, physicians are content with naming diseases after one or more of their principal symptoms; and these denominations suffice for all the purposes of nomenclature, if they are so far prominent and uniform as readily to recal to the mind the thing signified. No medical man, we believe, ever heard the term hydrophobia, since its first reception as a word, without thinking of the disease produced by the bite of animals in the rabid state; and hence, though it may be our duty to put on record some of the more remarkable synonyms, we must say that we think very lightly of all the attempts which have been made since the days of Polybus to exchange it for one that may seem more expressive. Few rational physicians expect to find the history of a disease condensed into a sort of essence in its name; and it ought not to be forgotten that the most comprehensive appellation is not always that which produces the most rapid suggestion—the principal end, we presume, of all individual nomenclature. Nevertheless, several distinguished French authors, of late years, have seemed obstinately bent upon some innovation; and we find, for example, in the excellent *Dictionnaire des Sciences Médicales*, and the still more recent *Dictionnaire de Médecine*, two standard works, the term hydrophobia appropriated to all cases exhibiting a dread of swallowing fluids, but *not* connected with the bite of a rabid animal; to designate, in short, every form of what is in Britain named simple hydrophobia. On the other hand, to the disease resulting from the contact of rabid animals, *rabies canina*, *rabies*, or *rage*, is in these works exclusively applied. Both terms are employed in a sense entirely conventional; for the dread of swallowing fluids, or hydrophobia, in the literal sense, is present almost alike in the simple and rabid forms of the disease; and it seems ridiculous to apply the epithet *rabies canina* to a disease which has been produced by the bite of a wolf or a cat: and the term *rabies*, whether separate or joined with *canina*, involves the incurable fault of signifying furious delirium, a state of mind which is scarcely ever present in the disease. The ancients did not by any means fall short of the moderns in this curious research after an expressive appellation. Cælius Aurelianus allows the investigation a due share of his excellent chapter on hydrophobia; and so many authors have since adorned the pursuit with separate dissertations, that a fanciful person might almost imagine that in the name, as in the virus of hydrophobia there lurks something contagious. The ancient Greeks seem to have had a specific term for the madness of dogs, namely, λύσσα or λύττα, and we see it so employed by Homer, *Iliad* ix. 239. From this they formed a verb λυσσάω or λυττάω, and the adjectives λυσσότηρ λυσ-

σώδης, rabidus, rabiosus; terms which Homer makes his chiefs apply to Hector, while bearing all before him in the field of battle, and consequently presenting no bad image of that indiscriminate rage and effort at destruction generally displayed by the dog in a state of madness. The participle *λύττων* is likewise made use of by Plato in his Republic, to characterise a prince of ungovernable fury. Hence the term *κυνόλυσσα, canis rabies*, or *dog-madness*, has been repeatedly employed to designate this affection of the canine race; and it has been extended to the hydrophobia of man by Andreas and others. This, however, is still more extreme; for the translation of *κυνόλυσσα* is *dog-dog-madness*! an absurd pleonasm, there being no lyssa except that of dogs. The very argument urged against the term hydrophobia, that dogs drink during their whole disease, ought to have taught writers that the disease of the dog is not the same as the disease he excites in man; and consequently that neither lyssa nor synolyssa, nor any other term which properly marks the disease of the dog, can rightly be applied to that of the human species. From the patient being unable to swallow any kind of moisture, some of the Greeks named it *hygrophobia* in preference to hydrophobia. Others gave it the appellation *phobodipsia*, to express the presence of thirst generally accompanying the dread of swallowing, or the dread of liquids themselves. By Polybus it is named *pheugydros*, because those affected are observed to shun or fly from water: Aurelianus translated this by the term *aquifuga*, in which, for obvious reasons, he has been little imitated. From two ambiguous passages in Hippocrates, hydrophobics have been called brachypotæ, i. e. *parvibibuli*, and the disease brachypnosia: but the word *βραχὺς, short*, may also be applied to the intervals, and thus express in brachypnosia two very opposite things, either the act of drinking little, or of frequent drinking at short intervals. It is simply named *canis rabidi morsus* by Africanus and Avicenna. Mead proposed to name it *δυσκαταποσία*, or difficulty of swallowing drink; and Rush, full of its relations to fever, will have it called the "hydrophobic state of malignant fever." Quite recently, Dr. Good has attempted to restore the primitive Hellenic term *lyssa*, by inscribing the disease entasia lyssa.

Notwithstanding this profuse luxuriance of nomenclature, the term hydrophobia has always been and still is that by which this affection is distinguished by the rest of mankind, as well as by the best medical authors. It is the name employed by Celsus, Aurelianus, Galen, Boerhaave, Sauvages, Dessault, Linnæus, Vogel, Sagar, Cullen, and Pinel; and is still the only denomination by which the disease is known in the common language of the inhabitants of France and England, and under forms more or less translated amongst all the nations which inhabit Europe. Nor does there appear to us the least reason why it should be changed, since, as we have shown above, it accurately answers in all the circumstances necessary to a simple name, and involves no theory with regard to the exciting cause or the intimate nature of the disease, but on the contrary seems a sort of etymological reduction of its essential character to the simplest terms; hence we venture to

pronounce, that in defiance of all the efforts of ingenious men to the contrary, it never will be changed. Had it contained any intrinsic misrepresentation, any inherent source of fallacy, we should not have deemed the highest antiquity a sufficient reason for discussing its merits, far less for retaining it in a work of this description. But as it cannot be accused of either, and the reader was not to be left without some knowledge of its multiplied synonymes, we have endeavoured to bring them before him in as brief a manner as perspicuity would allow.

The nosological relations of hydrophobia appear scarcely less to have perplexed medical writers than those of its nomenclature. Concerning two radical facts all seem to be agreed; namely, that there is one form of hydrophobia shortly succeeding to the bite of a rabid animal, and which is to be distinguished nosologically from all others; and secondly, that there are several slight evanescent forms of the hydrophobic spasm, which appear distinctly as mere incidental symptoms of hysteria and other common diseases; and are accompanied with little danger, and which, "ought not to be classed as constituting a little or variety of the genus *hydrophobia*. But between these two extremes there occur an immense number of intermediate instances, resting on testimony respecting which no rational doubt can be entertained; whose origin can be traced neither to injury from a rabid animal, nor to any previous disease existing in the system. For the moment, these may be divided into four different sections; first, those cases which arise almost immediately after the application of some obvious exciting cause, such as the bite of an animal not rabid, of the patient himself, a wound, or the influence of fear; secondly, those which are preceded by an obvious exciting cause, but between which and the appearance of the disease a considerable time intervenes; thirdly, those cases which appear to originate without any probable exciting cause having preceded; and fourthly, the numerous examples of hydrophobia which occur indeed after the bite of a rabid animal, but at an interval much beyond the period at which this peculiar injury is believed by the generality of physicians to be no longer capable of manifesting its powers. It is in the due allotment of these various candidates for nosological distribution that the difficulty of effecting a systematic arrangement of hydrophobia is mainly placed. It is not easy to invent a specific name which shall comprehend the whole or even the majority of them; for if, with M. Sauvages, we comprise them under the term *hydrophobia spontanea*, it is unanswerably replied, do you call the diseases of the first and second section spontaneous when their causes are obvious and acknowledged? nay, it is for you to prove that hydrophobia is ever generated spontaneously, since it is denied by the ablest authors. Again, if with Cullen, we employ the term *simplex* to signify this series of complaints, we are instantly told there is no reason to believe that these are of a more simple nature, or involve fewer symptoms than the cases proceeding directly from the bite of a hydrophobic animal; and that if we make use of the word *simplex* merely in contradistinction to the term *rabiosa*, such an application of it

is entirely conventional. Nevertheless, as the terms *hydrophobia rabiosa* and *hydrophobia simplex* are very easily understood and contrasted with each other, especially since the latter term implies that the *hydrophobia rabiosa* is complicated (according to general belief) with the action of a poisonous virus, they are in common use in this country, and may occasionally be employed in the present article. As, however, all that seems wanted for the second species of hydrophobic affections is such an epithet as decides that the cases arranged under it do not originate from the bite of a rabid animal, (the multiplicity of causes, and our total inability to trace these causes to their obvious effects, rendering every other appellation more or less exceptionable,) we humbly conceive that some such specific terms as the following would obviate every objection.

Genus Hydrophobia.—Great restlessness and hurry of mind; horror of and difficulty of drinking fluids, accompanied by clonic spasm of the pharynx, and spasmodic constriction of the muscles of the chest.

1.—*Hydrophobia Lyssodes*, succeeding, in the period of two years, to the bite of an animal supposed to be rabid.

Species 2.—*Hydrophobia Paralyssodes*, not preceded, within the period of two years, by the bite of a rabid animal, or by any other than anomalous causes.

We shall thus reconcile popular nomenclature with the admirers of Dr. Good and of the language of Homer, avoid all verbal criticism, and enable future reasoners to arrange the different modifications which the disease assumes as *varieties* under their respective species; while the symptomatic imitations of the disease may be disposed as synonyms under an anomalous species of *hydrophobia symptomatica*, as has already been done by several eminent authors. In this manner we have—

Hydrophobia Lyssodes.—Varieties, *canina, felina, avicularis? insectorum? fomitum? salivæ?*

Hydrophobia Paralyssodes.—Varieties, *traumatica, inflammatoria, phrenitica, meticulosa, nervosa, pathetica, febrilis*.

The symptomatic species are, *hysterica, febrilis, hypochondriaca, maniaca, melancholica, cynanchica, venenata*.

Let not our readers imagine that the reflection we have bestowed upon this arrangement is barren of all useful application. On the contrary, nothing is so common, on the narration of a new case, as to hear it asked,—but is it certain that the case is one of genuine hydrophobia? Were the pathognomonic symptoms present? Was it not rather one of those fatal spasmodic affections of the throat in the production of which animal virus has no share? And a person unacquainted with nosological arrangement often finds it difficult to answer such queries, as he must necessarily waver both with regard to the date at which the poison may still work its effects, and the circumstances which connect the approach of the animal with the ultimate symptoms, if he do not even hesitate much about the symptoms themselves. From the usual neglect of such an arrangement may be fairly traced that scepticism regarding hydrophobia

which we so often meet with among members of the profession sufficiently sensible and unprejudiced, but whose attention has been otherwise directed. It appears unnecessary to dilate upon the criticisms which have been made by authors upon the group of symptoms which have been assumed by various nosologists, as constituting the character of the disease. Nothing was more natural than that the fears of mankind regarding the communication of this formidable affection,—fears which may be traced to the time of Aristotle,—should clothe it in all the terrors suggested by an apprehension so justly vindicated by what they observed to take place in other animals. Posterity has added very little in this respect to the horrible train of suffering already so graphically described in the pages of Aurelianus; and if some of them, since exploded by the critical science of our own day, were believed in and quoted as characteristic by the nosologists who have preceded us, these writers seem hardly to be chargeable, in fairness, with more blame than the misfortune of having lived before these errors were discovered. They are not answerable for their age; and excluding these faults, enough still remains in their definitions to enable us to recognize the disease they describe; and if there did not, it would still be very poor logic to infer that, because their definitions had failed, the disease was indefinable or did not exist. The hydrophobia of Cullen was the same as that of which we treat, although he erroneously believed it to be characterized by a desire to bite and a loathing of liquids. In the last place it were equally illogical to consider the occasional absence of some one of the characteristic symptoms a sufficient reason for withholding the general name of hydrophobia from the disease, and yet this has been a great stumbling-block with some of our most ingenious writers. Such reasoning is correct only in abstract mathematics and abstract logical discussion, where the things defined, being pure entities of imagination, can suffer no gradation without demanding a corresponding change of terms. But in nature, and more especially in organic beings, every thing is gradation and change; and no genus of plants or animals, and still less of diseases, could be subdivided into its species and varieties which do actually exist in nature, were this rule to be rigidly observed. No disease, for example, can be better defined by nosologists than pneumonia; yet how often do the physicians of the present day, by the aid of the stethoscope, proximate auscultation, and other well-known forms of minute observation, discover latent modification of it in every degree of advancement, which but a few years ago would only have come to their knowledge long after by the appearance of adhesions which they might accidentally observe on dissection. Instances might be multiplied to almost any number; but it will be more practically useful to observe that a new case of disease is to be classed by the physician rather according to its general coincidence with the symptoms of some well-known type or form, than according to the presence or absence of some individual symptom; a circumstance which, in the varied irritability of the whole system or of single organs, is often quite fortuitous: and the writer who should deny that the fatal disease suc-

ceeding to the bite of a mad cat, for example, is not hydrophobia, because it is accompanied with scarcely any dread of water, although it agrees in all other indications, may seem to reason with the metaphysical accuracy and the scrupulous definition which distinguish a geometer, but we should distrust his knowledge of the principles of physic, a science which requires great allowance to be made for incidental variations.

From the earliest antiquity of which we have any record, the dog has been the companion of man. In the book of Exodus cattle torn by wild beasts are ordered not to be eaten, but to be given to the "dogs,"—an expression which proves that these animals were already the constant attendants of man, and assisted in his pastoral labours. It was no doubt the impurity of their food that has rendered their name synonymous with every thing that is impure or vile throughout the whole of the scriptures. Still there is no allusion made to hydrophobic disease any where in the sacred volume, a circumstance which is perhaps best explained by the fact that, even down to the present day, canine madness is unknown in Syria and Egypt. We have already said that the disease was well known to Homer, and applied by him, with his usual critical exactness of similitude, to the indiscriminate havoc with which Hector sweeps through the battle-field of his enemies. Thus,—

Ἐκτωρ δὲ μέγα σθένει βλεμμαίων
μαίνεται ἰκπάλως, πίνονος Διὸς, οὐδέ τι τίει
Ἀνίρας, οὐδὲ θεός· κρατερὴ δὲ ἰλύσσα δίδουκιν.

Iliad ix. 237.

Τοῦτον δ' οὐ δύναμαι βάλλειν κῆνα λυσσητῆρα.

Iliad viii. 299.

ἡ λυσσώδης, φλογὶ εἰκλος, ἡγεμονεύει
Ἐκτωρ.

Iliad xiii. 53.

The poet with much propriety puts these words into the mouth of Ajax his enemy, for *dog* was already a term of reproach among the Greeks, (Iliad i. 225,) as well as the Jews. He nowhere mentions the disease as actually existing in man. In the writings of Hippocrates, there occur at least two passages, the singular language of which makes it not improbable that the physician of Cos had seen hydrophobia, and was then speaking of its symptoms, but that he did not recognise it as a separate disease, and merely considered it as a variety of phrenitis or mania, affections with which it has always been but too easily confounded:—Οἱ φρενιτικοὶ βραχυπύται, ψόφον καθαπτόμενοι, τρομώδεις. *Prædict. lib. i. p. 69.* Οἱ φρενιτικοὶ βραχυπύται, ψόφον καθαπτόμενοι, τρομώδεις ἢ σπασμώδεις. *Prænot. sect. ii. p. 131.* We transcribe the passages, but we are unwilling to strain them so far as Aurelianus and others have done; indeed, no indisputable mention of the disease occurs any where in his works, either in the genuine or the suspected. There is almost certain evidence, however, that the disease was well known to his friend and contemporary Democritus; for we are told by Cælius Aurelianus, that, in his book upon *Opisthotonos*, Democritus distinctly treats both of the hydrophobic disease in man, and its origin from the bite of a rabid animal, and that he seemed to consider it as a variety of tetanus, an opinion which has been embraced by many of the moderns:—"For Democritus, who was contempo-

rary with Hippocrates, not only makes mention of this affection, but even describes its cause when speaking of *opisthotonos*."* And in another place, speaking of the cause of hydrophobia, "Indeed Democritus, whilst treating of *emprosthotonos*, ascribes the seat of the disease to the nerves;"† by which in his time were chiefly meant the tendons, ligaments, and other white tissues. Now, we learn from several passages in Gellius, the contemporary of this well-informed author, that the works of Democritus were still extant in his time, and of frequent reference and high estimation; and it seems most improbable that Aurelianus would have referred to the chapters in which the passages were sure to be sought for, if he had wished to misquote, or to mislead the disputants in a controversy which, he informs us, was then become hackneyed, and the merits of which he appears to consider with perfect coolness. Democritus, be it remembered, was a great traveller, and may have become acquainted with the communication of hydrophobia to man in countries situated beyond that sphere of information to which the industry of the great father of medicine has ever extended. At all events his opinion made little impression on the Greeks; for we find Aristotle, nearly a century afterward, asserting that the hydrophobia may be communicated from one animal to another, but not to man. "Dogs," he affirms, "are subject to madness, cynanche, and a sort of gout or lameness. The first of these diseases renders them rabid or furious, and all the animals which they bite become equally affected with madness, with the exception of man. The malady occasions the death of the dogs affected, and of every animal that is bitten by another animal, still excepting man." (*Hist. Anim. lib. viii. c. 22.*) This repeated negation of the actual existence of human hydrophobia would scarcely have been made by so grave a writer as the Stagyræite, unless he had heard the contrary asserted under some degree of authority; nor could he have safely committed it to writing, unless he had previously contemplated the different circumstances. Indeed, Professor Sprengel seems to think that Euripides, who was prior even to Democritus, alludes to it in the *Bacchæ*, v. 337. "Acteon . . . mourut de l'hydrophobie. (*Euripid. Bacch. v. 335.*—*Apollodor. lib. iii. c. iv. p. 189.*) C'est la plus ancienne trace que nous trouvions de cette cruelle maladie." (*Histoire de la Médecine, tom. i. p. 117.*) Upon referring to the *Bacchæ*, however, we confess we cannot discover the most remote trace of an allusion to hydrophobia. In that part of the drama to which Sprengel refers, Cadmus is counselling Pentheus to join in the worship of Bacchus and Semele, to dread the danger of contemning the gods, and, as an example, to take warning by the fate of Actæon. The words are—

ὁρᾷς τὸν Ἀκταίωνος ἀθλίον μῦθον
δὲν ὠμόσσιτοι σκύλακες, ὡς ἐθρέψατο,
δικοπάζοντο, κρείσσον ἐν κυνηγίαις
Ἀρτίμιδος εἶναι κομπάζαντ', ἐν ὀργασίᾳ.

* "Etenim Democritus, qui Hippocrati convixit, non solum hanc memoravit passionem, sed etiam ejus causam tradidit, cum de *opisthotonicis* scriberet." *Lib. iii. 15.*

† "Equisdem Democritus, cum de *Emprosthotonicis* diceret, nervos inquit." *Ibid.*

Which may be thus simply translated into English :

Thou seest the wretched fate of vain Actæon,
All torn and scattered by the raw fed hounds
He cherished; meanwhile boasting in the chase
To excel the great Diana, forest queen.

Still the testimony of Apollodorus would be curious, if it evinced that human hydrophobia was known and believed in shortly after the time of Aristotle, and long before the age of Asclepiades; a fact which is strongly corroborated by what we have already stated from Aurelian, of the opinions respecting hydrophobia maintained by Andreas, who flourished two hundred and four years before Christ. Apollodorus, whose words follow, lived in Egypt, under Ptolemy Physcon, about one hundred and thirty-three years before Christ, more than half a century before the period at which Asclepiades flourished. His work is a history of the Gods, wherein, describing the death of Actæon, he says, — οἱ πλείονες λέγουσιν ὅτι τὴν Ἀρτεμιν γουομένην εἶδε. καὶ φασὶ τὸν θεὸν παραχρῆμα αὐτοῦ τὴν μορφήν εἰς ἔλαφον ἀλλάξαι. καὶ τοῖς ἱερομένοις αὐτῷ πεντήκοντα κυσὶν ἐμβαλεῖν λῦσαν, ἐφ' ὧν κατὰ ἄγνοιαν ἐβρώθη. Artemidorus, as we learn from the Symposiaca of Plutarch, must therefore have been mistaken, in asserting that Asclepiades the Bithynian was the first who introduced this disease to public notice. This Artemidorus, who lived down to about the time of Adrian, must not be confounded with the follower of Erasistratus, of the same name, who was a native of Sida, and who flourished, according to Sprengel, two hundred and twenty-three years before Christ, and is celebrated by Aurelianus for his doctrine respecting the seat of hydrophobia, which he placed in the stomach. In this he was partly opposed by Gaius, a follower of Herophilus, and who wrote a treatise on hydrophobia, or the "dread of water," about the same time; and who seems to have been inclined to place the seat of the disease in the nervous system, and more especially in the pneumo-gastric portion of the par vagum.* The nerves were divided by Erasistratus into nerves of sense and nerves of motion; the nerves of sense originated from the brain itself, the nerves of motion from its membranes; and in the latter number no doubt was reckoned the eighth pair, as we see it in this passage. Asclepiades, or at least the greater number of his followers, referred the chief seat of hydrophobia to the membrane of the brain; the irritation of which, according to him, was the principal cause of all mental diseases, as phrenitis, lethargy, epilepsy. (Aurelianus.) Others of them maintained that it chiefly occupied the diaphragm, as that membrane was much affected with pain during the disease. But Artorius, the most distinguished of his followers, who afterwards became the physician and familiar friend of Augustus, but perished at sea shortly after the battle of Actium, reverted to the doctrine of Artemidorus, and assigned to the stomach the honour of being the original seat of the disease.

We have thus been enabled, by the aid of mo-

dern research, to demonstrate to the reader, 1. that the hydrophobia of dogs has been known from the earliest ages; 2. that there is every reason to believe that human hydrophobia was considered as an established disease by Democritus and Polybus, and had been heard of by Aristotle; 3. that its nature and treatment were discussed in the school of Erasistratus by his immediate followers; 4. and lastly, that Asclepiades does not seem to have added any important observation to what was already known on the subject, though his followers rather than himself propounded some unsatisfactory conjectures as to the seat of hydrophobia. Nevertheless, the distinct account of the nature and treatment of this disease delivered by Celsus, who was an auditor of Themison, the successor of Asclepiades, at Rome, evinces rapid progress towards an accurate knowledge of this formidable affection, from the no very distant period at which it most probably became generally known to the world through the medium of the school of Alexandria. Instead of quoting a work so common, we shall merely extract the substance of what was known to this admirable eclectic. The disease named hydrophobia usually arises from the bite of a rabid dog, the wound of which has not been properly treated by preventive measures. The suffering is terrible, the patient being tormented at the same time with the dread and the desire of water; and under this he gradually sinks with very little chance of recovery. The only known remedy is to throw him unaware into a pond before he sees the water, where, if he cannot swim, he will swallow a sufficiency of water while he sinks and rises by his own efforts; but if he swims, the same end is to be attained by the assistants dipping him under water from time to time. In this way the thirst and dread of water are both made to disappear. There is some danger, however, lest the enfeebled patient should be carried off by cramps or convulsions from the effects of the cold water; to avoid which he is immediately to be put into warm oil. Free doses of opiates combined with aromatics and antispasmodics may be given either as antidotes or remedies; but if the disease has already supervened, they may be given in pills in preference to the fluid form. When the dog which inflicts the bite is known to be mad, the virus is to be extracted by the cupping-glass. The wound is then to be cauterized, unless it happen to be in muscular or nervous parts: if the cautery cannot be permitted, bloodletting will be useful. The sore after the cautery may be dressed with the usual irritants; but if the cautery has not been employed, the wound must be treated with more active escharotics, and finally healed up. Immediately after the accident, some send the patient to the bath, where he is made to sweat freely, and lay open the wound by scarification in order that the poison may escape in greater quantity, and follow up the practice with a liberal allowance of the strongest wine, which is an antidote to all poisons.

Such was the state of knowledge with respect to this disease in the Augustan age, and Sprengel thinks it owed a considerable share of its precision to the singular circumstance of Themison, the distinguished professional teacher of Celsus, and of nearly all the medical men then living, having

* "Gaius, Herophili sectator, libro quo de timore aquæ scripsit, ait cerebrum et ejus membranam pati. Etenim voluntario motu servientes nervi atque stomachum colligantes, initium vel originem inde sumpsisse noscuntur."—Aur. ib.

himself become affected with simple hydrophobia, and narrowly escaped; an event which we may be sure would be copiously alluded to in his lectures, although Aurelianus gravely asserts that he was always threatened with a fresh attack the moment he began to describe the disease. "Ferunt," says Dioscorides, "Themisonem medicum amico aquam timenti (*ὁδροφοβῶντι*) prompte et humane inservientem, in eandem incidisse affectionem, nec nisi post multos labores servatum." (Lib. vi. de canis morsu, p. 733.)

It seems almost certain that Dioscorides was contemporary with Themison, and he would not have omitted the practice of bloodletting in hydrophobia recommended by Celsus and Eudemus, had it been known to him; nor yet the ingenious expedient of endeavouring to sweat out the poison by means of the hot-bath, or the formidable auxiliary of repeated submersion in cold water. Let us give Dioscorides, however, with the vulgar, to the reign of Nero, and we shall see that terror had already begun to magnify the natural horrors of hydrophobia. "Some patients," he affirms, "bark like dogs, fly upon and bite all near them, and like the former animals communicate the disease to those unfortunate members of their own species whom they have torn." Like Celsus, he makes distinct mention of the poisonous virus presumed to be injected by the teeth of the dog, and orders it to be sucked out by the mouth or by the cupping-glass, which is to be strongly exhausted for this purpose. His precepts for scarification are precise as well as judicious; he insists on the excision of the bitten part, and in certain cases recommends amputation. In these severe precautions he speaks from his own experience, by which he has preserved many persons that were bitten, from the supervention of hydrophobia, which disease, when once established, he deems quite incurable. He is the first writer now extant who declares that he had himself seen and treated the disease. The absurdities concerning hydrophobia collected by the elder Pliny only merit allusion in so far as they evince that the terror and exaggeration it produced were much greater among the vulgar than among physicians; but the perusal of the able treatise on hydrophobia which occurs in Cœlius Aurelianus affords sufficient proof that with the latter also the alarm was progressive. He, or the author he has been supposed to translate, lived about the same time with Galen, in an age still very learned, about the year of Christ 200-220. Not only do his hydrophobic patients bark like dogs, and communicate the disease by biting to man, but "their voice has a barking tone, and they roll their bodies up from head to heel, in the spiral manner assumed by the dog in laying himself to rest: they walk with the level, slow movement of persons carrying water in a full vessel; the tongue projects from the mouth; the bile that is vomited is most frequently black." A moribund patient ran upon a mad dog whom chance presented, and bit him furiously, then rolled himself up like a ball and expired. To inhale the air contaminated by the breath of the rabid dog was sufficient to produce the disease, &c. Still we are not to measure the importance of Aurelianus by the scale of his errors, or, to speak more truly, by the errors of his age; his descrip-

tion of the phenomena of the disease is for the most part surprisingly faithful; indeed, so exquisitely graphic, that to copy it here would be to anticipate much we have to say in the succeeding history of the symptoms. His notions of the prognosis and diagnosis are generally just and sagacious; and though his method of cure derives a very distinct character from the theories of his own sect, (the methodists,) yet he has added with an impartial hand the treatment recommended by others. Lastly, he has given a very instructive view of the different controversies respecting hydrophobia which prevailed in his time, and compared them with each other with an intelligent fidelity which, in spite of his barbarous Latin, is always highly interesting. No student of hydrophobia should omit to read this part of his work. Galen, his contemporary, and in some measure his predecessor, was a great collector of what had been done before him, and his opinions swayed the schools for 1300 years after his death. It may be sufficient, then, to say that the sentiments of Galen with regard to hydrophobia were those of all mankind at the revival of letters. He appears to have turned his powerful mind to this subject with particular attention. He invented several antidotes against hydrophobia; one of which, the ashes of the river crab, he assures us he had never known to fail. He compares the operation of the canine virus to the action of slow poisons, which, though given daily, only produce a visible effect after a certain time. The virus is like *wood placed near the fire*, which becomes gradually hotter and hotter, and at length bursts into flame and is consumed. The virus is by no means idle in the wound, although it does not betray itself by the least symptom for many months, in one case known to himself, for a whole year. Canine virus thus proceeding step by step slowly generates a disease, which sinks deeply into the solids, and is therefore so much the more tractable, just as we see taking place in the leucæ and other obstinate forms of leprosy. The dread of water he conceives to arise from mental aberration, which he calls *impaired judgment*. In addition to his antidotes, he orders the excision of the part bitten to be made of a circular form, in order that every part tainted may be removed, and the disk thus laid open is to be kept raw by escharotics for forty days. Alyssum calycinum, or madwort, is recommended for a cure; as also the liver of the mad dog which had bitten the patient. He gives a tolerably fair account of the signs of rabies in dogs, at least in the more violent cases. He attributes the original occurrence of hydrophobia among dogs to the spontaneous corruption of their fluids; and as his theory of the origin of diseases, now better known by the name of the humoral pathology, referred almost all complaints to a similar degeneration of the humours, he finds occasion to recur frequently with triumph to this instance of the canine virus. On one occasion he gravely draws a parallel between the self-generated poison that produces hydrophobia, and the self-generated poison that, as he imagines, produces phrenitis. The reader will at once observe that the notion of spontaneous hydrophobia, so long maintained, and not yet entirely relinquished by some authors, as by M. Rochoux, is a legitimate

portion of one of the most exploded doctrines of Galen, and is supported by no better evidence at present than it was in the time of its ingenious author. With the exception of some oriental flourishes, such as the presence of little dogs in the urine of hydrophobic patients, we find the Arabians copy the Greeks with great closeness. But as some of them, Avicenna for example, are more systematic and more copious than the Greeks themselves, they may still be read with advantage. Thus the last-named author notices both the peculiar apoplectic termination of hydrophobia, and the changes occasionally affecting the urinary organs; facts which scarcely occur in the Greek or Roman writers. Africanus, a learned follower of both in the darkest age of our era, has added nothing new.

We have thus come to modern times, and in these we have not been able to resolve the question at what time arose the custom of smothering hydrophobic patients by means of beds or pillows. Of this horrid practice no trace is to be discovered before the sixteenth century; and next to the burning of witches, it affords the most pregnant example of fear, purely imaginary, becoming the cause of the most detestable public crimes. The apprehension of danger from the breath, saliva, or bite of the unfortunate sufferer, combined, it would seem, with an obscure notion of the disease being attended with something like demoniacal possession, were the original apologies for resorting to this cruel security, the consummation of which the morbidly timid patient dreaded from the approach of every person that entered his apartment or advanced to his bed. Hence the fury, the repugnance, and frequent attempts to injure the by-standers, so prominent in the histories of hydrophobia recorded during the two last centuries, and so rare in the present. Professional scepticism and critical inquiry, by showing that these fears were entirely without foundation, have alone relieved humanity from the reproach of these delusions, and the sufferers from the unspeakable horror of being murdered on their death-beds, often by the hands of those whom of all others they most loved; for the frequent opportunities of inspection after death, afforded by the now zealously cultivated science of anatomy, has never cast any additional light on the subject.

In presenting a view of the symptoms of rabid hydrophobia, we are enabled to derive less benefit from arranging the phenomena according to the order of time than in most other diseases. The latent period is so irregular in point of duration, and affords so few marks of the presence of disease in the system, that some able physicians have felt inclined altogether to dispute its connection with hydrophobia. The stage of recrudescence, however, observes a tolerably uniform relation towards the succeeding disease, since it generally occurs a few days before the latter is constituted; but then it is often wanting, and even when present, seems sometimes a precursor, sometimes a symptom of the third stage. Nay, the pharyngeal spasm and dread of fluids, the nervous agitation and gastro-pneumonic symptoms, have all been described as occurring in almost every possible order of succession in different individuals. The true key to this endless diversity is found in the

fact, that by far the greater number of the symptoms which fall to be recorded are of a secondary character, in consequence of which the time and intensity with which they appear are greatly regulated by the intensity and time at which the cardinal symptom they follow has showed itself. These cardinal symptoms are five in number: first, a depressed, excited, or altered state of the nervous system of the individual; second, a depressed, excited, or altered state of the mind; third, fever; fourth, difficulty of swallowing fluids; fifth, gastro-pneumonic symptoms. From one or other of these every remaining symptom is believed to flow. But as observation teaches us that any one of these may be the first to show itself, and any other of them may follow it in succession, it is easy to discover, without resorting to the law of permutation, that the varieties in this respect presented by the cases actually recorded must be very numerous, though all coinciding in one common circumstance—that whatever may happen to be the order in which these cardinal symptoms supervene, they never extinguish each other, or again disappear. Still, as it is the nature of the human mind to pass forwards from cause to effect, and consequently according to the progress of time, we shall adhere to established practice in this respect, and tracing the symptoms in that order in which they most generally occur, rest satisfied with having endeavoured to select the course which presented fewest faults. We divide this disease, therefore, into three periods, namely, the stage of *delitescence*, the stage of *recrudescence*, and the stage of *spasm*.

First stage, or delitescence.—In the first stage there are generally few symptoms to be observed, except such as are usually found to occur from the bite of the most healthy animals. The wound, whether dressed, or, as often happens, neglected, heals up kindly, leaving a cicatrix, which differs in no respect from that which supervenes to a similar wound inflicted by the teeth of an animal in the best health. It may be remarked that in many cases the injuries inflicted by hydrophobic animals do not involve any extensive laceration, a circumstance which may be attributed to the sickness of the animal, and the unsteadiness of purpose during this malady. The younger Cuvier has observed that the great characteristic of the animal mind, as compared to that of man, appears to be the facility with which it passes into the state of rage or fury, and remains governed by its influence; but in the hydrophobic dog this instinct seems often to be modified into a snappish irritability, by which the creature is easily induced to bite, but does not inflict the wound with much energy, nor attempt to repeat it. Huntsmen, we are told by Rush, accordingly divide the rabies of dogs into the *sullen* and the *furious* hydrophobia, in which latter form the lacerations inflicted by the dog are deep, large, and frequently repeated. In another place we shall endeavour to show the effect of education and of the original disposition of the animal in determining the frequency of the sullen and the furious forms of the disease; but for an example of extreme injury of this kind the reader is referred to Dr. Hamilton's Appendix, page 325. The man had a large wound on the throat, which laid the trachea quite bare to a considerable extent, and which likewise appeared to

be considerably bruised; one on the cheek, which enlarged the mouth a full inch; a smaller one, lower on the chin, and another, lower than the former one, on the throat, which evidently proved that the animal had changed his hold.

In most cases, however, pain has been felt in the cicatrix a considerable time after the accident; but such a feeling is so frequent in the seat of wounds recently healed, that its occasional presence after the bite of mad animals ought not perhaps to be considered as any thing singular or characteristic. In several examples upon record (Edin. Med. Surg. Journ. vol. iii. p. 414,) slight fever came on very soon after the accident, and continued till the appearance of the hydrophobia, which in such instances supervened in the course of a few days. But as in general the period of delitescence in genuine hydrophobia is seldom shorter than forty days, or longer than twenty-four months, such cases have by many writers been considered to originate purely from the fever or the mechanical irritation, and consequently referred to the non-rabid species. We may take an opportunity to remark that we have here, as well as in our definition, assumed two years as the longest period of delitescence, because it seems to be the opinion maintained by the most rational medical writers upon this subject, from Discorides downwards; and because Drs. J. Hunter, R. Hamilton, and S. Bardsley, have shown that all the credible cases on record occurred before the eighteenth month; likewise because we have heard of no instance of recrudescence taking place in the wound after this period; and, finally, because so just is the instinctive impression left by experience, that every medical man would hesitate were he to hear in the course of his practice of an individual case of hydrophobia referred to a cause much anterior to this limit. This, however, we may do, without pretending to assert that it is impossible for the cause of hydrophobia to lurk longer in the system than two years; but we say that the connection between the bite and the spasm has not been satisfactorily traced upwards beyond this point, and that if we were to take a thousand persons who had survived the bite of a mad dog during two years, we should not at any time afterwards find one of these persons become affected with hydrophobia without the infliction of a new bite.

In the period which intervenes between the healing of the wound and the second stage, little satisfactory has been observed; a few individuals have become retired, gloomy, and melancholy, the countenance expressing considerable anxiety; but as the pulse, skin, and other indexes of the functions continue natural, it seems impossible to affirm that these signs of depression are not the sole offspring of mental anxiety regarding the hazard in which they in general know but too well their life is placed by the accident. The other symptoms attributed to this stage by authors seem purely accidental.

Second Stage, or Recrudescence.—The commencement of this period is deservedly one of great alarm to the patient, and accordingly it is one about which the medical man is for the most part consulted early, and the progress of which, therefore, he is furnished with a fair opportunity of observing. It may be added that, when it

occurs, the patient and the practitioner have each a longer warning, and for that reason a more promising chance of obtaining a cure of the hydrophobia which generally follows; although some have said that the recrudescence itself is an indication merely of the greater activity of the virus and the more exasperated form under which the malady is about to appear. At first a pain is perceived in the cicatrix, at times attended with itching, but in general resembling the aching of rheumatism, which in some cases shoots to some distance along the limb affected, and in others degenerates into a species of torpor in the part itself. In one case under our own care the sensation of the thumb bitten was that of torpor, and such extreme rigidity that its joint could not be bent; meanwhile the sensation of pain was in the neck and shoulder. The thumb was without redness or swelling. Sometimes the cicatrix is merely affected with a sense of coldness, with stiffness, extending along the limb; and in one case the arm thus affected became paralysed. In a few cases the pain does not begin precisely in the wound, but in some part near the trunk, as the shoulder or hip. The scar becomes red, swollen, sometimes livid, and in one case was surrounded by a papular eruption, (Edin. Med. Surg. Journ. 1807;) and in the course of a short time it opens and discharges a peculiar ichor. Meanwhile flying convulsive pains are felt in various parts of the body. As the disease proceeds, the patient, according to Dr. Marcet, complains of pains shooting from the wound to the region of the heart, and in general both he and Babington, with Professor Callisen, have observed in different cases that these recrudescence pains seem always to follow the course of the nerves, and do certainly never inflame or irritate the lymphatic vessels and glands in the vicinity, though passing in a parallel course towards the trunk. Thus a bite on the upper extremity produced pain of the arm and shoulder, but did not affect the axillary glands; and from a similar wound of the leg, the pain was conveyed to the hip and loins, but no irritation of the saphenic systems of lymphatics, or of the glands of the ham and groin, were observed to take place. We may add to the above, the entire absence of any fact contrary to this observation in the works of the numerous authors who have written on the subject. In some cases the wound does not open, but a sense of torpor, pain, and occasionally of roughness in the integuments, shoots along the limb which has been wounded. In an instructive case of this kind related by Mr. Oldknow, of Nottingham, in the fifth volume of the Edinburgh Journal, though the patient was wounded in three distinct places by the same dog, namely, the scrotum, the thigh, and the left hand, yet the uneasy sensations were perceived in the arm alone, *though last bitten*; as if the hydrophobic, like tetanic action, were most easily excited by irritation of the extremities. These recrudescence symptoms took place forty-two days after the bite, and four days before the hydrophobia became confirmed. It is seldom that they occur longer than six days before the disease becomes marked, and the most general term of their appearance seems to be two or three days before hydrophobia supervenes. In one case which we attended, and which we have also de-

scribed, the patient died on the seventh day after the pain commenced in the part bitten, and fifty-six hours after the hydrophobia had distinctly commenced. The recrudescence symptoms, therefore, occupied more than four days. With regard to this point, however, and to the relative frequency with which the symptoms of the second stage are present or absent, no very precise information can be obtained. They are rarely mentioned in the more ancient cases, and occur so frequently in those of modern date, that the difference can only be attributed to the older writers having considered the state of the cicatrix with little attention. By Aurelius, however, and consequently by the authors whose collective views he represents, this symptom was beheld in a most important light; "*Præpatitur enim ea pars, quæ morsu fuerit vexata; unde initium denique passionem (sc. hydrophobicam) sumere, nemo negat.*" This, however, is not the only medical observation that seems for a time to have suffered a certain degree of oblivion. In point of fact, it has been proved by Dr. Hamilton that by far the greater number of hydrophobic cases commence between the thirtieth and fifty-ninth day after the bite, and consequently at a time when the wound produced at first by the animal, and afterwards enlarged by the surgeon, is in many cases scarcely healed up, and almost always retains that high degree of sensibility proper to recent wounds, and which generally gives rise to considerable pain upon any great change taking place in the system; often, indeed, from mere vicissitudes of the weather. In several instances the pain has been perceived immediately after a debauch, and in one remarkable example it darted into the part the moment the patient was told that another person bitten by the same dog had died of hydrophobia. Though there can be no doubt, therefore, of the actual occurrence of this recrudescence in examples taking place long after all the superinduced sensibility of the part had disappeared, or where re-opening, discharge, or eruption had taken place around it; yet it is not easy to come to a conclusion in cases where the circumstances have been different. A late distinguished nosologist, Dr. Good, has received this phenomenon of recrudescence, which without doubt is very general, into his definition of hydrophobia; and we have judged it necessary therefore to explain, as far as was attainable, the modification to which this character is frequently subjected.

Third Stage, or Hydrophobic Phenomena.—This assemblage of symptoms, from its fatal event, the pity, consternation, and horror excited in beholders, and its obvious diversity from all other maladies afflicting the human race, whilst the latent and recrudescence periods which succeed the application of the exciting cause differ little from any other morbid states of the system, has very generally been considered as constituting the whole generic disease of hydrophobia. In strict accuracy, however, this whole group is to be considered merely as a symptom which may be resolved into separate parts, but yet simply indicates a single stage, such as is well known to occur symptomatic of many states of disease or irritation in the system; nor is there any better reason that the patient's health is entire and the disease qui-

escent, during the first two periods, than in that period of calm composure, facility of drinking and swallowing, absence of pain and mental suffering, which appear so generally for some time before the sudden death of the patient, and which sometimes, as in Dr. Johnston's case, interposes itself in the midst of the disease under the form of remission. We are in no hurry to anticipate the different views that have been taken of the mode or train of action by which the bite of a rabid animal produces this horrible disease; being different, they cannot all be true, and could therefore render us little service here. But, however unknown, they exert an operation on the day in which they render the disease cognizable to the senses, which they could not put forth before, and have therefore been undergoing a series of changes themselves, or operating a series of changes in the constitution from which has resulted this increase of power. From the moment of the bite, then, a morbid action is in progress and accumulation, and he who would deny this may equally deny that the death of the patient, in many instances so visibly disjoined from the paroxysmal state, is owing to the same cause; he must deny, also, that it produces the return of this state after the remission. Yet this series of paroxysmal symptoms is that to which the attention of the practitioner is chiefly directed, and he is, therefore, very easily led to consider it as the essential part of the disease. For some days previous to that on which the disease presents itself, the countenance of the patient indicates anxiety, and he is himself conscious of a restless, rather depressed state of mind. The eyebrows are contracted, the face tumid, and there is headach with tremors. In a certain number of cases a sense of general chilliness, like that preceding fever, is perceived, before any more marked symptoms appear. He is sometimes drowsy through the day, and in other instances has his sleep broken and disturbed in the night. The disagreeable feelings originating from the cicatrix go on to increase; occasional sighing, unaccountable flushes and rigors of momentary duration, and in a few cases slight febrile symptoms succeed. A sudden loathing of food has been repeatedly observed at this period, the patient being sometimes surprised at finding his usual appetite converted into aversion on sitting down to table; and in other instances he becomes suddenly affected with nausea or vomiting. In some persons the peculiar pain, usually referred to the scrobiculus cordis and diaphragm, has been first perceived at this instant, and in one or two cases appeared to originate in the violent efforts made to vomit; but the symptom generally comes on considerably later. A sense of stiffness, gradually becoming painful, is now felt in the back part of the neck, and extending forwards along the basis of the jaw towards the root of the tongue and the *pomum Adami* of the larynx. Sighing is more frequent; the respiration is easily hurried; and there is often some headach complained of at this period. If the patient attempt to swallow any thing, he finds himself unable to perform that office; the matters introduced are rejected with violence from the mouth, and the muscles of the mouth and pharynx are seen by the bystanders to be thrown into violent convulsions, in which not

unfrequently the muscles of the face participate. This is the pharyngeal or hydrophobic spasm, which, by creating a dread of swallowing fluids, has given name to the disease; for although patients are generally able to swallow food and other solid substances with tolerable facility, yet any attempt at drinking, be the fluid what it may, is almost sure to be followed by the spasm and sense of suffocation. Though in most cases the painful spasm is the only cause of the dread of swallowing fluids, and eventually of the fluids swallowed; yet this fear may, in its turn, become the cause of the spasm, the patient, by endeavouring to avoid its recurrence, often originating the very motions which produced it.

The same error of function is frequently observed to take place in these parts in persons who find a natural difficulty in swallowing pills, in painful cynanche, and in eating and drinking while the mind is much engaged upon something else. The parts are scarcely quite voluntary, as is proved by its being impossible to make them perform their office when they are altogether dry; and accordingly our knowledge of the position of objects within them derived from their mere sensation is always obscure, and the efforts made in consequence sometimes prove misdirected or fallacious. In drinking it is not necessary that greater efforts should be made than in eating; but from the facility with which fluids glide along, they often present a larger mass, which requires a greater effort to be propelled at once into the pharynx by the organs of deglutition; and as they easily slide into the smallest cranny, they render the closest approximation of the two lips of the glottis, and of the epiglottis upon these again, indispensably necessary; and as the movement of drinking is generally of the continuous kind, the oppression of the respiratory processes is always considerable, even in health, as is demonstrated by the strong inspirations rendered necessary after a large draught. They must eventually, however, be much greater in hydrophobia, where difficult respiration and irritability of the larynx and fauces are already at their maximum. Besides, in the movement of swallowing, the larynx is drawn upwards and forwards, and the root of the tongue thrown backwards over the larynx, a circumstance which must greatly increase the tendency to suffocation resulting as described; hence the very great augmentation of this spasm while the larynx is being drawn up. As the disease proceeds, this symptom becomes more severe, and calls in a more extensive train of concomitant evils; of which number are laborious respiration, sighing, vomiting, flutulent eructations, a sense of a ball or pressure on the throat, urgent thirst, a burning pain along the course of the spine, neck, and vertebral column. The increase of saliva at this period seems to arise partly from the vehement irritation of the salivary glands which is produced by these movements, as a similar state occurs in many healthy persons, when induced from anger or loquacity to move the muscular parts in the basis of the jaw with great activity. In other cases, however, the saliva is said to precede the spasm, particularly in animals; and in all such instances it must be referred to the specific effect of the poison upon the salivary organs, a series of glands which, of all others in

the body, most readily yield their secretion to a new stimulus. The best authors are agreed that it is the experience of the painful sensations thus produced which in general gives rise to this fear of drinking, which is afterwards, by a too natural process of association, extended to liquids themselves, and finally to polished bodies, to light, to cold, to fresh air, to names or sounds, or indeed to any thing that serves to suggest to the mind of the patient the horrible idea of his sufferings while attempting to swallow fluids. In this opinion we feel ourselves obliged to coincide, as well from the result of our own experience as from the consideration of a number of recently well-attested cases, in which the patients not only denied every antecedent dread of fluids, but made many spirited and occasionally successful efforts to overcome that spasmodic resistance which alone prevented their transmission to the stomach. If we add to this the fact of the dread of water disappearing during the intermissions which have occurred in some cases, and in that final remission which occasionally takes place before death, we shall see that the spasm is the chief cause of the dread of water; and that if the latter had depended, as some think, upon a peculiar modification of the mind produced by the bite, it would not be so frequently absent. The disease is now fairly constituted; the patient is tormented with thirst, every attempt to allay which by drinking only serves to bring a new and more severe paroxysm, the convulsions of which often extend themselves to every muscle of the body, whether of head, trunk, or extremities. There are vomiting of a greenish or dark-coloured matter, eructations, inflation of the stomach and bowels, great pain in the region of the diaphragm, restlessness, heat of skin, and sometimes considerable frequency of pulse. The latter has counted as high as one hundred and fifty beats in a minute. In addition to the headach and singular cast of countenance already mentioned, a peculiar brightness, 'a wild and sparkling expression' of the eye, compared by authors to that observed in incipient ebriety, and a retraction of the angles of the mouth approaching to the sardonic grin, and referred to the well known sympathy subsisting between the diaphragm and zygomatic muscles, are symptoms confined to the head and face. The latter is sometimes suffused, sometimes pale, or varied with large, irregular, ruddy spots. A great plurality of testimonies has satisfactorily established that a certain change or alienation of mind takes place during this disease; but in what the alienation consists, how it is to be described, or where it has its origin, are questions which have all been violently disputed. The most general form under which it appears is a certain promptitude of action and loquacity while engaged in conversation, which is chiefly evinced by the patient rendering longer answers and more circumstantial explanations than he might naturally be expected to do at another time; yet his ideas are said to be perfectly coherent, his reasoning just and consecutive. But the susceptibility of the mind, also, as well as of the body, becomes generally increased, and in this point the analogy with incipient ebriety fails, with the exception perhaps of a very few instances. This morbid susceptibility is manifested by a tendency to take alarm at inadequate causes,

and to form suspicions without any probable grounds; and, in fact, the dread of water itself, and of every thing suggesting the *idea of water*, may in certain subjects be merely another of its indications. High delirium is seldom present except during the extreme violence of a paroxysm, and then but rarely; and as to the states of mental alienation, vulgarly designated by the terms mania and melancholia, they can scarcely ever be said to be present in this disease, however universally the former opinion may once have been diffused. It is fair, however, to remark that the reasoning faculties cannot be altogether entire in a patient who indulges undue suspicion, and who, contrary to previous habit, launches into verbose harangues upon every trifling occasion; for it seems to be the very essence of sanity to perceive justly the relation of its possessor to present external circumstances, which relation is by such persons evidently neglected. We dare not, however, go to the length of proposing for this peculiar susceptibility of mind the term of *lyssomania*, so many patients having expired of this disease without having exhibited the least symptom of suspicion or loquacity. There is still ground for apprehending that their fears are in some instances owing to the vulgar apprehensions of the rough treatment under which the last scene of hydrophobia was till very lately generally believed to terminate. Thus, taking one of many instances, the patient Groves, whose case is related by Dr. H. Maclean of Sudbury, in 1792, had imbibed the idea that "he was to be smothered between beds, and in the most earnest manner entreated us not to shorten his sufferings in this manner." Indeed, only twenty years before, an attempt had been made by the attendants in the Leicester Infirmary to destroy a hydrophobic boy, Nourse, in a similar manner, and they were only prevented from effecting their horrid purpose by the timely intervention of Dr. Vaughan. Groves was a powerful man, in the prime of life; and when we consider the characteristic timidity of hydrophobic patients, we may well conceive that a very great number must have suffered under this apprehension, without daring to give it utterance. So late as 1814, Dr. Albers of Bremen was sent for by a hydrophobic patient in order to bleed her to death, and thereby release her from her sufferings; and she seems to have considered this as quite within the line of the doctor's ordinary practice. The loquacity, though in most instances the result of the peculiar nervous excitement present, may in others arise from the new and terrific circumstances under which the patient is placed, something like what is often observed in persons led forth to execution; and it is no doubt greatly promoted by the accelerated circulation and intensity of sensation which accompany the hydrophobic spasm. Both are symptoms, however, very generally present, and it is under that view they are brought into notice here.

The whole of the symptoms above expressed may establish themselves in a few hours after their commencement, though in general they can scarcely be said to become so fully developed before the second day; and death most usually happens on this and the third, according to Hamilton's table, although in a considerable number it has taken place after twenty, twenty-

four, or thirty-six hours; and in others it does not happen before the fifth day, and in some few instances does not before the eighth or ninth day. Hence there is seldom much time afforded for contemplation of the more exasperated form into which they subsequently pass, but yet they have been observed and described by medical writers with great exactness, and have gradually become separated from the fictions with which they were combined by ancient authors. The sense of thirst, and sometimes also of hunger, become much more urgent; there is frequent vomiting of a green or bilious matter, which does not relieve the pain of stomach or the tension of the præcordia. Besides these greenish and black fluids, which are probably different forms of bile, authors have described the matter vomited as sometimes glairy, sometimes cineritious, and sometimes resembling coagulated blood. The patient is tormented with a burning heat and dryness in the fauces; and the saliva, no longer receiving its due admixture of watery fluid, becomes thick, viscid, and adhesive, and frequently accumulating about the glottis of the patient, and thereby threatening immediate strangulation, causes the unhappy sufferer to make every effort to blow it forward out of the mouth. It is the sound made by this effort which produces that faint resemblance to the barking of a dog, and that appearance of froth adhering to the lips of the patient, which have been so absurdly described as characteristic of the disease. Surgeons, who know that suffocation is produced in good health by a little blood from the tonsils being allowed to accumulate about the glottis, will be at no loss to comprehend how this acrid saliva must irritate the sensitive and frequently inflamed fauces of hydrophobic patients, and make them anxiously endeavour to remove it. Besides, they are often at this period seen to labour under such extreme difficulty of breathing that bronchotomy has been practised for their relief; and it is probably to this cause also we are to attribute the anomalous movement of the cheeks and lips described in some patients, and the occasional presence of black blood in the left side of the heart after death. The restlessness, the tremors, the guttural and general convulsions, return now with much more frequency, and are elicited by the slightest causes; the mind becomes much agitated, and in several cases seems quite unsettled during the paroxysms; impatience of the slightest contact with the skin, of light, and of sound, is frequently present to a remarkable degree; and when the pulse and heat of skin are considerable, a person who saw hydrophobia in this stage for the first time might easily mistake it for phrenitis; but the skin is generally cool, the urine natural, the blood yields no buffy coat, the pain of head is inconsiderable, and the delirium transient. The pulse varies extremely in velocity, but is generally quick, and has been counted as high as 150; it is seldom, though sometimes, strong and hard; and the feeling it impresses on the finger as to fulness, creeping, &c., is by no means uniform. Meantime, the powers of nature are gradually suffering exhaustion, under these repeated paroxysms of action, in which muscle and nerve seem alike to participate. The patient, who usually complains of debility from the commencement,

whatever force he may be found to exert during the paroxysm, appears to become rapidly weaker, until at length, after one or more desperate exacerbations, life is extinguished. In a few cases he unexpectedly becomes tranquil, and most of his sufferings subside or vanish; he can eat, nay, drink, or converse with facility; and former objects, associated with the excruciating torture of attempting to swallow liquids, no longer disturb his feelings. From this calm he sinks into repose, and suddenly waking from his sleep, expires. Sometimes, on attempting any new movement, he dies suddenly; but in many cases he is carried off from this deceitful calm by a sudden and violent convulsion. In the great majority there is no calm or intermission, but the paroxysms, becoming more and more violent, at length carry off the patient. The muscles remain rigid long after death, and the eyes in some instances retain their peculiar brightness, and the iris its contractility, till the following day (*Gorcey*); nay, in one case the pupil, which had remained constantly dilated during the disease, returned to its natural dimensions after death.

Such is the most general progress of the disease, but there are many varieties observed to occur in different individuals, a circumstance which has given rise to many controversies. At times hydrophobia intermits, and at others remits. From the histories on record it would appear that these interruptions tend somewhat to prolong the duration of the disease, but have no distinct effect in rendering it less fatal. This conclusion, however, is not universal, and the circumstances which lead to these temporary suspensions of hydrophobia are not entirely unknown. The alvine secretion, perspiration, and urine, seem generally to continue in a natural state throughout the disease; but the skin frequently becomes intensely sensible, causing the patient to start or scream with horror on the slightest touch. The settling of a fly upon the surface of the body, the contact of cold air, or of heated air moving in a current, produce the same insufferable sensations and the same tremors. Perhaps the dread expressed of mirrors and smooth objects is rather to be attributed to the patient's associating with them the effects of cold upon this irritability of the skin, than with the torture experienced in the act of drinking. We may probably refer to the same source, the observation of Eudemus (A.C. 23), that the trickling of a tear down the cheek will sometimes excite the paroxysm. In a few instances, however, the skin is hot and dry; in others, it is harsh to the feel, but without heat; and in one or two cases it is described as appearing livid; sometimes it is described as covered with a profuse perspiration. In Dr. Johnston's case, the bowels were confined throughout the whole disease, and so closely constricted was the extremity of the rectum by spasm, that every attempt of the medical man to introduce the clyster-pipe proved fruitless, although made with abundant firmness. In nearly all the cases that have come to our knowledge, the urine was natural, a most remarkable circumstance considering the waste constantly going on from the blood by the saliva, and by the pulmonary and cutaneous exhalations, and the impossibility of introducing

a fresh supply of moisture. In a few instances, however, it has been remarked to be scanty, in others of a greenish, and in others of a pale lemon colour. Generally speaking, the organs which excrete this fluid have scarcely been known to be affected with spasm in hydrophobia, although this is a common symptom in hysteria and hypochondriasis, diseases which it resembles in many particulars. In one of Mead's cases, however, (the first,) there was difficulty of passing urine: the patient had "strangury to a great degree, exciting cries on attempting to pass urine; the urine was as well coloured as ordinary." In short, the glandular organs appear to be but slightly affected, and perhaps never primarily in hydrophobia, with the exception of the salivary lachrymal apparatus. Some persons experience an extreme soreness in the scalp on its being touched, and others, as we have seen, have a similar aversion to contact on any part of their surface, declaring that it hurts them; others experience more or less of pain in the region of the larynx or trachea, during the whole or part of the disease; and some have suffered pain and enlargement of the thyroid gland, generally on one side only. During the latter stages of some forms of hydrophobia, the lymphatic glands around the basis of the jaw became sensibly enlarged. Cases are related, in which the first indication of spasmodic action about the neck does not occur in the muscles attached to the basis of the skull, but in the root of the tongue, in the muscles originating from the os hyoides, and it is described as commencing by a sense of rigidity and stiffness merely in that position: on looking into the throat, for the most part nothing is to be seen; but in other instances turgescence and the general signs of inflammation are distinctly visible upon simple inspection. Externally, in some rare instances, the larynx, or the thyroid gland, or the submaxillary gland, have appeared to the medical attendants to be somewhat enlarged.

It has already been observed that those bitten by cats have seldom the dread of water, or the difficulty of drinking it to any great degree; so that to many of them the fable of Tantalus, if ever it alluded to hydrophobia, becomes an allegory misapplied. Such is the notion of Dr. Good, who probably omitted the fear of water from his definition on this account; but the proposition is not rigorously true. In Dr. Vaughan's case of a boy bitten by a cat, he "sobbed deeply at the sight of water, turning away with perturbation." Mr. Bellamy also, and the patient described by Dr. White, (*Hamilton*, pp. 340, 430,) were both distinctly affected with the hydrophobic spasm; and perhaps the only reason for this supposed peculiarity in the bite of the cat, and which has induced this learned nosologist to create two new species, 1, the *rabies felina*, with little spasm, and, 2, the *rabies canina*, with much spasm, has been the simple fact that the cases on record of hydrophobia from cats are too few to afford a firm basis for any inference. In other cases there is no nervous agitation, in others no vomiting, in others no tracheal irritation, in others no fever; many have the respiration nearly free to the last; some await their end with considerable tranquillity, their mind being little disturbed during the whole

scene; while, besides those affected in the manner we have described, there are others who become delirious from the middle period of the disease.

Finally, it is not the modification of one individual symptom that is to fix the attention of the medical observers in hydrophobia, but the changes in one or other of those great original groups to which we have said each individual must belong; the chills and flushes, the tremors, the excessive cutaneous tenderness, the intolerance of light, of sound, of pungent smells, the preternatural activity and force of action, the tendency to certain motions, as leaping upwards, running backwards, climbing; the facial, guttural, and thoracic spasms; the great increase of muscular force, the general convulsions, and at length paralysis of the limbs; the amaurosis, and mental aberration, are symptoms many in number and various in aspect, but all flowing distinctly from one source, a nervous system irritated and finally exhausted by the action of the poison: the priapism, spasmodic contraction of the cremaster muscles, and involuntary emissions, which occasionally occur, have the same origin. That satyriasis ever attended these last symptoms in the hydrophobic patients of Britain, we have not been able to learn. There are good reasons for thinking it never did, as being familiarly mentioned by the ancients, it was not likely to be passed over in the great exactness of modern description. French writers, however, assert that it frequently occurs so combined in that country; and the respectable Portal bears witness to his having seen several instances of furor uterinus occurring in hydrophobic women. This is probably another example of variety resulting from the diversity of national education. Many irritations of the nervous centre are known to produce these symptoms, and if they are sometimes occasioned in hydrophobia by spasmodic contraction of the perineal muscles, the origin of that spasm is the same. Neither must it be forgotten that the reasoning powers, the present conversation, and the previous knowledge of a patient, as well as his physical power of enduring pain, will considerably modify all the mental phenomena; and when the fever is vehement, there will be a further change of these phenomena from that cause. The respiratory phenomena must likewise vary according to these leading symptoms; the *sighing* will have more relation to the fever; the *sobbing* more to the nerves. The theory of sighing is well known; but that of sobbing is evidently of the nervous class, and has been traced by Sir Charles Bell to the sole action of the respiratory system of nerves. It is exactly the movement produced by throwing cold water suddenly upon the naked shoulders, and was long since described as such by practical authors. (*Hamilton, App.*) This affection of the respiratory class of nerves lent some countenance to the peculiar hostility of the rabid virus to the eighth pair, to which we have elsewhere alluded.

The changes which take place in the functions of the organs of sense are abundantly curious. At first there is a distinct increase of their power, the exercise of which seems far from disagreeable to the patient himself; and hence the wandering aspect and rapid movements of his eye: he listens

to sounds, and detects smells, which no one else can observe. Sometimes he speaks of a disagreeable smell exhaling from the wound, and possibly with correctness, it being no great argument to the contrary that the bystanders cannot perceive it. M. Magendie attended a hydrophobic patient, who, though born deaf and dumb, heard very distinctly during the paroxysms. Neither is the sense of touch at first disagreeable; and one patient whom we attended compared it to tickling. But in a short time they all become affected with pain, and finally with anæsthesia or paralysis; the patient hears indifferently, has numbness in certain parts, the pupil becomes dilated, the sight indistinct, and at length lost. This progress from an agreeable excitement to pain and collapse seems to mark the progress of some mischief accumulating upon the nervous system. The super-vention of partial paralysis, paraplegia, and even hemiplegia, tends much to confirm the same opinion; nay, in the case just alluded to there was an universal paralysis, or, in other words, an apoplexy; and we remarked in our notes at the time, that it differed in no respect from a severe case of apoplexy, except that the stertorous breathing was less.

Nothing can be more various than the different frequency of hydrophobia in different countries and seasons. In South America, Syria, Egypt, and Barbary, it is said to be very unfrequent, and indeed scarcely known; even in Britain, where the population is dense, and the chances of multiplying the disorder correspondingly increased, hydrophobia is a somewhat rare disease; and we may meet every day with experienced practitioners who have never seen it. In the mortality bills given in Dr. Willan's able work on the diseases of London, there occurs only one case in the course of five years; and in Edinburgh there has not occurred a single case in the last twenty-five years. On the contrary, it is pretty frequent in many countries on the continent of Europe, as will appear by the following curious statistical table of the ravages made by human hydrophobia in the kingdom of Prussia:

Years	1810,	1811,	1812,	1813,	1814,
Deaths,	104,	117,	101,	85,	127,
Years	1815,	1816,	1817,	1818,	1819.
Deaths,	79,	201,	228,	260,	356.

(*Edin. Med. Surg. Journ.*, 1824.) From this it appears that the deaths in ten years amounted to 1666, or to 166 yearly, which considerably exceeds the number of authenticated cases known to have been put on record throughout the world when Dr. Hamilton wrote his book in 1798. The deaths were most frequent in the provinces of Marienwerder, (228,) and Bromberg, (162.) In Breslau it was 90, in Oppeln 53, in Trier 46, in Aachen 58. On the contrary not a single case occurred in Stralsund; and it was rare (5) in Dusseldorf and in several other places. Hufeland observes that those provinces in which it is most abundant are contiguous to forests containing wolves, to the forests of the Ardennes, of Russia, and of Poland. Hydrophobia is very rare in Sweden. Odhelius declares that the disease is so uncommon that up to his time, 1777, not a single case had been communicated to the Academy of Sciences. Crete, and one or two other of the Grecian islands have

been described by the ancients as particularly obnoxious to this disease, whilst it was rare in the adjacent continents; but this was probably the mere result of the greater number of dogs reared in them, the breed of these islands being celebrated all over the world. It is the salacious nature of this animal, and the absence of all limits upon continents to the extent of his promiscuous intercourse, that gives rise to the difference so long observed between the dogs of islands and those of the main land. In islands, the number of breeds, and consequently the number of mixtures, have a limit, and in small islands like those of the Mediterranean, a sufficiently narrow one: consequently a character of breed once fixed will run small hazard of materially degenerating; for every new tendency will be more or less in an intermediate relation between the breed and the medium character of all the other races. It seems not improbable that the innate fierceness and love of independence, with its consequences, suicide, ardour for general liberty, and aversion to foreigners, which philosophers have long imputed to the human inhabitants of islands, particularly those of Britain and Japan, may be owing to a similar circumscription of family intermixture. Analogous facts may be observed in the Celts and Jews; but we omit this consideration to remark that the same insular circumstances that give rise to the peculiar characters of these far-famed breeds of dogs, may also have generated and propagated a tendency to hydrophobia in those animals. In the Manchester Royal Infirmary, which may be considered the central hospital to nearly half a million of population, very few cases of undisputed hydrophobia have occurred within the last eight years, and in private practice we can only hear of ten cases which have occurred during the same time.

Hydrophobia attacks every sex and age without discrimination. Soranus, the ancient methodic physician, had observed it occurring in infants at the breast, and this remark has been confirmed in later times. No temperament, no strength or weakness of body, no mode of existence or habit of life, is spared; and, upon the strictest investigation, it does not appear that any one of these circumstances, though they are known so materially to modify even diseases resulting from specific contagion, has ever produced the least modification of the symptoms in those attacked with hydrophobia. It seems, in particular, to invade alike every class of society: the superior intelligence, cleanliness, and comfort, of the classes raised above the necessity of daily labour, is found to afford them no security; and, considering that their exposure to the exciting cause must be considerably less, there appears to be a full proportion of cases occurring in such persons put on record in the writings of physicians. It must be observed, however, that a great number of those who have been bitten, escape the disease, and that this good fortune cannot be without a cause. Blacks are obnoxious to hydrophobia as well as whites, but in what proportion to the latter has not been ascertained. Some have inconsiderately asserted that men of the Arab race are exempted from its ravages; but this is sufficiently confuted by the familiarity with which Avicenna and other Arabian physicians speak of the disease.

In studying hydrophobia we must avoid a source of error, from which false reasoning and many false facts have flowed from the time of Celsus Aurelianus; who seems entitled to some praise for the invention of a sophism that has been so much employed by his successors, and so well received by the mass of mankind. "If Homer," says he, "knew of dogs, and of the hydrophobic disease to which they are subject, he must also have known of the hydrophobic disease of man; for the disease of the dog is the cause of the disease in man; and if he knew of the cause of the disease, he must of necessity have known the disease itself; for where the cause was present, the effect would naturally follow. By a parity of reasoning it has been inferred, that wherever dog-madness is, there human hydrophobia must also be; that the climates which produce the one must produce the other, and that the symptoms which are produced in the one must be produced or imitated in the other. It is chiefly owing to these extravagant conclusions that we are often unable to discover whether an author is speaking of the disease in man, or of the disease in dogs; that we find all the fabulous symptoms imputed to the mad dog by the first writers, described in the hydrophobia of man by medical authors comparatively modern; and that, up to the present hour, the influence of climate or local position is supposed to exert some influence on the production of this disease. Two things, however, are clear; first, that a place may be for a length of time free from hydrophobia, and yet suffer greatly afterwards from the direct demonstrable importation of that malady; and, secondly, that the disease may be raging amongst the canine race of a district, where formerly cases of human hydrophobia have occurred, and do afterwards occur; and yet from the activity of the police, chance, which gives up only every twenty-fifth person to the confirmed disease, and another series of chances comprehending the confinement, detection, or death of the animal himself, may combine to render the canine disease devoid of all bad consequences at that time, without our being forced to suppose that climate or atmosphere has in the smallest degree interfered. As these facts seem important, we shall illustrate them by a brief example. In 1798 Dr. Hamilton assures us, on good authority, that canine madness had not been seen in the island of Jamaica within the last fifty years.

In 1822, that excellent observer, Dr. James Thomson, of St. Thomas in the Vale in that island, put upon record the following decisive facts regarding the same subject in the Edinburgh Journal. Dr. Thomson had an opportunity of observing the cases of two hydrophobic patients in Jamaica, whose malady resulted from the bite of rabid animals. Upon dissection he did not omit the spinal marrow; but except slight inflammation of the throat, not the smallest appearance of disease was manifested. Neither did he find any thing in the bodies of three different animals which died mad. Simple heat will not create the disease, as it is not more common in tropical regions. Some years ago almost all the dogs in St. Domingo were infected, from the bites of some rabid animals that were brought from America; and it has, since that period, been repeatedly

traced to infection from that quarter. It has also been repeatedly communicated to the race of dogs in this island. The dogs kept for the destruction of rats upon sugar estates, are occasionally seized with madness. Dr. Thomson once saw an instance of a goat bitten by a dog, and where mercury was given. The poor creature ran at the mouth terribly for some days; but soon afterwards died mad. He has been informed that herds of swine become occasionally mad, biting and tearing each other. It is obvious, therefore, that the disease has been imported into Jamaica since 1798, at which time it is supposed the island had enjoyed an immunity from it of fifty years; and this immunity, which authors had attributed to climate, was in reality the effect of accident. Insular situation rendered it easy to exterminate the dreadful visitant, and a large period of freedom from its ravages succeeded.

What relation the disease may have to the different seasons of the year, or to various modifications of the weather, will be more properly considered amongst its causes.

Causes.—The most careful investigation by the anatomist has hitherto discovered nothing in the dissection of the bodies of those destroyed by hydrophobia, which throws the least light upon the theory of its cause. The bodies of many patients who expired under frightful sufferings, have not exhibited the slightest indication of disease. In others, an early and careful examination of the fauces discovered no morbid appearance during life; and the few organic changes which have been described in other cases are too various in locality and degree among themselves, and being mere traces of inflammation, are too easily explained as the consequences of the violent straining, and spasmodic action of these parts, and of the acrid secretion, or halitus, whose combined irritation they undergo during the latter part of the disease, to enable us to deduce from them any conclusions as to the seat or the mode through which the exciting cause works out its fatal effects. The details, therefore, afforded by pathological anatomy, we shall do better to reserve for another place; and we now proceed to consider the causes of hydrophobia, in their triple relation of *predisposing*, *remote*, and *proximate*.

With respect to predisposing causes, we have nothing but the most loose analogies: persons of the nervous temperament, and of a feeble habit of body, and melancholic and irritable individuals, are occasionally liable to obstructions of the great functions of the throat, breathing and deglutition; and these impediments appear universally to be of the spasmodic kind. The globus hystericus, the dysphagia sicca, the hydrophobic spasm, spasmodic croup, and even spasmodic dysphagia, are all members of this family, and exhibit the common character of supervening suddenly; not unfrequently, indeed, from mental emotion also, or gastric irritation, particularly dyspepsia. But these are merely evanescent accidents, and have no right to be considered as having the same origin with the terrible spasms of human hydrophobia. On the contrary, we have already seen that the hydrophobia of man occurs in every possible temperament, age, and habit, and it is therefore most illogical to infer that they have any thing in com-

mon in their origin. In plain truth, the excitement which produces the spasms in question, produces the same effects in the most robust, sedate, and fixed of human constitutions; and taking their own view of the matter, who is it, of all such speculators, that would dare to assert that he knows the exact measure of force exerted by the cause of hydrophobia? Or that he states on demonstrable grounds, that there ever exists in human bodies an irritability too small in degree for it to produce its specific effects? We say then, that the notion of a nervous or melancholic temperament predisposing to human hydrophobia is an *ex post facto* observation, drawn from what is seen in the symptoms after the disease is formed, and not a genuine clinical remark, chronicled in the latent stages, and confirmed by comparison of cases. The few other predisposing causes that have been occasionally alluded to are too improbable to deserve notice in the present day; being those causes which have been noticed as producing the non-rabid hydrophobia, which are afterwards to be disposed of, and which may very well be allowed to remain in the class of exciting causes of that distinct species, till they have been shown to act as predisposing causes of rabid hydrophobia; an assumption altogether gratuitous, and of which at present there does not exist one instance upon record.

As we advance to the *exciting* causes, however, our information acquires a more satisfactory character. That the bite of a dog, labouring under a particular form of madness, is often succeeded in man by the symptoms above described, and in animals by a disease remarkably analogous, and equally fatal, is a proposition which is confirmed by the testimony of all ages and nations, and has never been called in question by any respectable writer. But numberless, and many of them indeed extremely interesting, questions have arisen out of this admitted fact, and are still occasionally proposed for our solution, with regard to the time, manner, and circumstances under which the apparently trifling injury, which precedes, produces the fatal consequences which follow. Does the disease ensue from the influence of fear alone? And, if so, is this fear created by the terrible appearance of the animals, by the prejudices of the patient, by the apprehension of the medical attendant, or by all these terrors acting together? Is it the simple result of laceration extending, as in tetanus, its irritation from the part wounded to the more susceptible portions of the nervous and muscular system? If so, we are to consider it merely as a form of tetanus, or rather as a different disease originating from a parallel cause? And in either case, would the claws, or other rigid parts of the animal produce similar effects by a scratch? If so, why do the symptoms of hydrophobia differ from those of tetanus? Again, is the disease communicated by a poison or virus which passes into the wound, during infliction of the bite? If so, does it come from the saliva or the tooth, or is it the saliva itself in a morbid state? Is it absorbed into the system, or does it remain in the wound? If absorbed, does it modify the whole blood and secretions, or merely the secretions of the saliva; and does it imbue this in man with the power of communicating the

disease? If the virus is not absorbed, by what mysterious operation does it induce distant parts of the system to create a similar virus, and at length to undergo such vehement and fatal action? Into what condition is it passing during the state of recrudescence; and how does it bring to pass the phenomena which constitute this state? How long or how short a time may it remain latent in the human system? Can it act by inhalation or mere absorption? Can man communicate it to his kind, or to other animals? These are questions which, however numerous, require to be considered in the etiology of the present disease.

We have already shown that the disease does not arise from the influence of fear alone, nor is it ever imaginary. The rabid animal is often quite unsuspected when he inflicts the wound; and in other cases the patient is in a condition incapable of appreciating danger, or of connecting in his mind the former injury with his present feelings. The case of Richard Brown, in the *Edinburgh Journal* for 1810, affords important testimony to this effect. To the inquiry, is hydrophobia merely a tetanic affection, originating in the laceration produced? a fuller answer will be returned in the diagnosis; but order meanwhile makes it necessary to remark, that tetanus and hydrophobia must either be the same or two different diseases. If they are the same, where is the locked-jaw and tonic spasm of tetanus in the latter? The frothy, overflowing saliva, the thirst, vomiting, clonic guttural spasm, tremours, and mental aberration of hydrophobia in the former? In short, what medical man ever mistook one for the other since the days of Democritus? If they are different diseases, why attempt to class them together under the same appellation? No man pretends to explain distinctly how a lacerated wound excites the phenomena of tetanus; and we should be committing the old logical blunder *ignotum exponere per ignotius*, if we coincided with the attempt to explain the operation of the cause of hydrophobia, of which we know so very little, by the theory of tetanus, of which we know nothing. If it be said that there is an analogy between the exciting cases, the spasmodic paroxysms, and the fatal results of the two diseases; it may be answered that this analogy entirely fails in the diagnostic particulars above enumerated; and perhaps still more essentially in the fact, that tetanus never engenders madness or a desire of biting in the lower animals, and is never communicated by a bite from one to another. This last circumstance renders it impossible for us to consider hydrophobia as produced and matured by any series of proximate actions parallel to those which produce tetanus. By the argument of exclusion, therefore, we are obliged to admit the principle of a virus, for we know of no other mode, and we shall find that, besides this necessity, the absolute existence of such a virus is all but demonstrated by many positive analogies. The saliva of the animal inflicting the bite is evidently changed in its nature, being morbidly abundant, viscid, and frothy; wounds inflicted through clothes are less frequently followed by the disease than in those which occur in bare parts, as the hands and face; thus in Oldknow's case above quoted, no recrudescence took place in

the scrotum or thigh, because, in wounding these parts, the teeth of the animal had been wiped as it were, by passing through the person's clothes, before they could reach the soft parts within; but it took place in the hand, though the part last bitten, because the animal, which had been forced to let go its former hold only after using considerable violence, had time to shut his mouth and wet his teeth again in saliva, before inflicting the wound. Introduced by a wound into carnivorous animals, it evidently reproduces a similar saliva wherever it excites the disease. In one omnivorous animal, man, the same fact has been proved by Magendie, by means of injection; and from the testimony of Dr. Thomson, above quoted, and many other writers, the same thing seems probable with regard to another, the hog, when introduced by a bite; and the symptoms of the malady ensuing, with the addition of the biting tendency, peculiarly resemble those which take place in man. Amongst the herbivorous animals a large salivary apparatus is necessary for their food, which does not undergo its ultimate chymification in the first stomach: and it is not impossible that the changes produced upon these organs by the rabid poison may be too small to generate the new virus. After all, the virus may be there, but in too dilute and feeble a state to manifest itself in the few rude experiments which have yet been made by physiologists upon this subject.

There does not, however, appear on record any indubitable case or history in which hydrophobia seemed to be communicated from one herbivorous animal to another; but this does not weaken the analogy to virulent poisons observed in the hydrophobic bite of the other two classes. Again, the effects of the bite, like those of a morbid virus, for the most part, manifest themselves within a certain time after its infliction, by far the greater number becoming ill between the thirtieth and the sixtieth day, and a great majority of these again about the fortieth, the day before, or the day after. Every morbid virus, however, presents irregularities in the time of its manifestation, and that which remains the longest latent, by affording time for the occurrence of a greater number of causes for its evolution, must be that which presents the greatest number. Hence it is, that the syphilitic and hydrophobic virus exceed all others, and nearly coincide between themselves, in this irregularity. Nay, the fact that dogs frequently communicate the disease by a bite during this latent period, seems to evince that there is a morbid assimilation in progress long before the appearance of the symptoms; a circumstance which is perfectly in accordance with the idea of a virus; but which cannot well be understood on any other supposition. The train of symptoms occurring in the wound itself, which we have ventured to comprehend under the term recrudescence, correspond very well with the idea of a virus. Why should the wound, after a considerable lapse of time, again become painful, red, and swollen, unless some cause of irritation still remains lurking within it? Why should it re-open after such an *increased* action, of which augmented adhesion is understood to be the only natural result? Wounds re-open in scurvy, purpura, pest, and putrid fevers, because the weakened vessels easily part from each

other at their points of inoculation; and cannot, moreover, deposit new matter in proportion to the rapidity with which the recent texture, now almost dead matter, is taken up by the absorbents, and the bond of union is thus first destroyed by the absorbents from within; just as it would certainly be the first to yield to the action of escharotics from without. But the state of the parts seems totally different here; and that they are ultimately separated from each other by the irritation of some matter lodged within the place of the wound, seems proved by the peculiar nature of the ichor discharged, by the eruption which sometimes takes place around the cicatrix at the same period, and by the livid colour frequently observed to surround it. The latter, it is believed, owes its frequent appearance about specific sores to their acrid matter inflaming and contracting the valves of the contiguous veins, by which it is absorbed into the system. Thus, though we cannot give ocular demonstration of hydrophobic any more than of any other virus, its existence rests exactly on the same foundation as that of all others. This virus cannot proceed immediately from the teeth, for their flinty sheath of enamel remains unchanged during the whole disease, and they present no pores, canals, or openings through which the noxious matter may distil, no poison-bag as in the fang of the serpent. The saliva, therefore, is the immediate vehicle of the poison; but it does not follow from hence that the salivary glands themselves are its primitive source. Troillet contends that the virus proceeds from the bronchial membrane of the lungs, which is in a state of inflammation. The tonsils, too, are known to secrete a matter very different from the ordinary appearance of saliva; and anatomy in many cases detects a very fetid product in the follicles of the arytenoid glands of the larynx, which is believed to be the cause of offensive breath during life; and the breath of hydrophobic patients is often observed to be extremely disagreeable. The lungs are in a state of morbid action during a great part of the disease, and the effects of the impingement of acrid halitus from these organs upon the membrane of the fauces become very manifest in certain cases, as in the symptomatic aphthæ of phthisis pulmonalis, and the blistered chops which frequently precede mercurial salivation. The virus, then, may either be an addition to the saliva, analogous to that of oxalic acid, which Brugnatelli discovered in it, or it may be the whole saliva morbidly changed; and, at present, in a state of animal chemistry that cannot distinguish between the bland mucilage of gum arabic and the most virulent poison of serpents, the decision of this question cannot be of much importance.

"Is the virus absorbed into the system, or does it remain in the wound?" We have above observed, that if the hydrophobic virus is absorbed, it does not specially affect to find its way into the body through the medium of the lymphatic system; it may enter the circulation still more rapidly however by means of the veins; and the lividity described about the cicatrix at the commencement of the disease seems to point out this as its actual course. To those who suggest that the poison may remain confined to the part, and thence im-

part, from its malignant focus, a portion of virus to the blood as it circulates through it, till the whole is imbued, it may be answered that, though the suggestion is possible, we know of no fact, and see no analogy in its favour; whilst, on the other hand, it is matter of familiar observation that all other poisons, under the same circumstances, are rapidly absorbed, and may in many instances be prevented from producing their specific effects by mechanical impediments interposed in the course of absorption. This last analogy is also fatal to the ingenious suggestion that the poison may remain in the part, and by nervous sympathy, or, in other words, by irritation communicated from thence along the nervous system, may dispose that system to produce all the morbid phenomena which constitute the disease, and the vitiated poisonous secretion among the rest: just as we perceive in hysteria, proceeding from the topical irritation of worms, or in the non-rabid species of hydrophobia. In short, a virulent specific poison inserted into a wound, and producing, by absorption, convulsions, fear, contagious secretions, and death, is not only an ordinary, but an almost universal event; but a poison of the same character that should lurk in a small corner of the patient's flesh, obstinately resisting all the powers of absorption for months, and finally, without departing from thence, create a malignant poison capable of reproducing itself through thousands of living beings in succession, would be a fact entirely unprecedented; and as it has not been proved to have happened, is therefore at present only a supposition extremely improbable. There remains, therefore, no just or tenable ground for believing that the hydrophobic virus enters the system in any other way than through the ordinary course of venous absorption. To the questions arising from this admission, we can only attend with propriety when considering the *proximate* cause or *theory* of the disease.

The dog and cat, and animals closely allied to them by natural characters, have alone been proved, by correct observation, to possess the power of communicating this disease. The fox and the wolf are the kindred of the dog; and these, with the latter and the domestic cat, are all the animals which appear upon credible testimony to have produced a genuine rabid hydrophobia by their bite. From all the examples of which the history can be believed at present, it does not appear that age, sex, or variety of breed, or other corporeal circumstances, exert any influence with regard to the disease in these animals. It is true that in Mr. Gillman's account of the death of a sow and her two pigs, all bitten at one time by the same mad dog, whose disease on dissection he fully ascertained, age seemed to have some effect. The pigs were seized respectively on the tenth and fourteenth days after the bite, and the latter died three days after; while the sow was not affected till the twenty-seventh day, and struggled with the disease for five days before she expired: but there are other cases directly the reverse of this result. Indeed the external circumstances which are generally supposed to favour or actually to cause its production in those creatures, are far from being unscrupulously admitted by medical writers. Hunger, putrid food, confinement, violent

treatment, great atmospheric heat, great cold, suppressed salacity, checked perspiration, the growth of a peculiar hydatid or worm under the tongue, intestinal worms, epidemic contagion, want of water, self-generated contagion, have all been assigned as causes of the appearance of hydrophobia among animals. With regard to hunger, it is known that the pangs of this state induce a high degree of fury in the wolf, but this recedes when his famine is allayed. It is not hydrophobia, and it does not even appear that the dog, whether domestic or wild, even when dying of hunger, exhibits the same fury. Finally, by far the greater number of cases occur in dogs and cats that are highly fed and pampered. Putrid food seems an aliment as natural to the dog as to the vulture or maggot. The greater number of dogs are lured to it from afar by the odour, and feed upon it with delight. The great majority of dogs kept in kennels are fed upon nothing else; and if we except a chance of the disease running through a kennel when once it occurs, hydrophobia is not very frequent among dogs so preserved. Add to this, that many tribes of mankind, as the sturdy natives of Kamtschatka, who abhor all food that has not been some time putrid, are yet far more healthy than others on the same parallel, as the Esquimaux, who eat their victuals fresh; and the undeniable fact that favourite lap-dogs and favourite cats, whose taste has been long rendered too nice by indulgence to eat putrid meat of any description, do yet very frequently become mad, and communicate by their bite hydrophobia to man, and rabies to other animals. Great abundance of carrion, however, by congregating a number of dogs from all quarters, whether healthy or infected, must greatly tend to disseminate the malady. The same must be the result of confinement, where many dogs are kept within the same kennel; and there is very competent authority that the bites of a rabid animal thus enclosed amongst others, may often be traced through a great part of their number, although they are not all seized with the disease, and experience has not proved that confinement usually becomes the exciting cause. It sometimes happens that dogs suspected of hydrophobia undergo very cruel treatment, but this is more frequently after than before they have manifested that irritability, snappishness, or fury, which are generally deemed characteristic of the disease. By far the greatest number, however, of those affected have suffered no violence from man, and it seems much more probable that in almost every instance they derive the fatal poison from infection communicated by the bite of another dog already diseased.

The most common notion respecting the origin of hydrophobia in these animals is, that it is excited by great atmospheric heat, as for example by that of the dog-days; and hence the annual panic in our own and most other countries, the tying up, muzzling, and killing of dogs, and many other sanitary regulations of police during the hot season. That absolute heat will not of itself determine the appearance of hydrophobia among animals has been already established, from the rare occurrence of the disease in tropical countries. Still there is no reason why autumnal heats should not increase the frequency of the disease in more

temperate regions; and the consonance of general opinion with the notions of most writers seems to favour the idea. M. Trollet found the dates at which 114 different dogs had become affected with the disease to spread themselves throughout the whole circle of the year; but the most considerable of them were comprehended in the months of May and September; on the contrary, they were fewest in January and March. The dog loves heat, and delights to saunter about or lie half asleep upon the ground out of doors in warm weather. Hence many more strange dogs are brought into contact with each other, and the chances of infection multiplied; while the excitement produced by the heat may perhaps render them less cautious than ordinary of meeting each other. In point of fact, however, a general register of cases is said to exhibit the disease occurring pretty uniformly through every range of temperature, and every season of the year. Hildenbrand and Roser conceived that the extreme excitement which in this animal prompts the venereal appetite, disturbs the nervous system so much as to induce a degeneration of the saliva, a change which takes place easily, because the dog never sweats, and consequently the fluids are carried towards the mouth in much greater quantity in this than in other animals. This notion has received some support on the continent, (*Sprengel*, vi.); but it is not easy to see how a state of excitement, which is common to all animals, should produce a specific affection in so few species, and in these again only in a very few individuals; for by far the greater number of animals become mad by having been bitten by other animals. We had supposed, indeed, that the idea of spontaneous hydrophobia had been long since exploded, for the simple and obvious reason that it cannot be proved ever to take place; for we have not yet ascertained all the circumstances under which hydrophobia may be communicated in animals, nor how long the disease may be dormant in their system. So that we should never be safe in asserting that any case was spontaneous, or had arisen without any external cause. Moreover, it is still strongly disputed, whether, from simple irritations within our system, contagious disease can in any case be propagated. Without examples and without established theory, therefore, the notion of the spontaneous origin of hydrophobia, originating at times in the same manner as typhus is supposed to do, from some internal actions, must, like the origin of all epidemics, be referred to the obscure chapter of medical hypothesis which treats of the general origin of diseases. With regard to want of water, no such privation is suffered by a vast majority of the animals from which the disease seems to proceed; and as to the worm under the tongue, it is an anatomical delusion.

We have already alluded to the false, though very general conclusion, that hydrophobia, because it always originates from the same cause, ought always to manifest the same symptoms in whatsoever species of animal, or whatever individual of these species it may occur. Every day's experience refutes this fallacy. The precepts of the Baconian philosophy of induction now triumph over the ancient *a priori* method of conjecture in every question of science; and in the present dis-

ease, by enforcing the results of strict observation, have banished from the histories in which it is recorded those imaginary analogies by which, however specious, they were formerly defaced. But the variations of symptoms brought into view by this improved mode of investigation are so numerous and discordant, that the causes of these discrepancies between the forms of the disease as it occurs in different species and different individuals become a fair and legitimate object of inquiry. First then, it must be observed, that in the appearance of the symptoms some modification may be expected from the degree of sagacity or intellect of the animal affected. Man, who is distinguished over all other creatures by the superiority of his reasoning faculties, and by the power of correcting morbid associations by the employment of these faculties, may be well supposed to resist the establishment of many diseased combinations of ideas, originating in the perverted sensations peculiar to this malady, which would instantly have undisputed possession of a quadruped. And thus also in man himself, with adults, so long as there is no delirium there is little or no fear of water, or of circumstances suggesting the recollection of water; but when the delirium is once become high, the person no longer suffers merely from the pangs endured from attempting to drink, but associates in his mind those tortures with the fluids which produce them or matters that resemble them. On the other hand, infants, weak-minded persons, young and stupid animals, seem to yield to this very natural association, and further to combine it with self-preservation almost from the commencement of the hydrophobic attack. On the same principle, it is hardly to be supposed that a carefully educated and sagacious dog will so readily yield to the suggestions of these morbid feelings, or so soon resort to the means of self-defence which in brutes are inseparably combined with attempts to destroy the object of their fears, as would a wild and masterless animal; and this is probably the reason of that indiscriminate fury observed in the mad wolf, now believed by naturalists to be merely the dog run wild, as it probably is the cause why hydrophobia is so often communicated by dogs of which no one knows the owner. Hence it is that wild dogs in this state fly at all things in their way and tear them with violence, while the fully domesticated dog, unless highly provoked, rather snaps than tears. In a most formidable experiment performed on a little favourite dog, in the year 1826, Mr. White, of Brighton, found it no easy matter to induce the animal to bite his arm, although it was so far advanced in the hydrophobia as to die in a day or two afterwards. This may also afford an explanation why many dogs lap water, and even swallow it for a considerable part of the disease; whilst others seem to be completely deterred from it by the great pain it occasions. Thus the sow and pigs described by Gillman, would not swallow fluids, but showed no aversion to the sight of water, although the sow, in addition to the extreme irritability of surface which they all manifested, became subject to that panaphoby, or universal alarm, in which many of the ancients believed the essence of hydrophobia to consist; the older animal thus having sagacity to form an asso-

ciation between pain, and consequently danger, and the contact, sound, or approach of external agents which produce them; while the younger ones did not seem to form the same combination. Besides the influence of sagacity upon the mode of avoiding pain and danger, something may also depend on the physical structure of the throat: the pharyngeal spasm does not always constitute the whole difficulty of swallowing; there is very frequently joined to it a feeling of immediate suffocation, and a terrible oppression of the whole respiratory functions, somewhat resembling the worst forms of asthma. When these are wanting, the patient may be more easily enabled to overcome the spasms of the pharyngeal muscles; when they are present, he will be deprived of this power. Finally, this effect may be considerably modified by the force and direction with which the pharyngeal spasm happens to bear on the opening of the larynx; and all the results may be greatly modified by the state of augmented sensibility, or by the absolute inflammation, perhaps, which exists in those parts.

Having premised these sources of variety, we shall briefly state the symptoms which generally appear in the dog; and which are, after all, abundantly akin to the symptoms of human hydrophobia: but as a great deal of error and certainly little benefit has hitherto been derived from their study, we shall, in a dictionary of human diseases, consider ourselves entitled to treat the malady of the dog with great brevity, and to pass over that of the other animals in perfect silence. Some time before the hydrophobia makes its actual appearance in the dog, he exhibits some singular departure from his ordinary habits, such as picking straws, threads, or small bits of paper, from the floor; licking the noses, &c., of dogs, or other animals with which he is domesticated; becoming suddenly attached to animals formerly regarded with indifference; licking cold surfaces, as cold stones, or cold iron. He is observed to be shy, lonely, and irritable; he avoids the approach of other dogs, and sometimes of man, and appears to be less eager for his food, or altogether to neglect it; his ears and tail frequently droop, his look is suspicious and haggard, and sometimes, from the very commencement there is a slight redness and watering of the eyes. In a short time saliva begins to flow from his mouth, and passes by degrees into a viscid foam. Respiration is difficult, and performed with panting; the tongue hangs out of his mouth. At this period, inspection of the fauces often shows them to be red and inflamed. He has fever, the skin is sensible to the touch, but he still obeys the voice of his master, though now easily provoked to snap at other objects. In many dogs the signs of fury never rise higher than this; but in all there is a repugnancy to control, and a readiness to be roused to extreme rage on the appearance of a stick, whip, or other instrument of punishment; and all attempts at intimidation only serve to increase their rage. Nevertheless, indiscriminate aggression, and unprovoked fury are occasionally to be observed determining all the motions of the rabid dog; he flies at every creature he meets, bites all the dogs, and gnaws the wood of his kennel; and when admitted into a field where sheep, goats, cattle, hogs, geese, or

other timid unoffending animals are collected, he tears and pursues every individual of the flock he can approach. The cat is an early object of his rage, and even the horse and elephant have not unfrequently sunk under its baneful effects. Vomiting frequently precedes or accompanies the disease, the respiration appears laborious, tremours are frequent, and the animal is at length destroyed apparently by convulsions. Inspection of the dead body exhibits, with the same irregularity, phenomena entirely similar to those detected in the bodies of the victims of human hydrophobia. It is generally believed that the latent period is shorter in dogs, and indeed in most animals, than what it appears to be in man, but this point is not very well ascertained, and there is abundance of evidence of the poison having remained in the dog for several months before the disease was produced. Nay, it seems pretty certain that he has frequently communicated hydrophobia to man and other animals during this apparently latent period; a circumstance which shows that the virulent assimilation is even then going on in the animal's fluids; and suggests great caution in our intercourse with these creatures.

Many have asserted, from Aurelianus downwards, that dogs occasionally communicate hydrophobia to man, to their own species, and to other animals, by their exhalation and saliva alone, without inflicting a bite. To inspire the visible vapour they exhale, to receive their saliva upon the skin or into the mouth, even to be scratched by their nails, or by the nails of a cat, has been supposed to be sufficient to induce the disease. There are certainly a few cases related of hydrophobic patients which seem to come under this description; but as has been well observed by Dr. Bardsley, it is much more probable that, in such cases, some small portion of the cuticle had been deficient at the part with which the saliva came in contact, and thus afforded all the facility of a wound to the conveyance of its poison into the system. The ancients were well aware of the possibility of this, for Celsus observes that the integrity of the lining membrane of the mouth is necessary to the operations of the *Psylli*; and Dioscorides expressly orders those who were to suck out the poison of a rabid dog, first to wash their mouth with astringent wine, and afterwards to lubricate the cavity with oil. With regard to dogs, Mr. Meynell observes, that such of them as have been thought to become affected merely by the contagion of the same kennel, will generally be found, upon minute examination, to exhibit the marks of bites, although concealed by the hair from ordinary observation. With regard to the effects of a scratch, these resolve themselves into the great probability of part of the saliva of the rabid animal having been introduced by the claw which produced it, or having afterwards fallen upon the open wound. In fact, both dogs and cats do very frequently present their foot to the head or mouth, when affected by any uneasiness in that quarter; and they frequently rest themselves with their head reclining upon the fore paws. All such cases, however, are comparatively rare, and there is reason to suspect that many of these histories were examples of non-rabid hydrophobia. From what we know of the great absorbing powers of

the lining membrane of the stomach and lungs, it seems not improbable that the poison, if introduced into the saliva, as by kissing a rabid animal, by admitting pieces of cloth, leather, sticks, and the like, impregnated with the same saliva by its bite, into the mouth, the venom might find its way to the stomach and even to the trachea and lungs, and thence, by absorption, be received into the system; and there are some very positive testimonies on this head extant among the older authors; but nothing satisfactory of the kind has been observed during the last two centuries: and we feel ourselves compelled to pause before we admit the inference. The same caution must be observed with regard to the many animals, in addition to those above mentioned, which have been named by medical writers as the propagators or victims of hydrophobia. The camel is alluded to by Aristotle; the leopard, the bear, the horse, the ass, and the game-cock are mentioned by Aurelian, as animals propagating the disease; Penada (*Saggio*, &c. 1793,) has recorded a case of hydrophobia resulting from the bite of an insect; and the lion and tiger are vulgarly believed to be capable of producing the same effects. Later investigations seem to show that the herbivorous animals do not easily communicate the disease; but the whole evidence adduced is jejune and meagre, and the paucity of cases of communication may entirely result from the pacific disposition of such animals. It is the nature of the carnivorous to be easily roused to rage, combat, and violence. The Author of nature has made them so, because by combat and violence he hath destined them to support their existence; but the pacific races that crop the flowery mead, and participate, without resistance, in the bounteous repast with which they are everywhere presented, have neither habits nor motives which febrile or nervous irritation might prompt into violent action: and into them the same great Author has instilled fear only as a motive of flight, seldom as a motive of aggression or resistance. Hence, probably, the extreme paucity of their bites altogether, and the assertion that they never reproduce the disease; an assertion which we look upon as calculated to diminish circumspection, and to inspire more confidence than is warranted by the evidence upon which it is founded: we wish that in hydrophobia no other conclusions had been originally drawn from such slender premises, and afterwards expanded into general laws.

It would be of much importance to ascertain, out of a given number of persons bitten, the actual proportion that become affected with hydrophobia. It is difficult, however, to come at any thing like distinct truth upon this point, apparently so obvious: for the dog is either immediately killed or tied up, and, consequently bites only a small number, or he runs wild in the country, so that the number of his victims cannot be ascertained. Mr. J. Hunter, however, asserts that he knew an instance in which, of twenty-one persons bitten, only one became affected with hydrophobia; Dr. Hamilton seems to think that one out of twenty-five becomes affected. In 1780, a mad dog in the neighbourhood of Senlis took his course within a narrow circle, when he was killed, after having bitten fifteen persons, of whom three

afterwards died of hydrophobia. The French government ordered the most eminent physicians to resort to the spot, examine the cases judicially, place the patients in hospitals, &c.; so, though the original number is too small to warrant a strong inference, yet it presents the proportion of the number bitten to the number ultimately infected in one instance with exactness. At Brive, a wolf bit seventeen persons, and of these ten died hydrophobic.

The causes which are said to produce the non-rabid form of hydrophobia, having no great connection with each other, and being incapable of inducing a successive propagation of the disease either to animals of the same or of a different species, they cannot be supposed, as yet, to have all come to our knowledge:—

1. Superficial wounds, particularly of naked and prominent parts.
2. Nervous irritation of various kinds.
3. Violent intermittent fever.
4. Injuries of the brain and spinal chord.
5. Morbid conditions of the stomach.

The symptoms of the disease induced by these causes do not differ materially from those which result from rabid hydrophobia, and we therefore supersede the unprofitable labour of repeating a detail of these indications. Whoever wishes to consider them minutely will find the particulars of many cases, at great length, in the article *Hydrophobie* of the *Dictionnaire des Sciences Medicales*, and the same condensed, we may be allowed to say, not with great skill, in the *Dictionnaire de Medicine*. Perhaps the best case of the kind on record is that of Lindsay, which occurred from hunger, excessive labour, and mental anxiety, and has been described with great care by Dr. S. Bardsley in his valuable *Inquiry into the Origin of Canine Madness*. It may be remarked that Lindsay must have long laboured under hypochondriasis; for a man that could remain, as he relates, from 1782 to 1794, in the constant dread of his family dying of hunger, without having once suffered it in all the twelve years that intervened, either wanted the usual powers of generalization common to other men, or was no stranger to the disease characterized by a *metus mortis a causis non æquis*. Lastly, the symptomatic forms of hydrophobia must, in a great measure, be referred to their nosological arrangement given above. We do not hold ourselves answerable for a disease, more or less than appears there, having exhibited symptoms of hydrophobia. Observation cannot yet be complete in this respect; and it is certain that our means of judging of the veracity and discrimination of writers describing such cases are very far from being in that state. They are quite unimportant as regards idiopathic hydrophobia; because hitherto no connection has been established between them; and it is seldom that the disease in which symptomatic hydrophobia originates is better understood than hydrophobia itself. It follows that the only proper place for the consideration of such anomalous symptoms is under the disease in which they arise.

The proximate cause or theory of hydrophobia demands particular attention. Empirical trials, of which the practitioner often thinks but too highly, confounding what succeeds with the ordi-

nary progress of nature, powerfully modified by external circumstances, have held out no flattering unction to human vanity here. Every thing has been tried, and every thing has failed. And unless reason shall discover so much of the theory of hydrophobia as enables us to resist the evil or counteract its commencement, the malady must be given up as incurable; as one certainly for which there is no longer any hope from experiment. It will not be much to the profit of the reader, however, to record every extravagance which may have escaped the profession during two thousand years of ceaseless speculation upon this topic. We shall, therefore, content ourselves with chronicling a few of the most remarkable opinions that have come down to our own times, several of which have been adopted by different sects in the medical world.

Having already shown beyond all rational contradiction, that hydrophobia is certainly the result of a morbid poison introduced into the system of the animal which it affects, the *modus operandi* of the exciting cause, according to these various hypotheses, becomes much circumscribed. For example, if, with Mead and Rush, we consider hydrophobia as a fever, then must the inoculated virus be allowed to produce it after the manner in which the exanthematous viruses produce their respective febrile eruptions, or the different miasms, when inhaled, engender fevers. Of course we can make no allowance for Dr. Mead's perversion of the nervous fluid, as it is no longer believed to exist. But there is no more difficulty in comprehending how the rabious poison may produce its peculiar fever and spasms, than why the poison of small-pox produces a severe fever, often with convulsions and vomiting, and a severe inflammation of the muco-cutaneous membrane; or why the infection of pertussis produces a fever with peculiar spasmodic coughing, and a copious discharge from the mouth and fauces. Nor is there any more difficulty in comprehending these latter effects, than in conceiving why croton oil, introduced into the circulation by abrasion or puncture, excites violent action in the bowels; tartar-emetic in the stomach; and squill in the kidneys. They are the simple result of that original quantity of irritability wherewith these parts have been furnished, and by which alone they become suscep-

tible of the influence of the given irritant applied in a certain dose.

Diversity of property, whether of organic or inorganic structures, is the great beauty of creation, and constitutes the essence of individual natures, or that character by which they are distinguished from every other thing, and are thus solely the things they are. It is the principal medium through which its divine architect conserves the actions of the machine, which, in this sense, become just so many fulfilments of his original purpose. Such effects of external upon susceptible bodies differ in little from the action of an acid upon an alkali, being equally the result of special properties previously impressed upon each; and are facts not to be explained but observed. The blood of an animal imbued with the canine poison may have its power of irritation exactly in that degree of modification which produces most vehement effects upon the nerves of voluntary motion, and upon the distributions and connections of the eighth pair; and yet not to be in a state capable of effecting the least impression upon the liver, spleen, kidneys, or uterus: and, on the other hand, the motor and pneumogastric series of the nervous system may be originally endowed with exactly such a degree of susceptibility as enables them to originate those high indications of excitement which they exhibit in hydrophobia, with frequent febrile re-action whenever the virus is applied to them through the medium of the blood. The peculiar effects of every individual virus hitherto discovered, prove that this mutual coaptation of the stimulus and sentient fibre to each other is not merely a vague supposition of what may be, but an actual induction supported by the analogy of every known example of inoculated virus. We repeat then, that this notion of the hydrophobic poison producing great nervous irritation and fever, from which all the other phenomena naturally result, is far from being wild and fanciful; and, independently of the names of its distinguished authors, merits due consideration. It has the advantage of embracing nearly all the phenomena, as it is not necessary that the fever should appear on any particular day, or appear at all, just as we see obtain in tetanus and whooping-cough; neither when it does come, does there seem much excuse for so keen a verbal critic as Dr. Rush terming it *malignant*. The vomiting, gastric pain, appearances on dissection, as well as the peculiar character of the matter ejected, the thirst and spasmodic irritation of the throat, and the necessity of some portion of the acrid saliva being received into the stomach, are circumstances which have induced many distinguished men to believe that the virus first exerts its malignant influence upon the stomach, and from this, as a centre, radiates its action to the most distant points of the system which have any consent with the stomach, by that sympathetic irritation which we see prevailing in so many gastric diseases. This view is also ingenious, and comprehends a great many of the phenomena of hydrophobia; but it appears liable to some fatal objections; it does not explain the total absence of gastric symptoms in many individuals, and of traces of disease in the tunics of the stomach in many others; and there is frequently no rejection of solid food by

hydrophobic patients, or of solids and fluids by dogs, as happens in gastritis, and might be expected to take place if the stomach was in any way the primary seat of hydrophobic irritation. The affection of the respiratory organs also, seems quite too violent to be an effect of mere gastric irritation.

Still less tenable was the ancient hypothesis, that the virus of the mad dog first acted upon the liver, producing a large secretion of black bile: that this black bile accumulating, frequently gave rise to the symptoms of melancholy and hypochondriasis, diseases which were then supposed to be produced by that fluid: that the black bile then made its way into the stomach and excited hydrophobia, very much in the same way we have just sketched. There is no black bile, and the occasional appearance of bile in the stomach is the effect of the vomiting, not the cause. The same series of objections apply to the opinion which refers the principal focus of hydrophobic action to simple inflammation of the pharynx and larynx, or of the two former, or of the latter alone; in all these situations the marks of inflammation are often entirely absent. The sensibility of the fauces, the copiousness of the salivary secretion, the thirst and suffocating spasm, bear no proportion whatever to the presence, absence, or degree of these traces of inflammation which scarcely ever appear at the commencement of the disease, and are therefore consecutive of some other and later part of it. Besides, the general sympathies of the fauces are not very extensive, and they are so ordinarily the seat of inflammation that it would not be rash to assert that no one case out of a million exhibits a regular specimen of hydrophobia, even in its non-rabid form; while scarcely one case in a hundred is without a regular display of them in the rabid form. This consideration mightily reduces the number of chances in favour of the phlegmasian hypothesis, which counts many able supporters.

Authors have conjectured that the initial seat of the virus might probably be somewhere in the respiratory apparatus, in the larynx, bronchi, lungs, diaphragm, thoracic muscles, or all of them together. This conception has certainly the advantage of coinciding with appearances at a very early stage of the disease, in which frequent sighing, a panting motion of the chest, uneasy respiration, an occasional sense of suffocation and fainting, are generally experienced: it has the further advantage of explaining what takes place in the pharynx, gullet, and stomach, much better than the assuming these symptoms to be primary; and elucidates the perverted state of respiration considered as their consequence. But the theory affords no rational explanation of the fever, the mental aberration, the salivation, the tremours, the spasms; and these objections seem fatal; for no theory of a disease can be admitted which leaves as much as it illustrates unexplained. We have said enough when we mention M. Dessault's theory of organic worms; of which the day is long past.

It seems hardly necessary to observe, that those ancient authors of the Alexandrian school, who ascribed the seat of the disease to the brain and its membranes, merely did so because they considered these organs as the primary origins of the nerves; the nerves of sense being conceived to

proceed from the mass of the brain and spinal marrow, while the nerves of motion were believed to spring, by small roots, from the membranes that invest them. This is also the comment of Aurelianus, and we are warranted therefore in affirming that their theory of hydrophobia differed not essentially from that of Mead and Rush, and does not therefore require to be considered apart; since, like these authors, almost all the ancients admitted the absorption of a virus. Themison, Aurelianus, and others of the methodic sect, conceived that the virus inflamed and dried up the blood, thereby producing a deficiency of secretion in the fauces and gullet, great thirst, and a general constricted state of the system. In short, it was a well-marked example of the *strictum*, and accordingly directed all their efforts to subdue this state of rigidity by introducing fluids into the colon, plunging the patients into water, and other contrivances. M. Magendie's method of injecting tepid water into the veins might be expected to answer the same purpose; but it is impossible to prove the existence of constriction in hydrophobia; thirst is not always present; and the whole theory has been long since exploded, as incompatible with the doctrine of the circulation and with the general principles of pathology.

Of late years, since the experiments of Legallois, Wilson Philip, and Magendie, [and Dr. Marshall Hall], respecting the structure, function, and relations of the spinal cord have become so justly celebrated, Dr. Reid of Dublin, and several continental writers, have endeavoured to revive a part of the above ancient theory, and to replace the principal seat of hydrophobia in the spinal marrow. Some slight dilatation in the vessels of this part, and vestiges of inflammation noted in one or two dissections, seem to be the only new facts upon which, in connection with the light thrown upon the spinal portion of the nervous system by those experimentalists, this idea is at present supported. But it leaves the mental phenomena, the salivation, the spasms of the face, the tenderness and unnatural appearance of the skin, the gastric, and particularly the diaphragmatic irritation, altogether unexplained; for it is scarcely necessary to observe that the nerves of the stomach and diaphragm originate much above the points where such congestions are observed; and which, though they be often totally absent, are not therefore to be totally denied, since both men and animals (Gillman's pigs for example) often exhibit a distinct paraplegia some time before death. It is not improbable that the paraplegia here alluded to in man is that which has given rise to the numerous fables of the older authors, of hydrophobic patients rolling themselves up like a ball, crawling on all-fours, and attempting to lap water in the horizontal posture, like a dog, &c. "In a state of despondency," says Dr. White, of Bury St. Edmunds, "and with agonizing groans, the patient threw himself down, as we thought, in a corner of the room, and soon after crawled about in a restless manner, dragging his legs after him, which proved to us that he fell on the floor from his lower limbs being palsied."

Amidst so many ingenious hypotheses, if we are finally asked which of the number appears to us to be on the whole the most consonant to rea-

son, we at present say that an explanation of the phenomena which does little violence to the recognised principles of pathology may most easily be drawn from the first, which assumes that the inhibited virus, like most other poisons, mainly and initiatively spends its force upon the nervous system. It is a well-known fact that all severe injuries inflicted upon this system, whether in the way of stimulus or depression, manifest the gravity of their influence most remarkably in that series of organs supplied by the eighth pair: and conversely, experimentalists, as M. Desmoulins, have found that the smallest pressure even of a drop of blood upon the origin of this nerve in animals almost instantly extinguishes life. The affection, then, so strongly marked, of the parts supplied by this nerve in hydrophobia, and the curious circumstance of its never extending its ravages below its pneumo-gastric termination, may perhaps be considered merely as an index of the deadly virulence of the cause. Still we have shown above that there is no difficulty in comprehending, with the ancient Gaius, that the poison of rabies exerts a peculiar inveteracy of action upon the origin of the respiratory column and the commencement of the eighth pair, just as the vomiting, dysphagia, and laborious respiration, occurring from a violent blow on the head, may either be assumed as the known ultimate effect of general compression, or as a modification of these by some special injury at the same time inflicted on the origin of the same pair.

Diagnosis.—Properly speaking, there is scarcely any disease that a careful practitioner would confound with hydrophobia; but in cases where no rabid impregnation is suspected, the disease may be mistaken for phrenitis, mania, fever, or tetanus; and, in the incipient stages, for melancholy, hypochondriasis, and hysteria. It can only be mistaken for any one of the three latter during a few hours from the commencement. Hysteria and hypochondriasis advance by slow degrees, and rarely have fever, difficulty of respiration, tenderness of skin, or salivation. Melancholy is altogether a chronic disease, and never has convulsions, spasms of the throat, dread of water, difficult respiration, and vomiting among its symptoms. It is true that phrenitis, and what was long classed as a form of it, delirium tremens, have tremours, suspicious fears, tenderness of skin, convulsions and difficult swallowing; but there is no affection of the stomach or respiratory system, no vomiting, no salivation: nay, spasmodic difficulty of swallowing occurs not in one case out of a hundred. From mania it is distinguished as soon as the spasms, difficulty of swallowing, and salivation appear. Indeed the mental aberration, the aversion to certain objects, and the fever which is occasionally present in both, seem to be almost the only points of resemblance. Dr. Rush has entered into a long argument in order to evince the identity of fever and hydrophobia; but though hydrophobia has fever, it does not follow that hydrophobia is the same thing as fever; or, in other words, is fever alone. In short, we have often repeated that in many cases of hydrophobia fever actually supervenes; and that where it does occur, it is seldom a primary symptom. The distinction of hydrophobia from tetanus has been

made the subject of much discussion. The two diseases seem first to have been compared with each other by Democritus; but it cannot now be known whether he, or indeed any of the ancients, considered the apparently tetanic phenomena of hydrophobia to arise from the wound alone. On the contrary, they seem almost all to have admitted the existence of a virus; and from the earliest periods to have attempted to account for the symptoms by the operation of this poison upon some peculiar series of organs, from the excitement of which they conceived all the visible symptoms to proceed. Democritus traced it to the tendons or muscles; the followers of Herophilus and Erasistratus, the great discoverers of the functions of the nerves, naturally referred the virus to that system; Asclepiades traced it to the stomach; the methodists to their favourite *strictum*, &c. But none who admitted the reality of the disease appear to have disputed the existence of the virus.

Dr. Mease, of Philadelphia, in 1793, published an able work on hydrophobia, in which he contended for the uncertainty of the virus, and makes out hydrophobia to be purely a nervous affection. Charles Bader, in a dissertation on hydrophobia, published 1792, maintains that there is much less of contagious character in hydrophobia than is generally believed, and draws a formal parallel between tetanus and hydrophobia. The non-rabid form of hydrophobia is occasionally symptomatic of tetanus; and both tetanus and hydrophobia seem to originate most readily from a small punctured or lacerated wound. Both exhibit signs of recrudescence in that wound a short time before the spasms supervene; both exhibit paroxysms of universal convulsion, and occasionally fever, and both carry off a great majority of patients before the sixth day. These are the chief circumstances in which the two diseases agree; and to appeal to more minute but very uncertain points of correspondence, as has been done by the writers who contend with such zeal for their identity, would add nothing to the justness of the comparison. But we have already shown, when discussing the questions respecting the *modus operandi* of the cause of hydrophobia, that there intervene many undeniable discrepancies between the two diseases; and to these many others must be added. Tetanus, as its name implies, consists essentially in a *tonic* spasm, generally occupying the muscles of the lower jaw, of the neck, of the spine, and the limbs; of the thorax, abdomen, and diaphragm; and always observed more to affect the extensors than the flexors. These contractions of the muscles are occasionally relieved by intervals of ease, but never by entire relaxation; nay, in successful cases, Dr. Currie assures us the deep indentations made in the face by the terrible contractions of its muscles are visible afterwards for many years, and imprint on the countenance a severer character than it previously possessed. A stiff immoveable state of the lower jaw, scarcely to be overcome by any ordinary force, is present during almost the whole of nearly every case of tetanus, and has acquired, for that variety of the disease in which the muscles of the spine are little extended, the name of *trismus*, or lock-jaw. On the contrary, the spasms of hydrophobia are always *clonic*, that is to say,

they are always of brief duration, and are succeeded by a period of complete relaxation, generally of many hours duration in the beginning of the disease, unless provoked by attempts to make the patient swallow; and even at the last fatal paroxysm, tonic spasm, and particularly locked-jaw, are very seldom to be observed. A discharge of saliva is an exceedingly rare occurrence in tetanus; in hydrophobia it is a general and characteristic symptom. Thirst is rare in tetanus; it is characteristic of hydrophobia. Vomiting and gastric pain or uneasiness scarcely ever occur in tetanus; they are so general in hydrophobia as to be mistaken by many for the essential circumstances of the disease. It is only in rare forms of tetanus that attempts to drink bring on guttural spasms, a dread of fluids, and their violent rejection when introduced; but in hydrophobia this is the pathognomic trial which fixes the character of every case, with a very few unimportant exceptions. In tetanus, the mind is almost always clear to the last; in hydrophobia, almost from the beginning, numberless deviations from the usual habits of thought and action indicate an incipient stage of mental aberration, which often passes on to delirium or raging madness. In tetanus, fever is rarely present; in hydrophobia, it is frequently present. From tetanus, many recover; from hydrophobia, none recover. Tetanus takes its rise from cold or from any sort of wound; hydrophobia from the bite of a rabid animal. Tetanus, though the usual result of small punctured and lacerated wounds, rarely follows from the bite of a rabid animal; hydrophobia with much greater frequency in proportion to the number of persons bitten, it is said so much as one out of every twenty-five. Tetanus seems more frequent in warm climates; hydrophobia in cold climates, or at least indifferently. Tetanus seems to occur almost any time after the injury; hydrophobia chiefly from the thirtieth to the sixtieth day. It has never been contended that the bite of a tetanic animal communicates tetanus; but it is acknowledged that the bite of a hydrophobic animal communicates hydrophobia. The countenance of a tetanic patient bears no resemblance to the physiognomy of hydrophobia: in the former the eye is natural, and the general aspect is that of suffering; in the latter, the eye is preternaturally bright and glistening, the face occasionally exhibiting frightful convulsions, and the pain of the diaphragm is not characterized by a constant sense of the sternum being dragged towards the spine, as is the case in tetanus; while tetanus, on the other hand, scarcely ever exhibits that laborious panting respiration, that tremour of the whole muscles, and that intolerant sensibility of the surface and of the organs of sense, which distinguish hydrophobia. Indeed it is perhaps only by reasoning upon the uncommon as if it were the ordinary case, that any person, although exposed to the illusion of his own ideas in the retirement of his closet, could mistake the one disease for the other.

Morbid Anatomy.—Whoever pursues with care and attention the various dissections of hydrophobic patients which have at different times been published, will be obliged, however reluctantly, to admit that the pathology of rabies canina is still involved in considerable obscurity, and that no

distinctive pathological character of the disease has as yet been satisfactorily determined. The *brain* has been examined with much care and attention. In some instances the *dura mater* has been found to assume a darker hue than usual. The capillaries of the *tunica arachnoidea* and *pia mater* have also been met with minutely injected with blood. This state of these membranes occurred in the dissection of a case published by Dr. Marshall, as well as in several others on record. Trollet has noticed the gorged condition and dark colour of the *plexus choroides*. Effusion of serum has been observed between the *dura mater* and *tunica arachnoidea*; between the latter membrane and the *pia mater*; between the *pia mater* and brain; and also in the ventricles. The substance of the brain itself has been detected in a harder state than natural in one or two instances; in others, it has been found to have undergone a certain degree of "*ramollissement*." Both Bonetus and Lieutaud, however, have alluded to cases in which this organ presented no marks of disease.

Inflammation of the *pharynx* and *œsophagus* has been noticed in several dissections of hydrophobic patients; but cases are on record in which no inflammatory appearance in these parts has been observed. On examination of a patient of Dr. Rutherford's, who died of rabies canina, Dr. Monro was unable to detect any morbid alteration, either in the *pharynx*, *œsophagus*, *larynx*, *stomach*, or *intestines*. In one instance it will be shown that we have met with an abrasion of the internal membrane of the *œsophagus*. In a fatal case of this disease, too, related by Dr. Ferriar, a morbid appearance presented itself in the lower part of the *œsophagus*. About two inches above the *cardia*, the epidermis of the *œsophagus* was abraded in irregular points, and exposed an inflamed surface of a dark red colour; still lower, the abrasion became linear and extended into the *stomach* itself. The edges of the epidermis surrounding the abrasions were unequal and elevated. A similar affection was traced along the lesser curvature of the *stomach*, but growing fainter in its progress to the *pylorus*, where it was least discernible, and about which it seemed to terminate. The whole of the inflamed parts bore a striated appearance resembling the effect of corrosion, darkest in the *œsophagus*, and lighter and more indistinct towards the *pylorus*. In two cases mentioned by Dr. Vaughan no inflammation of the *œsophagus* appeared on dissection. The *internal coat of the stomach* has been discovered in a highly inflammatory state in not a few instances of rabies; and dark purple-like suffusions have also been observed upon it. This organ has also been found to contain a smaller or greater quantity of coloured matter. It has been supposed that this inflammatory condition of the mucous membrane of the *pharynx*, *œsophagus*, and *stomach*, satisfactorily accounts for the sense of suffocation, extreme thirst, morbid antipathy to liquids, and burning heat along the whole *œsophageal tube*, mostly experienced by the hydrophobic patient; but it must be recollected that such a state of these parts is by no means constantly present, as is proved from the cases related by Dr. Hamilton and other writers; and hence it is not essential to the existence of the disease. From the examinations of M. Trollet, it appears that

the mucous membrane of the *trachea* and *bronchi* afforded evidence of inflammatory action, and was covered over with a considerable quantity of frothy mucus; and the membranes of the brain, particularly the *pia mater*, exhibited marks of great vascularity. The frothy matter he supposed to be the product of the inflamed mucous membrane. "*La bave écumeuse des hydrophobes*," he observes, "*est un produit de la membrane muqueuse enflammée, puisque nous l'avons toujours vue dans les parties des voies aériennes où cette membrane étoit vivement colorée, et qui étoient le siège de la douleur. Elle est chassée sur les lèvres de l'hydrophobe dans la dernière période de la maladie, comme le mucus altéré dans l'agonie d'une personne affectée de phthisie ou de catarrhe, lorsque la respiration est stertoreuse et laborieuse.*" La-louette has also noticed this peculiar frothy matter in the *trachea* and *bronchi*:—"Une humeur," he remarks, "*que l'on peut comparer à une salive écumeuse qui enduit toute l'arrière bouche ainsi que le larynx, le pharynx, la trachée artère, et les grosses divisions des bronches. Elle se trouve en plus ou moins grande quantité chez les différents sujets.*" That the lining membrane of the *trachea* and *bronchi* is sometimes in a state of inflammation cannot be denied, but we are satisfied that Trollet's view of the pathology of rabies is too limited; for it will be found, upon a comparative examination of the number of dissections of hydrophobic persons on record, that the *stomach* has been more frequently met with in a morbid condition than the *trachea*, *bronchi*, or any other part of the body. The *salivary glands* have occasionally been observed of increased size and vascularity. In some instances there has been inflammation of the pulmonary tissue, but more frequently great venous congestion.

Dr. Ferriar was almost disposed to consider the disease as dependent on the obstruction of the pulmonary circulation, but his conjecture has not been supported by subsequent pathological investigation. The *pleura* have been noticed in a thickened and inflamed state; and we meet with fatal cases of hydrophobia in some of the earlier medical records, in which various derangements of the *heart*, *pericardium*, *liver*, *spleen*, and *mesentery* are described; but it is impossible to peruse these dissections, without being convinced that the morbid changes enumerated are merely accidental, and the result of other causes than the virus of rabies. Some pathologists of eminence, amongst whom may be mentioned the names of Salin, Brera, Sanders, and Reid, supposed that they had satisfactorily proved that the symptoms of hydrophobia proceeded from a morbid condition of the *spinal marrow*; but it may be correctly stated that their opinions have not been confirmed by the general experience of the profession. In some examples of this disease, (as in the two which we shall notice,) unequivocal marks of vascularity of the membranes of the *spinal cord* have been present; but, generally speaking, not the least vestiges of inflammatory action either in the *medulla spinalis* or its investing tunics have been discovered. In one instance, related by Mr. F. Godrich, the whole cord was considerably inflamed; and opposite the two last cervical and dorsal vertebrae the cellular substance was studded with dark patches of coagulated blood, the theca

vertebralis thickened, and the cord in an active state of inflammation. The larynx and pharynx bore not the slightest vestige of disease. We may, however, venture to assert that no such connection as that of cause and effect exists between an inflammatory state of the spine and the phenomena of hydrophobia; for it is well known that effusion of serum into the theca vertebralis, and other signs of increased vascular action in the spine, have been frequently met with in diseases very different from the one under consideration.

As dissections of hydrophobic patients are by no means frequent, it may be instructive briefly to detail the *chief* morbid appearances detected in *five fatal cases* of this disease which have come under our own observation. In one, where the patient died in seven days from the period of his first experiencing pain in the bitten part, and in fifty-six hours from the commencement of the hydrophobic symptoms, the following morbid alterations were observed:—*Brain*.—Vessels of the dura mater preternaturally distended with blood, the vessels ramifying in a distinct manner. Pia mater somewhat distended, and a larger quantity of blood interposed between the membranes than usual. Left ventricle with the usual quantity of fluid. The substance of the brain of the usual consistence. When pared off in slices, the surfaces showed numerous brown spots. The vessels of the basis, or cerebellum, were more than usually turgid, and somewhat more of fluid effused than usual. *Pharynx and larynx*.—No appearance of inflammation. *Thorax*.—Lungs perfectly sound. Heart flaccid. No coagulum in its cavities; two ounces of fluid within the pericardium. *Œsophagus*.—Upon opening the œsophagus, a substance was found lying closely within the orifice without filling up the cavity. This membrane was nearly the length of the œsophagus; when inflated with the blow-pipe, it assumed a tubular appearance. The abrasion of the internal membrane seemed to extend as far as this substance. The external membrane of a deep red colour. The whole internal surface dotted with purple-like suffusions. *Stomach*.—Contents about one pint, the external membrane of a deep red colour. Its inside covered with broad dark purple-like suffusions, especially about the cardiac orifice. The intestines sound; the liver of the usual healthy character; appearance of bladder natural. The same marks of disease usually exist in most cases of hydrophobia after death, with the exception of the remarkable membrane found in the œsophagus of the one now described, which was considered by all present a portion of the internal membrane of the œsophagus. In *another* instance, on opening the head, the sinuses were found gorged with blood, and the vessels of the arachnoid and pia mater exhibited marks of highly increased vascular action. The lateral ventricles contained a small quantity of serous fluid, and the plexus choroides was of a pale colour. The substance of the brain was softer than natural. The vessels of the spinal arachnoid and pia mater were minutely injected. The lungs and the bronchial mucous membrane were perfectly healthy. The heart and its large vessels were also sound. The lining membrane of the pharynx and œsophagus was somewhat redder than usual. The stomach presented some few slight ecchymoses; the

intestines were free from disease. In a *third case* in which the body was carefully examined by a very distinguished anatomical teacher, Mr. Turner, there was considerable vascularity of the pia mater, with slight serous effusion in the lateral ventricles. The substance of the brain was of a firm consistence. Strong adhesions existed between the costal and pulmonary pleura in both cavities of the chest. The lungs were in a state of great congestion, and when cut into, a considerable quantity of bloody fluid flowed from their substance. The membrane of the trachea and the larger bronchial ramifications were here and there marked with dark purple-like suffusions, and had assumed throughout a darker hue than usual. On an inspection of the inside of the fauces, pharynx, and œsophagus, a scarlet uniform redness was observable. The heart was sound. The stomach exhibited evident marks of congestion, if not of inflammation. Numerous small dark-coloured spots appeared about the superior orifice, and might be traced along the larger curvature of the organ. These spots very much resembled the marks of small shot. All the other viscera of the abdomen, with the exception of the liver, which was slightly indurated, afforded no marks of disease. The pia mater tunic of the spine, like that of the brain, was much more vascular than natural. The *fourth* instance was that of a boy, nine years of age, who was bitten by a mad dog about three months previously to the occurrence of the symptoms of the disease. He was under the care of a highly respectable surgeon, Mr. Brownbill, of Salford, to whom we were indebted for an opportunity of attending the inspection. The patient died in sixteen hours after the malady had fairly developed itself. Within the cranium nothing unusual could be detected, except a slight turgescence of the vessels of the pia mater, and rather more distension of the choroid plexus than usual. The fauces, œsophagus, and parts adjacent were in a natural state, but the effects of inflammation were very evident upon the lining membrane of the trachea and the larger bronchial tubes. The lungs were sound, but somewhat distended with blood. The stomach contained a small quantity of brownish fluid, but no diseased appearances were detected in it. The other abdominal viscera exhibited nothing peculiar. The spinal marrow was inspected with much care, but there were no marks of inflammation either in its membranes or substance. In the *fifth* and last case we have witnessed, where death occurred in thirty-four hours after the first unequivocal symptoms of the disease had been present, the following were the appearances on dissection. The brain was in a natural state. The fauces and lower part of the œsophagus afforded slight signs of inflammation; the vessels on the inner coat of the stomach were much more distinctly marked than usual; and a few spots of extravasated blood were observable along the cardiac extremity of the organ. The other abdominal viscera were sound. Nothing unusual presented itself either in the trachea or bronchi. The lungs were somewhat turgid with blood. The spine was free from disease.

All the attention we have been able to pay to the anatomical character of rabies canina leads us to agree with Dr. James Johnson in the following remarks: "That it cannot be denied, but

that the most evident indications of inflammatory action attend the symptoms, and distinguish the pathology of hydrophobia; that we have often inflammation of the œsophagus, pharynx, and larynx, and occasionally of the brain and spinal cord; yet it is generally admitted that these appearances are more the consequences than the cause of the disorder, and that although frequently present with, they are by no means essential to the existence of hydrophobic action." That they are not *essential* to the existence of the disease is proved by the fact that, in several cases on record, in which the post-mortem examinations have been made by eminent and experienced pathologists, no morbid appearances have been detected in any organ or tissue of the body. Some of the morbid appearances noticed above are no doubt produced by the violence of the convulsive motions which invariably accompany the disease. Lalouette, an able French writer on rabies, has remarked, "L'ouverture de plusieurs cadavres de personnes mortes à la suite de la rage, ne m'a présenté aucun phénomène particulier à cette maladie. On ne trouve nulle part aucun signe de phlogose sanguine, ni d'inflammation. Je n'ai observé nulle part aucun signe de dissolution, aucun engorgement ou phlogose humorale; aucune gangrène interne, ni même aucune apparence de disposition à cette diathèse."

Treatment of Hydrophobia.—The reader will in all probability be prepared, from a perusal of the preceding account of the *pathology* of hydrophobia, to anticipate the conclusion, that in a disease on whose nature anatomical investigation throws such feeble light, the treatment must necessarily be unsettled, and in a great measure conjectural. Dr. Good correctly observed, that the mode of cure in this affection is a field still perfectly open for trial; for, at this moment, we have no specific remedy, nor any plan that can be depended upon, after the disease shows itself. There is, perhaps, no malady to which mankind is liable, that has called forth such a host of remedies for its removal, and alike defied their single and united powers. The long list of the *materia medica* has been ransacked to discover some one article capable of arresting the progress of this disease, but all have hitherto proved inert. It would be absurd to do more than simply name several of the substances to which ignorance and superstition have attached importance in the treatment of hydrophobia. Amongst these may be classed the celebrated pulvis antilyssus, the theriac, the alyssa-plantago, the rhus coriaria, the scutellaria, the genista, the Ormskirk medicine, and the tonquin powder. Each of the above remedies has had the title of a specific attached to it, and enjoyed for a time unmerited reputation. In the consideration of the treatment of hydrophobia, it appears to us proper to notice, first, the *prophylactic measures* which are indicated; and, next, *the means to be employed after the disease has been once developed*.

It is fortunate that the community at large are now more strongly convinced than formerly of the extreme folly as well as danger of resorting to the use of the several vaunted specifics for the prevention of hydrophobia, and thus delaying application to the well-informed and regularly educated

practitioner on the immediate occurrence of the bite. It cannot be too strongly impressed upon the minds of the public, that not a moment is to be lost in soliciting judicious medical aid after the bite of a rabid animal; for, the longer the delay, the greater the danger of the virus entering the system and producing the disease. We shall endeavour to point out the prophylactic plan which seems to afford the surest ground for a proper confidence and security against future mischief. The wound should be well and perseveringly washed from the earliest moment of its infliction. The patient may himself adopt this simple practice until surgical aid be obtained. Dr. Haygarth has suggested that the ablution of the wound may be well effected by directing upon it a continued stream of water from the spout of a tea-kettle, held up at a considerable distance. "If the canine poison," he observes, "infused into a wound were of a peculiar colour, as black, like ink, we should all be aware that plenty of water and patient diligence would effectually wash out the dark dye, but this could not be effected by a slight and superficial ablution." After the bitten part has been well and thoroughly washed, it then becomes a question what further means should be employed to prevent absorption of the virus. Upon this point, it will be found that scarcely any two practitioners are agreed; some giving the preference to *excision*, and others to the *actual or potential* cautery. The use of the actual cautery has been chiefly recommended by some of the earlier writers, and is a practice but seldom adopted in the present day, though it is by no means destitute of advantage under particular circumstances. The application of caustics *alone* to the wound has been relied upon by some eminent practitioners. Mr. Youatt, who may perhaps justly be considered the first living authority on canine madness, has warmly advocated the use of the caustic. He recommends the nitrate of silver. Troillet prefers the hydrochlorate of antimony. Earle, in his evidence given before a Committee of the House of Commons in 1830, says that he does not place much reliance on any caustic, except strong nitric acid, for it acts very deeply, whereas "other caustic, for instance, caustic potash, when there is any wound, becomes decomposed by the blood, and does not penetrate to the depth that nitric acid does; and nitric acid forms a dry eschar." Other surgeons, on the contrary, strongly advise the employment of the potassa fusa. Mr. Youatt considers the lunar caustic perfectly manageable, and, when sharpened to a point, as capable of being applied with certainty to every recess and sinusity of the wound. "The potash and the nitric acid," he observes, "will destroy the substances with which they come in contact, but the combination of the caustic and the animal fibre will be a soft or semi-fluid mass. In this the virus is suspended, and with this it lies upon and remains in intimate contact with the living fibre beneath. Then there is danger of re-inoculation; and it would seem that this fatal process is often accomplished. The eschar formed by the nitrate of silver is hard, dry, and insoluble. If the whole of the wound has been exposed to its action, an insoluble compound of animal fibre and the metallic salt is produced, in which the virus is

wrapped up, and from which it cannot be separated. In a short time the dead matter sloughs off, and the virus is thrown off with it." Mr. Youatt informs us that he has been bitten four times by dogs decidedly rabid, and at each time he freely applied the caustic to the wound; and he has remained free from the complaint. He has also operated on more than four hundred persons of whose disease there could be no question, and has not lost a patient. His experience is opposed to the practice of keeping the wound open for several weeks after the application of the caustic, for he supposes, that if a minute portion of the virus should perchance remain in the wound, by applying stimulating ingredients to the part there is considerable risk of exciting the absorbents to action, and producing that disease which would not otherwise have had existence. "Destroy the part at once by the knife or the caustic," he observes, "and then adopt the mildest means speedily to heal the wound." The testimony of Mr. Youatt in favour of caustic is unquestionably very weighty, and entitled to the utmost consideration; but still the fact cannot be concealed, that in the hands of other practitioners, the results of the use of the caustic have not been equally favourable. In the case of Rowley, noticed by Dr. Hamilton, caustic was very carefully applied to the wound by Mr. John Hunter shortly after the infliction of the bite; still the hydrophobic symptoms appeared, and the youth died. It would not be difficult to multiply the cases of failure after a fair trial of the caustic. Mr. Youatt allows that every surgeon must decide for himself respecting the comparative value of caustic and the knife, but he requests that those who prefer the caustic may be no longer exposed to so much gratuitous abuse. He does not condemn the use of the scalpel, but gives a decided preference to the caustic, and only employs the knife in order fairly to get at the wound. It appears, however, from the facts already before the public, that the general experience of the profession is in favour of an *immediate excision* of the bitten part, as affording the best security from danger. Some practitioners have strongly recommended the conjoint use of excision and the caustic.

We shall now briefly give our opinion of the best and most certain means of preventing the disease. It appears to us that *complete excision* of the bitten parts, when at all practicable, ought to be adopted without a moment's unnecessary delay for the trial of caustic or any other external irritant; for it is but seldom that any bad effects ensue from the bite, when this simple operation is carefully and effectually accomplished, and we really consider the medical man who omits this practice guilty of unpardonable neglect towards the unfortunate being who may be doomed, from his want of energy, to writhe under the agonies of this most horrible malady. Indeed the excision of the wounded part should always be employed even in cases where the animal is only supposed to be rabid; for though some degree of momentary pain may be occasioned by the knife, this is of trifling consequence when compared with the mental tranquillity which must result from the conviction of a perfect immunity from the disease by the operation. The force of the above remarks

will be felt, when it is considered that canine madness is *incurable*, according to the present state of our knowledge; for we are satisfied, from careful and extensive research on the subject, that when the symptoms of this disease have been once fairly developed, notwithstanding the most vigorous and diligent attempts of medical men to remove them, no cure has ever yet been effected, but the unhappy sufferer has had to struggle with torments such as the imagination cannot conceive, and which must be witnessed in order to be believed. This is a melancholy truth for mankind to know. When excision has been neglected on the first infliction of the wound, still we consider it highly proper that it should be performed at even a distant period from the bite; for it seems to be an established fact that the virus of a rabid animal does not, like other morbid poisons, such as small-pox, cow-pox, syphilis, and plague, always produce its effects within a limited time. Dr. Todd Thomson has expressed his opinion that the hydrophobic virus is not regulated by the usual laws of morbid poisons, and on that account he is inclined to believe that it remains in the bitten part, and the individual is safe till the habit becomes predisposed to the action of the poison, so that the part may be advantageously excised in the intervening time. A case is related by Professor Rust where the wound was excised thirty-one days after the bite, and after the hydrophobic symptoms had appeared, and still the patient's life was saved. When the wound is so situated that the whole of the bitten parts cannot be completely removed, then of course we must trust to the application of caustic, to scarification, or the actual cautery. Under these circumstances it is of the highest importance that the caustic be carefully and effectually used, for the safety of the patient in a great measure depends upon the manner in which this operation is in the first instance performed.

In order to ensure the removal of every part with which the dog's teeth may have come in contact, (for the smallest portion left may produce the disease,) it is necessary accurately to ascertain the depth of the wound, and the direction in which the teeth have penetrated. Unless the excision be carried beyond the bite, the operation fails to afford the patient a security from future danger. The surgeon cannot use too much care in removing the bitten part. We are informed that in one case Mr. Hunter removed the parts, as he thought, freely, and there was nothing on the under surface of the piece cut out that led him to suppose that he had not gone beyond the bite. But on examining the surface of the wound, he found a part in the middle which was hollow underneath, which showed he had not gone deep enough, but had left a ridge as it were over part of the passage made by the dog's teeth, and which could only be discovered by examination after the operation. (*Dr. Hunter, Transactions of a Medical Society.*) Though we have strongly recommended that the wounded part be cut out whenever it can be done with safety, still we see no objection to the application of caustic afterwards to the excised surface, as affording additional security from the greater probability of every particle of the virus being removed or destroyed. With proper deference to

the experience of Mr. Youatt, as given above, respecting the impropriety of keeping the wound in a state of suppuration, we must observe that the facts stated on eminent German authority in favour of the practice seem to be incontrovertible. Dr. Wendt states that from the year 1810 to 1824 one hundred and eighty-four persons bitten by dogs were admitted into the Breslau hospital; of whom half were bitten by dogs absolutely mad, or supposed to be mad, and from the whole two only died. It is true, that besides keeping up a copious discharge from the wound for six weeks or longer, mercury was employed internally so as to induce salivation; still by far the greatest stress was placed on the external treatment. It is also mentioned in a very able review of several German essays on hydrophobia, (Ed. Med. and Surg. Journal, 1825,) that at Zurich "the treatment consists of deep scarifications of the wound, the besmearing it with pulvis lyttæ, the application of a blister to the part, the keeping up a discharge from the wound and the blister during six weeks, and the rubbing-in of mercurial ointment till symptoms of approaching salivation come on; internally, belladonna or calomel is given." In the same journal an account is given of the treatment pursued by T. M. Axster, senior surgeon of the large hospital at Vienna; and that of Dr. Hausbrand, district physician at Braunsberg, in cases of bites from animals. During twenty-seven years, Mr. Axster states that not a single old patient was ever brought back to the hospital with hydrophobia. Besides using internally, during three or six successive days, a grain of pulvis lyttæ with six grains of canc. ocul. and sugar, he applied externally over the wound a blister, and dressed it with the pulvis lyttæ or some stimulating lotion during the space of six weeks. Dr. Hausbrand first employed active bleeding in the earliest stage of the disease, then made deep scarifications of the wound, encouraged the flow of blood, washed the wound with salt and water, applied an ointment composed of unguentem basilicum and powdered cantharides, and kept up the suppuration during the space of three months at least. Internally, he directed the patient to take for three evenings a powder with camphor and opium, to drink elder tea, and keep up a copious perspiration. Eleven persons bitten by dogs actually mad, treated in this manner, remained perfectly free from the disease. We have noticed these four prophylactic modes of treatment chiefly with the view of showing the nature and efficacy of the local means employed, and the evidence in support of the practice of continuing a discharge from the wound during several weeks. It must be recollected, however, that caution is necessary in drawing a positive conclusion in favour of any particular prophylactic measure, as the disease is by no means a necessary consequence of the bite; for it is a fact founded on the observation of a considerable number of cases, that upon the average not more than one person out of twenty-five who have been certainly exposed to the bite of a mad dog has become infected with the disease.

In noticing the inefficacy of the Ormskirk medicine, pulvis antilyssus, tonquin remedy, &c., Dr. Hunter says the question may be here asked, ad-

mitting the frequent failure of these remedies, have they not sometimes prevented the disease? The answer would certainly be in the affirmative if every person bitten by a mad dog who did not use some means of prevention were seized with the disease. But this is not the case; for in the human species the proportion of those bitten who are seized with hydrophobia is much less than of those who escape, even where no means of prevention are employed; we can, therefore, infer nothing in favour of these prophylactics, because they have been given in cases in which no hydrophobia has supervened. (*Hunter, opus ante cit.*)

The application of a tight ligature to the affected part, at a short distance above the laceration, is strenuously recommended by Dr. Good, from the first, even before the process of ablution, and the measure is sanctioned by the authority of Ambrose Paré, Troillet, and other eminent writers. "Analogy," says Dr. Good, "is altogether in favour of this operation, for it is well known to be one of the most important steps we can take in confining the poisonous effects of the rattlesnake and other venomous animals, and of mitigating its violence by the torpor which follows." We have had no experience of the beneficial effect of the ligature after bites from rabid animals, but we see no objection to the adoption of the practice. Cupping-glasses have also been applied to the wound. Celsus even recommended them. (*De Medic., lib. v. p. 199.*) More recently, the cupping-glass has been strongly advised by Dr. Barry, who has performed a variety of ingenious experiments relative to the absorption of several vegetable, mineral, and reptile poisons. It has been his aim to prove that absorption cannot take place in vacuo, and certainly the results of his experiments seem to us satisfactorily to establish the fact. We conceive that the cupping-glass is likely to prove a highly efficacious remedy in cases of wounds inflicted by poisonous or rabid animals, and we strongly recommend its early and diligent application *after* a careful excision of the injured part; for it by no means supersedes the use of the knife. Mr. Youatt rather objects to the cupping-glass, for he expresses a fear lest the virus, forced from the texture with which it lies in contact by the rush of blood from the substance beneath, may inoculate or become entangled with the parts of the wound; still he thinks that it may be useful after excision of the part, but as connected with the caustic, that it can be of no avail. Amputation has been deemed advisable by some surgeons when the bite has been situated in a part, as in one of the fingers, to which a cupping-glass could not be effectually applied; or when a limb has been bitten in many places, or very deeply in parts not admitting of excision, as through the tarsus or carpus. Mr. Samuel Cooper thinks that under these circumstances immediate amputation might be warrantable *before* the accession of the symptoms. He has noticed a case that occurred at Guy's Hospital some time ago, in which a limb was amputated after the symptoms of hydrophobia had appeared, but without the least check being put to the complaint. "The performance of amputation," this able surgeon justly observes, "previously to the commencement of the symptoms, is a very different practice from that of amputating parts after

the symptoms have begun." (Good's Study of Medicine, last edition.)

It may be proper here to allude to the plan proposed by Dr. Marochetti for preventing the development of hydrophobia. He believes that the hydrophobic poison, after remaining a short period in the wound, fixes itself for a certain time under the tongue, at each side of the frænum, where one or two little tumours or vesicles appear, in which may be perceived with a probe a fluctuating liquid. Dr. Marochetti states that the usual time of the appearance of these small knots is within the third and ninth day after the bite, and that if they are not opened within the first twenty-four hours after their formation, the poison is re-absorbed into the system, and all hopes of the patient's recovery are banished. He, therefore, strongly recommends that such persons as have the misfortune to receive a bite from a rabid animal should be examined under the tongue immediately, and that attention should be paid to this part during six weeks; for if these vesicles do not appear in this time, he considers the patient to be perfectly secure from future danger. When, however, they are detected, he directs that they should be instantly opened with a lancet, and then cauterized with a red-hot needle; and that the patient should gargle assiduously with a decoction of broom, and take daily one pound and a-half of the infusion of the tops of the same plant, or four drachms of the powder. Professor Rossi has also published a case in the *Annali Universali*, in which a cure of hydrophobia is said to have been effected by taking a glassful of vinegar, and the *genista lutea tinctoria* internally, and by having the sublingual glands cauterized three successive times. In the examples of hydrophobia which have fallen under our own observation and that of some other practitioners, the knots or vesicles under the tongue, described by Dr. Marochetti, have been looked for in vain; and, indeed, their supposed presence seems to be a mere anatomical delusion. It may be correctly said that Marochetti's statements have not been confirmed by the general experience of the profession, so that practitioners may be undeceived in any expectations of security they might be induced to form from adopting his process to the neglect of the means noticed above; for the results of such misplaced confidence would be irremediable. We venture to repeat our conviction of the imperative necessity, in every case of injury from a rabid animal, of deeply and effectually cutting out the bitten part when it can be done with perfect safety, and of the propriety of keeping up a free discharge from the wound for several weeks by the aid of some active external irritant; and that when the operation of excision is inadmissible, recourse must be had to scarification, lunar caustic, or the actual cautery.

Amongst the chief preservative means that have been employed *internally* in conjunction with the local plan of cure, we may merely mention belladonna, cantharides, mercurials, emetics, volatile alkali, broom decoction, and chlorine: for it would be a waste of the reader's time to present him with a detailed examination of the individual efficacy of these several remedies as preventives of the fatal consequences of the bites of rabid ani-

mals, since the most ample experience has proved them to be altogether unavailing, and therefore undeserving of future confidence. To the vaunted specifics before named no further allusion is necessary.

Having thus considered the *prophylactic measures* which are indicated, we may next notice *the means to be employed after the disease has been once developed.*

This part of our inquiry is attended with some degree of difficulty, because no successful method of cure has as yet been discovered, after the characteristic symptoms of hydrophobia have once appeared. "There is, indeed, no disease," as Dr. Good justly remarks, "for which so many remedies have been devised, and none in which the mortifying character of vanity of vanities has been so strikingly written on all of them. In the loose and heterogeneous manner in which they have descended to us, they seem, indeed, to have followed one another without rational aim or intention of any kind." The whole subject of treatment is difficult and afflictive. We scarcely know how to reply to the important question,—What plan of cure is a practitioner to adopt when he meets with a case of rabies? but it is necessary to attempt an explanation of the mode of treatment which, on the whole, seems to be the most suitable for adoption.

The limits of this article would be extended to a very unnecessary length, were we to do much more than enumerate the various remedies that have been tried in this disease; but a brief notice of them is required, for without a knowledge of what has been attempted, much time must be lost in useless trials and fruitless repetitions.

Amongst the various articles in the *materia medica* which have been employed for the relief or cure of hydrophobia, *opium* is entitled to be first mentioned. This drug, in various forms and in very large quantities, has had the most full and ample trial; but experience has too often proved its inefficacy in this disease. Dr. Vaughan exhibited fifty-seven grains of opium in the course of fourteen hours with little or no effect upon the symptoms; and in one case Dr. Babington administered one hundred and eighty grains in eleven hours, without any benefit, and without even procuring sleep. (Medical Records and Researches.) In another instance Dr. Marcet gave opium, iron, and arsenic, to a great extent, but with a like unsuccessful result. Magendie introduced opium in large quantities into the veins of rabid dogs, but without producing its ordinary narcotic effect; and Dupuytren and he afterwards injected eight grains of the extract of opium, in solution, into the crural vein of a young man labouring under hydrophobia in its severest form; but the experiment only afforded temporary relief, for he expired on the fifth day from the attack of the disease. Dr. Richard Pearson strongly recommends the injection of warm water in very small quantities, and impregnated with narcotic substances, into the veins of hydrophobic patients, for the purpose of subduing the spasms which prevent deglutition. This object being attained, he proposes the administration of a strong cathartic, copious dilution with mucilaginous liquids, camphor, and other antispasmodics; and after the

operation of these medicines, sponging the body with cold water and vinegar, and giving at the same time internally the nitric or muriatic acids, and lastly some of the vegetable tonics. Dr. Booth considers the acetate of morphia as far preferable to opium for injection into the veins of the hydrophobic sufferer, as its dose and powers are more definite than those of the latter drug. In conducting the injecting process, he suggests that twenty-four minims of the solution of acetate of morphia (equal to four grains of opium) mixed with two drachms of distilled water, be introduced into the cephalic vein; and then, after waiting for about ten minutes to observe the effect, that the operation be repeated at like intervals until a decided sedative impression be produced. (Booth on Hydrophobia.) Dr. Brandreth made trial of injection of the acetate of morphia, as recommended by Dr. Booth, in a well-marked instance of hydrophobia, and found that it mitigated the sufferings of the patient in a most decisive manner. In a case of more recent occurrence, we have ourselves witnessed the injection of the acetate of morphia, but we regret to say that it altogether failed in diminishing the violence of the symptoms, and retarding the fatal progress of the malady. The operation was skilfully performed by a very respectable surgeon, Mr. Barton, in the presence of Dr. Hull, Mr. Fernely, Mr. Boutflower, Jr., and other medical gentlemen. Dr. Ward has strongly advised opiate frictions in hydrophobia; and in more than one instance they have succeeded in calming the irritability of the system, and obtaining a temporary abatement of the distressing spasms of the muscles of respiration and deglutition. Upon the whole, it may be correctly asserted that opium possesses some claims to future confidence as an antilyssic remedy. *Mercury* is another substance which has been highly lauded for its efficacy both in preventing the disease, and removing it after it has actually appeared. It has been very freely employed internally and by friction, on the authority of Dessault, Kaltschmid, James, du Choisel, Andry, Selig, Königsdörfer, Walther, and other writers; but unfortunately (as an able reviewer justly observes) there are too many cases on record of persons in whom the external wound has been improperly managed, dying of this complaint, notwithstanding the exhibition of large doses of mercury, to warrant much reliance on this remedy alone. (Edinburgh Medical and Surgical Journal, vol. xxi.) *Belladonna* has also enjoyed the reputation of a valuable remedy in hydrophobia; but the success which seems to have attended the administration of this drug in the practice of Brera and Massahen, has not been present in a number of cases observed by different physicians. *Acids* (particularly the oxy-muriatic and acetous) have been freely used and warmly recommended by Aselli, Previtali, and Brugnatelli; but their inefficacy has been proved in several instances. In the case of a young man named Brassendale, which came under the notice of Dr. Bardsley, the aqueous solution of chlorine was fairly tried, but with an unsatisfactory result. *Alkalies*, *cantharides*, *antispasmodics*, as camphor, assafoetida, musk, and castor; *diuretics*, oil, internally, and by friction; *arsenic*, *prussic acid*, *stramonium*, *white hellebore*, *acetate of lead*, and

the *warm bath*, have also been used, but with no better effect.

Venesection has long been considered a powerful remedy in hydrophobia, and has been frequently employed to a very great degree. It has been chiefly advised by those authors who believed in the inflammatory nature of the disease. Mead, Nugent, Fothergill, Shadwell, Ferriar, Hartley, Innes, and more recently Tymon and Schoolbred have been the warmest advocates of an early and vigorous use of the lancet; and several cases have been quoted, on the authority of some of these writers, in proof of the efficacy of the practice. Having carefully perused these histories, we feel a difficulty in admitting that the patients were really rabid. Rutherford, Parry, and Troillet have employed profuse and repeated depletions, sometimes even to delirium, but without any curative result. Indeed, the evidence of Troillet on this point may be deemed conclusive. "Gueyette," he relates, "a été saigné trois fois jusqu'à défaillance, et malgré la perte de sept livres de sang, la rage a continué sa marche funeste. Une terminaison si contraire à celle que nous avons lieu d'attendre nous a fait jeter un regard plus attentif sur l'observation du Doctor Schoolbred; elle n'a pu soutenir l'épreuve de l'analyse; et nous sommes convaincu que son auteur s'est laissé égarer, comme Nugent, par quelques symptômes, qu'une erreur trop commune a fait attribuer exclusivement à la rage. La saignée à défaillance, que des médecins célèbres avoient déjà conseillée, sera abandonnée de nouveau." (Traité de la Rage, p. 367.) It appears also from the experiments of MM. Magendie, Dupuytren, and Breschet on rabid dogs, that profuse venesection was of no avail in arresting the disease.

The *cold affusion* has been attended with palliative effects. In the case of Nixon, who was admitted into the Manchester Royal Infirmary, the patient experienced much relief from having cold water dashed upon his body. He not merely stated how grateful the practice was to him in removing the burning heat of skin and other distressing symptoms, but even solicited its occasional repetition. *Electricity* and *galvanism* have also produced a diminution of suffering in more than one example of hydrophobia. In less than half an hour from the period of the electrical machine being put in motion, Dr. Bardsley's patient, Warren, became more calm and tractable, and expressed a desire to drink some water, which he was able to perform with comparative ease and readiness, and with no small marks of pleasure and even triumph. (Medical and Physical Journal, vol. xiii. p. 159.) [Dr. Mease (*Amer. Med. Intelligencer*, Sept. 1, 1840,) has strongly urged the application of a solution of potassa so as to inflame the surface along the spine, as advised by Dr. Hartshorne in tetanus.] *Tobacco* has occasionally been prescribed, and with apparent benefit. The fumes of the plant have been introduced into the rectum; an infusion of the leaves has been employed in the form of enema; and it has been applied externally as a cataplasm to the scrobiculus cordis. Though this drug has failed in preventing the fatal termination of the disease, still it has been shown to have the power of controlling the violence of the spasmodic actions of the

muscles of the throat. The *guaco juice* has been highly spoken of by Sir Robert Kerr Porter as a cure for this affection; but it has been freely exhibited in the London hospitals in more than one instance of hydrophobia, and without success. A few months ago, Dr. Elliotson employed this remedy, but it totally failed. That able physician has also prescribed the *carbonate of iron* in large doses. One hydrophobic patient took nine ounces of the carbonate in the course of eighteen hours, but it proved equally inert. In the case of a boy under the care of Mr. Brownbill, to which we have before alluded under the head of pathology, we made trial of the *strychnia*; but it seemed to exert little or no influence upon the symptoms. In this instance the inhalation of the *nitrous oxide gas* was also attempted on the suggestion of Mr. Jordan, and produced for a short time some degree of exhilaration and propensity to laughter; but owing to the extreme difficulty experienced in continuing the process, the further effects of the gas were not ascertained. Dr. Bright has advised the adoption of *mineral tonic* remedies combined with some of those diffusible stimuli which are useful in calming the irritability in many hysterical attacks. He has proposed the injection of the muriated tincture of iron into the rectum, as being a powerful chalybeate, and in some cases possessing the quality of allaying spasmodic action. (Medical Reports, part ii. p. 607.) *Violent sweating*, through the influence of highly heated air, has been recommended to the notice of the profession as a remedy in this affection; but we are not aware that it has been sufficiently tried to enable us to determine its real claims to further use. We have seen the hot air bath of great advantage in a very severe instance of traumatic tetanus; and hence it may be deserving of trial in hydrophobia. *Tracheotomy* has been proposed by Mr. Mayo, as an experiment in this malady. Dr. Hunter has alluded to two cases in which the relief obtained by *running* was very remarkable; in one the amendment was so considerable, that the patient did not look like the same person after running about a quarter of a mile. This experiment, however, has not been since adopted.

[For an account of the various agents employed in hydrophobia, see Staub, art. *Hydrophobie*, in Encyclop. Wörterb. der Medicin. Wissenschaft. xvii. 234: Berlin, 1838. To avoid the severe spasms, which are induced by the sight of any thing glistening, it has been advised that the sufferer shall be kept in almost perfect darkness; and it has been suggested by M. Allier, (*Médecinisch. Zeitung*, 1834, cited in *Brit. and For. Med. Rev.* July, 1840, p. 279,) that at the commencement of an attack, compression of both carotids may be used with advantage.]

Having arrived at the conclusion of our inquiry into the history and treatment of rabies, and examined the various means that have at different times been proposed, with the view of arresting the progress and subduing the symptoms of the disease, it is painful to be obliged to confess that no specific or successful mode of cure have up to the present period been discovered. It has been shown that men of the first eminence have directed their utmost attention to the subject, but have unhappily failed in establishing a remedy

for this justly reputed opprobrium of medicine. Under these circumstances, humanity seems to dictate the adoption of those measures which best serve to soften the torments of the unhappy patient. As far as we are capable of judging from recorded facts, we should say that the liberal administration of stimulants and cordials, the internal exhibition of opium in very large doses in the interval of the exacerbations, injection of narcotics into the veins, opiate frictions and opiate clysters, abstraction of blood from the upper part of the spine by cupping, electricity, the tobacco injection, and the cold affusion, are the means which have had the most decided power in producing a remission of the more distressing symptoms of hydrophobia, and thus alleviating the agonies of the wretched sufferer.

We think there is reason to hope, from the more correct information we have of late obtained respecting the manner in which the disease affects the animal, and from the frequent and careful performance of experiments with the virus itself, that a more intimate acquaintance with the nature of the poison may yet be obtained, which may at length lead to the establishment of a successful method of treatment. In order to forward so desirable a result, it becomes each member of the profession to make new experiments on the subject; to watch with minute attention every case that occurs in the course of his practice; faithfully to notice every circumstance of importance connected with the malady, and to adopt any untried plan of cure founded on rational principles. "It would, perhaps, at length contribute," the late Dr. Fothergill has justly remarked, "to remove this uncertainty, if those who are applied to on these interesting emergencies would consider themselves as obliged, by the honour of their profession and the ties of humanity, to note with all possible precision and impartiality every incident in the progress of this disease; and whether they pursue the hints here suggested, or take up more rational ones from their own store, would communicate the result to the public. By this method the field of conjecture would be contracted, and our successors directed to new objects of investigation. The result would be not less honourable to those who engage in the search, than beneficial to mankind in general."

The prescribed limits of this article will not permit the consideration of the several judicious plans which have been proposed by some eminent and enlightened members of the profession for extirpating canine madness from the British isles.

J. L. BARDSELY.

HYDROTHORAX.—From ὕδωρ, water, and θώραξ, the chest. *Water in the chest.* This term is now confined to designate the effusion of serum into the cavities of the pleura.

Although so celebrated an author as Laennec has divided hydrothorax into idiopathic and symptomatic, we are by no means inclined to coincide with his views. If idiopathic hydrothorax mean any thing, it means a disease in which effusion of serum is the only affection, and in which there is neither inflammation of the pleurae nor serious disease in any other organ. Such an affection we have never seen, nor have we found upon record

any satisfactory example of it. At the same time Laennec himself has stated that even in the dead body it is not always easy to distinguish between this, which he terms hydrothorax, and chronic pleurisy; the fluid effused exhibiting every variation from a limpid, pellucid serum to concrete albumen in the form of false membranes. Dr. Forbes has observed, in a note to this place in his translation of Laennec, that English authors are better acquainted than the French with the inflammatory origin of many dropsies; and from the hint thrown out, we have little doubt but that with us he is inclined to refer all such cases to different degrees of pleurisy. That effusion of serum is the first symptom in this disease Laennec himself has stated, and that he has found it so marked as to dilate the chest within a few hours from the commencement of inflammation. The cases also which he has given as illustrating idiopathic hydrothorax tend still more to confirm this view of it; for although the first patient recovered once under the use of acetate of potash, she had in a few months afterwards a fatal attack of pleuropneumonia on the right side; thus showing a tendency to inflammation in the pleura; and her recovery on the former occasion might have been owing to the effusion which thus, if we adopt Dr. Parry's views, resolved the inflammation. In the second case, not only had the patient suffered from organic disease of the heart, but while the lower two-thirds of the right pleura contained a limpid fluid, the upper portions were united by plentiful cellular tissue, which was strong and obviously of long standing, and necessarily the result of previous inflammation. Rayer, in the article *Hydrothorax*, in the *Dictionnaire de Medecine*, also adopts this view of the affection we are considering, and remarks, that although Lieutaud has noticed four cases out of seventy in which no organic lesion is mentioned, yet they are related with so much brevity as to leave very considerable suspicion of their being incomplete; more especially as Morgagni has not left a single example of hydrothorax in which some such lesion did not exist. For a more complete development of this part of our subject, we refer, therefore, to the article *PLEURISY*, (for the affection in question is really a pleurisy, and must be treated upon the principles applicable to that disease,) only here calling particular attention to what appears to us to be the fact, that there is no such disease as hydrothorax independent of inflammation of the pleuræ or organic disease of some other part.

That affection, however, which Laennec has termed *symptomatic hydrothorax*, is of very frequent occurrence, and, to use the language of this author, there is scarcely any disease, acute or chronic, general or local, in which it may not exist. Affections of the lungs and of the heart, however, are those which it most frequently accompanies, and it is by interfering with their functions that suspicion of the presence of effusion is often first excited.

In this as in most other diseases, no one symptom will suffice to detect its existence: we must have recourse to its past history as well as to its present state; and when the symptoms appear to fail us, the greatest advantage may be derived from percussion and auscultation.

Symptoms and Diagnosis.—Were we accurately to speak of the symptoms of hydrothorax, we should be compelled to say with Laennec, Rayer, and other modern authors, that there is really no symptom of the disease excepting oppressive dyspnœa. It would, however, be dismissing the subject too hastily to remain here, for we may certainly trace its history somewhat more satisfactorily.

As we have already stated, that which has been termed *hydropleuritis* is, in fact, an acute pleurisy, and the fluid effused is ill-matured pus, or serum mixed with the common products of inflammation, pus and coagulable lymph. In all these cases also the pleuræ exhibit more or less alteration, in being more vascular than usual, or in being covered with fictitious membranes more or less firm. When, therefore, the fluid poured out in such cases is very considerable, they must be regarded, not as dropsy of the chest, but as cases of empyema, and will require the treatment appropriate to this affection. (See *EMPYEMA*.) Omitting, therefore, any further mention of these cases, we proceed to the history of symptomatic hydrothorax.

As this is the consequence of a great variety of maladies, so the early symptoms are rather referable to the original disease than to the effusion. Thus, when effusion follows disease of the heart, the early dyspnœa, the starting during sleep, the inability of lying down, the difficulty of mounting an ascent, are dependent on the original malady, and are frequently observed when little or even no fluid is discovered in the cavities of the pleuræ. These symptoms are, however, unquestionably aggravated by the supervention of dropsy, and when the latter originates from organic disease of the heart, it is itself an additional source of exhaustion to the system, and materially accelerates the fatal termination.

To whatever affection of the thoracic viscera hydrothorax is to be traced, the earliest symptom of effusion is an œdematous state of the eyelids, occurring chiefly in the morning. This is sometimes so little remarkable, that it escapes attention until inquiry be made by the medical attendant; and often it is only remembered when the feet and ankles have been observed to swell in the evening. That there is no exception to this rule we will not venture to assert, but in all the cases which have been presented to our notice, we have never yet met with any. The progress of the disease from this point is exceedingly variable, and this variable-ness seems to depend much upon the nature of the original affections. In diseases of the heart the early progress is usually slow, the breathing being manifestly more difficult than before the external œdema was perceived, but for some time not aggravated in any remarkable degree. Gradually, however, the external œdema increases, and, *pari passu*, the thoracic oppression, the difficulty of lying down, the dyspnœa, &c. become more distressing. At first, probably, little attention is paid to the difficulty of assuming the recumbent posture, the patient satisfying himself with having his head raised by more pillows. The necessity for having additional pillows continually augments, till at length perfect orthopnœa is established, and he is only able to sleep in a chair. The dyspnœa undergoes also at times very severe exacerbations, the

cause of which is not very readily ascertainable. In a tray painter, whom we examined a few years ago, these paroxysms came on every morning between two and three o'clock, and lasted for an hour or more. He was compelled by the sense of suffocation to start out of bed, and while the attack lasted he placed himself against an open window, gasping in the most terrific manner for air. We saw him only three days before his death, which took place suddenly, and on examination the lungs were found to be œdematous; upwards of two quarts of serum were contained in the cavities of the pleuræ, and a few ounces of coffee-coloured fluid in the pericardium. The only other morbid appearance in the whole body was hypertrophy of the left ventricle. While the symptoms now referred to continue to increase, the face likewise becomes more and more œdematous; the cheeks assume a purple hue, and the lips become livid and at times almost black. The duration of this state varies considerably in different individuals, sometimes lasting for weeks without any alleviation of symptoms, sometimes admitting of great relief by medicine, and intervals of almost perfect ease; at other times its progress is extremely rapid, a few days only intervening between the first symptom of effusion and dissolution. The termination is in many cases very sudden, and in fat individuals sometimes a very slight effort is sufficient to break the thread of life. It is no unusual circumstance for such persons to die while in a privy, apparently in the act of evacuating the bowels, the slight straining which they are then compelled to make being more than the system is able to bear.

In the symptoms which we have now enumerated, we have endeavoured as much as possible to confine ourselves to those which may fairly be regarded as the consequence of effusion. They are, however, in general so much complicated with the symptoms of the original disease, that probably, notwithstanding these precautions, we may have been led into error. It must, however, be remembered that the original disease during this time is not stationary. Valvular concretions may continue to increase; aneurisms become more and more dilated; or whatever other organic change the heart may be the subject of, be proceeding, independently of effusion, to a state inconsistent with health and life. Accordingly, the symptoms of these changes are aggravated at the same time: the palpitations become more frequent and more severe; frightful dreams, sudden starting from sleep, &c. &c. more and more marked; and the vital powers are manifestly daily yielding. It ought not to be forgotten that these two diseases thus acting upon each other, may give rise to such a congestion in the lungs as will be best relieved by bleeding. Much caution and attention, however, ought to be paid to the state of the patient before we conclude that this is the case, since if bleeding be unnecessarily resorted to, it will unquestionably debilitate the patient and hasten his dissolution.

What we have now said refers to hydrothorax as dependent upon disease of the heart; it sometimes, however, succeeds to bronchitis and pneumonia; and in this case the progress is somewhat different. The palpitations and other cardiac symptoms are usually wanting, and there is nothing more mani-

fested than increased dyspnoea. Previously to this becoming very marked, however, the face and feet swell as in the former instance; the patient then requires the head and shoulders to be raised, and at length, as in the former case, he is unable to lie down at all, but remains constantly in a sitting posture. In these cases the termination is seldom so sudden as when the heart is diseased, neither does the countenance exhibit in the same degree the purple and livid appearance. This, however, may be owing to the fact, that the effusion is seldom so great when the consequence of disease of the lungs, as when attended by cardiac disease; and it seldom occurs till the original disease has so far weakened the system as of itself to threaten a speedy termination.

In addition to the symptoms and history now given, we have yet farther means of diagnosis in succussion, percussion, stethoscopic auscultation, and admeasurement.

Succussion, as has been already explained under the article *AUSCULTATION*, consists in forcibly shaking the patient's body and observing the sound thereby produced; and, at the same time, to produce any appreciable sound, it requires the presence of both a gaseous and a liquid fluid in the chest. In hydrothorax it can only be serviceable when the cavity of the pleura communicates with the external air through an aperture of the lungs, or when gas is evolved within the same cavity without any such aperture. We are not, however, aware that either of these circumstances has been ever noticed in the real hydrothorax, although the former is common enough in empyema arising from the bursting of a pulmonary abscess into the cavity of the pleura.

Percussion returns a dull and flat sound over every part of the chest where there is effusion, and the extent of the effusion may be partly judged of by the extent of surface which affords the dull sound. There are, however, many other diseases of the chest besides hydrothorax which prevent percussion from affording the healthy degree of resonance, and to distinguish hydrothorax from these we must be indebted to other means, and among these the stethoscope is one of the most valuable.

The stethoscope, if employed very early, and while yet the effused fluid is in very small quantity, affords that peculiar sound of the voice which Laennec has termed *ægophony*. This, however, will very rarely happen, for usually the effusion is considerable before application is made for assistance. The only information which the stethoscope affords under these circumstances, is a want of respiration everywhere excepting at the root of the lungs.

When, however, we have thus learned from percussion and stethoscopic auscultation that the lungs are impeded in their functions, we have yet to learn what the change is which thus prevents the ingress of air, whether the impediment arises from condensation of their substance, whether from empyema or real hydrothorax, or from any other cause, such as aneurisms, tumours, &c., compressing their substance. In order to arrive at this information, we must estimate the general symptoms and those afforded by percussion and stethoscopic auscultation together.

In the article *EMPHYEMA*, the principal affections have been enumerated which might be confounded with that disease, as tubercular consumption, hepatization of the lungs, tumours in the cavities of the pleuræ, &c.; and for the most part the same means of distinction exist between these affections and hydrothorax. It still remains to be shown what means are afforded us of distinguishing empyema from hydrothorax, and this can only be done by an accurate investigation of the preceding symptoms.

In hydrothorax the serous diathesis always prevails, and there is, at the same time with effusion into the cavities, effusion in the cellular tissue either of the face and ankles only, or of the extremities, sometimes of the whole surface of the body. Now, even in empyema we may also have anasarca partial or general, but upon inquiry we shall in this case find that the symptoms of the chest have long preceded the appearance of dropsy, and the latter, instead of appearing the direct consequence of the thoracic disease, would rather appear to be the mere result of debility; — the cough, the dyspnoea, the emaciation especially, having usually proceeded to an extreme before there was the slightest appearance of effusion. In hydrothorax, on the contrary, the appearance of œdema of the face and ankles long precedes the more severe affection of the chest: sometimes even the ankles attract attention for a little while by swelling, and then subside for a considerable interval, or they swell so slightly as to be forgotten. In empyema, again, the stethoscope will usually prove that respiration is well carried on in one lung at least, although the other may be perfectly useless. This, however, can seldom happen in hydrothorax; and were we to judge from our own observation, we should even be inclined to say that it never happens. Whenever hydrothorax exists to any extent, that is, whenever there is any considerable quantity of serum in the cavities of the pleuræ, the lungs participate in the dropsical disposition, and fluid is effused into their cellular texture. This must, therefore, materially impede respiration, and as it must exist nearly equally in both lungs, there can never be the decided difference between the two sides that is observable in empyema.

Perhaps we ought not to omit all mention of *admeasurement*, more especially as effusion, real dropsical effusion, may exist to a much greater degree in one side than in the other. That side in which the effusion is greatest will certainly be more dilated than the other, as is the case in empyema; but if with this difference of measure we unite the indications of the stethoscope, we cannot be in much danger of confounding the two affections.

Bichat has recommended an experiment in doubtful cases of hydrothorax which deserves some notice, especially in distinguishing it from empyema. This consists in placing the patient in an horizontal position, and pressing upon the abdomen from below upwards, thus limiting the descent of the diaphragm. The fluid effused into the pleuræ is thus forced to compress the lungs, the sense of suffocation becomes most painful, and the countenance assumes a livid hue. Now as distinguishing hydrothorax from any diseases occupying both sides of the chest, this appears

scarcely available; but in distinguishing it from empyema, which occupies only one side, it may be a most valuable resource. Dr. Townsend, in the admirable paper upon empyema, to which we have before referred, remarks that if the pressure be made on that side in which effusion is present, no result follows, because this side being already useless, no additional pressure can add to the inconvenience; but if it be made on the sound side, this being the only side which is useful for respiration, the expansion of the lung is prevented, and the utmost distress induced. In distinguishing hydrothorax, then, from empyema, much use may be made of this experiment, although it by no means answers in the manner which its celebrated author proposed.

Prognosis. — The prognosis of hydrothorax is always unfavourable, because it is never a simple disease, but always the consequence of some other malady, which would, even without effusion, eventually terminate in death. This opinion, however, is only applicable to a complete restoration to health, for to a comfortable state it is frequently in the power of medicine to restore the patient. So far as the mere effusion is concerned, it may in many cases be removed again and again; and as this is often the most threatening source of danger, the prognosis may for a time be reversed. Still every fresh occurrence of dropsy of the chest makes even a temporary recovery less probable, and in giving any opinion of the disease we must take into our consideration both the stage of the original disease, and the frequency with which effusion may have occurred. Under all circumstances our opinion ought to be most guarded, and it is at least wise never to omit the announcement that death may be sudden.

Appearances on Dissection. — If we were to enumerate all of those which are at different times found in hydrothorax, we could scarcely omit any long exhausting disease of the human body, certainly none of the thoracic viscera. This would, however, be proceeding much farther than would be useful. Some diseases, however, are much more liable to terminate in hydrothorax than others, and such are those in particular of which the heart, the great blood-vessels, and the lungs, are the subjects. Accordingly, valvular disease of the heart, active and passive aneurisms of the same organ, aneurisms of the aorta and arteria innominata, chronic bronchitis, and tubercular consumption, are more frequently met with than any other organic changes in hydrothorax. Some changes are also observable in the state of the pleura, but this is only very manifest when actual inflammation has been present. We have seen a vascular state of this membrane, and various degrees of factitious membrane deposited upon it.

The quantity of fluid varies very considerably, and in our experience it has always been greater when dependent upon disease of the heart and great blood-vessels than on any other cause. M. Itard places the largest quantity at twelve or fourteen pints, and Portal quotes a case from Wolfius in which sixteen pints were found. Morgagni seldom mentions the precise quantity, but usually states it at some pounds. With one exception, the largest quantity we have met with did not ex-

ceed nine pints. In the excepted case, which was an aneurism of the arteria innominata, the quantity effused must have been at least fourteen or fifteen pints.

The colour of the effused fluid is usually amber, sometimes, however, mixed with coagulable lymph, but this only happens when there has been inflammation of the pleura. Laennec has indeed very justly observed that from the appearance of the effused fluid alone it is not always easy to decide whether the affection has been hydrothorax or empyema, the serum assuming many grades between a limpid fluid and coagulable lymph. This fact is of great importance in practice, as Dr. Forbes has remarked: it is essential that the physician remember that the inflammatory and serous diathesis may exist together, or supervene one to the other. The plan of treatment must therefore be varied accordingly.

Like the effusion into the other cavities of the trunk, the fluid is sometimes of a dark coffee colour, sometimes bloody, and assumes every variety of hue between the pellucid serum and blood itself.

Treatment.—The same general principles apply to the treatment of hydrothorax which have been mentioned under the article *Dropsy*. Although the original cause of effusion is an affection of some organ of the chest, or some disorder of the general system, yet the immediate source is the serous membrane, and regard must be had to its condition. Even in a very weakened state of the body the pleura may become inflamed and demand an antiphlogistic treatment. When this is the case, it is an important object of inquiry how far antiphlogistic remedies may be carried with advantage or even with impunity; and upon this point some few considerations present themselves to our notice.

When towards the termination of chronic diseases local inflammation occurs, we have a very different physiological state of the system to contend with from that which would be present should such inflammations take place from an immediately previous good state of health: not only under these circumstances have we no general plethora to overcome, which indeed might happen when the system had not been weakened by disease, but there is a positive wasting and probably actual inanition. Now even in common circumstances it is never advisable to carry bloodletting farther than is sufficient to overcome the immediate inflammation, for although no evil result may be at once apparent, no one can have followed the footsteps of some modern bleeders without seeing the most deplorable consequences of over-depletion. Months and even years are often necessary to restore the system to that equilibrium in which the mens sana in corpore sano can again be enjoyed. We have no hesitation in asserting that many of the most lamentable cases of hysteria and habitual nervousness owe their origin to this mis-called heroic practice, and in females particularly that helpless capriciousness, which is so often burthensome to themselves and tormenting to their friends, has been derived from repeated bleedings for pains in the side, which have upon very slight investigation been referred to the presence of acute pleurisy. If then this happen with

persons in health when bled improperly, the consequences of unnecessarily large bleedings in chronic diseases are still more disastrous. In the latter stages of tubercular consumption we have seen patients hurried to their graves by wild attempts to cure a pleurisy, without any consideration of their previous state, and even in pneumonia fatal effusion has instantly followed a large bleeding, when perhaps a moderate one would have restored the individual to health. In the treatment of hydrothorax dependent upon an exhausting organic disease, an error in this respect would be almost certainly fatal, for we well know that hemorrhage, even without previous debility, is one cause at least of dropsical effusions.

By what we have now said, however, we by no means intend to proscribe bleeding in water in the chest, but merely to urge that due caution be practised in employing it. Two circumstances may occur in hydrothorax which may render bloodletting necessary, the occurrence of pleurisy acute or sub-acute, and congestion in the lungs: the latter is particularly liable to happen when hydrothorax is connected with valvular disease of the heart. In the former case local bleeding is always preferable, both because it may be taken much more immediately from the seat of disease, and also because it has less effect upon the general strength of the system. Another advantage is derivable also from cupping, which neither general bleeding nor leeches are calculated to afford, and this is a more permanent determination of blood to the external surface from the action of the cupping-glasses. That cupping has a decided advantage over leeches need hardly be mentioned. In our opinion the latter never ought to be used when the former can be employed. Both the quantity of blood taken is more satisfactorily ascertained, and the patient is not fatigued or inconvenienced in any degree equal to what is the consequence of employing leeches.

When it is necessary to draw blood on account of congestion in the lungs, recourse must be had to general bloodletting, and the quantity must be guided by the effect upon the disease. We know of no very certain sign that this congestion has place when hydrothorax is present, excepting the occurrence of hemoptysis; and wherever this happens with valvular disease of the heart, we should not hesitate to bleed, and it will usually be found advisable to repeat the bleeding at longer or shorter intervals. In general it will be necessary to take only a small quantity of blood at a time, sometimes not exceeding six or eight ounces; but the benefit afforded by this is very decided, and the debility induced is not enough to prevent recourse being again and again had to venesection for relief.

Purgatives and diuretics naturally suggest themselves as the medicines most likely to afford relief in hydrothorax, and to each belong advantages which are not possessed by the other. The relief afforded by elaterium and croton oil is unquestionably much more speedy than that which can be obtained by the employment of diuretics. Unfortunately, however, they exhaust the patient in a much greater degree, and cannot be safely employed in a very debilitated condition of the system. The mode of giving elaterium has been

mentioned under the articles anasarca and dropsy, and we have nothing to add to the observations there made. We may make a similar remark regarding digitalis and other diuretics. Here we will do no more than repeat what we have frequently said already, that the dropsy is only symptomatic, and that it is to the cure of the original affection that we must look for the perfect restoration of the patient; and our success in practice will mainly depend upon the accuracy of our diagnosis as to the original cause of the effusion.

The last point to which we shall allude in the treatment of hydrothorax is the propriety of tapping, an operation which we can scarcely conceive applicable to genuine hydrothorax. Most of the cases in which paracentesis thoracis has been employed, were in fact cases of empyema; and unquestionably there are many instances on record in which complete success was obtained by its performance. In the article hydrothorax, in Good's Study of Medicine, we have but another instance in addition to those referred to by Dr. Forbes, of practitioners confounding empyema and hydrothorax together. He has mentioned a successful case by Dr. Arthur of Dublin, which, without doubt, was an instance of empyema, as it had been the result of a preceding pleurisy. But empyema is usually confined to one side of the chest, the opposite lung being comparatively healthy; and hence, by drawing off the fluid, we have some chance of the compressed lung recovering itself, and we at least take off any inconvenience which may arise from the quantity of fluid narrowing the cavity of the sound pleura. In hydrothorax, on the other hand, both sides are affected, though perhaps not in an equal degree; and whenever the effusion is sufficiently great to suggest such an operation, there is the greatest probability that the cellular texture of the lungs themselves is likewise the seat of effusion. Hence it must be always doubtful to which the dyspnoea ought to be referred, effusion within the cavities of the pleura, or effusion within the cellular tissue of the lungs; and at the best, the usefulness of the operation must be very problematical. It is not, however, very likely, that in real hydrothorax it will ever be proposed. [For the best mode of performing the operation, see the article EMPYEMA.]

JOHN DARWALL.

[HYPERÆMIA. (See CONGESTION.)]

[HYPERÆSTHESIA, *Supersensitiveness*; from *ὑπὲρ*, over, and *αἰσθησις*, "sensibility." Augmentation of sensibility. This may affect the several senses; as in nyctalopia, hyperacusis, hyperosphresia, hypergeusia, hyperaphia, &c. A highly exalted state of sensibility is occasionally seen, in which the sufferer is so impressible or nervous—as it is usually termed—that he cannot bear the slightest unusual impression on any of the senses without fainting, and without the minutest changes of atmospheric density and temperature producing disagreeable sensations.

This great nervous impressibility may be caused in various ways. It supervenes, at times, on long protracted and profound mental exertion, on want of sleep, great fatigue, and any thing that exhausts the nervous system; but it more frequently follows profuse evacuations of every kind,—too

copious bloodletting, or hypercatharsis; a rigid diet; and still more, abstraction of those excitants to which the nervous system may have been habituated,—as alcoholic liquors or tobacco. Some of the most distressing cases of supersensitiveness, which the writer has seen, have occurred in persons who had suddenly left off chewing or smoking.

The treatment must, of course, vary with the cause, which must be removed whenever practicable. A tonic system of management, with a generous diet, and a thorough change of all surrounding influences, must be advised. Narcotics, especially hydrocyanic acid and lactu carium, have been recommended, but they are rarely of service. The more active narcotics—as opium—are often found, indeed, to be positively injurious. The supersensitiveness may be diminished whilst the patient is under their influence, but it recurs to a greater extent when the narcotic influence has passed away.

ROBLEY DUNGLISON.]

HYPERTROPHY, (from *ὑπὲρ* and *τροφὴ*, signifying an excess of nutrition,) is a term applied by pathologists to that condition of a tissue or organ which presents an increase of substance, not arising from any transformation of tissue, or from the development of any morbid product, but simply from a preternatural growth of its proper organic textures. For example, a muscle is said to be in a state of hypertrophy when its size exceeds the ordinary standard, provided it still retains its muscular structure; but the term hypertrophy could not with propriety be applied if the increased size of the muscle were produced by the transformation of its fibres into fat, or by the development of a tumour in its interior.

As hypertrophy is only an increased development of the natural structure, it cannot strictly be considered as constituting a disease, unless when it deranges the functions of the hypertrophied organ, or exercises an injurious degree of pressure on the neighbouring parts. The muscles on the fore-arm of a pugilist or of a blacksmith, though hypertrophied to double their natural dimensions, are so far from constituting a disease, that they afford a good criterion of the health and strength of the individual: whereas there are few diseases more formidable than a similar condition of the muscular walls of the heart. Indeed it is only of late years that hypertrophy has attracted the attention of anatomists as occurring in any other organ than the heart. The accurate researches of modern pathologists have, however, clearly demonstrated that several tissues, especially the muscular, the adipose, the cellular, the mucous, the cutaneous, the nervous, the vascular, the fibrous, and the osseous, are liable to this affection; and that any organ into whose composition these tissues enter, may be generally hypertrophied throughout its entire structure, or may have the hypertrophy confined to one or more of its component parts. Sometimes, indeed not unfrequently, it happens that by virtue of a sort of balance in the nutritive powers of the part, in proportion as one tissue is hypertrophied another becomes atrophied, in which case the original structure of the organ is so completely changed, that it becomes exceedingly difficult to recognise it. In hypertrophy of

the white acini of the liver, accompanied with atrophy of the red acini of the same part, the natural appearance of the organ is materially changed; and in those cases where its cellular tissue is so hypertrophied as to form large masses of a pearly white colour, intersected by opaque membranous septa or partitions, producing an appearance not unaptly compared to the section of a turnip, the natural structure of the viscus is so completely altered that pathologists have not hesitated to refer the alteration to the development of the non-analogous accidental production named scirrhus.

As the effect of excessive nutrition is to increase the number of molecular atoms which enter into the composition of the part, it generally follows that a tissue or organ in a state of hypertrophy becomes thicker and larger than in its natural state. Sometimes, however, the effect of hypertrophy is to increase the density rather than the bulk of the part, as is exemplified in hypertrophied bones, which occasionally become as dense and as compact as ivory, without undergoing any change in their external form or dimensions. Indeed the size of an organ would in many instances afford a very erroneous index of the state of its nutrition, for we know from observation that the hollow organs may be in an extreme state of hypertrophy without having their size apparently increased, in consequence of the super-numerary particles being deposited on their internal surface, and at the expense of their cavities, as in concentric hypertrophy of the heart: and that, on the other hand, these organs may be greatly increased in size without being in the slightest degree hypertrophied, as is exemplified in the skulls of hydrocephalic persons, and in passive dilatations of the heart, bladder, stomach, &c.; in all of which cases the parietes of these organs are in fact thinner than natural, and their increased size is produced by mechanical distension independently of any increase in the number of their integrant particles. Thus it appears that the natural cavity in a hollow organ may remain unaltered in its dimensions, or may have its capacity either increased or diminished, at the same time that its parietes are hypertrophied. When the dimensions of the cavity remain unaltered, the thickness of the walls, as compared with their ordinary standard, will afford a correct index of the state of their nutrition; when the capacity of the cavity is diminished, the walls may appear considerably thicker than usual, in consequence of the contracted state of their muscular fibres, independently of any increase of substance; and on the contrary, when the cavities are much enlarged, their walls may appear thinner than usual, when in reality their substance is increased, though from its excessive distension it is apparently diminished.

But it is not in the hollow organs alone that an alteration of size may take place independently of any increase of the nutritive function, for considerable enlargement is often produced in various organs by an accumulation of blood in the capillary vessels. There is perhaps no viscus that exhibits this enlargement from congestion in a more marked degree than the liver, especially in those cases where any obstruction exists to the free exit

of its blood. We recollect one case, particularly, of aneurism of the aorta compressing the inferior vena cava so as to obstruct considerably the flow of blood from the liver, in consequence of which that organ was enlarged to such a degree as to descend almost to the crest of the ilium. Suddenly, however, the aneurism gave way, and the pressure being thereby removed from off the cava, the hepatic veins were allowed to unload themselves, and the liver had nearly resumed its natural situation and dimensions when the post-mortem examination was made. The spleen is likewise often greatly increased in size by the accumulation of blood in its interior. We have repeatedly observed this effect produced in those cases where the liver was small, indurated, and knobbed on its surface. Another reason why the size of an organ does not always afford a correct criterion of the state of its nutrition is, that the hypertrophy is often confined to one elementary tissue of the part, while one or more of the other tissues which enter into its composition waste away and fall into a state of atrophy, which more than compensates for the increased size of the hypertrophied tissue.

Instead of increasing either the size or density of the hypertrophied tissue, it sometimes happens that the exuberance of nutrition is manifested by the formation of vegetations or projections from its surface, as in fungoid excrescences of the mucous membrane, exostosis, &c.

Hypertrophy may exist simple and uncombined, or may coexist with other alterations of the tissue or organ affected; thus it may be combined with hyperæmia, or on the contrary with anæmia; hence it is that we sometimes find the parts affected of their natural colour, sometimes presenting different shades of red or brown, and sometimes, also, colourless and exanguious. In like manner their consistence is in some cases unaltered, in others, (and they are the most numerous,) increased, and in others again diminished, the tissue hypertrophied being at the same time in a state of softening. (*Andral, Pathol. Anat.*)

We shall now proceed to consider briefly the principal alterations produced by hypertrophy in the different tissues and organs, the causes which seem to favour its production, and the effects to which it commonly gives rise.

Hypertrophy of the Muscles.—The effect of hypertrophy on a muscle is in general to increase its size and render it firmer than ordinary; its fibres become more condensed, contain a larger proportion of colouring matter, and a less quantity of serous fluid; the fat deposited in the interstices of the muscles usually diminishes, while the blood-vessels undergo an increase of size proportioned to the extent of the hypertrophy. Such are the alterations which the muscles of the pugilist undergo during the process of *training*, as it is termed, and such is also, to a certain extent, the condition of any muscle or set of muscles kept in constant and active exercise. On this principle is founded the system of gymnastic exercises, which, when judiciously conducted, have been found so efficacious in improving the strength and correcting the tendency to deformity so often arising from irregular or defective muscular development. Unfortunately, however, it is not the vol-

untary muscles alone that are liable to hypertrophy; the muscular structure of the heart and of the air-tubes, of the intestinal canal, and of the bladder, are likewise subject to this affection, and in them it is often productive of the most distressing and dangerous consequences. In these musculo-membraneous organs we constantly find hypertrophy of the muscular fibres produced by any cause, whether organic or functional, which increases the frequency and energy of their contractions, provided it continues to act for a sufficient length of time. Thus, diseases of the valves of the heart or its great vessels, by opposing an obstacle to the exit of the blood, stimulate its muscular parietes to increased action, in order to overcome these obstacles, and this increased action eventually leads to their hypertrophy; but the same effect may likewise be produced by long-continued palpitations arising from mental emotion, or from any other cause whatever. (See HYPERTROPHY OF THE HEART.) In the same way hypertrophy of the muscular fibres of the bladder is produced by an obstacle to the evacuation of its contents, such as enlarged prostate, fungous tumours, or strictures of the urethra, which obstruct the passage of the urine, and so stimulate the bladder to increase its efforts in order to propel its contents; the same effect is also produced by the presence of calculi or gravel, or by any other cause which irritates the bladder directly or sympathetically, and causes it to contract with greater force and frequency than natural. When the bladder is thus affected, its muscular coat may be uniformly thickened, or the hypertrophy may be confined to certain fasciculi which project from its surface like the muscoli pectinati of the auricles, and give the interior of the organ a remarkable sacculated appearance. These fibres never acquire the red colour which muscles of the same size have in other parts of the body when hypertrophied by exercise; but like the muscular fibres of the intestinal tube, they remain pale, even when hypertrophied to an extreme degree. The muscular fibres of the bronchi likewise acquire an excessive development from the increased exertions which they are called on to make during protracted attacks of dyspnoea or of violent coughing. In old asthmatic persons, and in the still more numerous class of patients who suffer repeated attacks of dyspnoea from organic disease of the heart and congestion of the bronchial membrane, we have constantly found the transverse muscular fibres of the bronchi, which in the natural state are scarcely perceptible, so increased in size as to form distinct fasciculi.

Another frequent cause of hypertrophy of the muscular parietes of these organs is *inflammation*, especially when of a chronic character, and affecting their lining or investing membranes. Thus, pericarditis, terminating by the formation of adhesions, is often followed by hypertrophy of the heart; and though it is difficult to adduce positive evidence that inflammation of the internal membrane of the heart is capable of producing hypertrophy of its walls, yet the conclusion is almost justified by analogy. The effect of chronic inflammation of the mucous membrane of the bronchi in producing hypertrophy of the subjacent muscular fibres has already been noticed. A similar effect

is frequently produced by irritation or chronic inflammation of the mucous membrane of the bladder, arising from the presence of calculi, &c. In chronic dysentery the muscular fibres of the colon are in general greatly hypertrophied. Hypertrophy of the muscular coat of the stomach is also frequently produced by chronic irritation of the mucous membrane of that viscus. (*Broussais, Phlegmasies Chroniques.*) The hypertrophy of this tunic is usually accompanied with a similar condition of the other sub-mucous tissues, and this state of the viscus is commonly described as the effect of scirrhus degeneration. In such cases, on making an incision through the thickened parietes of the stomach, we find—1. The mucous membrane sometimes sound and sometimes altered in various ways. 2. Immediately beneath this, a layer of a milk-white colour, varying in thickness from less than a line to several inches: this is the sub-mucous cellular tissue. 3. Beneath this layer appears another, distinguished by its bluish colour, semi-transparent, and with a peculiar kind of lustre, traversed by an infinite number of opaque lines: this is evidently the muscular coat in a state of hypertrophy. 4. Still more externally there may appear a second layer of a dead white colour and homogeneous texture; this is in fact the sub-peritoneal cellular tissue, which has become thickened and indurated like the sub-mucous. In some cases, the cellular tissue remains unaltered, and the muscular coat alone is hypertrophied so as to produce considerable thickening of the stomach or intestines. It is in the pyloric portion of the stomach especially that this form of hypertrophy has been observed; and this is also one of the parts where in the natural condition the muscular coat of the alimentary canal is of the greatest thickness, and its action most remarkable. On opening the abdomen of a living animal we find that the right end of the stomach, the pylorus, and the commencement of the duodenum, are continually animated with a contractile motion. This motion is most distinct during the process of chymification, whence it follows that whatever tends to excite the mucous membrane of the stomach must tend to increase the action of the muscular fibres of the pylorus, and eventually to produce in them a state of hypertrophy. (*Andral's Path. Anat.*) We have seen these fibres hypertrophied to such a degree as to measure nearly two inches in thickness, and to present a striking resemblance to the gizzard of birds. Dr. René Prus observes that the frequent vomitings which occur in persons labouring under chronic gastritis may contribute very much to produce the hypertrophy of the muscular fibres that so often succeeds to protracted attacks of this disease.*

From whatever cause the hypertrophy of the hollow muscular organs arises, the effect of the excessive development of their fibres is to increase their force and irritability, and consequently the frequency and energy of their contractions. The bladder, when hypertrophied, says Dr. Baillie, becomes extremely irritable, the inclination to make water is frequent, and repeated efforts of the muscular coat are required, which increase its thickness more and more. In like manner the irrita-

* *Recherches sur la Nature et le Traitement de Cancoer de l'Estomac.*

bility of the transverse fibres of the bronchi is increased in proportion to their increase of development, until the slightest irritation becomes sufficient to excite them to violent contractions. In such cases, any irritation of the mucous membrane produces violent paroxysms of dyspnoea and coughing, which in their turn increase the hypertrophy of the muscular fibres, and so the disease becomes progressively aggravated. Similar effects are likewise produced in chronic dysentery by hypertrophy of the muscular fibres of the rectum and colon, until eventually the presence of the least quantity of feculent matter is sufficient to induce the most violent spasmodic efforts for its expulsion.

The symptoms produced by hypertrophy of the heart are of such importance as to merit a special article to be devoted to their consideration; to which, therefore, the reader is referred.—See HEART, (HYPERTROPHY OF THE).

Hypertrophy of the Adipose Tissue.—The adipose or fatty tissue is of all others the most subject to hypertrophy: it is in general largely developed in infants immediately under the integuments, but seldom accumulates at that age on the internal organs. After the second or third year the tendency to obesity usually disappears until the period of puberty, at which time, especially in females, it again makes its appearance, though it very seldom becomes excessive before the age of five-and-twenty. It has been calculated (*Dictionnaire de Médecine. Art. Polysarcie*), that the average weight of an adult of ordinary robustness is about eleven or twelve stone, of which fat constitutes about one-twentieth part; in some cases, however, it is developed in such enormous quantities as to constitute from one-half to four-fifths of the entire weight: and there are cases on record of persons becoming so prodigiously laden with fat as to weigh from thirty-five to forty stone. M. Dupuytren has published an account of the dissection of a remarkable case of this kind. The individual (who was a poor beggar woman, totally dependent for her daily sustenance on the precarious contributions of charity,) measured five feet one inch in height, and five feet two in circumference. The subcutaneous layer of fat was three inches deep on the thighs, four inches on the glutei, and seven inches on the mammae. In the interior of the body the only parts which were completely exempt from fat were the skull and the spinal canal. In the thorax there was no fat developed between the fibrous and serous layers of the pericardium; but it was accumulated in enormous quantities at the base and on the surface of the heart, and in the mediastinum, and was also deposited in large masses between the costal pleura and the ribs. The pulmonary pleura contained no fat. In the abdomen the peritoneum was everywhere coated with a thick layer of fat, except where it was reflected over the liver, the spleen, and the small intestines: between the peritoneum and the diaphragm it was developed in large quantities, as also between the peritoneum and the muscular coat of the stomach and colon, from the latter of which it hung in fringes two inches long and three quarters of an inch in diameter. In the mesentery it measured two inches, and in the greater and less omentum one inch in thickness. No organ appeared to

have undergone the fatty degeneration except the mammary glands. The muscles retained their red colour, and even seemed to have acquired an increased development, as if for the purpose of increasing their force in proportion to the increased mass which they had to move. (*Journal de Corvisart, tom. xii. p. 292.*) This case exhibits a striking instance of the influence of idiosyncrasy in producing general hypertrophy of the adipose tissue; for the individual in question was scantily supplied with a most meagre diet, and took a great deal of exercise every day; in short, led precisely that kind of life which is supposed to be least favourable to the accumulation of fat. Hypertrophy of the adipose tissue may likewise occur as a local affection. We not unfrequently find (more especially in persons advanced in life who have indulged freely in the pleasures of the table) fat accumulated in such quantities in the abdomen as to give the belly a size altogether disproportioned to the rest of the body. The mammae in some females are enormously laden with fat; and the quantity of this substance deposited on the glutei muscles is so great in some cases as to constitute an absolute deformity, as in the African woman, named *the Hottentot Venus*, who was exhibited in this country some years ago. Lobstein relates the case of a child, one of whose thighs was so laden with fat as to measure twice as much in circumference as its fellow of the opposite side. (*Traité d'Anatomie Pathologique.*)

It seldom happens that fat is developed in such quantities on any of the internal organs as to impede their functions, unless in cases of general obesity; the heart, however, is sometimes greatly overloaded with fat, particularly at its basis, along the septum, and at the apex of the right ventricle. Indeed, this condition of the viscus is by no means uncommon in advanced life even in persons of moderate embonpoint. We have generally found it coinciding with a pale flabby condition of the muscular fibres, and not unfrequently combined with a general dropsical diathesis. It does not appear that this condition of the organ produces any material or permanent derangement of its functions, or that it is characterized by any peculiar symptoms by which its existence may be recognised during life. Fatty tumours are occasionally formed in different parts of the body, and constitute another variety of local hypertrophy of the adipose tissue.

Respecting the immediate or proximate cause of hypertrophy of the adipose tissue, little is known beyond conjecture. Some individuals accumulate fat under circumstances in which others would almost die of inanition. Certain circumstances, however, have been ascertained by experience to be peculiarly favourable to obesity, among which may be enumerated full living, sedentary habits, and the want of mental excitement. Castration has likewise been observed to promote the accumulation of fat, and the same effect is produced by the removal of the ovaries from the female.

Hypertrophy of the Cellular Tissue.—The following description of the anatomical characters of this lesion has been borrowed from M. Andral, to whom we are indebted for the first and most accurate account of this morbid alteration of structure.

“The cellular tissue is frequently affected with

hypertrophy: in those parts where it naturally possesses but little consistence, and resembles a sort of organized mucus, it acquires, when hypertrophied, a greater degree of firmness and density; and in the parts where its density is naturally considerable, its laminae and filaments acquire an unusual thickness, become blended together, assume a dull white colour, or a peculiar grey semi-transparent appearance, and offer considerable resistance to the scalpel. When the hypertrophy has arrived thus far, we observe between the organs, or the different parts of the same organ (according to the seat of the disease), a whitish substance in the form of laminae, or of irregular masses, intersected by numerous lines and striæ; and if we examine the structure of these masses, and trace their formation, we find that they are evidently composed of portions of cellular tissue, which become progressively more and more condensed, and finally present the appearance of a homogeneous mass, which, according to its colour and degree of condensation, resembles either the interior of a turnip, with its dull white striæ, the fat of bacon, or imperfect cartilage, such as is found in the fetus.

"These different alterations of structure have hitherto been confounded under the generic denomination of *schirrus*, whereas they are all produced by hypertrophy of the cellular tissue, in some cases simple and uncombined, in others conjoined with some product of a morbid secretion into the areolæ of the cellular texture." (Op. cit.)

Hypertrophy of the sub-mucous cellular tissue of the alimentary canal is very frequently produced by chronic irritation of the mucous membrane, more especially in cases of chronic gastritis and dysentery. In the urinary apparatus it is also often caused by irritation or chronic inflammation of the membrane to which it is subjacent. Hypertrophy of the sub-mucous cellular tissue of the urethra is one of the most frequent causes of stricture. We have never observed the sub-mucous cellular tissue hypertrophied to any great degree in the air-passages of the respiratory apparatus. The sub-cutaneous cellular tissue is often very much thickened in the neighbourhood of old ulcers, and of eruptive diseases of long standing. Hypertrophy of the cellular tissue is likewise observed in the parenchymatous structure of several organs: sometimes the proper texture of the part remains unaltered in other respects, and the only change observable is, that the cellular tissue which intersects and supports its structure is rendered thicker, harder, and more opaque than natural. This appearance is often observed in the pancreas, thyroid, and mammary glands. More frequently, however, the proper tissue of the part falls into a state of atrophy, or even disappears altogether, and the cellular tissue which formed its original frame-work acquires a preternatural development, so as to form considerable masses of a white colour and striated appearance, not unlike the section of a turnip. This alteration of structure we have observed most frequently in the liver and spleen. Another form of hypertrophy of the cellular tissue is that in which one or more of its cells are dilated and their walls thickened, as in the serous cysts which are found in the kidneys and ovaries, and attached to the choroid plexus.

Hypertrophy of the Mucous Tissue.—This is a frequent result of long-continued or often repeated attacks of inflammation. When the mucous membrane of the stomach or intestines is affected with hypertrophy, it generally becomes harder and denser than ordinary, so that it may be torn off in large shreds. This affection is more common in the stomach and colon than in the small intestines: the membrane, while becoming thicker, sometimes preserves a smooth and uniform appearance; sometimes, being thickened unequally, it presents a number of elevations separated by sinuous depressions. In the large intestine the hypertrophy of the mucous membrane is sometimes so excessive that it exceeds in thickness all the other coats taken together. In the small intestines we have seen the valvulae conniventes longer, thicker, and at least twice as numerous as they usually are. When the hypertrophy only affects isolated points of the mucous membrane, it produces elevated patches and tumours of various forms, sizes, and textures, which have been designated by the names of vegetations, fungous excrescences, polypi, &c. according to the forms they assumed, and the varieties of consistence and colour which their texture exhibited. (Andral.) Sometimes the hypertrophy, instead of involving the entire texture of the membrane, affects only the villi which cover its surface, and in some cases the hypertrophy is confined to the mucous follicles, and the membrane appears studded over with small conical whitish bodies, having each a central pore or orifice in those parts of the intestines where the follicles are isolated; these conical bodies are separate and distinct, but where the follicles are aggregated, they become confluent, and by their assemblage form large clustered patches. Hypertrophy of the follicles occurs most frequently at the lower portion of the small intestines. Like the other varieties of hypertrophy of the intestinal tube, it is usually found in those who have laboured under diarrhœa and other symptoms of local irritation for some period before death.

That portion of the mucous membrane which lines the larynx and bronchi frequently becomes hypertrophied in persons affected with chronic irritation of those parts. The anatomical characters of hypertrophy of this portion of the membrane are nearly the same as in the alimentary canal. In some cases the membrane is generally thickened, in others the thickening is confined to a circumscribed point, where it produces a projecting tumour or vegetation. Andral relates two cases in which the rima of the glottis was almost completely obstructed by whitish cauliflower vegetations of this description. Hypertrophy of the follicles with which the mucous membrane of the air-tubes is so thickly studded, has repeatedly been mistaken for tubercles, and also for the eruption of small-pox. M. Reynaud found the mucous membrane of the bronchi covered with villi in an individual who had laboured under chronic cough and dyspnoea for many years: as no villi are visible in the natural condition of this membrane, their appearance must be ascribed to the effects of hypertrophy. Hypertrophy of the mucous membrane of the minute bronchi, producing considerable diminution of the calibre, is a constant cause

of dyspnoea, especially when situated at the orifices of the off-setting tubes. It is to this cause we must attribute the permanent sonorous and sibilous râles that are to be heard in the lungs of some asthmatics. In the genito-urinary organs the mucous membrane presents nearly the same changes from hypertrophy as those we have already described, namely, general thickening or enlargement of its mucous follicles, vegetations, excrescences, &c. These excrescences present considerable variety of texture, some of them consisting of a hard homogeneous tissue apparently destitute of vessels, others of a soft and highly vascular tissue, while others are formed by a mere prolongation of the natural membrane; so that this portion of the mucous membrane, like all others, presents two varieties of hypertrophy, one in which its substance is thickened but its texture not altered, and another in which its texture no longer retains its natural characters. (*Andral, Op. cit.*) M. Louis found the mucous membrane of the bladder covered with villi in a patient who has been affected with hematuria for a number of years. (*Recherches sur la Phthisie.*) In this case also they must have been morbidly developed, as they do not exist in the natural state of the membrane, or, if present, are so minute as not to be perceptible.

Hypertrophy of the Skin.—The cutaneous tissue, like the mucous, may be hypertrophied throughout its entire structure, or in some one or more of its component layers. Andral relates a very remarkable case of general hypertrophy of the skin occurring in an old woman who died of phthisis in the hospital of La Charité. She had formerly had an ulcer on her right leg, but for the last thirteen years the sore had been cicatrized, while the limb had gradually acquired an extraordinary development. On dissection the thickened integuments were found to consist of the following layers: 1. the corium or cutis vera; 2. the papillary tissue, (*bourgeons sanguins* of M. Gautier); 3. over the papillæ three layers more or less distinct, according to the situation in which the examination was made. The first of these layers appeared like a delicate white line, which, as it dipped in between the papillæ, assumed an undulating appearance: this layer was analogous to that described by M. Dutrochet as the epidermic layer of the papillæ. Immediately over the undulating line just described, appeared another layer of a dark grey or brown colour; when sliced obliquely, it presented the appearance of net-work formed by a number of delicate dark-coloured filaments crossing each other in every direction: this reticular layer was evidently analogous to the coloured layer in negroes. The third or most superficial layer presented a much greater degree of thickness and hardness than the preceding, and in some places exhibited a degree of consistence equal to that of horn: this layer exists only as a rudiment in man, but in animals is more perfectly developed for the production of the various species of shell and horn. 4. External to all these parts was situated the cuticle. (*Andral, Op. cit.*)

Hypertrophy of the Vascular System.—This may be considered as it affects the large blood-vessels, or as it is confined to the capillary system of vessels. The pregnant uterus affords an ex-

ample of hypertrophy or preternatural development of all the blood-vessels which supply the organ; in like manner tumours and all morbid growths are accompanied with an increased development of the arteries and veins which supply them. It is not, however, always easy to determine whether this hypertrophy of the vascular system precedes or follows, is the cause or the effect of, the increased growth of the solids. Dilatation of the aorta, especially at its arch, is often accompanied with considerable thickening of its parietes: in some cases this increased thickness is caused by the uniform hypertrophy of all the coats, in others the middle coat only is affected; when in this state, its natural organization becomes much more apparent; the yellow fibrous tissue of which it is composed becomes as evident in the human subject as it naturally is in the horse, but never presents any trace of muscular fibre even in the most extreme state of hypertrophy. (*Ibid.*)

The morbid alteration of structure described by authors under the name of *accidental erectile tissue*, is caused by hypertrophy of the capillary vessels of the part, which become increased both in size and number, and by being clustered and matted together like the vessels of the placenta, (*Lobstein, Anat. Path.*) form vascular patches or tumours of various shapes and sizes. In some cases these tumours are composed entirely of the capillary vessels in a state of hypertrophy; in others the tumours are composed principally of other anatomical elements, such as excrescences from the mucous membrane, encephaloid tissue, &c., and the capillary vessels, though greatly increased both in size and number, form merely an accessory part of the structure of the morbid growth.—(*See FUNGUS HÆMATODES.*) M. Recamier states that the greater number of hemorrhoidal tumours are composed of the capillary vessels of the anus in a state of hypertrophy. (*Dictionnaire de Médecine.*)

Hypertrophy of the Nervous Tissue.—This has been observed in the brain, spinal marrow, and nerves. The anatomical characters of *hypertrophy of the brain*, as described by Dr. Dance, in the fifth volume of the *Répertoire d'Anatomie*, &c. are the following: "The convolutions of the brain are compressed and flattened, the intervals between them disappear, and it seems as if the investing membranes of the brain had become too tight for it; the substance of the organ is firm, contains but little blood, and appears remarkably dry when cut into. The ventricles are almost entirely effaced, and the various surfaces of the brain deprived of their ordinary moisture." The affection generally involves both hemispheres, but is sometimes confined to one, or even to a part of one. Andral met an instance where the left thalamus opticus was one-fourth larger than the right, which was of its natural dimensions. Laennec mentions, in the second volume of the *Journal de Corvisart*, his having found the brain compressed and squeezed, as if the skull were too small to contain it, in different individuals whom he had supposed to be affected with hydrocephalus. In a memoir published in the *Revue Médicale* for December, 1828, M. Meriadec Laennec has detailed several cases of this disease, from which he

concludes that this change of structure is not excessively rare in its occurrence; that it is constantly accompanied with symptoms of epilepsy; that it develops itself with much greater rapidity than hypertrophy of any other organ, which he attributes to the organization of the texture in which it is seated; and, lastly, that the causes of the lead colic appear to have a very great influence in developing hypertrophy of the brain. In some cases the increased growth of the brain is so considerable as to produce an evident enlargement of the skull.

Dr. Elliotson relates the case of a lad who was remarkably precocious; his head was larger than the ordinary size of adults; he suddenly became apoplectic, hemiplegic, and died. On dissection the brain appeared much larger than it should be, and looked as if it had been ready to burst the skull asunder. (*Medical Gazette*, No. 217.) A similar case is recorded by M. Scoutetten, in the seventh volume of the *Archives de Médecine*. A child only five years old had an enormously large head, totally disproportioned to his age and size; his intellect was not in any way remarkable; his general health was good; and he died of an acute attack of gastro-enteritis. On dissection, the dura mater was found firmly attached to the skull, and the brain filled the head so completely, that on the roof of the skull being removed, it started out as if it had been relieved from considerable pressure: it was principally the superior and posterior parts of the hemisphere which had acquired this extraordinary development; for on making a perpendicular incision into the lateral ventricles, it was necessary to make a section three inches deep to reach them from above, while from below they were within an inch of the surface. It does not appear that this condition of the brain is constantly attended with any particular derangement of its functions; in the case related by M. Scoutetten, there were no symptoms of cerebral disease; in M. Laennec's cases the symptoms were those of hydrocephalus. In those detailed by his cousin M. Meriadec Laennec, the patients had paroxysms similar to those of epilepsy; and in the cases observed by Andral, the symptoms were in some instances analogous to those of epilepsy, and in others the individuals were suddenly seized with convulsions, in the midst of which they expired. (*Op. cit.* p. 775.)

Hypertrophy of the Spinal Marrow presents the following characters: its substance is remarkably firm, and so increased in size as to fill up completely the cavity of the vertebral canal. (*Andral*, *Op. cit.*) Laennec found the spinal cord affected in this way throughout its entire length. Andral found the cervical portion of the cord hypertrophied in a child affected with epilepsy. Hutin, (*Bibliothèque Médicale*, 1828,) Ucelli, (*Clinica dello Spedale della Sta. Maria di Firenze*, 1823,) and Ollivier, have likewise described this disease: respecting its pathology nothing certain is as yet known.

The Nerves are also liable to an excessive development from hypertrophy. The ends of the nerves after amputation often become very large, and have their sensibility morbidly increased. Bichat describes this alteration as occurring frequently in the neighbourhood of organs affected

with cancer. Gendrin found the *nervus sapaenus* of three times its ordinary thickness, in the neighbourhood of a chronic ulcer on the leg of an old man. The same appearances have been also seen and described by Swan. (*Observations on some Points relating to the Nervous System*.)

A remarkable instance of hypertrophy affecting detached points along the course of the nerves, in a cretin, is recorded in the *London Medical and Physical Journal*, for 1826. The inferior maxillary nerve presented several swellings as large as peas in all its branches, and the portio dura of the seventh, the eighth pair, and almost all the spinal nerves were similarly affected; the ganglions of the sympathetic were much larger than usual; that opposite the sixth vertebra was as large as a hen's egg flattened. This preternatural development of the ganglionic system has likewise been observed by other anatomists in cases of congenital idiocy. (*Essai sur l'Idiotie*, par Belhomme.) Dr. Duncan found the abdominal portion of the sympathetic nerve increased to three or four times its natural size in a case of diabetes, and Lobstein found the supra-renal plexus greatly hypertrophied in a case of diseased supra-renal capsule. We have already stated, when speaking of hypertrophy of the vascular system, that in all cases of preternatural development or morbid growths, the blood-vessels which supply the part exhibit a proportionate increase of size; the nerves have not been observed to undergo a similar change. In hypertrophy of the nerves, it is important to distinguish whether the nervous pulp is affected, or merely its neurilema.

Hypertrophy of the Fibrous Tissue.—This is usually produced by irritation or chronic inflammation. This tissue has a remarkable tendency, when hypertrophied, to be transformed into fibro-cartilage, and to pass from thence by a second transformation into bone. These successive changes are frequently exemplified in the margins of the different orifices of the heart and in the valves, the thickening and subsequent ossification of which often arise from hypertrophy of the fibrous tissue, which enters in a rudimentary state into their anatomical structure.

Hypertrophy of Bone.—The osseous system presents two forms of hypertrophy, according as its animal or calcareous substance is principally affected. In some cases both these alterations are combined. The bones are sometimes found uniformly enlarged throughout their entire structure, so as to attain in some instances to double their ordinary size and weight. This form of hypertrophy, which seems productive of no inconvenience during life, is seldom or never confined to a single bone, but affects the entire set, whether of the cranium, the thorax, the pelvis, or the upper or lower extremities; it is generally supposed to be congenital. Dr. Gall states that the skulls of idiots from birth are much thicker than those of other men, (*Dict. des Sciences Méd.*, art. *Crane*), and Lobstein remarks that the skulls of dwarfs are not only large in proportion to the other parts of the body, but that they actually exceed in size and weight the skulls of ordinary sized persons. (*Traité d'Anatomie Pathologique*.) In rachitis the bones affected usually present an increase of size, accompanied with a diminution of weight

and consistence, owing to hypertrophy of their animal substance, and the atrophy of their calcareous particles; but in some time after the rachitic affection has subsided, the bones usually attain a preternatural degree of density and strength. Mr. Stanley has observed that the copious deposition of calcareous matter, by which this change is effected, takes place principally at the inner side of the incurvated bone. (*Medico-Chir. Trans.*, vol. vii.) In the disease known by the name of *fragilitas ossium*, the atrophy of the animal substance, which is the immediate cause of the brittleness, is frequently accompanied with hypertrophy of the calcareous matter. The ivory-like induration, or *eburnation* as it has been termed, is most frequently met with in the flat bones of the cranium, and in the extremities of fractured bones between which a false joint has been established. A minor degree of condensation of the osseous structure is frequently caused by injury and inflammation of the part, or of its investing membrane, as in the union of fractures, &c. Dr. Gall preserved in his museum the skull of a soldier who received several severe blows on his head from the butt-end of a musket at the battle of Ohakow; he became delirious in consequence, and lived in that state for thirty years; the bones of his skull were exactly like ivory. Several anatomists have observed that the skulls of furious maniacs are remarkable for the extreme density and compactness of their texture: this alteration is in all probability connected with the irritation of their meningeal membranes. Nodes and exostoses are examples of local hypertrophy of the osseous system.

Hypertrophy of the Lungs.—Laennec has remarked that when one of the lungs is destroyed, or from any cause rendered unfit for the performance of its functions, its fellow acquires a double energy, consequently an increase of nutrition, and after a certain time an augmentation of volume, and becomes at the same time firmer, more elastic, and compact. In place of collapsing when the chest is laid open, it sometimes protrudes from it, as if the space that contained it were too small. In instances of this sort it cannot be doubted that the air-cells are enlarged, and that their parietes have acquired a preternatural thickness, although it is extremely difficult to prove this even with the aid of the microscope. Hypertrophy of the lungs is sometimes formed in a very short space of time: in the case of a man who had pleurisy and consequent contraction of the chest, the opposite lung was found hypertrophied in the highest degree only six months after the commencement of the disease. (Laennec on Diseases of the Chest.)

Hypertrophy of the Liver.—This gland is frequently affected with hypertrophy. In its natural state it is composed of two distinct substances; one reddish, formed chiefly by the minute ramifications of the capillary blood-vessels; the other white or yellowish, which seems chiefly destined for the secretion of bile; these two substances, together with their frame-work of cellular tissue, form the parenchyma of the liver, and the hypertrophy may be confined to either of the substances singly, or may affect them all conjointly. These different forms of hypertrophy produce several

varieties in the colour, consistence, and form of the organ, which are usually attributed to the development of new morbid productions, such as *schirrhus*, *cirrhosis*, &c. There are two degrees of hypertrophy of the white substance; in the first, the parenchyma of the organ is traversed by lines or circumvolutions of a yellowish white colour; in the second, both its interior and exterior are studded with numerous granules, either isolated or agglomerated, and remarkable for their colour, resembling that of yellow wax; these yellow granules, which are merely the white substance in a state of hypertrophy, Laennec regarded as an accidental tissue developed in the liver, and termed it *cirrhosis*, from its colour. This affection is described by Baillie as the *common tubercle* of the liver, and is generally known in this country by the name of *drunkard's liver*. The red substance is likewise susceptible of a very remarkable kind of hypertrophy, which produces in the interior of the liver small hard red masses, distinguished from the surrounding parenchyma by their greater consistence and deeper colour. The cellular tissue of the liver is likewise liable to hypertrophy, in which case the organ loses its peculiar structure and organization, and large patches are found in it occupied only by cellular tissue in a state of hypertrophy. In all those cases the hypertrophy of one of the elementary tissues of the liver is accompanied with a corresponding degree of atrophy of the other tissues; but in some instances they all participate in the hypertrophy, and the parenchyma of the organ acquires an extraordinary development. This increased growth of the parenchymatous structure of the organ may take place in all the three lobes, or may be confined to one of them. Sometimes the right lobe is the one affected, and constitutes almost the entire organ, the left appearing like a small appendage attached to it; sometimes, again, it is the left lobe that is particularly enlarged, and the liver then projects considerably into the left hypochondrium, and, when felt through the abdominal parietes, might be taken for the spleen; in other cases the projection is observed only in the epigastrium, when it might be mistaken for a tumour of the stomach. (*Andral*, Op. cit.) The causes that give rise to the different forms of hypertrophy of the liver are as yet unknown, it being a mere hypothesis to attribute them to inflammation; neither are we acquainted with any peculiar symptoms by which they may be detected or discriminated during the life of the individual from each other, or from other organic changes of that viscus. When the liver is much increased in size, its dimensions may be ascertained with tolerable accuracy by the extent of surface, which yields a dull sound on percussion.

Hypertrophy of the Spleen.—The spleen is more frequently perhaps than any other organ enlarged beyond its natural dimensions: this increase of size, which is sometimes very considerable, is most commonly produced by the accumulation of blood within the splenic cells, but in some cases arises from a true hypertrophy of the parenchyma of the organ. When cut into, the natural structure seems to be preserved, except that it is much more solid and condensed than usual, and is intersected by a number of opaque white lines,

formed by the hypertrophy of its septa. Dr. Baillie states, that though this may be looked upon as a monstrous growth of the spleen rather than as a disease, yet it may produce inconvenience by its pressure, and by altering in some degree the situation of the neighbouring viscera. (Morbid Anatomy.)

Hypertrophy of the Pancreas.—This gland is sometimes greatly hypertrophied, and as the cellular substance which intersects its substance participates in the affection, the viscus loses a good deal of its natural appearance, and is converted into a hard white mass, intersected by opaque membranous septa, not unlike scirrhus in other parts of the body.

Hypertrophy of the Kidney.—The kidneys are sometimes found much larger than usual, without exhibiting any other change of structure; indeed, it generally happens that when one is incapable of performing its functions, either from original malformation or disease, the other, having double duty to perform, becomes preternaturally enlarged. Hypertrophy of the kidneys is said to be a frequent appearance in diabetes. (Andral.) We have, however, seen several exceptions to this statement.

Hypertrophy of the Lymphatic Glands.—The lymphatic ganglions are frequently found in a state of chronic enlargement. We have seen the mesenteric glands in *tabes mesenterica* increased to four or five times their natural size, without presenting any appearance of degeneration or transformation of tissue. Cruikshanks mentions an instance in which the lymphatic glands in the neighbourhood of the bifurcation of the trachea were affected with this morbid change to such an extent as to cause fatal suffocation. In the internal iliac glands it is not uncommon, so as to form large indurated masses, and in the female may operate as a cause of difficult parturition, equally fatal to the mother and the child. (Anatomy of the Absorbing Vessels.)

Hypertrophy of the Thyroid.—Hypertrophy of the thyroid constitutes the disease known by the name of goitre or bronchocele, which is endemic in certain countries, and is generally supposed to depend on certain conditions of the air and water. (See BRONCHOCELE.)

Hypertrophy of the Thymus.—It is by no means uncommon to find the *thymus* preternaturally developed in scrofulous or rachitic children. We have seen it so large in some cases as to cause an evident projection of the sternum.

Hypertrophy of the Mammary Glands.—The mammary glands are sometimes enormously developed. Dr. Joerdens relates an instance in which they grew to such a size as to reach down to the thighs. (Hufeland's Journal.)

Enlargement of the prostate arising from an increased development of its natural structure is by no means uncommon at an advanced period of life: this affection may involve the entire gland, or may be confined to one of its sides, or to its middle lobe. Hypertrophy of the prostate causes considerable difficulty in voiding the urine by mechanically obstructing the neck of the bladder; it likewise occasions a difficulty in passing the feces by its pressure on the rectum.

From the brief sketch we have drawn of some

of the most remarkable effects of hypertrophy on the several tissues and organs in which it has been observed, it appears that this affection is one of extremely frequent occurrence, and productive of a great variety of morbid appearances which pathologists have only recently learned to refer to their true source.

If, from the consideration of the physical characters of this affection, we turn to the investigation of its immediate or proximate cause, we find that it consists in an excessive activity of the natural function of nutrition. In order to describe the mechanism of this excessive nutrition, it will be necessary to premise a few observations on the mode in which this process is accomplished in the natural or healthy state. The process of nutrition essentially consists in the several solids alternately receiving from and returning to the common nutritive fluid, the blood, a succession of particles similar to those of which their structure is naturally composed. The appropriation of the new particles is termed assimilation, and the detachment and removal of the old particles is known by the name of de-assimilation, or of interstitial absorption. Various opinions have been entertained by pathologists respecting the mechanism by which these changes are accomplished. According to Bichat, each organic tissue is supposed to have its appropriate exhalant arteries, from which it derives the materials requisite for its nutrition; these exhalants he supposes endowed with a peculiar sensibility, by virtue of which they are enabled to select from the blood and convey to their destination those precise ingredients which are fitted for the building up of the tissue or organ they supply; for example, he supposes that the bones possess a set of exhalant actions, which convey nothing but the calcareous phosphates; that the muscles have likewise a set of exhalants that convey only fibrine; and that there are likewise a particular set of nutritive exhalants for conveying albumen, gelatine, &c.: he likewise supposes the existence of a separate set of vessels for the removal of each of these substances. The existence of such a series of vessels has, however, never been demonstrated by dissection, and it is now generally believed that the elements of all the secretions are contained in the blood; that this fluid, holding all the different elements in solution, is conveyed by the capillary circulation to the intimate structure of the different solids, and that it is only by the plastic force inherent in the solids themselves that these elements are separated and applied to their destined purposes. According to this view of the subject, it is the several tissues themselves and the molecules of which they are composed that select their constituent ingredients from the blood, and appropriate them to their construction and support; and the power of assimilation is shared by every particle of every living solid in the body. This faculty of assimilation is compared by Lobstein to the action of a crystal, which when plunged in a saline solution attracts towards itself and promotes the crystallization of those saline particles homogenous to itself, which were suspended in the fluid; so in like manner he conceives the organic molecule selects from the blood those elements which are homogeneous to it. (Traité d'Anatomie Pathologique.)

In hypertrophy this assimilation or plastic force is preternaturally increased, and the consequence is that an excessive quantity of nutritious particles are assimilated, and the tissue or organ affected is over-nourished, that is, hypertrophied. Andral supposes that the same effect may be produced by a defect in the activity of the de-assimilating powers; that the absorbents do not carry away the materials they ought; and that in this way an accumulation of nutritious particles takes place independently of any increase in the assimilating powers of the part; and he adduces, in support of this hypothesis, the well-known fact that hypertrophies which have been combated in vain by bloodletting and emollient applications, often yield to the use of stimulants, such as iodine, mercury, &c. Again, the production of this alteration of structure has been by many pathologists attributed to an increased afflux of blood towards the part affected. This increased local determination of blood may readily be conceived to perform a very important part in the production of hypertrophy, but cannot be considered as its sole, or even as its most efficient cause; for it is evident that the increased determination of blood to an organ can of itself only produce the congestion of that organ, but can never cause its hypertrophy unless when aided by a corresponding increase in the assimilating powers of the part; and if we admit an increase of those powers, the other condition becomes unnecessary, for the increased powers of assimilation, by their more active appropriation of the nutritive particles contained in the ordinary supply of blood, are sufficient to produce the preternatural growth of hypertrophy of the heart, independently of any increase of the quantity of the nutritive fluid. (*Andral, Op. cit.*)

Lastly, hypertrophy has been described by some authors as having an inflammatory origin; but this etiology of the affection, though correct in many instances, is inapplicable to many cases of excessive nutrition. In those unhealthy districts of the Alps, for instance, where bronchocele exists as an endemic disease, the individuals affected are for the most part sickly, pale, and exanguinous; there is no evidence in them of any inflammatory actions, either present or antecedent, and yet not only the thyroid, but the liver, the tongue, and the bones are often hypertrophied to an extreme degree in these cases: so also in scrofula and rachitis, the mesenteric glands, the upper lip, and the ends of the bones are often considerably enlarged, and yet such persons are not instances of increased vigour or of the inflammatory diathesis.

It is true that in many cases the first phenomenon which presents itself to our notice in the part where hypertrophy is subsequently to take place, is a degree of local irritation, attended with more or less of sanguineous congestion; but there are also many cases besides those we have specified where no symptoms of any such antecedent irritation can be observed. Indeed, as M. Andral remarks, its existence cannot always be fairly admitted either from analogy or induction; and even when present, it can only be regarded as giving rise to some derangement in the process of nutrition, but is altogether inadequate to account for the peculiar character of the alteration which ensues. In theory we have no reason to suppose

that the hypertrophy or increased nutrition of an organ is necessarily preceded by inflammation, and in point of fact we ought not to admit a necessary connection between these two orders of phenomena, since in many cases we find them existing singly, without the slightest proof of having been preceded or accompanied by the other.

In the present state of our pathological knowledge, it is perhaps premature to speculate on the proximate cause of hypertrophy, or to found our treatment exclusively on either of these theories: until we know how the process of nutrition is accomplished in health, it is idle to theorize on its accomplishment in disease. If we cannot comprehend how muscle or bone is formed from the blood in their due proportion, it need be no matter of surprise that we cannot explain how these substances are occasionally formed in excessive quantities. But though we cannot scrutinize the first causes of these processes, we may nevertheless observe the influence of circumstances in modifying their results, even though we cannot in all cases comprehend the precise mode of their operation. Thus, we learn from observation that the extirpation of the testes in the male, or of the ovaries in the female, has a marked tendency to produce an excessive development of the adipose tissue; in like manner we learn that a residence in certain countries causes hypertrophy of the thyroid; that syphilis produces nodes and exostoses; rachitis, enlargement of the ends of the bones; scrofula, of the lymphatic ganglions, &c.; and that irritation of the mucous membrane of the colon produces hypertrophy of the subjacent layer of cellular tissue, although the *modus operandi* of these causes is by no means equally obvious.

We would, therefore, recommend that the treatment of this affection should not be founded exclusively on either of the theories that have been formed respecting its proximate cause, but that the existence of hypertrophy being once ascertained, we should endeavour to discover, *experimentally*, what are the most efficient means of combating and subduing it. By adopting this method of proceeding, iodine has been discovered to possess the power of dissipating hypertrophy of the thyroid, and mercury has been proved a no less powerful agent in removing certain forms of exostoses. (*Andral, Op. cit.*)

The **exciting causes** of hypertrophy, so far as we are acquainted with them, may be divided into those which act through the medium of the constitution, and those which act locally. To the first class may be referred,—

1. That condition of climate or soil which renders bronchocele and cretinism endemic in certain districts of the globe. (*See BRONCHOCELE.*)
2. A peculiar idiosyncrasy or predisposition to the excessive development of the solids generally, or of certain tissues or organs in particular. This state of the constitution is remarkably exemplified in the disposition which certain individuals evince to accumulate fat under circumstances where others would almost die of inanition, as in the remarkable case of obesity related in a preceding part of this article. A still more remarkable case of general hypertrophy is recorded in the first volume of the *Journal Hebdomadaire*, p. 76. The individual was a strong healthy country girl, until,

at the age of 18, the menstrual discharge ceased suddenly after exposure to a violent storm, and from that time she became subject to headach, numbness of the limbs, and shortness of breathing: these symptoms were attended with a gradual and progressive hypertrophy of her muscular, cutaneous, cellular, and adipose tissues, until at the end of eleven years after the suppression she presented the following appearances. Her height remained unaltered (five feet two inches); the skull was of the ordinary dimensions, but appeared exceedingly small in comparison to the face, which was enormously developed; the skin of the forehead, the eyelids, and eyebrows, nose, lips, cheeks, and chin, were of such a monstrous size as to suggest the idea of a mask meant for a giant at least eight feet in height. The tongue was so large as to fill the mouth almost completely; the neck could only be compared to that of the Farnese Hercules. The mammaræ were of an enormous size, and reached almost to the chin. The circumference of the trunk was equal to the height of the individual: but this prodigious size was not caused by the excessive accumulation of fat alone, as the muscles were everywhere largely developed, and appeared perfectly defined under the skin. The upper and lower extremities seemed disproportionately short on account of their enormous bulk, and the hands are represented to have been quite a curiosity for their size. The heart was hypertrophied in the same proportion as the other parts of the muscular system, and at each contraction struck the chest with such violence as to give the ear, when applied over it, a very smart blow. The brain likewise participated in the affection, and its faculties gradually merged into a state of idiocy. In this case, though the origin of the excess of nutrition may be traced to the suppression of the menstrual discharge, it is impossible to refuse admitting an idiosyncrasy on the part of the individual, as suppression of the catamenia is not necessarily or even generally followed by any such alteration in the nutrition of the solids.

3. Syphilis and the abuse of mercury, which are known to produce hypertrophy of the osseous system in the form of nodes and exostoses.

4. Scrofula and rachitis, which have been observed to cause enlargement of the thymus, lips, and tongue, of the lymphatic and mesenteric ganglions, and of several parts of the osseous system, especially the ends of the long bones.

5. Full living and sedentary inactive habits, which usually dispose to excessive development of the adipose tissue.

Such are the principal general or constitutional causes of hypertrophy which observation has pointed out; but it must be confessed that the enumeration is by no means complete, and that the subject requires further investigation.

Among the principal local causes of hypertrophy may be enumerated the following:—

1. Irritation or inflammation, especially when it assumes a chronic character. We have already stated that this is by far the most frequent cause of hypertrophy. On referring to the descriptions we have given of this affection, it will be found that in a great majority of cases, hypertrophy of the mucous, cutaneous, and cellular, as well as of the fibrous and osseous tissues, may be referred

to this source. In such cases the hypertrophy is sometimes confined to the tissue which was previously in a state of irritation, while sometimes, after the tissue originally affected has returned to its natural healthy condition, the adjacent tissues retain a chronic form of disease, and fall into a state of hypertrophy.

2. Increased exercise of the functions of the affected organs. The agency of this cause in producing hypertrophy is most evident in the muscular and glandular system. It has been observed that persons who have lost the use of one arm or leg generally acquire an extraordinary degree of strength in the other, from the increased use that is made of it. In like manner, when one of the double organs, such as the kidneys or lungs, is rendered incapable of performing its functions with effect, the other, having double duty to perform, acquires a proportionate increase of development. Examples of hypertrophy of the muscular structure of the heart, bronchi, stomach, intestines, and bladder, arising from increased exercise of the fibres, have already been adduced.

Treatment of Hypertrophy.—For all that is practically important respecting the treatment of hypertrophy, we must refer to the different articles in which the various species are noticed individually. We shall here content ourselves with a few general observations.

In the treatment of hypertrophy the first and most obvious indication is to remove, if possible, the exciting cause of the disease, as until that object is accomplished, our treatment can at best be but palliative, and in general, when the cause which originally produced the hypertrophy is removed, the nutrition of the organ promptly returns to its natural standard: "*ablata causa, tollitur effectus.*" As the alteration of nutrition is in most cases preceded or accompanied by evident symptoms of increased vascular action, the usual remedies for inflammation, viz., venesection, strict antiphlogistic regimen, and perfect rest, are those most generally indicated; but we must not suppose that these remedies are equally applicable in every case, as the state of the constitution, and the circumstances under which the hypertrophy occurs, sometimes indicate a different or even opposite mode of treatment. When, for instance, the affection arises from scrofula, rachitis, or the residence in a country of cretins, the antiphlogistic regimen would only serve to aggravate the disease, and pure air and generous diet become in such cases the most valuable remedies. So, in like manner, when hypertrophy of one of the lungs or kidneys arises from increased action that is thrown on it by its fellow being incapacitated for performing its functions with effect, the diminution of its increased action, either by the exhibition of appropriate remedies, or, more effectually still, by restoring its fellow to the due discharge of its functions, will be found more efficacious in reducing the nutrition of the hypertrophied organ to its healthy standard than the most active depletory treatment. Again, it would be in vain to attempt combating by general or topical depletion the hypertrophied condition of the walls of the bladder so long as the presence of calculi in its interior kept up the irritation of its mucous membrane, and thereby maintained its muscular fibres in a

state of frequent and violent action; for by such treatment we do not remove the cause of the disease, but only palliate its effects. Even this, however, becomes an object of considerable importance to the practitioner, when the cause of the hypertrophy is of such a nature as to baffle our attempts at its removal; as, for instance, in hypertrophy of the heart arising from organic disease of the valves.

There are but few medicines with which we are acquainted that possess any specific control over this affection; of these the most effectual are iodine and mercury. The former has been found a specific in bronchocele, and has occasionally succeeded in dissipating enlargements of the lymphatic glands; and mercury has been found highly serviceable in removing enlargements of the bones, especially when proceeding from a syphilitic taint. When the hypertrophy arises from any of the constitutional causes we have enumerated, the treatment should be directed to the removal of that morbid state of the system on which it depends, and of which it is merely a symptom, and the tonic or antiphlogistic regimen prescribed, according as the system requires to be invigorated or reduced. So, likewise, with respect to the topical treatment of this affection: when the part affected admits of such, the applications must be varied according as it exhibits excessive or deficient vascular action: in the first case local abstraction of blood, fomentation and cataplasms may be applied, while in the second case stimulating applications and blisters will occasionally be found serviceable. It is impossible, therefore, to lay down any general plan of treatment universally applicable; each form of the disease must be treated with reference to its exciting cause, and more as the effect of a pre-existing disease than as a specific affection. In a general pathological article like the present, it would be foreign to our purpose to enter into a detailed account of the appropriate treatment of all the varied forms and different varieties of hypertrophy.

R. TOWNSEND.

HYPOCHONDRIASIS.—1. *Definition and characteristic of the disease.*—Hypochondriasis, or the hypochondriac malady, is a disease in which symptoms of dyspepsia, such as flatulence, eructation, with a sense of uneasiness in the stomach and hypochondria, are combined with a remarkable lowness of spirits or a desponding habit of mind, and a constant disposition to attend to every minute change in the bodily feelings, and to apprehend extreme danger from the most trifling ailments. The last-mentioned feature in the complaint has been particularly selected and strongly described by the nosological writers. “Desperant ægri de suâ valetudine recuperandâ ob ructus, borborygmus, palpitationes, tremorem præcordiorum, fugaces vertigines, flatulentiam. Hinc persuasi fatum lethale sibi imminere, omnia symptomata et minimas mutationes in corpore suo scrupulosè observant, narrant et describunt medicis, suisque querelis alios mox et alios defatigant, ingenio cæterum et appetitu pollentes.” (*Sagar. Nosolog.*) By some writers hypochondriasis has been regarded as a mere variety or accidental modification of dyspepsia. Nearly in this light it ap-

pears to have been considered by Hoffmann, who wrote an able but somewhat prolix treatise “de malo hypochondriaco.” (*Opera Hoffmanni*, tom. iii.) He termed it “a spasmodico-flatulent affection of the primæ viæ, namely, of the stomach and intestines, arising from a disturbed and inverted peristaltic action, by sympathy throwing the whole nervous system into commotion, and deranging all the functions of the animal economy.” Sydenham in his celebrated treatise on hysteric diseases identifies those disorders with hypochondriasis. He says that the most peculiar symptom is the “making large quantities of urine as clear as rock-water.” This, on “diligent inquiry, he found to be the distinguishing sign of those disorders, which we call hypochondriacal in men and hysteric in women.” Hoffmann strenuously opposed this doctrine, and insisted on the position that, although the hypochondriacal and hysterical diseases have many symptoms in common, yet they have also several peculiar ones, which fully manifest an essential difference in their nature. Among the reasons which he assigns for this opinion, some of which are quaintly expressed, is the circumstance that “no hypochondriacs were ever judged to be dead, and intended to be interred, which,” he says, “is credibly reported of hysteric subjects.”

2. *Description of the phenomena.*—A most striking circumstance in the description of hypochondriacal affections is the remarkable difference which is observable between the appearance of the patient and the state of his health as collected from his own account of his symptoms and internal feelings. The individual who labours under this malady seldom presents any external indication of disease; he has often the appearance of sound and even of robust health; yet, if we listen to his statements, every function of life, every part in the whole fabric of his body, is in a state of disorder, and the source of acute and almost perpetual suffering. It was observed by Hoffmann that as fever is the most general of acute diseases, and pervades the whole frame and every function of the body, so among chronic complaints this seems to be equally extensive in its influence, affecting the nervous system in every part, and everywhere giving rise to local pains or feelings of distress. The more constant of these complaints are referred to the alimentary canal, and it is in the functions belonging to that part of the animal economy that evident traces of real disease are chiefly to be discovered. The patient complains of distension of the stomach and hypochondria, which are inflated with wind; he often refers his uneasiness chiefly to the left hypochondrium, where there is in reality considerable fulness and induration: in some instances, there is considerable enlargement of the abdomen, with a degree of hardness and a feeling of consolidation which excite suspicion of some organic disease. The tongue is generally clean, or covered with a slight brown coat; the stomach is the seat of every symptom of disordered action; the appetite is often irregular, sometimes voracious and hardly to be satisfied; more frequently there is a total want of inclination to eat, and even a loathing for food; after eating, the patient complains of a sense of weight and uneasiness in the stomach; sometimes this amounts to rather severe pain, which recurs at a short interval after

every meal; and eructations, cardialgia, or a sense of burning heat at the extremity of the œsophagus, ensue, and after a long time wind is expelled in large quantity, with a sense of cramp succeeding the effort; sometimes viscid mucus is brought up, with half-digested food and a fluid so strongly acid as to corrugate the throat and set the teeth on edge. In other cases nausea prevails almost constantly, and prevents the patient from taking sufficient food for supporting strength; when a small portion is swallowed, it produces great irritation in the system, headach, pulsation in the epigastrium, and flushing in the face; occasionally these symptoms are relieved by vomiting. The patient experiences severe pains through different parts of the abdomen, which he describes as burning, twisting, tearing, and distending the bowels; seizing suddenly different parts of the alimentary canal. He feels a momentary relief when wind is expelled, but the sense of distension soon returns. The bowels are often disposed obstinately to constipation; this state gives way occasionally to looseness; when this last condition supervenes, or when it is brought on by cathartic remedies, all the feelings of distress are aggravated; in addition to his former evils, the patient now suffers an intolerable anxiety, a sense of sinking, fainting, trembling, and apprehends that every minute may be his last: he complains of violent palpitations, pulsations of arteries in the abdomen, burning heats, intolerable anguish, whenever his bowels are brought into action.

In the early periods of the disease the complaints refer more particularly to the abdomen; in a more advanced stage this class of symptoms is not diminished, but others are superadded, consisting of a variety of morbid feelings in different parts of the body, but more particularly in the head. Patients complain of violent pains in the forehead and temples, sometimes in the occiput; of severe and distressing headach with intolerance of light. In more frequent cases, they experience, not pain, but some indescribable sensations which are more difficult to endure than the most severe pain; a sense of intolerable pressure on the top of the head threatens at every moment to extinguish consciousness and life itself; the head is as if squeezed in a vice, the scalp is drawn tight, and the eyes are felt as if starting out of the sockets; these sensations alternate with vertigo or a feeling of giddiness; the eyes sparkle, twinkle, grow dim; vision is impaired; it is impossible to look at a book or to direct the eyes for a moment to any near object without experiencing a sense of confusion; there is a noise in the ears like the ringing of bells, bursting, boiling of tea-kettles, rushing of water; the sound of a steam-engine, strange voices, sudden cracklings, whizzings. The power of attention is destroyed, at least the patient is persuaded that such is the fact, though when aroused, by any sudden intrusion, from his tale of sufferings, he is as lively and acute as ever; he cannot think, his ideas are confused. Sometimes he fancies that his understanding is utterly destroyed, that he shall become insane and die in a madhouse. The susceptibility to all impressions on the senses is morbidly increased. Light, sounds, noises, are intolerable. Mental exertion is often the most difficultly endured of all the causes of excitement. If

the feelings are aroused, or the attention is kept alive, especially if it be in the later part of the day, sleep is entirely banished, and a state of general irritation is induced.

The mind labours under a degree of morbid excitement in hypochondriac patients; but this is very distinguishable from all the modifications of insanity. The morbid feelings of the hypochondriac are real; they depend on physical disturbances of the system, which he apprehends to be much greater than they are; and this apprehension leads them to dwell upon them, and make them the subject of conversation whenever he has an opportunity of doing so. Yet he sometimes appears to suspect that the long detail of his sufferings may fatigue the patience or excite the contempt of those who listen to him, and he will even suppress a part of the catalogue of his symptoms, which he is at the same time anxious to communicate. The uncomfortable feelings of the hypochondriac are excessively magnified by his fears and the concentration of his thoughts and attention to his disease, and he may sometimes express weariness of life and a desire that his existence may soon terminate; but it is certain that he is insincere in these expressions, and that he is always under the utmost anxiety to try every possible method for the preservation of his life and the restoration of his health. Such persons will often consult all the physicians of reputation in their vicinity, and will even have recourse to quacks, old wives, and nostrum-mongers; nor is there a remedy that can be suggested too absurd to merit at any rate a trial. An elderly gentleman, who had been for some years labouring under hypochondriasis, combined with amaurosis, sent for a physician in great haste, eagerly requesting an immediate visit. The object of the invalid was to inquire whether any danger would arise from his adopting a remedy which had been strongly recommended by a neighbour or friend. This was to put a piece of stone-brimstone on his head, and walk about the room having it there fixed. He had been persuaded that some great benefits would be derived from this attempt, if it could only be put in practice without risk. The same individual would describe with the greatest minuteness the sensations which he experienced after taking a dinner-pill, and trace its progress through the whole intestinal canal. He could tell by his feelings where the aloes became dissolved, and where it mixed with the aliment, as exactly as if he had seen through the parietes of the abdomen and the coats of the intestines. He would walk about his room in despair, wringing his hands and bemoaning his condition; yet if any person mentioned by chance the subject of a controversy which he was carrying on in a periodical journal, he would forget all his miseries, and enter into conversation with lively interest.

Besides the morbid sensations referred to the abdomen and the head, there are others which affect the limbs. These are sometimes described as if they were neuralgic pains running along the course of the nerves. More frequently feelings of numbness, deadness, tingling, are described as occurring in the legs, arms, or fingers; the head is said to feel dead and benumbed; sometimes this sensation is referred to the back or to the

limbs. Sensations which are considered as most characteristic of hysteria are occasionally described by hypochondriac patients. There is a sort of constriction round the throat, threatening suffocation; but this does not amount to globus hystericus, nor is it accompanied with fits of panting or anhelation. The urine, as in many other disorders affecting the nervous system, is copious and colourless. Sydenham mentions the case of a nobleman who laboured, as he says, under "an hypochondriac colic." Whenever he was worse, he voided a clear colourless urine, and on any abatement it became straw-coloured. He was nearly convalescent, when some person coming in suddenly and putting him into a violent passion, "he immediately thereupon made a large quantity of very clear water." The limpid urine of hypochondriac patients has been examined by M. Vauquelin, and found to contain rosacic acid. (*M. Georget, Dict. de Médecine.*)

The functions of the thoracic viscera are sometimes disturbed in hypochondriasis. As in other diseases attended with dyspepsia and flatulence, the heart suffers interruptions in its action; the pulse is often intermitting, more frequently it is variable and irregular; the patient is troubled occasionally with attacks of palpitation, and these are sometimes so severe, and the action of the heart is so violent, as to excite suspicion of organic disease. Nothing is more certain or better known to medical practitioners than the fact that hypochondriacal and hysterical subjects have often been treated under the impression that they laboured under hypertrophy of the ventricles. In some instances hypochondriasis is attended with attacks of dyspnoea and constriction of the chest, a feeling of something squeezing the throat, and other phenomena approaching to those which characterize the paroxysms of hysteria.

All medical authors who have treated on hypochondriasis, and all judicious physicians who have well considered the complaint, are agreed in testifying that the evils which it inflicts are far from unreal and imaginary. To treat them as such, or to let the patient perceive that we do not fully sympathize with him, that we consider his complaint as one which it is in his power by an effort to shake off, is most impolitic and injudicious. Dr. Cheyne, who gave to this disease the designation of the *English malady*, says emphatically, that "of all the miseries which afflict human life and relate principally to the body, nervous disorders in their extreme and last degrees are the most deplorable and beyond all comparison the worst."

No definite observations can be made as to the rise, progress, and duration of hypochondriasis. The causes are chiefly of slow and continued influence, and their effect displays itself for the most part gradually and almost imperceptibly. The disease has been brought on suddenly by some powerful impression on the nervous system, as, for example, by some cause which occasioned overwhelming grief or vexation; but such instances are comparatively few. It continues for years, sometimes through the life of the individual, who cannot escape from the exciting causes which gave rise to it; but it does not of itself shorten life. There is reason, however, to believe that hypochondriacs are more subject than other persons to acquire

organic diseases of the abdominal as well as the thoracic viscera; yet on this subject no exact reports are to be found. The long duration of the disease, the circumstance that persons who labour under it are seldom throughout its course under the care of the same practitioners, and especially that they do not in the ordinary course of things die in hospitals, are sufficient to account for the deficiency of exact information on these points.

3. Diagnosis.—One of the most difficult considerations connected with hypochondriasis is the diagnosis of this disease from others with which it is more or less liable to be confounded, and this is likewise the most important point of view in which the subject can be contemplated. The complaints of the hypochondriac are so multiform that they suggest a great variety of morbid affections, and some of these are among the most severe diseases to which the animal economy is subject. The disorders which are symptomatic of hypochondriasis must in their turn be distinguished from the organic diseases which they simulate, or some fatal error will be likely to arise when the medical practitioner either pursues a more active method of practice than the real circumstances of the case require, or neglects to adopt energetic remedies when absolutely necessary in order to avert impending danger.

When an individual is known to labour under hypochondriasis, this circumstance will often throw light on the nature of his temporary ailments. If such a person complains of dreadful pains in the head, vertigo, temporary loss of sensation and of memory, or of palpitation or intermission of pulse, we shall be on our guard, and shall less readily ascribe such complaints to disease in the head or in the heart, than if they occurred in patients under different circumstances. Still the diagnosis is imperfect unless it is absolute on the negative side, for hypochondriacs may and do become the subjects of organic diseases. Nor is the constitutional disorder of these persons always so marked as we might imagine from the foregoing description of their disease. Hypochondriasis does not affect simultaneously and in every case all the functions said to become deranged. Sometimes its manifestations are distinct and strongly marked in the state of the abdominal viscera, and in such cases there is comparatively little ground for mistake. Sometimes the functions of the heart are considerably deranged when the symptoms are elsewhere obscure. In these instances we know that experienced and skilful practitioners have been deceived. When the disorder is principally seated in the head, it likewise occasions difficulties; and these difficulties are not lessened by the circumstance that the diagnosis is on the negative side.

In order to distinguish hypochondriasis from diseases locally affecting the abdomen, an attentive examination will sometimes be required. (See ABDOMEN, EXPLORATION OF THE.) Care must be taken to distinguish the disorder which we are now considering from organic diseases of the stomach, in cases attended with long-continued vomiting of the ingesta; from affections of the liver and pancreas; from the results of stricture in the intestinal canal: in other instances, from recent though still sub-acute diseases of the same

canal, as from gastro-enteritis, which Broussais is disposed to identify with hypochondriasis. The latter distinction is not always exempt from difficulty; there are many obscure cases in which the disorders are intermixed; and where they exist separately, the diagnosis is not so easy as many persons may be inclined to imagine. We cannot wholly rely on the presence or absence of pain when pressure is made on the abdomen. Little or no pain is in general produced by such pressure in cases of hypochondriasis; and it commonly occasions suffering in some part, when there is much abdominal inflammation. But the mucous membrane of the bowels may be the seat of disease without giving occasion to pain on pressure. On the other hand, hypochondriacs are ready to exclaim whenever they are touched; the excited state of their apprehension augments the real feeling of uneasiness, which depends upon increased sensibility of the sub-cutaneous nerves. It will be found, however, that they bear a strong and continued impression better than a slight and momentary one. The state of the bowels in hypochondriasis is generally rather constipated, and often loose and irritable in gastro-enteritis; but these observations are not very unfrequently reversed. The absence of febrile symptoms; the capability of using exercise; the more healthy appearance of the countenance; the preservation of muscular strength and fulness, with the condition of the appetite, which in many cases of hypochondriasis is unimpaired, and in others greater than usual; will in most instances enable the practitioner to distinguish this disease from gastro-enteric inflammation.

The signs have often been laid down by which disorders of the heart depending upon organic causes are distinguishable from the irregularities arising from dyspeptic and nervous complaints. During the paroxysms of palpitation which belong to this latter description of disease, symptoms are often perceived which lead to the suspicion of organic affection. M. Andral has indeed observed that the pulsations of the heart are often irregular, and accompanied with a "*bruit de soufflet*" in cases purely hypochondriacal or nervous. He has observed violent palpitation succeeded during the interval of the attacks by morbid dyspnoea and even perceptible swelling of the face, in cases which were independent of any organic disease of the heart.

These remarks will be sufficient to show that practitioners should be upon their guard in pronouncing as to the nature of disorders in the functions of the heart affecting hypochondriacs. It would be superfluous under this head to go into detail on the pathognomonic signs of organic diseases of the heart, as these have been fully considered in their proper place. The proof that complaints referred to the heart are hypochondriacal and not organic is likewise in a great measure of a negative kind. If the patient is low-spirited and nervous, if he has been known to be subject to hypochondriasis, the probability is on this side. If he has never undergone any apoplectic, epileptic, or paralytic attack; if he preserves his natural and habitual degree of muscular power, and his senses are not in any way impaired; if all the functions of his brain are uninjured, we may al-

most venture to conclude that the complaints which he makes of morbid sensations in the head do not indicate so much danger as he supposes. Still, when these complaints are accompanied by discoverable signs of irregular circulation; when the vessels are full and beating forcibly, the head hot and flushed; and when the general appearance indicates a plethoric state of the vascular system in the head, it will be advisable to relieve this state of depletion, either general or local, according to circumstances.

Hypochondriasis must be distinguished from insanity. The discrimination is not difficult. Persons who labour under the former disease have possession of their reason, and the sufferings they describe are really experienced by them, though not so dangerous as they are supposed by the sufferer to be. If a hypochondriac begins to declare that his head or his nose is too large to pass through a door-way, or displays any other hallucination, he has become a lunatic: his disorder has changed its nature, and this conversion takes place occasionally, though it is by no means so frequent as many persons probably apprehend. Hypochondriacs, though low-spirited and dejected, are in a very different state of existence from persons labouring under melancholia. The apprehensions of the former are all centred on the state of their bodily health: on other subjects, they think and often converse rationally and with cheerfulness. The melancholic views all things through a medium of gloom and despondency. Lastly, the feelings and affections of hypochondriacs are not in that perverted and unnatural state which is one of the characteristics of madness in nearly all its forms.

Causes of Hypochondriasis.—There is no particular constitution or temperament of body, at least there is none distinguished by known external characters, that is remarkably subject more than others to hypochondriasis. We have observed this disease frequently affecting persons who bore all the external marks of the sanguine temperament as well as others who had the characters of the melancholic.

The middle period of life, and perhaps the interval between the twenty-fifth and the fiftieth year, is the age which is principally disposed to this disease. It seldom attacks young persons, or, for the first time, those advanced in years. Men are more subject to it than women, though in the latter it not unfrequently occurs. This, however, is seldom the case in respect to young females. With them disorders of the nervous system are more disposed to assume the character of hysteria. Females upwards of fifty years of age are often subject to dyspepsia, flatulence, eructations, gastrodynia, attended with gloom, depression of spirits, and other symptoms of the hypochondriac malady, though not frequently in so strongly marked a form as that which it assumes in men.

The predisposing causes of hypochondriasis, or the antecedent circumstances which are followed by that disease, belong to two different classes, one of which are influences affecting the mind directly and the functions of the body only through this medium: the other series of morbid agents produce their effect, in the first instance, on the

abdominal viscera and the processes of physical life; the affection of the mind which follows being apparently dependent on this derangement.

These morbid influences are sometimes blended in the habits of life which produce a peculiar tendency to hypochondriasis. Such are the modes of existence which allow of little bodily exercise, and at the same time occasion an overstrained and continued exertion of the mind. The state of manners in civilized society gives rise to this unfortunate combination of circumstances in a thousand ways, and multiplies, together with the comforts of life, all the sources of mental fatigue and over-exertion, and consequently the number of hypochondriacs. Intense and long-continued exercise of the intellect in one pursuit, whatever it may be, is frequently the cause of this disease. Hence hypochondriasis has been termed the disorder of literary men, "*morbus literatorum*;" and Hoffmann says that its victims are chiefly "*vir chartis impallescens et inter libros sepultus*." Clergymen, school-masters, persons employed in diplomatic business, and in other occupations requiring activity of mind, and giving occasion to sedentary habits, are equally liable to be attacked by it.

Among the classes of sedentary men who frequently become hypochondriacal are tailors and shoemakers. Their constant habit of sitting at their trades, and their peculiar modes of sitting, probably occasion a torpid state of the intestinal canal, and disorder of the functions connected with it. Their minds are also active beyond their craft; witness the proverb, *ne sutor, &c.* and the number of preachers, theosophists, founders of sects, and political reformers, who have arisen from the cobbler's stall and the tailor's board.

There are other classes of persons whose predisposition to hypochondriasis cannot be explained in the same way. Agricultural labourers, men who spend a great portion of their time in working in fields, in digging, making and mending hedges and ditches, and in solitary employments in the country, are frequently affected with low spirits and the other characteristics of this disorder. The solitariness of their employments is probably the chief predisposing circumstance.

Some medical authors are inclined to suppose that hypochondriasis arises almost solely from causes affecting immediately the brain and nervous system. Several French writers have maintained this opinion, and probably it may be better supported by facts in France than in this country. M. Louyer de Villermay, in his work entitled "*Traité des Maladies Nerveuses*," has adduced evidence which bears upon this inquiry, and it is only to be regretted that the sphere from which it was drawn was not more extensive. Out of thirty-six cases of hypochondriasis recorded by this writer, the disease appears to have arisen in twenty-two from "moral affections of a painful description," by which we are to understand causes giving rise to mental distress: in eight cases out of the same number it was occasioned by too close application to study; in two it arose from fright or sudden alarm; in two it followed an immediate transition from a state of life requiring great activity to one of ease and leisure. These facts are favourable to the opinion that hypochondriasis

is a primary disorder of the nervous system, a conclusion which has been adopted and supported with much ingenuity by M. Georget. This writer considers the disease in question to be one of the brain, excited by the influence of moral agents, or by those causes which act in a hurtful manner on the mind, and through that medium on the brain. He observes, in support of this opinion, that hypochondriasis is most common in the higher classes of society, among persons occupied in official and diplomatic business, or devoted to literary pursuits. "England," he adds, "is perhaps the country where this species of nervous disease chiefly abounds: this is principally owing to the prodigious activity of mind which exists in that country; to the miseries which are contingent on the great development of industry; to fortunes rapidly acquired in commerce by a number of individuals who subsequently pass their whole lives without employment, in excesses of every description." In this last particular, M. Georget has expressed himself rather conjecturally than from a knowledge of facts. It cannot be truly said that a considerable proportion of those persons who accumulate property in this country by the exertions of industry, abandon themselves afterwards to excesses of all descriptions. Indeed the excesses of vulgar dissipation are not to be reckoned among the ordinary causes of hypochondriasis. This disease seldom attacks persons who are addicted to the immoderate use of fermented liquors; it rather falls to the lot of those who are abstemious in this respect.

Hypochondriasis is not in reality confined to the better classes of society, or to persons of cultivated minds, on whom moral causes may be supposed to act with the most extensive influence. Cases occur frequently in hospitals, and therefore among the lower orders. The writer of the present article has had under his care, or at least under his occasional observation upwards of twenty years, two patients of this description who are among the most ignorant of the lower class of peasants. They both furnish strongly-marked examples of hypochondriasis; both have been tormented during a great part of the space above mentioned by the numerous and frequently varying but ideal miseries which accompany that disease. In both of these persons the nervous system appears to have been originally weak and susceptible of impressions; but the causes which actually gave rise to morbid phenomena in their constitutions could scarcely belong to the class of moral agents: they were circumstances which induced disorder in the physical or natural functions. The same conclusion may be drawn with great probability in most of those instances of hypochondriasis which occur among persons of the lower classes.

We may state in a summary manner that the causes which occasion hypochondriasis as an idiopathic complaint, are agents which exercise an hurtful influence on the mind, and through it on the nervous system: too intent and long-continued application; studies and professions which require great intellectual exertion; anxiety respecting the success of schemes and prospects of worldly advancement; disappointment of various kinds, and consequent dejection; and lastly,

though this is by no means the least important article in the catalogue, the indulgence of vicious habits which tend to debilitate the mind and body. The noxious influence of these causes is exerted in the first place on the nervous system; the functions of physical life are affected by sympathy; nor are such affections difficult to understand or to reduce to the general analogy of facts in pathology; but this is a consideration which belongs to the next section.

There are very many instances of hypochondriasis in which, as we have before suggested, the predisposing causes are those which give rise in the first place to dyspeptic ailments, and to disordered actions of various kinds in the alimentary canal. Sedentary habits, a poor diet, the abundant use of warm diluent fluids, tea, coffee, and the like, a constipated state of the bowels subsisting habitually and long continued, are the most frequent of the causes reducible to this class. The disease appears to be more common among the lower ranks of society in this country than in France, and that, if we are not mistaken, is particularly the case with respect to women. A great number of the wives of cottagers, and old women who live with their own families, and not in domestic service, are fed in England chiefly on bread and tea, seldom getting either much animal food or any fermented liquors. Of these a considerable proportion are dyspeptic, and many are hypochondriacal.

Pathology.—Anatomical researches have thrown no light on the pathology of hypochondriasis, nor does it appear probable that the subject will ever be elucidated by such means. Organic changes of almost every description have been discovered in the bodies of persons who have been the subjects of this malady. Their diversity is too great to allow of the supposition that they are all connected with one complaint. The individuals in whose bodies they have been discovered have terminated their existence under various diseases. Hence the diversity of morbid phenomena, which, if it were possible to trace the connection of causes and effects, would probably be found to have stood in no near relation to the hypochondriacal ailments which affected the individuals in question without endangering life, or ultimately accelerating its termination.

Medical writers have long been divided in their opinions with respect to the seat and nature of hypochondriasis. Some have regarded it as a primary disease of the nervous system in general, or of the brain itself; while others have looked upon the affections of the nervous system as secondary, and depending upon sympathy with a disordered state of functions belonging to the abdominal viscera. These opposite opinions were espoused by Sydenham and Hoffmann, and each of them has found advocates among distinguished writers of the present time.

Sydenham, as we have before observed, considered hypochondriasis and hysteria as closely analogous, or rather as modifications of the same disease, depending merely upon sex. He says, that "the disturbed or variable disposition both of mind and body which prevails in hysteric and hypochondriac subjects arises from a disorder of the animal spirits, or from an inordinate motion of the

spirits."—"The spirits," he says, "which are subservient to the mind are, in reality, composed of the finest particles of matter, and border upon immaterial or spiritual beings." Sydenham's expression, "a disorder of the animal spirits," translated into the medical phraseology which is current in our own times, is well known to mean a disordered state in the functions of the nervous system. In connection with this opinion as to the nature of the disorder, the author remarks that it occurs to those whose minds, or rather whose nervous systems were "originally weak or have been rendered so by a long train of disorders, or their long continuance."

Hoffmann maintained the opinion that hypochondriacal maladies proceed originally from disorders of the stomach and intestinal canal, from irregularities in its peristaltic action, whence ensue dyspepsia, flatulence, colic pains, spasms, and all the local symptoms which gave to the disease the name of hypochondriasis. The general disorders of the nervous system are supposed by this writer to depend on sympathy.

The opinion which ascribes to hypochondriasis a local origin has been reduced to a more definite form by modern writers. M. Louyer Villermay, in his treatise on nervous diseases, maintains that the primary seat of the complaint is in the abdominal viscera, and especially in the stomach. Here, according to Villermay and many who have adopted his opinion, the disease consists in a morbid state of the nervous structure and of the vital properties of the parts, and chiefly in an excess of their organic sensibility, an expression which belongs to the school of Bichat. The disorders which affect other organs and nearly the whole animal economy in hypochondriasis, are the results of sympathy with the morbid condition of the nervous structure connected with the gastric system.

M. Broussais and his followers modify this theory according to their peculiar and favourite doctrines. The disease, according to M. Broussais, is seated primarily in the coats of the stomach, but it is not a merely nervous affection. It is the same state, or analogous to the same morbid state, from which so many other manifestations of disease in various parts of the system arise; namely, a chronic inflammation of the mucous membrane of the stomach. From the peculiar condition of this membrane with respect to its vascularity, arises its morbid sensibility, and from sympathy of other parts of the system ensue all the multifarious phenomena of hypochondriasis.

M. Georget has strongly opposed the opinion of those who place the primitive seat of hypochondriasis in the abdominal viscera. In his work entitled "*Physiologie et Maladies du Système Nerveux*," he has investigated this subject, and has deduced from his own observations, and from facts reported by various authors, the following inferences:—

1st, That the characteristic phenomena of this disease refer themselves to the head. 2dly, That the other symptoms which sometimes belong to cases of hypochondriasis are not constant: thus we find that there are some cases in which palpitation of the heart has been remarked; there are others in which no remarkable derangement in the digestive processes has been observed. 3dly, That al-

most all the exciting causes of the disease are such as are known to exert their influence directly on the cerebral functions. 4thly, That the most efficacious methods of treatment are moral remedies. From these considerations the author has drawn the conclusion that hypochondriasis is a primary affection of the brain.

It is impossible to give due attention to the arguments adduced by M. Georget on this subject without being aware that they have considerable weight. And yet the inference seems rather strongly drawn when we advert to the fact admitted on all hands, that no disease whatever has been traced with certainty in the brains of hypochondriacs. It must be taken into the account that morbid causes may, and do occasionally, act through the intervention of the brain, and induce disorders in other parts of the system much more real and considerable than the derangement occasioned, *in transitu*, in the brain. A man may receive some afflicting intelligence just before he is going to dinner, which may so spoil his appetite that he cannot eat. The function of the stomach is here impeded and deranged; not so that of the brain, although the impression is undoubtedly communicated through the instrumentality of the brain. In like manner trains of morbid causes may bring on repeated and at length habitual derangement in the functions of the alimentary canal, and of all the parts connected with it in structure and operation. These causes act through the instrumentality of the brain, but they are not productive of actual disease in the structure at least of that organ.

These considerations throw light on some of the theoretical questions connected with hypochondriasis. They tend to explain, so far as the analogy of facts occurring in the animal economy affords explanation, the circumstance that disorders in the natural functions, and particularly in those of digestion, arise from causes acting on the nervous system, and this without necessarily involving the supposition that there is disease actually seated in the brain and nervous system. The consideration that hypochondriasis is a disorder frequently, perhaps chiefly in its most aggravated forms, arising from the influence of causes which act, in the first place, upon the mind and on the brain, is therefore no adequate proof that the brain is disordered. The condition of the sensitive and intellectual powers, which are uninjured in this disease, seems to afford a presumption on the negative side of the question. Still, when we take into the account the mental dejection of hypochondriacs, the habitual state of their spirits, and the trains of morbid feelings, of painful sensations which torment them, we can scarcely refuse to admit that some unknown deviation from the healthy and natural state of the cerebral functions lies at the foundation of their ailments, though it is remote from organic disease, and of a kind of which we can form no conception. Many of the phenomena which accompany this disorder would lead to the opinion that the principal deviation from health and the natural state of functions is situated in some other part of the nervous fabric rather than in the brain. They might be thought referable to the system of ganglions in connection with the great sympathetic, or to what has been termed the nervous system of the viscera or of physical or organic life; since in

this is the immediate centre, as it appears probable, of that peculiar property or influence termed organic sensibility in the stomach and other abdominal viscera. But phenomena involving consciousness and affections of the mind can hardly be confined to this part of the nervous system; the brain must participate in the morbid disposition; unless we could persuade ourselves to believe, with Bichat, that the feelings or pathemata have their proper seat in the ganglionic apparatus.

We shall close this part of our subject by adverting to a circumstance which confirms the conclusion that hypochondriasis is a disease of the nervous system rather than of the digestive organs themselves. It is the fact that the complaint is in some instances suspended through long intervals of time, during which the individual subject to it is in perfect health. We have known hypochondriasis to attack the same person several times during his life. A gentleman, previously healthy, active, and vigorous in mind and body, temperate, and regular in all his habits, became, without any assignable cause, low-spirited, anxious about his health, fancying that he was in imminent danger of various diseases of which he could trace slight and evanescent symptoms in his own feelings. He then began to complain of indescribable sensations about the stomach, burning pains in the epigastrium, flatulence, sinking, internal weakness; of pressure on the brain, and various symptoms of distress referable to the head; in short, of nearly the whole train of symptoms which characterize the most complete examples of hypochondriasis. These complaints molested the unfortunate sufferer for several months: no remedies appeared to be of any service. At length the symptoms disappeared, and he regained perfect health, which he enjoyed for an interval of several years. During this period he bore no trace of any disease in the digestive organs. On the contrary, all the functions of physical life went on in a perfectly regular way. The attacks of his disease have recurred several times, and with the depression of spirits all the dyspeptic symptoms returned. It might, indeed, here be a question, whether the return of gastric and enteric disorder brought with it the recurrence of nervous symptoms, or, conversely, whether the relapse into disease of the nervous system was the occasion of renewed dyspepsia. The latter supposition is by far the most probable. Habitual disorders of the digestive functions are not frequently observed thus to cease altogether, and to recur without any distinct and perceptible causes. They do not leave their victim for some years in a state of perfect immunity from their influence, and attack him again in renewed and distant periods, while this is conspicuously the case with complaints affecting the brain and nerves: cases like that which we have described seem to approximate hypochondriasis to the class of disorders affecting primarily the nervous structure. They are incompatible with the supposition that chronic disturbance of the alimentary canal constitutes the whole essence of the disease.

But although it seems to be sufficiently evident that the actual seat of hypochondriasis, or the part of the organized fabric on the disordered state of which its characteristic symptoms depend, is the brain and nervous system, yet it cannot be

doubted, on a consideration of the predisposing causes, that the latter in some cases exert their primary influence on the state of the abdominal viscera. Severe and long-continued disorder of the digestive organs lays the foundation for hypochondriasis; as similar influences occasion other diseases of the nervous system. As long as the mind is unaffected, the complaint may be considered as simple dyspepsia, and the whole of the disease may be regarded as confined to the digestive organs; but when low spirits and dejection are manifested, and hypochondriasis properly so termed exists, the disease must be supposed to have involved the nervous system, and in some degree the brain.

Treatment.—The treatment of hypochondriasis would be easy and probably in most instances successful, if it was taken up on rational principles from the commencement of the disease or early in its course. This seldom happens to be the case. It is rarely that hypochondriacal patients apply for the advice of a physician until the failure of a variety of remedies administered by themselves drives them to seek for aid likely to be more available. When such an application is made, it is generally found that the patient has been a great reader of medical books; that he has repeatedly experienced in his own person the effects of every specific drug reputed to restore the functions of the liver and the chylipoietic system. It will often be found impossible to prescribe any remedy which has not already been tried, and given up in despair. Under such circumstances, the wisest course a physician could pursue, would be to repeat the precept of Montanus, often cited with applause, "*Fuge medicos et medicamenta, facileque convalesces.*"

The treatment of hypochondriasis should be divided into two departments, the dietetical or moral, and the pharmaceutical. Of these the former is by far the more important, whether in recent or inveterate cases.

The first indication which common sense points out for the relief or cure of hypochondriasis, and the beneficial tendency of which is confirmed by experience, is to remove the causes of the disease by laying aside the habits, and as far as possible reversing the moral influences which have occasioned it. Change of scene, a removal from customary occupations by travelling, is the best method of ensuring this object. In the good old times, when physicians had a double hold on the obedience of their patients, the monkish practitioners had an excellent resource in prescribing for hypochondriacs a pilgrimage to the tomb of St. Jago, or the shrine of the Three Kings; but when their patients had lost all faith in the relics of Melchior, it became necessary to substitute other expedients which are not always quite so innocent. The most popular of these has been a resort to mineral springs; Hoffmann extols the waters of Schwalbach and Pyrmont. Various medicinal springs have afforded a pretext for advising sick persons to remove from home, and out of the influence of circumstances which created and fostered their disease. The physician who has hypochondriac persons under his care will avail himself of those means for fulfilling the indication above suggested, which may best accord with the circumstances and the preju-

dices of his patients. Continued travelling has the best effect, and is on many accounts preferable to an abode in any one place. Even the accidents of diet and lodging to which travellers are exposed are often productive of benefit to patients of this class: and when such circumstances produce temporary disorders of a different kind, as rheumatism, colds, slight bowel complaints, minor evils of this description are found to take off the attention of the patient from his habitual malady, and even tend to introduce, when they begin to abate, a better state of health and spirits. A gentleman who had been for many months labouring under great nervous susceptibility, dyspeptic, and unable to take food without producing great excitement and distress, set out in this state to make a journey in the south of Europe. He was seized on his way with diarrhœa, which was kept up by the acid cookery and wines of France, and continued for some weeks. Instead of increasing his principal malady, these accidents materially lessened it, and even before the new disorder entirely ceased, all the old series of complaints, both of the digestive functions and the spirits, were in a great measure cured.

As the effect of remedies in these instances depends not less on their influence on the mind than on the body, patients should be advised to go to places where their attention is likely to be occupied; this must be determined by circumstances.

Habitual and regular exercise is very conducive to recovery from hypochondriasis. Sydenham says, "the best thing I have hitherto found for strengthening and cheering the spirits is riding on horseback some hours every day." He gives an instance of the efficiency of this remedy, in a "learned and reverend prelate, who, having applied himself too intensely to his studies for a long time, was at length attacked by a hypochondriac disorder which destroyed his digestion." After trying various remedies in vain, when reduced to great weakness by a colliquative looseness, he at length consulted Sydenham, who "immediately judged that it would be useless to order any more medicines as he had taken so many already, and, therefore, advised riding on horseback, directing him to take only such short journeys at first as he could bear without fatigue." "I entreated him," says Sydenham, "to continue it every day, to lengthen his journeys by degrees, and not to mind either meat, or drink, or the weather, and to take up with such accommodations as he met with on the road like a traveller. In short, he continued this method, till at length he rode twenty or thirty miles a day, and finding himself mended in a few days, he was encouraged by this wonderful success to continue in the same course for several months, in which space of time he rode several thousand miles. He was at length not only freed from his disorder, but became strong and brisk."

When the patient cannot ride on horseback, some other mode of exercise must be substituted. Walking is the most advisable, if the strength admits of it. Even females, when labouring under hypochondriasis, have derived great benefit from the practice of walking several miles every day, and by constantly observing the rule to do so when not prevented by intemperate weather.

The most effectual, however, of all rules for the cure of hypochondriacal patients is to withdraw

them from studies, or pursuits, or habits of whatever kind, which may have been connected with the formation and development of their disease. If this maxim cannot be fully acted upon, which will unfortunately happen in a great number of instances, it must ever be borne in mind, and followed to the utmost limit which the circumstances of the invalid will admit. In all cases it must be remembered that much depends upon keeping the mind as much as possible agreeably and actively engaged. Irreparable evils may ensue from allowing the patient to sink into a state of mental vacancy and despondency, and to brood on his own uncomfortable feelings.

Something may be contributed towards the cure of hypochondriasis in many instances, and perhaps in all towards its mitigation and the relief of symptoms by medicinal remedies. The choice and mode of administering these must depend upon the state of gastric and intestinal disorder with which the other ailments of the system are complicated. It will be well to bear in mind Broussais's theory of the disease, which is not without foundation in truth. If gastro-enteritis, or an inflamed or highly irritable state of the mucous membrane exists, of which there are frequently indications more or less strongly marked, the case must be treated accordingly. All stimulating remedies will then be improper, and the regimen most likely to prove beneficial will be the antiphlogistic. An attenuating diet, with semi-fluid farinaceous nutriment and cool drinks, the use of mild injections and the most gentle laxatives for the purpose of regulating the bowels, the occasional application of leeches to the abdomen, warm bathing, will be the principal means of relief. When the dyspeptic maladies are without any inflammatory combination, and allied to atony or want of strength and action in the alimentary canal, warm purgatives, combined with bitters, aromatics, and the drugs termed antispasmodic or nervine, are most serviceable. Rhubarb, or infusion of senna and gentian, with some aromatic tincture, may be given daily or occasionally; with them alkaline or neutral salts may be combined according to circumstances. Aloetics, and compounds containing other resinous purgatives, may be added if necessary, and combined with assafetida or the galbanum pill. The remedy which agrees with the greatest number of flatulent and dyspeptic persons for the longest period is composed of a drachm of powdered rhubarb in a half pint of warm peppermint water.

Tonic remedies are used with advantage in some cases of hypochondriasis; and of the class of drugs so termed, the sulphate of quinia and the sulphate or subcarbonate of iron are the most efficacious. The subnitrate of bismuth may almost be considered as the sole remedy of the kind in cases attended with gastralgia after eating, and with pyrosis. It may, perhaps, be superfluous to observe that all the remedies of this class are highly injurious in cases attended with a state of the intestinal canal bordering on gastro-enteritis.

J. C. PRICHARD.

HYSTERIA.—Hysteria is a name commonly given to certain paroxysms of disorder occurring in peculiar constitutions, and generally in females;

but in its full signification comprehends several peculiarities of a permanent character, as well as peculiar phenomena of occasional occurrence not amounting to the hysteric paroxysm. The latter phenomena sometimes appear singly, and sometimes in connection with morbid actions not hysterical, but to which they impart a peculiar or hysteric modification. Thus defined, and the definition will be found of practical application, we may almost admit without qualification the remark of Sydenham, that hysterical disorders constitute one-half of all chronic distempers.

The circumstances of the hysteric paroxysm may in part be described from observation; but some of them are only perceived by the individual affected. Of the latter kind is the sensation of a ball or solid body suddenly perceived in some part of the abdomen, and usually in the left iliac region, or in a situation corresponding to that of the sigmoid flexure of the colon. It is probable that accurate observation would detect a circumscribed swelling or fulness in that situation when the sensation comes on; but, both on account of the short duration of the symptom, and for other reasons easy to be imagined, this fact is generally taken on the testimony of the patient. A kind of vermicular motion of the abdominal muscles, and the sudden elevation and depression of the abdominal surface have been observed. There are, also, some precursory symptoms which are very troublesome to the patient, but not very easily described, concurring to produce what is called a *general* uneasiness and oppression; together with the more distinct symptoms of stiffness about the larynx, headach, and cramps. M. Georget says that the hysteric patients in the hospital of the Salpêtrière are so well accustomed to take warning by these precursory symptoms as never to be seized unexpectedly: they go to bed, and are tied down until the fit is over.

The sensation of the ball or globus, is described as ascending to the stomach, and then up the chest to the neck, becoming fixed in the throat; and to this sensation physicians have given the name of *globus hystericus*. In some persons who are liable to it on particular occasions, and in others who are occasionally affected with violent hysteria, the paroxysms of hysteria may end here. But in many, whilst the sensation itself is very distressing, it is attended with a sense of coldness and stiffness in the legs or in the trunk of the body, a depression of spirits, noise in the ears, and vertigo; and to these symptoms succeeds a temporary loss of sense and consciousness, and of command over the muscles of voluntary motion, which are either motionless, or violently and involuntarily agitated; the arms and legs being most generally affected, in short but repeated paroxysms, with vehement struggles, during which one of the hands is frequently struck on the breast, or the head lifted up and struck violently against the bed or the floor, or the patients tear their hair or otherwise injure themselves. Whilst these attacks last, the action of the heart is generally vehement, subsiding at intervals, but becoming again excited when a new paroxysm is coming on: the carotids are seen to beat strongly, and the veins in the neck swell. The face is flushed, and the skin is hot. The muscles of respiration

are in almost every case especially affected; the patient breathes slowly, deeply, and as if by sudden impulses; or sighs profoundly, or sobs heavily, or cries or laughs immoderately and without meaning. Violent expiratory efforts are made, seemingly opposed by spasmodic action of the glottis;* the hands are forcibly applied to the throat, as if the patient felt a painful spasm there, and suffocation was impending: sometimes the epigastrium seems to be the seat of intense suffering, and is rubbed or even violently struck by the patient. Some patients bite their hands or arms, or those of the unguarded bystanders. Occasionally, the bladder is affected with irregular action, and pale urine is copiously ejected.

Of a paroxysm of this kind the duration is uncertain; varying from a quarter of an hour to several hours. The recovery from it is often sudden and complete; a flood of tears, a burst of laughter, or a cry like that of one suddenly awakened, frequently ends it; or the patient, apparently exhausted, sinks into a state of quietude from which the recovery may be either sudden or gradual. The patient is sometimes unconscious of what has been going on around her, but is not unfrequently able to repeat what has been said by the assistants during the fit; a circumstance which not only suggests certain cautions to the practitioner, but has been made use of in the cure of this troublesome malady.

After such an attack, there is in some instances a temporary impairment or loss of voice, or of some of the muscles of voluntary or involuntary motion, as a paralysis of the arm, or of the bladder. In general, the only consequences are a degree of fatigue, and headach.

Such is the common form of the hysteric paroxysm; but it is subject to varieties, the distinction of which is on some occasions extremely important to the medical attendant, as well as to the patient. "This disease," says Sydenham, whose description of it is very minute and accurate, "is not more remarkable for its frequency than for the numerous forms under which it appears, resembling most of the distempers wherewith mankind are afflicted. For in whatever part of the body it be seated, it immediately produces such symptoms as are peculiar thereto; so that unless a physician be a person of judgment and penetration, he will be mistaken, and suppose such symptoms to arise from some essential disease of this or that particular part, and not from the hysteric passion." (Swan's Translation, Lond. 1749, p. 370.) Unusual forms of sudden illness, or unexpected circumstances in the course of disorders familiar to the observers, often excite much alarm until their hysterical character and origin are recognised.—Every form of hysteria, however various and transient, is, therefore, sufficiently important to deserve the attentive observation of the student of medicine: nothing else can lead to their ready recognition in future practice, where a mistake may prolong needless anxieties, and be even of serious consequence both to the practitioner and patient;

* Emphysema has sometimes ensued; supposed to proceed from the air being forced through the cellular tissue and mediastinum. See the article EMPHYSEMA in this volume, p. 13.

affecting the safety of one and the reputation for discernment of the other.

The ordinary varieties of the hysteric paroxysm chiefly consist of certain limitations of the preceding phenomena, with more or less aggravation of their severity in the parts or functions which happen in each case to be their seat. In many cases the symptom of globus, commencing in the abdomen, is accompanied with an incredible development of air in the intestines, which produces great distension and oppression, induces dyspnoea, various pains both in the abdomen and chest, and a sense of constriction in the throat, with irregular breathing or crying; but does not go on to convulsions of the voluntary muscles, nor to insensibility and complete loss of power. These attacks come on, perhaps, a few hours after dinner, and last for two or three hours: an immense quantity of air is at length got rid of by eructation, and then all the symptoms subside. If the eructation does not take place, the patient complains of severe anguish in the situation of the stomach; or, becoming too much oppressed to speak, rubs the epigastrium vehemently with her hand. There is evident distension of the upper part of the abdomen, which may, without eructation, gradually subside; and there is often great commotion in the greater part of the intestinal track, productive of violent rumbling, sometimes with alternate protrusion and subsidence of different portions of the abdominal parietes. But whilst the distension remains, other symptoms may supervene, apparently excited by it; as disturbance of the circulation in the form of palpitation; determination of blood to the head, producing severe pain, sometimes with vertigo, flushing of the face, suffusion of the eyes, and some degree of mental oppression or torpor; all of which seem in certain cases to be secondary to the gastro-intestinal distension or tympany. To these symptoms, or to a part of them, succeed in other patients all the other circumstances of the hysteric fit; the muscular agitation, the loss of the sensorial and muscular power, and the consequences of these accidents.

Certain obstinate cases of indigestion in females are in reality hysterical. The patients complain of much oppression after eating; the oppression sometimes amounts to temporary stupor, with a feeling of inability to move, which yields, however, to strong efforts or excitement; occasionally true hysteric symptoms, globus, disturbed breathing, convulsions, and insensibility, succeed, and even in the lighter forms give relief.

The irritability and disorder of the stomach in hysterical subjects is in some cases manifested by the occurrence of vomiting; the matter vomited being green or black, and like the grounds of coffee. (*Whytt.*) We have never known hæmatemesis occur in the fit, as mentioned by Georget. The appetite is very irregular, often craving things hurtful, and at hurtful hours, as meat, cheese, cucumber, &c., at night, and then only. Great depression of spirits is generally conjoined with these states of gastric disorder, and proneness to tears.

As no organs of the body sympathize more with the nervous system under the various impressions made upon it than those concerned in the function of respiration, so the hysteric constitution is particularly liable to disturbances of this function.

The intense susceptibility of such a constitution leads to the occurrence of hurried breathing when even slight emotions are experienced; and to sighing, sobbing, and violent inspiration and expiration when any of a more powerful kind are excited. There are patients in whom hysteria manifests itself chiefly by these irregularities, which are more or less induced in different individuals; in some very readily, being in them only transient in their existence; in others with more difficulty, and, when produced, evincing more violence and less facility of being controlled. The irregularity of breathing, occurring in paroxysms, and induced by accident, sometimes very closely simulates asthma; and this solution of paroxysms apparently asthmatic may be sought for with success when they occur in young persons rather than in older, and in females of an irritable temperament: the apparent asthma will often be found co-existent with other and less doubtful hysterical phenomena, and will admit of considerable or of permanent relief from what are called anti-hysterical remedies.

A loud, disturbing, dry cough, almost resembling a bark, is so peculiar to hysteria that it might well be called the hysteric cough. It occurs in paroxysms, and is brought on with much violence by slight mental impressions, as by an unexpected visit from a friend, or the approach of the medical practitioner. Individuals thus affected are commonly subject to all the other symptoms of hysteria. In some patients the hysterical attack comes on with an apparent spasm of the glottis, and a croupal respiration; in others it assumes the form of common asthma. Dr. Ferrier speaks of an hysterical hemoptysis, relieved on the supervention of the fit; but this, and the copious expectoration with profuse night-sweats, described by most of the older authors among the troubles of hysteria, we have not observed.

We were not long since in attendance on a patient of about thirty-five years of age, in whom there was a deficient, although regular, performance of the uterine functions, and in whom at each monthly period there was sudden suppressio mensium following the appearance of what the patient called her asthmatic complaint; of which, however, the symptoms were not those of regular asthma. They occurred at such times, and for a week or two afterwards, every other day, commencing with great coldness of the hands and feet, and headach; to which succeeded a peculiar difficulty of breathing, lasting all the day, and going off at night. The breath was not, in these attacks, as in asthma, suddenly drawn in and protractedly and sonorously expired, but the inspirations and expirations were short and panting, about forty inspirations being made in a minute; the pulse at the same time being very low and weak, and not more than *twenty* in a minute. There was a sense of weight amounting to pain, in the sternum; pain in the region of the heart and between the scapulae; and fulness and pain in the head; the face was flushed, and the eyes were protruded; a thick expectoration was described as sometimes inducing relief. We mention this case, however, chiefly because the symptoms of failing pulse, coldness and orthopnoea, often led the friends of

the patient to think that she was dying; and yet the complaint has now for several months entirely disappeared under treatment calculated to improve the general health, to regulate the uterine functions, and to allay the great susceptibility of the nervous system. We were informed that in two or three members of the patient's family consumption had supervened on similar symptoms; but all medical men are aware of the doubtful nature of this kind of evidence.

In no class of patients is an irregular pulse more frequently observed: when it is first felt, it is perhaps found to be very rapid; after ten or twelve beats this quickness subsides, but soon comes on again; and these alternations appear to be continual. Slight causes produce a more permanent excitement, during which the practitioner may be much misled; in a few days the excitement will be gone, and the pulse will be found languid and weak. If these caprices of the circulation are embarrassing when no serious disease is present, they become much more so in affections themselves important, as in acute inflammations, or in the commencement or course of continued fevers. Among the many modifications of the ordinary symptoms of fever by the hysterical constitution, we have remarked a singular inequality between the arterial pulsations and the respiration; the pulse being sometimes as slow as the ordinary respiration, and the respirations sometimes advanced to the ordinary rapidity of the pulse. These circumstances seem most common during the first three or four days of the complaint, and, occurring in any other than hysterical patients, would furnish ground for a very unpromising prognosis.

It is seldom that the hysterical respiration is unaccompanied with irregular or with hurried and vehement action of the heart; and it is particularly important to remember that an irregular as well as a very frequent pulse may be occasioned by many causes in an hysterical patient; by temporary causes, and by diseases unconnected with the structural affection of the heart. We have known delicate females, during convalescence from a fever, repeatedly bled for palpitation really dependent on weakness, to the lasting impairment of a constitution already morbidly susceptible. It is to be said, however, that mere hysterical palpitation is occasionally attended with so much disturbance in the impulse as well as in the rhythm of the heart, as to make its resemblance to structural alteration of the organ such as even the stethoscope fails at once to disprove: the practitioner's chief assistance in the diagnosis of such cases must arise from his observation of the transient and occasional character of the symptoms, and from his knowledge of the patient's constitution.

The pulsations of the aorta are also in some hysterical cases greatly disturbed, principally as regards their force, which becomes so much increased that the patient complains much of the beating in the abdomen, and the practitioner himself is harassed with the fear of organic disease. In the course of fevers we have found this affection existing in a very remarkable degree, generally together with other irregular symptoms; and the pulsation has been so vehement, and within a

space so circumscribed, as very precisely to convey to the hand the sensation of a large, defined, pulsating tumour.

In different individuals, and in the same individual in different attacks, the disorder to which the name of hysteria seems justly given, (because such individuals always show more or less of the hysteric character, and their various affections are more or less obedient to what may be called anti-hysterical remedies,) assumes shapes so various that it would be in vain to attempt to describe them all. There seems to be no function or organ in which irregularity may not be induced in an hysterical constitution; the irregularity occurring, and disappearing, or being overcome, with so much suddenness as to create a perfect analogy between such affections and the commonest forms of the disorder.

Thus in some cases the hysteric fit consists of temporary and partial loss of power, or a palsy of some of the voluntary muscles; sometimes of those of one limb; sometimes of those of the voice; and sometimes of all the voluntary muscles of the body, and the patient falls into a state of coma; is insensible; the face is flushed; the pulse beats regularly, even firmly; the respiration is calm and profound; and neither the sensibility nor the power of voluntary movement return for several hours. These cases somewhat resemble apoplexy, and cases are on record in which they have gone on to it: generally, however, they do not require active treatment. In the first case of this kind which we ourselves witnessed, a young woman fell down in the street, and we were at a loss to account for what seemed to us the rash prophecy of an experienced physician that she would recover in a few hours. These cases are mentioned by Whytt.* "Many hysteric women," he says, "are liable to be seized with faintings, during which they lie as in a deep sleep; only their respiration is so low as scarce to be perceived. Others, along with faintings of this kind, are affected with catchings and strong convulsions." A similar state may succeed to the more violent phenomena of hysteria; (*Louyer Villermay*, *Traité des Maladies Nerveuses ou Vapeurs*, &c. Paris, 1816,) and the functions of the heart and lungs may be so seemingly suspended, and the coldness so great, as to present the image of death. Pliny has recorded a case in which this state lasted seven days; and Lancisi mentions one in which a young woman recovered whilst the funeral service was performing. A more striking case occurred to Vesalius, who began to dissect a supposed dead body, to which life returned with the first application of his scalpel. Of the same kind, probably, was the case of a Lady Russell, in the early part of the last century, whose funeral having been postponed for a longer period than usual, afforded time for her happy recovery, which took place while the bells were ringing for prayers; the supposed dead person exclaiming that it was time to go to church. Cases of this kind constitute M. Louyer Villermay's *third degree of hysteria*. (*Dict. de Méd. Article Hystérie*.) We

see no shadow of reason for applying to them the name of hypochondriasis, as some have done, (*Hoffmann*): perhaps they would be more properly classed under the head of syncope.

Instead of these comatose forms, there may be rigid spasm of several of the muscles, especially of the limbs; the legs and arms may be stretched out, the fingers strongly compressed on the palms, and the toes as strongly drawn up. This state may be varied by an occasional start, accompanied with a short and forcible expiration, and at length give way instantaneously, often to proper remedial means. The spasmodic state is described by credible authorities as having in some cases lasted for several weeks.

That a disorder capable of producing so many irregularities of function should occasionally produce a counterfeit representation of various maladies, and should singularly modify the course of others, is not surprising; but the deception is not limited to functional affections, being often extended to the imitation of organic changes. Diseases of the stomach, of the liver, of the intestines, of the bladder, and also of the heart, the lungs, and the brain, have thus been supposed to exist.

Some of the inconveniences which, in hysterical patients, are to be referred to a depraved state of the stomach and bowels, with great distension, have already been mentioned. It is to be added that prolonged constipation, continuing even for weeks, and sometimes the opposite state of obstinate purging, occur in such cases.

Hysterical women will complain of symptoms of obstruction of the gullet, of the rectum, and even of the vagina: and the urinary system is in them much and variously affected. Spurious symptoms of calculus in the kidney, the ureters, or the bladder, may arise and be of little consequence: dysuria, or even a suppression of urine may occur; but more frequently, as in other instances of nervous disturbance, there is an unusual flow of it, and sometimes a kind of false diabetes. These circumstances make such patients an easy prey to quacks and pretenders in medicine, by whom we have known them to be persuaded of the real existence of scirrhus formations, or other serious diseases with which they were not in reality affected.

Jaundice has supervened, in some cases, on hysteria. We have known pale and feeble women who were liable to acute and apparently spasmodic pain in the situation of the liver, and in a situation corresponding to the course of the ureter: these cases were connected with uterine irritation, and had been vainly subjected to various remedies administered for biliary and for renal disorder. Such cases are among the many in which bleeding and purging, and salivation, the ready instruments of coarse and indiscriminate practitioners, are daily productive of irreparable mischief.

Pains, of variable severity, often very severe, are among the distresses of the hysterical. A fixed pain in the forehead, and generally over one eye, which has been termed *clavus hystericus*, the sensation being that of a nail driven into the forehead, is very common. It is one of the many attendants of uterine irritation, to which, however, hysterical affections have been too exclusively attributed: we have known it disappear entirely

* Observations on the Nature, Causes, and Cure of those Disorders which have been commonly called Nervous, Hypochondriac, or Hysteric, Edinb. 1765. Pages 64 and 66.

during pregnancy, and again become troublesome a few months after delivery; and it is generally preceded by a sense of weight in the head, and an oppression in the throat; and is sometimes relieved by a flow of tears.

More severe and general invasion of pain in the head may come on, with much of the character of phrenitis; with senses morbidly acute, and small and rapid pulse; but without acute delirium, or red and injected eyes: the face also is very pale, and there is much hysterical agitation.

There is another painful affection, often also, we believe, connected with irregularity in the uterine functions, and attended with constipated bowels, in which the patient's chief suffering is fixed in the left side, below the mamma, and above the situation of the spleen. There is most acute tenderness without swelling; the patient cannot lie on the affected side; and the disease resists for months, sometimes for years, all varieties of treatment. Although we have said that these cases are often connected with uterine irritation, the depraved state of the appetite, occasional sickness, and obstinate sluggishness of the bowels, make us doubt the propriety of laying great stress on the uterine disorder. In these cases, or in most of them, there is some pain of the back, referred to the lowest part; and there is a tenderness of the spine, confined to the dorsal region. The pain of the sacrum is a common complaint with females in whom the uterus is unhealthy, and yet who are not hysterical, and who have no tenderness about the dorsal vertebræ; and neither the dorsal tenderness nor the sacral pain is present in many of the examples of the *clavus hystericus*, even when most clearly arising from uterine irritation. These circumstances, which we have very carefully verified, are incompatible with the uterine theory of diseases which we shall have to notice when speaking of the *causes* of hysteria.

The female breast is in some hysterical cases the seat of much pain, and is also enlarged and hard; so that the patient dreads the occurrence of cancer, although at an age when the practitioner has no apprehension of it. Dr. Darwall mentions a case, in his remarks on spinal irritation, where this was combined with tenderness of the three superior dorsal vertebræ, and all the symptoms were relieved by cupping. Pains of the limbs are not unusual, and they are now and then united with an impairment of the motions of the hip or the knee, leading to a suspicion of disease of the joints. In very young but precocious females we have seen this curious complaint combined with strange affections of the sight and of the voice; of which one of the most remarkable instances that we remember occurred some years ago in the Edinburgh Infirmary: the subject of it was a girl of thirteen, and the lameness and partial blindness, and an appearance of fatuity, all disappeared under a steady application of Dr. Hamilton's purgative treatment.

Sudden and violent attacks of pain in the abdomen, with excessive tenderness of the surface, a quick pulse, and many symptoms which may be mistaken for those of peritonitis, sometimes take place in hysterical young women, yet without inflammation. It is to be observed that the tenderness, in all cases of hysterical pain, is most felt on

slight pressure, and is often evinced on the gentlest touch; which is not commonly seen in instances of internal inflammation.

The most severe examples of colica which we have met with have been in hysterical women; cases of excruciating pain, not yielding entirely for many days, during a great part of which time the cries of the patient have disturbed the whole house. These cases have been denominated flatulent or hysterical colic. In these cases, if the extreme tenderness on slight pressure is present, firm pressure is borne much better, and perhaps gives relief: the tongue is often clean, or has not the whiteness so general in enteritis; there are also intervals of relief from suffering, during which the patient's voice is calm, and the pulse not much quickened, or is sometimes slower than usual, without any sharpness, and even very low. Such attacks are often relieved by the defection of copious, dark-coloured, and offensive stools.

Inequality in the regulation of the animal temperature is another troublesome part of hysteria. Fits of coldness and of oppressive heat succeed each other; or the feet are cold and insensible to the hottest fire or to very hot water, whilst the head and face are burning, in which case there is commonly some delirium. A feeling of coldness running down the spine, which is familiar to nervous persons, is often present in the hysterical.

We cannot call to our mind an hysterical patient whose sleep was generally tranquil and undisturbed: many have complained of prolonged and distressing wakefulness, their nights being often passed in a state of perfect vigilia, and at other times rendered uncomfortable by restlessness and distressing dreams. Yet it has always appeared to us as remarkable, that, unlike epilepsy, the hysterical attack does not usually come on in the night, or after sleep.

Many pages might be filled with accounts of singular forms of disease, productive, according to the degree of information possessed by the attendants, of more or less wonder and perplexity, which have been observed in all ages, and which might justly be classed with hysteria. From the irritations occasioning mere restlessness, yawning, and what are called "the fidgets," up to the most capricious and violent disturbance of different parts of the system, there seems to be nothing strange or odd which hysteria has not at times exhibited. Among these curious phenomena may be mentioned a disposition on the part of the patient to repeat some unmeaning syllables from morning to night, or during several hours every day; or, whilst lying otherwise motionless and seemingly insensible to outward impressions, to sing loudly and for a length of time a few particular notes, repeating them a thousand times. Pious ejaculations, hallelujahs, and snatches of hymns, we have thus heard vociferated to the excitement of a mixture of awe and amusement in those around the patient, who will sometimes seriously inquire whether the physician does not believe the patient to be bewitched.

Dr. Parry's notes (*Posthumous Works*) contain the case of a young lady of fourteen years of age, in whom menstruation had commenced a year before, and who, after being present at an exhibition of fireworks when but recovering

from slight indisposition, complained of weariness and giddiness, and pain of head; on which ensued spasmodic motions of the hands and fingers, and convulsive actions of various parts, which continued for some hours. Two days afterward the attack returned, and, as she lay on her back, rather towards her right side, she threw the left arm and body backwards at measured intervals, exactly keeping time with two or three notes which she sang out with a strong and clear voice; and this scene was repeated every day from eleven to three at noon, and from eight to ten at night, leaving her much fatigued, after which she slept well. She was fond of music, and could both play and sing, but could assign no reason for the particular song so often repeated, but that "it was irresistible." These attacks were occasionally repeated for ten or twelve days more. When the treatment pursued began to take effect, the song began to disappear, but she was uncomfortable, or had an attack of headach, or cried and made pale urine at the usual hour of the attack. Dr. Parry succeeded in checking the convulsive motions by compressing the carotid artery: the patient was bled, leeches were applied, and purgatives and nitrate of potass and squill were administered.

The tendency of the phenomena of nervous disorders to return at stated intervals, although often observed, seems to have been forgotten in the instance of some of the most unusual forms, and cases of this kind have been erroneously classed, from the mere circumstance of the periodicity of the symptoms, with ague. (See the article *Chorea* in the 1st vol. p. 436; a case entitled *Leaping Ague*.)

Dr. Bright has given cases of hysteric hiccup, and of spasmodic exclamation, and of hysteric dysphagia. (Reports of Medical Cases, vol. ii. p. 457; cases cexi, cexii, cexvi.) In the latter case the introduction of the probang induced an hysteric fit, which was immediately followed by hysteria in several females in the same ward; thus illustrating the effects of *imitation*, which we shall have to speak of among the causes of this affection.

The name of simulated pregnancy has been given to some cases of hysteria, in which the abdomen enlarges gradually, sickness occurs, and so many signs of an impregnated uterus are present, that time alone can solve the doubts they raise. The catamenia are suppressed, the breasts are tumid, and there is pain in the back. Mr. Tate says, of these cases, "in what this engorgement consists, I am utterly ignorant: that it is not a mere accumulation in the colon, I know; and that it is substantial, I am equally sure." (Treatise on Hysteria, p. 117.) It is, we apprehend, a mixed state of vascular fulness and tympanitic distension.

Dread of water, the disengagement from the body of electrical sparks, the occurrence of spontaneous emphysema, and the phenomena of somnambulism, have been observed in the hysterical; and cases of misplaced senses, which are entitled to little credit. We have dwelt sufficiently on the anomalous forms of the disorder in some degree to prepare the inexperienced practitioner for the singular appearances which hysteria often assumes.

The older writers, whose observations were often made in religious houses for the reception of women devoted to celibacy, have recorded other examples, some of which we shall have occasion to refer to.

We shall not pretend to give any explanation of the surprising revelations or presentiments, or shadows of coming events, which have been said at times to be associated with the hysteric paroxysm. When the small portion of truth which such relations contain is separated from the fancy, the fable, and the fraud with which it has been invested, it may perhaps be rendered intelligible by the consideration that extreme excitement of the brain may lead in these states of disorder, as in troubled and vivid dreams, to combinations of images, and to probable suggestions concerning the course of events past or to come, which appear to a sober and healthy mind, unacquainted with such wild excitement, as too extraordinary not to be supernatural. Concerning animal magnetism, connected as it is with this part of our subject, we shall only express our hearty disbelief of most of the circumstances related by its supporters, and our conviction that the rest admit of explanation without having recourse to the principle the magnetizers so anxiously desire to establish.

Amidst such general disorder, the nervous system being so frequently, perhaps so invariably involved, the functions of the brain often become deeply affected. Increased susceptibility to impressions, celerity of movements, and capriciousness of motives, strongly characterize the hysterical female: her countenance indicates the mutability of her feelings; and when the constitution is intensely imbued with these characters, the most amiable sentiments are seen to be readily converted into jealous and fierce passions, and all sense of humanity to be lost in the gratification of cruel and remorseless impulses. Sydenham, whose industry and sagacity are equally discernible in all his writings, has left us a graphic picture of these effects, and his testimony will sufficiently assure the reader of their reality. "Upon the least occasion also," he says, "they indulge terror, anger, jealousy, distrust, and other hateful passions; and abhor joy, and hope, and cheerfulness, which, if they accidentally arise, as they seldom do, quickly fly away, and yet disturb the mind as much as the depressing passions do; so that they observe no mean in any thing, and are constant only to inconstancy. They love the same persons extravagantly at one time, and soon after hate them without a cause; this instant they propose doing one thing, and the next change their mind, and enter upon something contrary to it, but without finding it: so unsettled is their mind that they are never at rest." This description was perhaps intended by Sydenham to comprehend the hypochondriac character; and yet, although not to be taken as a general representation of the hysterical mind, we have seen it so exactly exemplified in the hysterical as to be greatly struck with the truth of this great physician's painting. Cases of this kind approach near to insanity; and, indeed, a mind subject to the violent agitations incidental to the hysteric constitution cannot be considered as perfectly sane. We would here beg to insert

a caution to which the young practitioner cannot pay too much attention. We are inclined to think that cases of hysteria, in which the mind was principally affected, have occasionally been treated as cases of simple mania, and the patients placed in confinement with lunatics. Nothing more likely to have the most unfortunate effects upon the patient could possibly happen; and no care can be too great to avoid a mistake which would in all probability render such a case incurable and hopeless.

The disposition to dread the approach of disease on the occurrence of slight feelings of an unusual description has frequently been observed in those disposed to mania, and is a leading feature in cases of hypochondriasis: it is also seen in some instances of hysteria. The physician is hastily summoned as if to a severe disease, and finds no real cause existing for the patient's alarm. A morbid susceptibility of all parts of the nervous system disposes, in them, all parts to diseased, or at least to undue impressions; to false or diseased sensations, and to irregular or diseased actions. Any function consequently may, in the hysterical constitution, be readily disordered; as the respiration, the circulation, the digestion of food: any part may be affected with pain and the usual symptoms of confirmed disease; and, at length, the parts thus affected may really become the seat of inflammation or other disorder, and undergo a change of structure. For these ultimate results of hysterical disorder the physician should in all severe cases be prepared.

As the deeper shades of hysteria border upon or enter the confines of insanity, so the lighter comprehend several varieties of constitution characterized by increased susceptibility, and in which, some time or other, it is found that peculiar impressions evoke some of the hysteric phenomena. With many of these cases the guardians of education are more directly concerned than the medical practitioner; and the principles of their management may be gathered from the valuable observations contained in the article *PHYSICAL EDUCATION*, in the present work. It is quite certain that the unhappy temper and violent irritability of hysterical females, combined with their constitutional tendency to the hysteric paroxysm, is in some instances sufficient to bring on, almost at the will of the patient, attacks which occasion much concern to their relatives or friends; we have seen undoubted instances in which a temporary loss of muscular power, a singular diminution of the action of the heart, and an inability to speak, but without loss of consciousness, originated in the desire of a self-willed individual to distress the spectators, or to overcome opposition to some wayward desire; as if the wish to feign an attack brought on a real paroxysm. Frank mentions similar cases, and others against which it is very necessary that a young medical man should be on his guard. (*Præcos Medicæ Universæ Præcepta*, cap. xiv. § lxxii. 22.)

It occasionally happens, however, that individuals whose education has long been completed, and whose temper and intentions are blameless, are driven by the intolerable sufferings of a highly susceptible nervous temperament to consult a physician; who will be more likely to be of ser-

vice to them in proportion as he regulates the treatment of them according to the principles of the prevention of hysteric paroxysms. Rank, fortune, and reputation, are insufficient to counterbalance the evils attendant on such a temperament; and, unfortunately, those who are most subject to its distresses seldom possess the firmness and perseverance indispensable to a perfect cure.

Modifications of Disease by Hysteria.—It may be supposed that a disease capable of simulating so many others may modify some rather remarkably. The most important of its modifications are seen in the course of fever. Rivière, Baillou, and even Morgagni, entertained the idea of a distinct hysteric fever as a species; but M. Louyer Villermay justly considers such cases as having been nothing more than examples of anomalous symptoms belonging to fever. We have seen nothing in practice to make the opinion of the former authorities credible: it seems to have been purely founded on theory. But the incipient symptoms of fever, its progress, and the circumstances of convalescence, may be much modified by the hysteric constitution. Irregularity in the respective frequency of the pulse and the respiration; an hysteric fit, of the comatose description, ushering in the febrile stage; a disposition to delirium in a state bordering on sleep, yet in which the patient is conscious of what is passing around her; a very singular exaltation of the *tone* of the voice, without increased loudness; a state approaching to catalepsy, but with consciousness remaining; sudden and unexpected, but not always complete recovery; and transient attacks of mania; we have on several occasions observed: and in almost every instance in persons living an easy and indulgent life, and, with the exception of one or two cases in upper servants, seldom among the poor.

In the course of a severe attack of fever in a young lady at school, great alarm was one evening occasioned by the supervention of what was supposed to be *croup*. There was laborious breathing, a loud croupal sound, and great distress apparently existing in the throat, almost amounting to suffocation; and the patient was unable to speak. Similar attacks recurred every night for three or four nights, lasting for an hour or two. These gave place to paroxysms of severe spasm in the stomach, occurring with equal regularity; and these disappeared on the supervention of what might be termed *paroxysms* of sleep, which came on with a febrile exacerbation every afternoon: in the midst of cheerful conversation, intended to make the patient forget her sleep, she would drop instantaneously into a state of sleep the most profound, lasting however, generally, not more than a quarter of an hour, sometimes continuing about an hour. On awaking from this sleep the spasm of the stomach sometimes recurred, and there was occasionally a disposition to the croupal phenomena. This was a tedious and severe case, and excited great alarm in the patient's friends, although there was never any great appearance of danger in the estimation of a medical observer. On the importance of remembering that these and other odd accidents may occur in fever it is quite unnecessary to dwell. Few things are more

gratifying to the physician than to be able, relying on his knowledge, to be calm and assured when all around him are in a state of agitation and dismay.

The patient who was the subject of the above case had been some months previously affected with rubeola: the eruption came out, and seemed to be disappearing at the usual period, when it suddenly broke out anew, and to such an excessive degree as to make it impossible to recognise the features of her face: whether or not this peculiarity was also connected with the hysterical constitution we cannot take upon ourselves to determine.

In another case of an hysterical young lady we have happened to witness two attacks of continued fever, with an interval of four years between them. On each occasion very severe hysterical symptoms have come on, recurring every day, or every other day, or observing longer periods, principally in the form of short spasmodic agitations about the chest and neck, followed by a disposition to crying, with more rapid agitation of the chest, apparently connected with irregular contractions of the diaphragm: a feeling of suffocation often ensued, sometimes with a temporary suspension of respiration, deep redness or blueness of the face, often only in spots or patches. The addition of such symptoms to the usual disorders of the febrile state constitutes a state of extreme and complicated disturbance and suffering, in which it is difficult to distinguish the effects of the fever from the hysterical accompaniments. Pain in the head, pains in the limbs and back, difficulty in moving, costiveness, dysuria, and many other symptoms, exist in such cases at the same time; and there is usually much tenderness of the spine, sometimes with, sometimes without uterine irregularity.

It would be impossible to enumerate the modifications which may take place in other diseases: any unusual assemblage of symptoms, or remarkable inconsistency in their respective severity or order, may awaken inquiry, and will generally be found to depend upon some degree of the hysterical character in the patient. The development of hysterical symptoms in the course of other maladies is occasionally dependent on weakness, either produced by the continuance of the disease or by certain accidents in its progress, or by particular kinds of treatment. Thus, in the debility of the stage of convalescence from fever, and after hemorrhage, and after parturition, and after the employment of very free bleeding, the occurrence of unmeaning laughter or tears, and other parts of the hysterical attack, are not at all uncommon, and always require some attention to their cause.

Whether hysteria has supervened upon some other disease, mixing with and modifying it, or has been in any other way produced, it has a tendency, when severe, long-continued, or frequently recurring, to produce further mischief, and new complications. Inflammatory actions, for instance, take place at or near the extremities or origin of previously irritated nerves; or, as some authors have expressed it, the disease of the system of innervation becomes combined with disease of the

vascular system; and morbid changes take place in the brain, spinal marrow, nerves, or some of the organs supplied by them. In the course of a long hysterical disorder, and yet more readily in the course of a fever in an hysterical patient, the tenderness of the spine may become excessive; and disordered sensations and impaired powers of motion will indicate that something more exists than mere irritation. These symptoms may disappear as the patient recovers strength; but they sometimes attain a degree of intensity requiring especial attention, and even inducing an apprehension of danger. The spinal tenderness in these cases is very different from that excessive sensibility to the slightest touch which some hysterical patients evince during the hysterical attacks, and which is of a very evanescent character, often alternating with, or perhaps accompanied by, an equally morbid sensibility of the limbs, or of the articulations.

Hysteria is one of the disorders of which the consequences are much less serious, as far as the life of the patient is concerned, than its more violent phenomena would lead an inexperienced observer to fear. It can hardly ever, perhaps, be considered as in itself fatal. The secondary diseases to which we have already said it may lead may be fatal. Congestion or inflammation in portions of the brain may occasion death; or the patient may die apoplectic. M. Louyer Villermay has quoted a case of a young woman of fifteen, in whom a most violent hysterical attack ensued on the sudden suppression of the catamenia in consequence of terror. The paroxysm continued more than two days; *nothing was done for the patient's relief*, and she died on the third day, being only fifteen years of age. The patient had complained of a feeling of suffocation, as if a tight collar was fastened round her neck; the hypogastric region was tumid; she could not swallow; she was convulsed; the action of the heart was tumultuous; in short she had had every symptom of violent hysteria. On dissection, the stomach was found contracted, and strongly incurvated, (*fortement revenu sur lui-même*); the left cavities of the heart were empty, as were also the pulmonary veins and the arteries; whilst the right cavities, the pulmonary artery, and the veins, were gorged with black blood, chiefly coagulated. The cerebral veins and the sinuses of the dura mater contained much blood; but there was no appreciable alteration of the brain or spinal marrow, or their coverings, or in the nerves. The ovaries were very large and very firm, and enveloped in a partially transparent tunic, (*une sorte de tunique albuginée, mais transparente dans plusieurs points.*) In the interior of the ovaries there was a large collection of round vesicles, filled with an abundant mucous fluid, which required for its escape the separate puncture of each vesicle. (*Traité des Maladies Nerveuses*, p. 70.)

The same author is one of the very few writers on hysteria who have especially devoted a section to the appearances found in fatal cases. He adduces the testimony of Riolan, Blancardus, Binninger, Vesalius, Diemerbroeck, and Morgagni, as to morbid appearances in the ovaria more or less resembling those mentioned in the above mismanaged and most unfortunate case; without,

however, concluding that such alterations, or any changes in the state of the uterus, are constant.

We spoke, some pages back, of the supervention of jaundice on hysteria, but this, like the occurrence of phthisis, can only be looked upon as an accidental complication. It may sometimes, however, happen that the patient, worn out by the long continuance of the malady and repeated paroxysms and frequent agitations, may become peculiarly liable to the supervention of the last mentioned disease; or may become affected with a slow fever, the body gradually wasting, and the strength decaying, and a premature death at length ensuing.

But among the peculiarities of the hysteric constitution, are to be reckoned some unexpected recoveries from states which seem to furnish an utterly hopeless prognosis. Of such singular cases and their termination we generally have an outline in the expression which all must on some occasion or other have heard employed, that such a patient fell into an odd state, and remained so for a year or longer; that nothing could be made of her case, and that at last she got better, nobody very well knew how or why. These curious reprieves are sometimes from what has appeared to be atrophy, or phthisis, or paralysis; but they have, we believe, occurred after a strong image had been presented of other incurable diseases and of impending death. M. Georget very properly guards the practitioner, therefore, against forming and pronouncing too hasty a prognosis in all cases of hysteria; observing that not only do such occasional recoveries sometimes unexpectedly take place, but that the course of diseases of a fatal character is often much more prolonged in the hysterical than in those of a different constitution. (Vol. ii. p. 288.)

Hysteria in Males.—We have met with a few instances which we consider to have been decided examples of hysteria occurring in males. The subject of one was a gentleman who had devoted himself with too great intensity to his studies, being designed for holy orders. After leading a life of great retirement at Oxford, and, in opposition to his temperament, of strict chastity, his mind became irritable, and he could not obtain refreshing sleep. On several occasions he was suddenly seized with violent sobbing, gasping, and anhelation, attended with a fear of immediate death by suffocation. During these attacks his face was flushed, the carotids pulsated strongly, and the heart was much disturbed; but he retained his consciousness. We were also acquainted, some years ago, with two gentlemen who were singularly intemperate in drinking, and in both of whom excess sometimes induced fits of sobbing and crying, with palpitation, a weak pulse, a loss of muscular power, a great dyspnoea, painful constriction of the chest, and fear of impending death. In cases of melancholia we have found the patients complain of violent agitation of the stomach and bowels, with a disposition to shed tears. We have known the silence of a sick-house unexpectedly disturbed by the uncontrollable and loud laughter of a patient dangerously ill of fever. Very decided hysterical symptoms came on during convalescence from fever in a boy who was a patient of the University dispensary: his mother

was much troubled with hysteric fits; the boy's affection was evidently caused by debility, and disappeared as he regained strength. Sydenham relates the following case, in which the cause and the result were the same. It deserves to be quoted, both as an illustration of the practice of that great physician, and on account of the important relation of such cases to the theory of the causes of hysteric disorders in general.

"I was called," says he, "not long since to an ingenious gentleman, who had recovered of a fever but a few days before. He employed another physician, who had bled and purged him thrice, and forbid him the use of flesh. When I came, and found him up, and heard him talk sensibly on some subjects, I asked why I was sent for; to which one of his friends replied, if I would have a little patience I should be satisfied. Accordingly, sitting down and entering into discussion with the patient, I immediately perceived that his under-lip was thrust outward, and in frequent motion (as it happens to fretful children, who pout before they cry), which was succeeded by the most violent fit of crying I had ever seen, attended with deep and almost convulsive sighs; but it soon went off. I conceived that this disorder proceeded from an irregular motion of the spirits, occasioned in part by the long continuance of the disease, and partly by the evacuations that were required in order to the cure; partly also by emptiness and the abstinence from flesh, which the physician had ordered to be continued for some days after his recovery, to prevent a relapse. I maintained that he was in no danger of a fever, and that his disorder proceeded wholly from emptiness; and therefore ordered him a roast chicken for dinner, and advised him to drink wine moderately at his meals; which being complied with, and he continuing to eat flesh sparingly, his disorder left him."*

This subject is of so much importance, particularly as regards the alleged dependence of all cases of hysteria on some disorder of the uterus, an opinion which cannot be admitted without materially influencing our practice, that we shall quote one or two more examples from authorities which cannot be called into question.

In Dr. Whytt's work on Nervous Disorders, which has already been more than once referred to, and which deserves, even at this day, an attentive and entire perusal, the following case is related, the connection of which with hysteria of the periodical character appears unquestionable.

"A boy of ten years of age, of a very sensible nervous system, who, in December 1747, had been seized with a palpitation of his heart, fell from his horse about the beginning of January. From this time the palpitation left him; but in a few days after he was attacked with a violent headache, returning sometimes once a day, at other times only every third or fourth day. During the fit his pulse became smaller and quicker, and often

* Op. cit. p. 381. Cases of hysteria in men are also mentioned by Louyer Villermy and by Georget: the latter quotes the words of Piso, (or Lepois, an author of the 17th century, whose name is latinized according to the custom of the time.)—*Hysterica symptomata omnia fere vis cum mulieribus communia sunt. Caroli Pisonis Select. Obs. et Consil., &c.* We have no opportunity of referring to the original.

intermitted; his feet were cold, but, by the violence of the pain, a plentiful sweat broke out and relieved him. As these headaches continued to increase, the patient lost his stomach and flesh, and looked pale. By the use, chiefly, of an electuary of the bark and valerian, in less than three weeks the pain of the head abated greatly; but his appetite grew worse, and he often complained of a nausea. These symptoms, however, were all removed in four or five days, by some warm stomachic and cordial medicines, but were succeeded by an intolerable pain across the middle of his belly, which, in the space of eight days, returned five or six times, and not only affected his pulse, as the headach had done, but sometimes occasioned a difficulty and pain in making water. This pain no sooner left his belly than the headach returned with greater violence than ever, so that the boy used to faint in some of the worst paroxysms. It had no certain periods, coming sometimes twice a day, sometimes only once in two days, and was attended with a sense of suffocation from wind, and a lump in his throat. He was easiest in the night, when he slept or lay quiet, but any considerable motion of his body always raised his headach. Before the fits he was observed to be uncommon lively, and disposed to laugh. On the 21st of February, at two in the afternoon, he was seized with fits of involuntary laughter, between which he complained of a strange smell, and of pins pricking his nose: he talked incoherently, stared in an odd manner, and his complexion changed to a livid colour; immediately after he was seized with convulsions, and then fell into a fainting fit, which lasted near half an hour."

The remainder of the case may be abridged. Purulent matter was subsequently discharged from the nostrils and the right ear, with some alteration in the situation of the pain, which shifted to the back of the head, and then to the left side of the abdomen, "between the short ribs and os ilium, confined to a space little larger than the breadth of a shilling. This pain was often so severe as to make him ready to faint: sometimes it shifted, and then he was seized with fatiguing fits of involuntary laughter."

This case appears to have resembled some of those mutable examples of the disease which are more commonly met with in females, and in which the relief given to one affection is but the signal for the raising up of another, constituting cases comprehended in Dr. Marshall Hall's excellent description of "Disorder of the General Health."

The fact of hysterical disorders appearing in male subjects is supported also by the highly respectable testimony of Dr. Ferriar. (Medical Histories and Reflections, vol. i. p. 128.) "Men," he says, "are frequently attacked by complaints which approach to the hysterical type. In the following instance a young man was affected with regular hysteric fits, in consequence of continued vexation and anxiety. In spring, 1789, I was desired to visit a patient about seventeen years of age, on account of fits with which he had been seized a few days before. I was told that they began with great dejection of spirits, sighing, and uneasiness about the præcordi. He then became

apparently insensible, but groaned much, and did not recover for a considerable time. He relapsed frequently, from slight causes, and often had three or four fits in a day. He said that he felt the globus hystericus at the approach of each paroxysm, and he said that he retained his senses, in some degree, to the termination of each. His pulse was weak and hurried; his tongue somewhat foul; and his countenance timid. His evacuations were natural. I do not recollect the particular nature of his employment, but it was of a sedentary kind. After clearing his stomach by an emetic, I directed some pills to be made up composed of opium and assafoetida, and to be given in such a manner that he took half a grain of the former and four grains of the latter every hour previous to the approach of the coming paroxysm. On the first day of taking the pills the fit came on, but in a slighter degree. The next day he was ordered to begin at a greater distance from the usual time of the fit. He took by this means three grains of opium, and more than a scruple of assafoetida. The paroxysm was effectually prevented by this dose, without producing the smallest uneasiness to the patient. Two of the pills were given at bed-time for a few nights afterwards, and the cure was finished by administering tonics."

In the above case the evidence of the *juvantia*, taken together with that of the symptoms, seems to leave no doubt of its being an example of hysteria; and we shall not dwell longer on this point, except to refer to a remarkable instance of temporary loss of voice from hysteria, occurring in a recruit in the East-India Company's service, and related by Mr. Watson, the surgeon of the ship on board of which the patient was a passenger. (Edin. Med. and Surg. Journal, vol. xi. p. 303.) The subject of this case was a strong healthy man, who complained first of giddiness and headach, was then convulsed, and had some of the symptoms of epilepsy, as distortion of the muscles of the face, and discharge of frothy matter from the mouth. After an interval of some hours these symptoms returned, with alternate laughing and crying, spasms about the throat, and inability to speak, although he was perfectly sensible. After being twice bled, and having a blister applied to his head, and taking some active purgative medicine, he recovered his speech in about forty-eight hours. The account he then gave of himself was that he was prevented from speaking by a tightness in his throat, which felt as if something was in it. Mr. Watson observes that but for the super-vention of those symptoms the case would have been considered as epilepsy. It is worthy of remark that another case occurred on board of the same ship about a fortnight afterward, of which the subject was an artillery-man, who, however, recovered his speech on the following morning. Mr. Watson, in conclusion, quotes Dr. Trotter (Medicina Nautica, vol. ii.) as saying, "We found not a few of the cases sent to the hospital-ships subject to very frequent fits of hysteria; and where this singular affection occurred, with as much violence of convulsion as we have ever marked it in female habits, attended with globus, dysphagia, immoderate risibility, weeping, and delirium."

These cases and authorities are, we think, sufficient to set the question at rest. The cases of hysteria in men must, however, still be considered as rare; although we have met with few observant practitioners who have not answered our inquiries on this point by stating that they had seen one or two examples very much resembling it.

Diagnosis.—The importance of not pronouncing serious diseases to exist which are only simulated is almost equal to that of not overlooking serious disease when it is really established: in the latter case the patient's life may be sacrificed to neglect; in the former it may be destroyed or endangered by unnecessary activity. For these reasons we have already insisted on the propriety of every opportunity being taken to enlarge the practitioner's knowledge of the varieties of hysteria; and it is equally necessary that he should keep in mind the tendency of all the violent forms of this disorder to pass to severer and more permanent lesions of function, and even to lesions of structure. Fortunately, the diagnosis of the most important cases is commonly the easiest; as it is more easy to recognise and verify the symptoms of severe diseases, the existence of which may be apprehended. Cases, however, will now and then present themselves requiring the greatest degree of circumspection, and the circumstances in which the patient is placed are often of a nature to produce agitation and haste, of which the effects are most pernicious. It is only by a careful study of the symptoms of diseases of the brain, lungs, heart, intestines, liver, kidney, and other important organs, and by a scrupulous comparison of all their symptoms with the case before him, that the practitioner can escape deception; for many symptoms may be present without real disease, and sometimes serious disease may be present and yet only partially represented by the ordinary symptoms. The slightest admixture of hysterical phenomena forms a sufficient ground of suspicion, and any great departure from the ordinary course and effects of maladies should alone awaken great vigilance. Great mutability of symptoms, or intervals of ease alternating with symptoms of much violence, will generally declare the nature of the case at once. There is, in truth, nothing so difficult to be written, or to be learned by reading, as diagnosis, in this as in all other instances; but habits of caution, of tranquil observation, and of careful consideration, may be learned by every practitioner of ordinary capacity; and, thus disciplined, he will seldom be deceived, even by hysteria.

To distinguish hysteria from epilepsy, a disease generally so much more formidable, is of such great importance that almost all who have treated of these diseases have attempted to lay down certain marks of difference between them. Yet M. Louyer Villermay informs us that M. Pinel, on instituting an examination of the patients detained in the Salpêtrière as epileptic, found a great number of women, several of them young women, who were only hysterical, and yet who were separated from their families and from society. (*Traité des maladies Nerveuses*, vol. i. p. 117.) To pronounce a young female patient epileptic is often in its consequences only second to pronouncing her insane: the disease is considered to be incurable, to

have a tendency to destroy the understanding, and to be transmissible to offspring; none of which terrible evils are associated with the name of hysteria.

The attack of hysteria is commonly less sudden and less violent than an attack of epilepsy. Epilepsy is often ushered in by a loud cry; the patient falls violently to the ground; the muscles of the face are severely convulsed; the eyes are distorted; the tongue is protruded and bitten, and frothy saliva forced out of the mouth. In hysteria there is seldom any incipient cry, although the patient may cry or laugh during the paroxysm; the patient, except in the comatose variety, does not fall suddenly, but, feeling the approach of the fit, is usually attacked after sitting or lying down: the muscles of the face, and the eyes, are usually tranquil, and the face is generally flushed, whereas in epilepsy it has often a ghastly paleness. The hysterical patient does not protrude or bite the tongue, nor is there a discharge of frothy saliva. The epileptic patient does not laugh or shed tears, but is in a state of fixed and intense agony; neither is globus a sensation known to him. After the fit the epileptic patient generally falls into a heavy sleep or sopor. During the paroxysm of hysteria the pupils of the eyes are commonly sensible to light, which is not the case in epilepsy. After the paroxysm the hysterical patient often remembers all that has passed, which the epileptic does not. It may be added that epilepsy is most common in men, in whom hysteria is rare; and that the character, habit of body, and history of the cases, will frequently afford instructive circumstances of difference.

It was Sydenham's custom, he tells us, always to inquire whether any particular disorder about which he was consulted in women did not chiefly attack them "after fretting, or any disturbance of mind;" and, in an attempt to make a difficult distinction, such an inquiry, and others of a similar tendency, will sometimes not be found superfluous.

"The patients and the nurses at the Salpêtrière," says M. Georget, "attach the principal importance to the three following characters of epilepsy: the want of precursory symptoms; the complete loss of consciousness; and the distortion of the mouth and state of the eyes. They say of a case of hysteria passing into epilepsy, that the patient begins 'to laugh on one side' and 'to turn her eye,'—*à rire de côté, et à tourner l'œil*." The cases here pointed to, cases of mixed epilepsy and hysteria, are certainly now and then met with; and their character is of course only to be determined by the assemblage of symptoms in each.

The remarkable impression left on the countenance by successive attacks of epilepsy is familiar to all medical observers: there are few instances in which the face presents no trace of the storms which have passed over it and over the whole frame. The same protruding eye and dulness and passiveness of look are not seen in the hysterical; and when the hysterical character is at all imprinted in the physiognomy, it is rather to be read in a changeful expression, and unquietness and want of repose in the face, which it is not easy to describe.

Causes.—A mere inspection of the various forms of hysteria would, one would suppose, be of itself sufficient to show that all were not very likely to arise from one kind of cause; but that, if all the causes are admitted to act on the brain, and through the nervous centre on the parts affected in the paroxysm, still the seat of the primary irritation is various. But, perhaps from the disposition in the human mind to avoid a complication of difficulties, many authorities have ascribed all the varieties and examples of hysteria to some one irritation, as, for instance, to irritation of the uterus. A comparison with one another of the examples of this disorder which have fallen under our own observation leads us to reject all such exclusive views of their origin, and to believe that the causes of hysteria may consist of any circumstances capable of producing a particular excitement of the nervous system, or certain portions of it, which excitement leads to all the other phenomena. Of the primary irritation we should say that by far the most common seat is the uterus and the intestinal canal; but that sometimes the irritation is such as primarily to affect the whole nervous system, as plethora, anæmia, atmospheric changes, and mental impressions. Such being the exciting causes, of the predisposing cause we can only say that it is a peculiar and constitutional susceptibility to impressions, with an inherent disposition to institute certain actions affecting particular organs and functions, the object of which actions seems to be the relief of the nervous system, sometimes by the equalization of the circulation. We are not more able to explain the form of these actions, or the hysterical paroxysm which supervenes on the cerebral excitement springing from the primary irritation, than we are to explain the ordinary phenomena of laughing or crying, arising from a similar cerebral excitement originating in impressions primarily affecting the mind.

That certain states of the uterus, causing peculiar sympathies in different parts of the frame, are the causes of hysteria, is an opinion of great antiquity, and has been supported by nearly every observer from the time of Hippocrates, who has often been quoted as saying that a woman's best remedy in this disorder is to marry and bear children. Whoever considers the sympathies excited by the changes which the uterine system undergoes at puberty and during pregnancy, and at the cessation of the catamenia; the altered form and character of the young female; the capricious wishes and taste, or *longings* of the state of utero-gestation; and the morbid actions of what is called the "change of life;" will without difficulty admit that the hysterical phenomena, bodily and mental, may very probably be called forth by peculiar conditions of the same dominating system in the female economy. Extensive experience confirms such an opinion; and the occurrence of hysteria in early life, or after marriage, or at a later period, is so often observed in individuals in whom there are evident signs of the activity of the uterine system, as to connect the two circumstances together in the firmest manner. Precocious development and disappointed hopes on the one hand, and excessive indulgence, or marriages immature or physically disproportionate on the other, are causes

of hysteria of which every practitioner finds illustrations within the circle of his own practice; as well as of the disappearance of hysteria after a long-desired marriage, or when means are taken to prevent hurtful excesses. In some females hysteria supervenes on puberty, continues to be more or less troublesome until the period of cessation, and then disappears. In others, as was remarked by Hippocrates, it disappears during pregnancy. And in the few cases in which death has seemed to supervene on simple hysteria, disease, as has already been mentioned, has been discovered in the uterine appendages. We cannot therefore be surprised to find that many ancient and modern writers have considered hysteria as being solely a manifestation of a disordered uterus; and that various theoretical notions have been engrafted, in the different periods of physic, upon this too exclusive opinion; some of which have been disproved by the progress of anatomy and physiology, such as the dependence of hysteria on the ascent of vapours from the womb, and of the symptom of globus on the ascent of the womb itself. To such notions we now only allude as curious remains of an age delighting in medical conjectures, and unpossessed of means of obtaining more accurate knowledge. But the facts on which such theories and practices conformable to them were built, yet remain; for nature and the laws of the human body are yet the same. In a susceptible female temperament, and in the unmarried state, the system of reproduction, every change in which involves many other changes, acts strongly on the system at large, and in certain circumstances disorders all the functions of the body and the mind; the digestion of food, the circulation of the blood, the judgment, the affections, and the temper; and in many of these cases all the mischief is removed by marriage, which, by awakening the natural functions and normal sympathies, allays the whole series of irritations or morbid actions. There can, therefore, be no reasonable doubt entertained that in a great many cases—perhaps we might say in the majority of cases—the cause of hysteria is some more or less discoverable irritation existing in some part of the uterine system, exercising its wide influence on the susceptibilities of a nervous system by nature too easily affected by all impressions. We may perhaps agree with M. Louyer Villermay to call this "a nervous disturbance, an exaltation of organic sensibility of this organ;" but we must add that his statement of the proofs of such a condition, drawn from the asserted state of the hypogastric region, of the vagina, &c. &c. (*Dict. des Sciences Méd. art. Hystérie*), however consonant with the older doctrines, has an air of inefficient practical observation which would almost lead us to doubt, with M. Georget, whether or not he had actually ever seen a case of hysteria. The very abuses to which such a theory has led and must lead, and the unjust suspicions to which it would often give origin, are sufficient to draw even a minute attention to its foundation.*

* For an illustration of this the reader is referred to the case of a nun in Sauvages' *Nosol. Method.* tom. iii. We cannot venture to quote the treatment, although recorded in a learned language. The substance of the ancient uterine theory and some of the singular methods of cure which originated in it may be read in Sennertus,

As far as the writer's experience has extended, and from observations made whilst recording very numerous cases, comprehending nearly all the forms of amenorrhœa, hysteria very rarely supervenes on the amenorrhœa of young women; and, compared with its frequency after the age of twenty, very seldom appears before that time. In cases, also, in which the hysteria has most plainly depended on the suppression of the catamenia, the comatose form of the paroxysm has appeared to be the most common. We have frequently found hysteria coexistent with chronic leucorrhœa and repeated attacks of menorrhagia, in circumstances clearly indicative of what might be termed an irritable uterus; in individuals liable to frequent miscarriages, and in whom the stomach and bowels suffered much sympathetic disturbance. In these cases there is, we believe, generally a disposition to change of uterine structure; insomuch that we should say that a patient who has obstinate hysterical symptoms, and now and then a paroxysm, in early life, or between twenty and thirty years of age, has, in a majority of instances, a predisposition to serious uterine disease, requiring great attention. As such patients advance in life, it will be found that the symptoms become more troublesome, and the sympathies of the whole constitution stronger; whilst in many of the cases there takes place a congestion in the vessels of the uterus, or a sub-inflammation, or indolent tumours are formed, or polypi are thrown out from the interior of the uterus, or the uterus descends lower than its natural position, or malignant disease makes its appearance. We should observe, although it seems to contradict the little that is recorded of the morbid anatomy of the disease, that in the most confirmed and striking examples of ovarian disease which we have met with, there have never been any hysterical symptoms, even of the slightest kind.

These observations, which are the simple result of some attention paid to this subject during several years, added to the fact that hysteria sometimes occurs before puberty, and sometimes after the cessation of the catamenia,* whilst they confirm the opinion of the frequent connection of hysteria with uterine disorder, lead us to regard it as having much less connection with the catamenial function than has been maintained, with a positiveness greater than we think extensive experience would warrant, by some of the most recent writers on hysteria. The question is of great practical importance; but we must now leave the consideration of it to the reader.

We are ourselves convinced, then, that the uterus is not the only organ of which the irritations may so affect the nervous system as to produce hysteria; and this not only from the above considerations, although supported by additional cases in which the uterine functions have continued to be

perfectly performed,† but because there is in many instances of hysteria such evident disorder of other functions, and so manifestly, as it has appeared to us, leading to every form of nervous irritation of the hysteric kind up to the paroxysm itself. We might, indeed, adduce the occurrence of hysteria in men as at once decisive of the question, but we do not think it absolutely necessary to the argument; although, if such cases are admitted, they must inevitably be taken as putting an end to it.

Among the most frequent causes of hysteria next to uterine irritation, must be placed gastro-intestinal irritation; whether from excess, or from improper food, or from depraved or deficient secretions, or from diminished peristaltic action, and the delay in the intestines of the natural excretions. The extent to which the proper evacuation of the bowels is neglected in female patients is almost incredible, and is so often the sole cause of the ailment under consideration and of many others, that we cannot wonder at the general acceptance of the aloetic or purgative treatment of their disorders. The presence of worms has sometimes excited hysteria; (the hysteria *verminosa*. Sauvages, Nosol. Method. tom. iii.) Perhaps it may often be an unsuspected cause: we have seen the most violent and repeated attacks of epilepsy, which had recurred for many months, cease after the passing of one large round worm. All the causes of indigestion may become causes of hysteria to those whose constitution of nervous system is predisposed to be acted upon in the specific mode, whatever it be, in which it is affected when the hysteric phenomena are produced. In many cases of hysteria there seems to be a peculiar sensibility of the gastro-intestinal mucous membrane, giving rise to irritability of the stomach and bowels, and thus disordering the nervous system; and such a state may sometimes be the exciting cause of hysteria, sometimes by its influence only predispose the nervous system to the specific irritation of hysteria on the supervention of any of the other causes. The effect of improper diet, either as regards food or drink, in increasing the nervous susceptibility to all impressions, is probably produced by the intervention of this gastro-intestinal exaltation of sensibility, of which indeed, in such cases, there are many proofs. It seems to be in this manner that luxurious livers and excessive drinkers are always at length punished by an uneasy digestion, and by all the pains of what is commonly called *nervousness*; which last, increasing by degrees, sometimes converts a brave man into a coward, and invariably disqualifies men more and more for great and original undertakings, and even for sustaining the ordinary reverses and agitations incidental to social life. When it is considered that the nervous expansion over the intestinal tunics has been described as analogous to the expansion of nerve constituting the retina, we can readily believe that much disorder may be effected by irritations of this nervous expansion without necessarily ascribing them to circumscribed attacks of enteritis, as M. Broussais has done. In many cases, in which no positive signs of such inflammations exist, the irritations cease or are greatly

tom. iii. lib. iv. pars ii. sect. 3, cap. 4. *De suffocatione uteri*; and a refutation of much of the theory may yet be referred to with advantage, in the writings of Willis, De Morb. Convuls. and Van Swieten. Willis notices the occasional occurrence of hysteria before puberty, of which we have seen one remarkable example.

* Willis, op. cit. See also Dr. Bright's Cases, vol. ii. case cxxx. This was a case of nymphomania after cessation, accompanying uterine disease. M. Georget would consider it a case of cerebral disorder.

† For a case of this kind, in which there was hysteria with temporary paralysis and no uterine irregularity, see Parry's Posthumous Works, vol. i. p. 370.

mitigated on the appearance of faces indicative of depraved secretions; cases described by the older physicians as abounding in *phlegm*. The motions in such cases are dark or olive-coloured, sometimes passed with much pain, although not hard, and seldom procured without medicine. The excessive flatus which is the torment of certain hysterical patients is in all probability connected with some morbid condition of the intestinal nerves; may in fact be looked upon as an excess of a natural product in the intestines, the result of deranged actions. Partly from the stimulus of so much air, and partly from the morbid condition of the intestines, which produces it, the muscular fibres of the intestines are thrown into commotion, or at least excited to vehement action, creating a feeling of movement and a rumbling noise which becomes a source of annoyance to the patient. Upon this disordered state spasm frequently supervenes, and it would seem generally to commence in the lower part of the intestines, near the termination of the colon in the rectum, and to ascend, producing the feeling of globus already described.*

It happens, however, not uncommonly, that even when the state of the uterus is the real cause of the hysteric disorder, the suppression or insufficiency of its accustomed secretions is followed by such derangement of the digestive organs, that the hysteric phenomena appear wholly to depend upon the latter; a fact which did not escape the observation of Whytt, who remarks that "when the menses are obstructed, the stomach generally suffers first, and by means of its *consent* with almost every part of the body, gives rise to many of the complaints which follow. Thus the hysteric convulsions and other violent symptoms which are sometimes occasioned by a sudden stoppage of the menses, do not seem to proceed immediately from the uterus, but commonly from the stomach and bowels, whose nerves are first affected either by their sympathy with those of the womb, or by the blood which should have been discharged by this organ being partly turned upon the alimentary canal." (Opus cit. p. 177.) But, on the other hand, it is equally certain that attention to the order of the phenomena in hysteria will often detect the priority of the intestinal disorder, which the uterine irregularity seems, in such cases, to follow as a consequence. Such are the complications met with in practice; baffling to those who trust wholly to their books, and only to be prepared for by a careful clinical education; a kind of education not confined to the schools, but within the reach of every practitioner who has access to numerous examples of disease.

Either the uterine disorder or the intestinal disorder, which are thus seen to have the power of producing each other, may produce the nervous irritation, or the congestion, or whatever morbid

* Other irritations of the intestines seem also to commence in the lower portion, and to proceed upwards. Diarrhoea commonly precedes vomiting in the cholera. Hernia excites irritation above the protruded portion of bowel or omentum. The symptom of globus has been noticed in some instances of severe gastritis, and is in such cases supposed to depend on spasm of the cardia extending to the œsophagus. Broussais considers it as indicating inflammation of the whole stomach; but what bears somewhat on the present subject is that in these instances the capacity of the organ has been found greatly contracted, reduced to the capacity of the small intestine. See GASTRITIS.

condition it may be, of the nervous system, or of certain portions of it, which induces the hysteric paroxysm. Either of them, also, may thus act as a cause predisposing to the hysteric paroxysm, or as a cause exciting it without the supervention of any other known cause.

Another cause of hysteria, also, sometimes predisposing to, sometimes exciting the paroxysm; sometimes connected with uterine disorder, sometimes leading to it; is a plethoric condition of the body, or of the nervous system, or apparently of portions of that system. The appearance of the patient commonly indicates the presence of this cause in patients who are indolent and overfed; but as it is often combined with an oppressive feeling of debility, with a pale or bloated complexion, and a languid pulse, and as the plethora may exist with reference to the strength of the patient only, it sometimes escapes attention.

Both hysterical and epileptic attacks are occasionally attended with hemoptysis. We think, also, that it is too common to set down cases of periodical vomiting of dark-coloured or sanguineous fluid as dependent on uterine disorder, when, although the menstrual discharge may be rather less than natural, really dependent on plethora. Patients of the description here meant complain of pain of the stomach, distension, flatus, and coldness of some portion of the abdomen, followed by the vomiting. The pain and other symptoms alternate with severe pain at the upper part of the head, accompanied with several symptoms which may be called nervous, such as a sense of coldness in the eyes, nose, and face generally; and they are subject not only to great agitation of spirits on slight occasions, but to severer symptoms, such as temporary insensibility, seemingly connected with fulness of the cerebral vessels. They also often complain of pains and swellings of the hands and arms, and feet and legs; they are soon and much disordered by errors of diet; inclined to be fat; subject to profuse perspirations on making slight exertions; and their bowels are constipated, as well as the catamenia deficient. In such cases the plethoric condition finds no natural or no effectual relief; and bleeding and medicine must be the substitutes for the dietetic restraint and proper regimen which often cannot be enforced, as well as for the vomiting which has already established itself.

All convulsive affections seem to be capable of being produced both by plethora and the opposite state of debility, or deficiency of nourishment. This may arise from defective powers of digestion and assimilation, or be a consequence of previous disease of some continuance, as leucorrhœa and menorrhagia; or of a recent confinement, (Whytt, Opus cit. p. 186, who also refers to a case in the Phil. Trans. No. 174); or of protracted nursing; or arise from various other causes which it is unnecessary to enumerate, including any which may lead to a depravation of the blood as well as to deficiency of its actual or relative quantity. It may be worth while to mention that repeated bleedings and excessive purging may have the same effect. (Saurages. Nosol. Method. "a repetitis phlebotomiis et catharticis.")

Some of the older writers laid considerable stress on the influence of a gouty constitution in predisposing to hysteria. Facts of this kind are

not easily verified; and hysteria may occur in a gouty family without being really connected with a gouty constitution. There can be no difficulty, in an age when a new and more enlightened pathology of the fluids seems to be dawning, in admitting so much of the ancient humoral pathology as to allow that either a gouty or any other morbid matter in the blood may be the occasional exciting cause of those nervous irritations which characterize a susceptible temperament, just as, in other cases, the same morbid matter, by irritating the nerves of the extremities, appears to excite the common pains of gout and rheumatism. The nervous irritation in these latter examples is sufficiently well established; the existence of a morbid matter yet remains to be proved.

Climate, seasons of the year, occupations, and sex, have generally been enumerated among the causes creative of a predisposition to what has been termed *morbidity*, and what we have spoken of as increased susceptibility of the nervous system. The situation of a country, its soil, its climate, and even its government, determine the occupations of the mass of its inhabitants, and by giving greater or less excitement to their faculties, naturally cause more or less activity and enterprise. The susceptibility which predisposes to various nervous disorders is thus undoubtedly increased or lessened. All the disorders of the mind are said to be less common in Spain and in Turkey than in England. But, as regards hysterical disorders, it is seldom that we have any reason to refer their origin to causes of such general operation; except it be to climate and to seasons of the year. Joseph Frank says that his own observation has taught him that spasmodic affections of all kinds are more frequent in Italy than in any other countries.* Yet the women of Lapland have been described, although we cannot quote our authority for it, as being so susceptible to impressions as to faint on any sudden noise occurring near them. We have ourselves often remarked the increased discomfort of hysterical subjects in warm and showery weather; and especially, without such decided reference to increased temperature, their aversion to the supposed disturbing influence of a cloudy sky: they sometimes say that they "can feel the clouds."

Dr. Mead enumerates hysterical disorders among those which are influenced by the moon; returning when there is a new or full moon: and he refers to a case related by Dr. Pitcairne, and to two recorded by Piso,† one of which was that of "a lady of quality, whose left cheek and part of the neck were wont to swell very sensibly about the new moon."‡ We have already spoken of the modern disregard of all notions of this kind, (see the article *DISEASE*, vol. i. p. 688.) and shall say nothing more on this occasion than that, true or false, fanciful or real, we have hardly ever known a patient affected with a nervous disorder whose attendants did not stoutly assert these much derided influences.

* Quamvis spasmi nec in regionibus septentrionalibus desiderantur, eos tamen longe frequentius in Italia observare, non doctæ observationes. *Prax. Med. Univ. Præc.*

† De morbis a serosa colluvie. Piso attributed hysteria to a serous colluvies at the origin of the nerves.

‡ Mead, On the influence of the Sun and Moon upon Human Bodies, and the Diseases thereby produced.

The influence of sex and of education is more generally admitted, and indeed much more palpably and generally evinced. Medical philosophers declaim, and will long declaim in vain, against a system of education which, apparently solely directed to securing an advantageous establishment to young females, leaves them at once artificial and ignorant; full of the terms of many kinds of knowledge, but wearied or disgusted with all; trained to subdue the feelings only so far as to form alliances from selfish motives, but unprepared to be the companions of intellectual men, or to bear the neglect which their insipidity, or motives as selfish as their own, too often entail upon them. The predominance of the uterine system, although much less marked in the generality of cases in this country than in those in which the observations of some of the continental writers have been made, is yet sometimes sufficiently declared; and the disappointments of females who begin to feel that they are no longer young, and yet who have not become wives, have in many cases effects sufficiently observable. English practitioners pay, perhaps, too little attention to these circumstances; and, exercising their profession in a country where the passions and emotions have but a limited external manifestation, and where the female character is less intensely expressed, sometimes seem to forget their silent operation on the frame, and are inclined to charge the medical writers of other countries with being somewhat fanciful and extravagant.

"The social position of women," observes M. Georget, (*Op. cit.* vol. p. 193,) "renders the sex, already subjected to peculiar ills from their organization, the victims of the most acute and painful moral affections. Their moral existence is entirely opposed to their faculties; they possess a will, and are constantly oppressed by the yoke of prejudices and social arrangements in their infancy and early life; of a husband in their youth; and of indifference in old age. Sensible and loving, they must only love when the master orders them: they are for ever constrained to concentrate within themselves the most powerful passions and the gentlest inclinations; to dissemble their desires; to feign a calmness and indifference when an inward fire devours them, and their whole organization is in tumult; and to sacrifice to a sense of duty, or rather for the happiness of others, the happiness and tranquillity of a whole life." "The education of young women, of which the tendency ought to be to repress the affective faculties, already too prominent, has, as now conducted, opposite effects. A mother would be in despair if her daughter did not give early indications of *acute sensibility*, and nothing is neglected that may endow her with this fatal present: inaction of the muscular system; the cultivation of music; frequent parties, balls, and public entertainments; the understanding unemployed; or books perused which do but excite certain feelings, and nourish illusions contrary to the actual state of society;—such are often the different influences to which girls are subjected at an age when the powers of the mind should have quite a contrary direction. The end answers to the means; one order of faculties alone is exercised; and this will become predominant over the reasoning faculties, and the

cause of a host of vaporous, hysterical, hypochondriacal and maniacal disorders."

Making due allowance for the different character and habits of the two countries, we cannot doubt the justness of these censures. And even in England, where an acute sensibility is less desired for young women than accurate powers of calculation, the improper expectations, the vain rivalries, the restless and frivolous pleasures of fashionable life, are but too well calculated to produce all varieties of nervous disorders in young persons whom an affected refinement has debarred from active and natural exercises, and whose minds have never been accustomed to the exercise of self-control.* In the middle classes different causes are in operation; and women of that class are at present subject to mortifications arising from the inferiority of their husbands in attainments and in cultivated sensibility to themselves. The gentle passions and the romantic feelings, utterly banished from the cold atmosphere of the higher ranks, have yet some sway in a class below them, and there produce occasionally their peculiar effects on the female frame.

But there are causes of disquietude which pervade every rank: for if the utmost attention to fashion could wholly still the voice of the natural feelings, it cannot suspend the inevitable flight of years and advance of old age; a phantom uninviting in its aspect to all, but to the fair, the frivolous, and the vain, a spectre of the utmost horror. On this subject M. Georget has expressed himself in language too applicable to every nation. "Man, as he advances in age, increases in power, in fortune, in dignities, in consideration. It is quite otherwise with woman: the progressive steps of life, when youth has once passed away, are for her an actual descent in the social ranks, and the sources of painful moral affections. There are few who can see without regret their attractions fading, and the flight of smiles and love, and the loss of the empire of beauty: these losses are felt the more keenly, because it is from others that the first knowledge of them is derived; for self-love makes many struggles, and the unwelcome persuasion is only established after many mortifications." "If devotion does not effect a salutary diversion in the ideas, or if a truly philosophical resolution does not early impart to woman the courage and firmness necessary for clearing this terrible abyss, the critical age becomes a stormy period, abounding in vapours, mental disorders, hysterical and hypochondriacal affections, often ascribed, without consideration of their origin, solely to that period of life, or to the cessation of the catamenia."

The causes acting through the mind which have now been mentioned, are occasionally exciting causes, but much more frequently only predisposing. Mental impressions of a more sudden and transient character may act as causes immediately exciting a paroxysm; such as anger, grief, terror, or great surprise. It is unnecessary to accumulate illustrations of the powerful effect of these impressions; the slight operation of them in

their lower degrees is familiar to the commonest observation. But from this slight operation, involving mere disorder in the vascular and nervous systems, indicated by blushing or paleness, by palpitation, by increased excretions, by hesitating speech, may be observed gradations to the more severe results of slowly formed disease of structure, as in the heart; or of changes more rapidly produced, though less important, as in the colour of the hair. More commonly, however, the severer results are produced by causes long operating on the mind: whilst the more sudden impressions, when their violence is greater than ordinary, produce a simple loss of power in the nervous and muscular systems; the state of syncope, from which there is a gradual recovery by moderate reaction: but this loss of power may be greatly protracted, no reaction may take place, and death may ensue; or overwhelming reaction may be produced and fatal apoplexy. Generally, however, the severer shocks lead to a reaction, which is violent without being fatal; and after the feeling of faintness or depression, or sometimes almost without time being afforded for that feeling, the muscles are thrown into disordered and energetic motions, and all the vascular and nervous actions become irregular or tumultuous, and assume the form of hysteria or of epilepsy. Even the mimic representation of the more agitating passions will sometimes produce these effects; and hysteria has converted the cries and screams of the actress into reality, whilst the female part of the spectators have been similarly affected. Dr. Gregory used to relate that when Mrs. Siddons first appeared in Edinburgh, these effects upon the audience were so common, that it became quite the fashion for the young men of the place to attend the theatre to carry off those affected; a service which was termed "carrying off the dead."

We cannot help again, in this place, endeavouring to impress upon the reader that sometimes the reaction after these sudden impressions takes the form of acute delirium. There is no inflammation of the brain or its membranes, no discoverable change to be detected after death, when death occurs; and the best treatment is *not* the active treatment sometimes resorted to, but the treatment proper for hysteria. Above all things, the practitioner must avoid sending such cases to a mad-house. Whenever such attacks are found to have suddenly supervened on an acute moral impression; after violent disappointments of the affections; vehement invasions of jealousy; or even after marriage, when there is reason to suspect the existence of peculiar physical circumstances which can here only be alluded to, the practitioner cannot be too little precipitate in his measures. One or two remarkable cases of the latter kind have come to our knowledge, where the result was fatal; and we think their real nature has not been sufficiently reflected upon.

Another mental influence productive of hysteria requires to be mentioned, because it suggests certain precautions in the management of such cases; namely, the influence of imitation. One hysterical patient in the ward of an hospital will sometimes produce many more. Of this an instance has already been mentioned on the authority of Dr. Bright; and these effects have been so often

* The reader may be advantageously referred to Dr. Parry's admirable remarks on the Effects of Habits in creating Predisposition to Disease. *Elem. of Pathol. and Therap.* vol. ii. See also the article PHYSICAL EDUCATION.

noticed, that, generally speaking, no place can be less suitable to patients affected with hysteria than an hospital. Even in private practice such communications of disease occasionally take place. Dr. Gregory used to mention an amusing instance of a lady's maid thus involuntarily imitating her mistress; and M. Louyer Villermay mentions similar accidents in the article *Hystérie*, in the *Dictionnaire des Sciences Médicales*. Dr. Darwin speaks of the inmates of a nunnery who were all afflicted, one after the other, and at length altogether, with a desire to imitate the inharmonious nocturnal sounds of cats. Dr. Whytt alludes to a disease common in the island of Zetland, and almost exclusively affecting young unmarried women; sometimes, however, appearing in the male sex; in which there was first violent palpitation, and then the patients fell to the ground; their arms and legs being either convulsed or rigidly extended, and their respiration difficult. The great inconvenience of this affection was, that when any one was attacked with it, at church, in the market, or in a public place, straightway all who had ever been subject to it were attacked again; whilst others, in the great disturbance thus occasioned, became for the first time similarly affected. All these examples merely illustrate the proneness to imitation which is observable in all persons in early life, and which continues longest to adhere to the character of nervous and very susceptible persons, and consequently to many women. This is particularly seen in schools, which have sometimes furnished remarkable cases of squinting, stammering, and awkward motions, solely occasioned by imitation.

The celebrated Boerhaave, his nephew Kaau Boerhaave informs us, was consulted concerning the occurrence of a more serious affection which was introduced into the house of charity at Haerlem. A girl having become subject to paroxysms of a convulsive disorder, in consequence of fright, one of the bystanders on the occasion of one of her attacks had become affected in the same way, and then a third, and afterwards a fourth; and subsequently almost all the boys and girls in the institution. Like the people of Zetland, too, as soon as one fell into a fit, all the rest followed. The malady was considered to be epileptic, and all the usual means of relief were tried without the least effect. Boerhaave, therefore, determined on trying what could be done by a powerful mental impression; and, with the concurrence of the magistrates, caused several portable furnaces to be introduced into the house, containing burning coals; and in these furnaces were placed irons bent to a peculiar form, for the purpose of being made red-hot. Assuming great gravity and dignity of manner, he declared, in the hearing of all the boys and girls, that other means being useless, it was requisite that whoever became attacked with the fits should immediately be burnt in the arm with one of the bent irons, and to the very bone. It is added that the children, terrified by the idea of this remedy, were enabled to resist all tendency to a recurrence of the troublesome disorder which had affected so many of them.

Dr. Haygarth was consulted, in 1796, respecting a convulsive malady which prevailed in the island of Anglesey, and chiefly affected females.

The symptoms were, a pain in the head or side, succeeded by violent twitchings or convulsions, during which the shoulders were nearly brought together. This disorder excited great alarm, and in the course of two or three months eighteen girls had become affected by it. Other instances are related in a pamphlet of Dr. Haygarth's, (*On the Imagination as a Cause and as a Cure of Disorders of the Body; Exemplified by Fictitious Tractors and Epidemical Convulsions: 1800*. See also Rees's Cyclopædia, article *Imitation*); and we shall not dwell longer on this part of the subject.

Before concluding our notice of the causes, we would observe, with respect to the cases of *hysterical asthma*, that, when the frequent connection between indigestion and asthma is considered, it will easily be supposed that the exciting cause of this particular form is often a disordered state of the stomach and bowels. But this complication is by no means invariable in hysteria; in which the asthma is often dependent on simple nervous irritation, produced by various causes; a fact which may be readily admitted when we recollect some of the nervous symptoms even of common asthma; the irritability preceding the attack, the *urina profusa*, the periodicity of the paroxysms. The nervous irritation may be of various origin: sometimes, doubtless, in the intestinal canal; often in the uterine system, particularly in the hysterical; and sometimes in impressions on the mind; the irritation being transmitted along the respiratory nerves with a facility which we only attempt to explain by referring to other instances of their prompt sympathies equally inexplicable.

The same observation may be extended to hysterical palpitation of the heart. No symptom more frequently arises from a disordered stomach than palpitation, and such may be its origin in some cases of hysteria. But the same system is a most familiar consequence of mental impressions, and of various other irritations; in all of which cases it is referred to the law of nervous sympathy. Few impressions capable of inducing nervous phenomena fail to produce palpitation; and sometimes it may be found that the paroxysm consists of palpitation; which perhaps takes a periodical form, with just so much of other hysterical symptoms as to create a suspicion of its real nature.

The headach, also, so commonly afflicting the hysterical, is known to be the commonest of all attendants on indigestion: it is also particularly common in females at the monthly periods. But it will undoubtedly often be found to occur in the hysterical as a direct consequence of nervous irritation; neither yielding to the remedies of indigestion, nor affected by the periodical functions of the uterus, nor relieved by repeated detractions of blood; indeed, sometimes much aggravated by the latter; but greatly mitigated, and sometimes banished very speedily and entirely, by what are called nervous medicines. We dwell on these apparent minutiae because they are really of importance in practice; and because great attention to the real causes of the hysterical phenomena will often save much time, and spare the patient from the infliction of much unnecessary medicine.

There are circumstances connected with the

hysterical headach, well known to all observers, but not easy to be explained. One is, the very common limitation of the pain to a small space above the eye. Sydenham was content to ascribe it to an "irregular motion of the spirits, in which all the spirits are collected in a certain point of the pericranium." It is easier to see the futility of this explanation than to furnish a better. Sydenham seems to have been much pleased with the solution, for he adds,—"and this contraction of all the spirits into a kind of point, differs little from the collection of the rays of the sun by a burning-glass; for as these burn by their united force, so those for the same reason cause a pain, by tearing the membranes with united violence." (Op. cit. p. 379.) The difficulty of giving a proper explanation of this peculiar pain is, however, not greater than that of accounting for the pain under the left breast in the tedious cases already described; and the pathologist is sometimes able to do no more than thus to escape one difficulty by pointing out another which is analogous to it. The intermissions and returns of the pain belong, in like manner, to many affections dependent on morbid conditions of the nervous system; and although, like them, sometimes occasioned by obvious recurring causes, are also sometimes as little understood as the paroxysms and intervals of neuralgia, of epilepsy, or of insanity.

Pathology of Hysteria.—Nearly all that can be properly said to have been ascertained respecting the pathology of hysteria has been incidentally spoken of in the foregoing description of the varieties of the disorder and of their various causes. The malady chiefly affects women, or men of a peculiar temperament, or whose constitutions have become enfeebled by intemperance, or by excessive study, or other causes capable of debilitating the nervous system, and of rendering its power of enduring impressions less than in the natural state. A nervous system thus susceptible by original constitution, or thus enfeebled, feels impressions more keenly, and responds to them more forcibly than is seen in firmer organizations, or in a state of perfect health, and, thus prepared, may be excited to disordered actions by numerous accidental causes. In the female system the exciting cause is very often an irritable or morbid condition of the uterine system. But, as this state of the uterine system appears to transmit an irritation from the uterine nerves to the nervous centre, which irritation is reflected from the centre to the nerves of other parts of the system; so similar irritations appear to arise, in other instances, from other extremities of the nervous system, and especially from the intestinal. In other cases, again, the nervous centres are more immediately irritated or disturbed. The reflected irritation, or that transmitted from the nervous centres, seems most readily to be conveyed to the nerves which preside over the motions of the intestines, and of the heart, and to those of respiration; parts and functions almost always the first seat of the hysterical phenomena. But the irritation may be more diffused; may affect the organs of locomotion and of sensation; and, partly from the specific irritation of the disorder, partly from the manner in which the circulation is affected, (for it is difficult in such a general disturbance to

assign a specific cause to each separate phenomenon.) there is a complete loss of the power of moving, and a loss of sensibility and consciousness. It is very probable that the primary irritation of the nerves is soon attended with some alteration in the manner in which the circulation of blood is carried on in them; and the nervous centres may be similarly acted upon. As the disease is seldom fatal, the appearances which have been found after death have for the most part been the mere effects of long-continued disorder of organs from whence the primary irritations have arisen, as of the uterus and its appendages; but in other cases, in which death has supervened in the form of apoplexy upon the hysterical paroxysm, the disordered circulation in portions of the nervous system has been sufficiently manifest in the apoplectic appearances. A state of fulness, of congestion, or of sub-inflammation, in portions of the spinal marrow, may probably often exist. There is, however, every reason to believe that conditions of the nervous system, inconsistent with the proper performance of its functions, often exist without any palpable change in the quantity of blood circulating in the portions of it which are morbidly affected; and that in such cases the functional disorder may leave no visible trace of any kind. On the other hand, sudden and violent changes in the state of the circulation very commonly affect the functions of some part of the nervous system; and even gradual changes in the mere quantity of the blood induce or predispose to all the irritations of hysteria.

If we endeavour to be more precise as regards the exact nature and place of the nervous lesion, we can only be assisted by recollecting the symptoms of an irritated, injected, inflamed, or disorganized brain; and also that the spinal cord may be in like manner affected in any part of its length. It has been observed by pathologists, that when the upper portion of the cord is affected by disease, trismus, impairment of articulation, and deglutition, and oppression of the breathing, are produced; and that even palsy and death from asphyxia may ensue. When the cervical portion has been diseased, tetanic rigidity or convulsions of the muscles of the neck, or palsy of the muscles of the trunk, and paralytic weakness of the diaphragm have been noticed; and results little different have been found in examples of lesion of the dorsal portion. (*Craigie*. Elements of General Anatomy and Pathology, 1st edit. p. 429.) In cases in which the lumbar portion of the cord is diseased, the lower extremities are almost always paralysed; and first, there is retention, and eventually incontinence of urine and of the feces. These facts, which may, perhaps, be considered as established, point in some degree towards the probable locality, though not very decidedly to the nature, of the irritation in some of the forms of hysteria.

That in all the cases, then, of hysterical disorder, there is a disordered state of some part or the whole of the nervous system, seems to be proved by all the phenomena, as well as by the causes which excite their appearance; but we see no reason to believe that there is always a state of vascular fulness, congestion, sub-inflammation, or any analogous condition of the blood-vessels. And,

although the disorder of the nervous system may be, and very frequently is, induced by evident uterine irritation, it no less evidently arises, in other examples, from causes productive of irritation in other parts of the body, and also from causes acting directly upon the mind. If, however, we cannot concede to M. Villermay, that the ancient and revived doctrine of the invariable uterine origin of hysteria is true; neither can we agree with M. Georget to consider it, as Willis had done before, a simple disease of the brain; nor with Mr. Tate, that it is always produced by a morbid state of the spinal marrow, connected with the irregular performance of the functions of the womb.

The existence of an original susceptibility in excess in the nervous system of hysterical patients is an assumption warranted, we conceive, by all observation. The natural or congenital constitution of the nervous system, and even of different portions of it, is most plainly discerned to be different in different individuals. From the very cradle may be observed a different degree of sensibility to impressions; and even a different countenance, impressed by the hand of nature herself, before human feelings have written their deeper lines upon it; a countenance indicative of a distinct and individual character, which is associated with an individual mode of receiving and being affected by external circumstances, and of exercising the internal faculties upon the impressions received. As the individual being grows up, the results of the original organization, modified but not changed by education and various accidents, are observed in all the varieties between stupid insensibility on the one hand, and morbid or too ready excitement and activity on the other. The excitement and the activity are in different individuals more conspicuously manifested in different parts of the mixed system of body and mind. Thus, some are seen to be endowed with almost inexhaustible muscular energies, and some with vast powers of intellectual perception and combination; whilst in some the functions of the mind are feeble or disturbed, and in others divers other functions are debilitated or disordered. In the hysterical patient we may observe the most intense development of susceptibility, connected with a singular proneness to irregular actions, often arising from slight causes; the natural proportion designed to exist between the impressions of the external world and the sentient human system being in them not preserved.

The various impressions which thus become the causes of hysteria, (to confine our attention to this form of their effects,) if always supposed to act by nervous excitation, yet sometimes so readily and so early excite the circulation, and without the visible antecedence of any nervous change, that the phenomena *seem* to be referable to the vascular disturbance. The greater susceptibility of the nervous, or greater irritability of the vascular system, in different constitutions, exercises considerable influence. It would seem as if a mental impression, or a disordered state of the stomach, or the presence of worms, flatus, or acidity in the intestines, or a disturbed uterus, may in one case produce a direct nervous excitement, and in another act first on the heart and arteries, and, through disorder in them excited, lead to irritations

in the brain and nervous system, and, lastly, through the irritation of the brain and nervous system, to disorder in several functions, different in different individuals; the respiratory organs being most affected in one, the intestines in another, the kidneys in a third, and the brain, (still a secondary effect,) in a fourth. The ultimate results are various; sobbing, or crying, or laughing in one case; in another, the hard and barking cough; in one, distension of the stomach and bowels, and globus; in another, diarrhoea or obstinate constipation; in one, copious urine, in another suppression; in one, confusion of mind, in another excessive caprice and love of change.

The links of such a disorder are too numerous to leave room for the affectation of laying down precise pathological rules as the measure of each case. Even another link must in some of the cases be added; for in the case of disordered stomach or bowels, for example, being the cause of the primary irritation which ends in the production of hysteria, that irritation itself, primary as it is with respect to the hysteria, is but secondary to some antecedent failure in the just performance of the vascular or nervous functions, or both, of the part in which such irritation first arises; and this failure itself may be occasioned by too great or too scanty a supply of blood, or too great or a deficient supply of nervous energy, or some other irregularity in the functions of one or both of these systems as relates to the constitution of the part the functions of which are first *seen* to be impaired. Yet it is upon a just consideration of some of these first links of a long chain that our best hope of a radical cure must in a great measure or wholly depend.

The object or final cause of all the diversified hysteric movements seems to be the equalization of the circulation of the blood, and the removal of an irritation of which the nervous system is conscious. We can recall no instance from our observation of convulsions excited without some intention, more or less obvious, to be effected in the general struggle. They commonly indicate the dominion of the irritated or pained brain, and are instinctive efforts for its relief; of which hysterical patients in particular sometimes express their own conviction.* It is justly remarked by the intelligent observer quoted below, that the muscles called into action in hysteria are chiefly those employed in *great exertions*.

Treatment.—We believe there are few disorders of which the practitioner generally undertakes the management with less willingness than hysteria. Its causes are so often obscure, or slight, and not to be wholly avoided, and its phenomena are so changeable and baffling under all kinds of treatment, that it is often left to itself, as a constitutional affection over which medicine has no power. Certainly very little benefit is to be expected from a bold and indiscriminate practice, and no immediate or striking results are to be looked for under the best considered plan of treatment; but those who take sufficient pains to as-

* Ce sont les malades elles-mêmes qui donnent cette explication, comparent ce qui arrive dans cette circonstance à l'espèce de roideur générale que l'on oppose machinalement à toute sensation douloureuse, vive, et instantanée.—Georget.

certain the origin and complications of each case, and have perseverance enough to pursue a plan of treatment adapted to a chronic affection, and often requiring the whole health of the body and mind to be modified, will find that there are many cases, very unpromising at first sight, which may by such means be greatly relieved or wholly cured.

Cases, assuredly, occasionally present themselves, so strange in their character, and so extensive in their complications, that the practitioner who has not been led to refer their almost innumerable symptoms to some general principle may imagine that they are only created to bewilder him and to discredit his art; and be to the last degree perplexed what plan of treatment to adopt, or with what measures to begin. Referring to the notes of a single case, not long ago seen by us, we find, contemporaneously existing, or at least complained of in a continuous catalogue detailed to the ear of the practitioner by a married female, of about thirty years of age,—headach; pain of ears and occasional deafness; frequent loss of voice; tightness of chest; dry, loud, sonorous, and very peculiar cough; dyspnoea; spasm about the throat, with blackness of the face supervening; pain of arms; palpitation; acute pain of the epigastrium, and sometimes in the left lumbar region; irregular appetite for food, and chiefly at night; costive bowels; very scanty and high-coloured urine, with copious whitish sediment, but sometimes abundant, and pale as water; menstruation quite suppressed, after being long defective; much pain of the lower part of the back; pain of the legs; disturbed sleep; great coldness and insensibility of the surface, particularly in the lower extremities, whilst heat applied to them produces mental excitement and a disposition to loud singing; the palpitations induced by exertion, as well as difficult breathing, cough, much agitation, and violent crying. Of such a case, a kind of epitome of all hysteric sufferings, the first view would seem to be most confused, and the first opinion most unfavourable. If the practitioner institutes a diligent search after local symptoms, he finds no satisfactory end to his search; and if he undertakes to prescribe for every symptom, as indicative of some local affection, he exhausts the art of prescription without success; new symptoms arise when old ones yield, and he at length gives up the contest in despair.

To attain clear views of the proper arrangement of these and all other gradations of the malady, it seems best, therefore, to speak of the treatment,—1. with reference to the paroxysm; 2. when hysteria depends on causes of a general nature, as plethora, or the opposite condition of various approaches to anæmia, debility, &c.; 3. when connected with uterine irritation; 4. with gastro-intestinal disorder; 5. of the treatment of some particular symptoms; and, 6. of the preventive treatment in general: we shall thus be enabled, without unnecessary subdivisions, and without neglecting complications which no arrangement can simplify, to comprehend every practical consideration of importance.

Treatment in the paroxysm.—During a fit of hysteria, the objects of all that can be done by the assistants are, to guard the patient from avoidable

injury, and to shorten the duration of the fit itself. The importance of both these objects depends, of course, a good deal upon the form of the paroxysm. When there are violent muscular agitations, the patient may be seriously injured without the care of those about her; and when much pain attends the fit, or when there is a deep coma or intense spasm, our anxiety must be greater to put an end to the attack.

All the details of the methods of restraint to be employed by the assistants may be resolved, whatever appearances of complexity may be given to them, into guarding the patient from injuring herself by her hands, by her teeth, or by striking the head and upper part of the body against any hard substances; and when these objects are gained, further restraint is useless, and perhaps hurtful; for the harmless although irregular actions which remain are to be considered as so many natural means of relief. The best way of guarding the patient from any injury from the teeth, is to put a napkin, several times folded, between them. According, however, to the degree of consciousness possessed by the patient, should the attendants endeavour, by firmness, calmness, and well-timed exhortations, to cause the person affected to exert her own power of self-control. For this purpose the operation of fear has sometimes been resorted to; and the success which has attended it shows that the patient is capable of being roused to exertion: but if sometimes successful, it is not always safe; violent convulsions have in some instances been occasioned by it, converting a quiet form of the disorder into one of an alarming aspect.

If the symptoms indicate a forcible determination of blood to the head, no attentions in the fit will more successfully mitigate the occasional convulsive actions than such as are directed to moderating such determination. The head may be raised, and towels wrung out of cold water applied to the forehead; warmth being at the time applied to the feet. All tight clothing about the neck or chest should be loosened. In the cases going on to complete coma, even venesection may be advisable. When there is less plethora of the vessels of the head, and the fit is obstinate, the patient being at intervals able to swallow, moderate quantities of stimulants are useful; as from half a drachm to a drachm of the spiritus ammoniæ aromaticus or fœtidus, or of the spiritus ætheris aromaticus or sulphurici compositus or nitrici, given in water, medicines which are more suitable than wine or brandy, because less permanent in their effects, and yet efficacious. Advantage may be obtained in slighter cases by sprinkling the face and chest with cold water, as recommended in the article HYDROCEPHALUS for the relief of convulsions; and an abatement of the symptoms is often procured by applying stimulating scents to the nostrils, as common smelling salts: formerly, the smoke of assafœtida or of burnt feathers used to be much employed; and we have witnessed singular effects in some cases of slight convulsion from smelling common mint. More troublesome spasmodic paroxysms, frequently occurring in the fit, may render the addition of the tinctura opii, in doses of twenty or thirty drops, desirable. When the spasms are very severe, and especially

when they assume the tonic form, there is commonly a degree of rigidity about the jaws which renders it difficult to administer medicine of any kind. In such circumstances the best effects are produced by enemata, particularly of assafœtida, of which one or two drachms may be so given; an ounce of the oleum terebinthinæ rectificatum is, perhaps, still more efficacious; we have seen complete resolution of rigid and apparently intractable spasm ensue in a few seconds after its administration in the enema domesticum: it is not necessary that the quantity of decoctum avenæ, which is the best vehicle, should be so great as when the object is to empty the colon; about ℥viii being sufficient. An enema of vinegar and water, or a mixture of these given by the mouth, are recommended by Riverius, (*Praxis Medica*), for the suspension of the fit.

Little more can be done in the paroxysms. To keep off a paroxysm is always important; and it is sometimes accomplished by the prompt administration of ℥ss. of the pulvis ipecacuanhæ, which we have also seen repeatedly successful in suspending the morbid actions of the paroxysm, especially in the croupal form described a few pages back. Extremes of heat or of cold have been remarked to bring on the paroxysms, (*Georget*), and should consequently be avoided as much as may be practicable. No effort should be left unmade to induce the patient to exert herself in opposition to the paroxysm: to resist it, as much as possible, by her will, and to feel pride in overcoming it. When any premonitory symptoms are perceived, cold water should immediately be applied to the head; and some of the stimulants already mentioned may be found prophylactic. Other parts of the preventive treatment will be mentioned afterward.

Treatment when dependent on plethora.—Cases of hysteria dependent on plethora may be complicated with defect in the uterine functions, with the suppression of some habitual discharge, or the retrocession of eruptions; and their relief is then to be principally expected from the re-establishment of the defective secretion, the restoration of a discharge to which the constitution has become too much habituated to endure its sudden cessation without derangement, or the solicitation to the skin of the eruption that has prematurely receded. Much more commonly, however, the plethoric condition of those subject to hysteric fits arises from neglect of exercise and from improper diet, and is best relieved by the general treatment of plethora, on which it is unnecessary here to expatiate. We have seen very good effects from one full bleeding; but the frequent repetition of venesection will not be well borne, and may even increase the susceptibility of the nervous system, and cause the continuance of the hysterical disorder in connection with the debility thus induced. The comatose or apoplectic form of hysteria will generally be found connected with too great fulness of the cerebral vessels, demanding careful attention, for such cases have proved fatal. Any immediate danger may be averted by taking away ten or twelve ounces of blood from the arm, or, what generally gives more decided relief, by cupping behind the neck, or rather between the shoulders, for the practitioner

must not permit himself to disregard the indelible marks of the scarificators. The remaining disposition to cerebral plethora will be easily kept in check by applying a few leeches behind the ears once a fortnight, or every three or four weeks, and by causing the patient to take twice a week, in the morning, gr. ii of the submuriæ hydrargyri with ℥i or ℥ss, or more, of the pulvis jalapæ compositus of the Edinburgh pharmacopœia, or a draught of infusum sennæ with two or three drachms of sulphas magnesiz, and a drachm of the tinctura jalapæ. She should be directed to rise early, to take a tepid or cold shower-bath twice or thrice a week on getting up in the morning, or at night on going to bed: the diet should be moderate, and not consist of much fluid food, as broths, coffee, cocoa, tea, &c. Animal food should only be taken once a day. The patient should not indulge in late hours, nor lie on too soft a bed, nor in a close or confined apartment. Female servants have been rendered liable to hysteria in consequence of sleeping in rooms having no chimney; a fact which it may be useful to notice incidentally, although not directly connected with the subject of plethora. Walking exercise should be most strictly enjoined; the neglect of it is one of the chief causes of the general ill-health of women; they commonly neglect exercise for many days, and then take it to excess; suffer from the excess, and refrain from walking for many days more; and these ill-judged alternations it is very difficult to persuade them to abandon. The lamentable effects of the neglect of exercise have been pointed out in the article PHYSICAL EDUCATION: we believe that more attention is now paid to exercises and recreation in schools for young ladies than used to be the case a few years ago; and that the voluntary indolence of those who are not at school is much more general, and attended with the worst effects. The exercise taken by the patient will, of course, be various, according to her rank or situation in life: fortunately the best kind of exercise is the cheapest; and of all modes of exercise riding in a carriage is the worst, tending much more to induce than to avert a determination of blood to the head. As respects horse exercise we fully concur with Dr. Parry, who says, "with regard to riding on horseback, it is usually a mere apology for the want of that exercise which Providence evidently intended that man should take by means of his own limbs, and not those of another animal. Accordingly we find, that exclusively of the positive diseases which spring from this mode of gestation when violent, those who trust to its more moderate use, and more especially those who substitute it for accustomed bodily labour, are at least as subject to dyspepsia, gout, dropsy, hemorrhage, the whole train of nervous affections, mania, hysteria, epilepsy, paralysis and apoplexy, as those who lead the most indolent lives." (*Op. cit.* vol. ii. par. 31, 32.) The same experienced and enlightened physician reprobated in strong terms the mental weakness which was opposed to all voluntary exertions, and which in itself, as proceeding from the neglect of proper exercise, furnished a powerful argument against it. He admirably points out the evils of very warm rooms; of late hours, which always imply so much time taken

from the day, and from the animating but little heeded effects of *light*; and all those indulgences for which climate or fashion furnish so many apologies. And he notices the instructive fact that various animals dependent on man, and treated with similar indulgence, incur similar penalties. "Thus singing-birds and lap-dogs, which are confined and highly fed, are subject to the whole train of nervous affections; as palpitation of the heart, breathlessness on slight motion, *hysteria*, convulsions, epilepsy, hemiplegia, and apoplexy."

When, by inducing better habits in these respects, and taking the immediate measures already pointed out, the plethoric condition is so far reduced as to obviate the occurrence of any inconvenience from the use of antispasmodic medicines, these may be variously employed, in combination with counter-irritation along the spine, and other measures which we shall have to mention after considering the next class of cases.

Treatment of cases dependent on various degrees of Debility.—Our classification must not exclude from our reader's mind those cases, not of unfrequent occurrence, in which the state of debility is combined with the state of plethora, and which require a judicious combination of several parts of the plan above laid down with that now to be mentioned.

When the general nervous susceptibility, and consequent hysteria on the supervention of slight occasional causes, are not connected with plethora or with vascular excitement of a general kind, venesection, low diet, and saline purgatives, or such as produce watery discharges from the bowels, may exceedingly increase the tendency to the disorder. Local vascular excitement in the brain, for example, or in some portion of it, or of the spinal cord, may require and be benefited by local depletion, and be relieved by external irritations, by means of blisters or the tartar-emetic ointment; but the general measures must be of a different kind. Medicines which increase the patient's strength will here be found to diminish the susceptibility of the nervous system to impressions; but they require to be given with peculiar cautions, for patients of the kind now alluded to generally profess an inability to take any tonic medicine without incurring headach, feverishness, and uncomfortable excitement. Their objections to all medicines in which they detect a bitter taste are uncommonly insurmountable; and the practitioner is precluded from the employment of the cinchona, cascarilla, calumba, and gentian, although some of these might really be serviceable. In such cases the best resource is found in the diluted sulphuric acid, of which seven or ten drops given in the infusum rose compositum, with a drachm of the compound tinctura cardamomi, will be found to form a grateful medicine, which the patient may take twice or thrice in the four-and-twenty hours with great advantage: the addition of *mxv* or *xx* of the tinctura hyoscyami will usefully allay any excess of nervous irritation. If the patient is found, as frequently happens, to make objections to chalybeate tonics, the objections will commonly be avoided by giving these most useful medicines in very small doses, without any sacrifice of their good effects. If the diluted sulphuric acid is given in distilled water, half a

grain or a grain of the sulphate of iron may be given in the draught: even a quarter of a grain or less, given in this manner, is productive of good effects: if more is deemed necessary, *gr. ii* may be given in a pill with the extractum anthemidis, or the extract of gentian, night and morning. If the tinctura ferri muriatis can be taken without inconvenience, it may be given in doses of from seven to ten drops twice a day. We have generally found these forms of medicine less objected to by patients than the mistura ferri composita, although the compound iron pill is taken without complaint, and in doses of eight or ten grains twice a day is a valuable tonic. Of the vinum ferri we have little experience; but this or the mistura ferri may be given so as to avoid any real or supposed inconvenience to the patient, in combination with the decoctum aloes compositum; a combination which may be especially useful when it is desired to promote the activity of the bowels, or to excite the periodical functions of the uterus. The most delicate females can generally take the sulphate of zinc or the oxyde, in doses of a grain twice a day in the form of pill, with some bitter extract, without difficulty; and we are much disposed to think that the general effect of the mineral tonics will be most satisfactorily perceived when they are given in these moderate doses. We give this opinion as the result of our own observation; but it is only reasonable to suppose that more advantage is gained by attempting the gradual invigoration of the functions, than by suddenly calling on the organs for actions of which the vehemence is disproportioned to their power. Whytt mentions a case in which two hundred and thirty grains of the filings of iron were given daily, divided into three doses, for some months together, in a case of indigestion. The carbonate of iron has also been lately given, as is well known, in enormous quantities; but this kind of treatment does not appear to us to be at all suitable to cases of hysteria. It does not seem that the natural mineral waters of Bath, which formerly enjoyed much reputation in nervous disorders, have of late years been much resorted to by nervous, or at least by hysterical patients; a fact of which we are assured by an obliging communication from Dr. Barlow, but which we have learnt with some surprise. If due care was taken to recommend their use in cases where the hysterical affection was connected with a debilitated constitution, we cannot doubt that it would be attended with great advantage. But the real merits of mineral waters are often lost in a meretricious fame: whilst fashion dictates their employment, they are used indiscriminately; and when the fickleness of fashion leaves them unpatronised, their good effects are no longer thought of.

The warm sulphureous waters of Cauterets and Bagnales (Bagnoles) are mentioned by Sauvages as being useful in *hysterica chlorotica*. About four pints are directed to be drunk daily for three days, and a bath is to be taken on the fourth; and the use of the waters and the bathing are to be thus continued for a month. Those of Seltzer, Spa, Vichy, Barèges, Pyrmont, and Carlsbad, have been recommended.

Sydenham had great confidence in the effects of a milk diet in cases of great debility. He also

thought highly of the infusion of various bitters in canary wine, and says that he sometimes advised hysteric women to drink a large draught of canary by itself at bedtime for some nights in succession, and that they were eminently relieved by it, "the whole body having been much strengthened, and such as were before cachectic becoming fresh-coloured and brisk thereby." He also very strongly recommends horse exercise.

To the ammoniatum cupri and nitras argenti, which have sometimes been given on account of their possessing not only a tonic property, but a specific power of allaying nervous irritability, we have never had recourse in hysteria. With the intention of improving the general health, we should especially recommend either the tepid shower-bath of sea-water or of salt and water every other morning; or the sponging of the greater part of the whole of the surface of the body with salt and water every morning. The warm sea-bath may be useful, or, if the patient can bear it, bathing in the open sea.

Change of climate, even within our own island, may become an object of consideration, by way of avoiding extremes of heat or cold. No medical practitioner of observation is now sceptical concerning the effects of changes of weather as well as of climate. We would ourselves generally undertake to predicate, from the actual state of the weather, the situation in which we should find patients of known susceptibility to impressions, or nervousness; and have often noticed their especial discomfort in warm and showery seasons, their continued indisposition in low, sheltered, warm residences, and their as certain relief when removed to a hilly locality. Some of these effects are perhaps accounted for by the variable weight of the atmosphere in various seasons, its lightness always seeming to produce oppression by permitting the expansion of the circulating fluids, except in particular constitutions, to whom such expansion seems to be suitable; other effects may be the mere result of temperature on the nervous substance; and some we should be inclined to ascribe to electrical variations which have not yet received adequate attention.

The refreshing air of Malvern, of the heights of Clifton, or that of the northern parts of the island, may be useful in the warmer seasons. Of that of Malvern we can speak confidently, as regards its surprising effects on pale languid females, whose appearance and health begin to improve almost as soon as they remove thither; it has this great advantage, also, that it may be enjoyed without exposure to the dissipations which seem to form an essential part of a fashionable watering-place. It is mortifying to observe how frequently weak and nervous patients, relying on a succession of medicines without end, neglect, in spite of every exhortation and every indication of reason, the best tonic and nervous medicine of all, and one which they can always procure by slight exertion—we mean the cool and pure air of the earlier hours of the day. If they cannot deny the unfavourable influence of passing twelve hours out of every twenty-four in the close atmosphere of a bed-room, the conviction has seldom any effect upon their habits. To supply the strength thus lost, recourse is had to various stimulants,

and the result is often the total destruction of health and comfort, and the conversion of all the years after forty into "a long disease."

The effect of various impressions on the mind is always to be considered in cases of benefit derived from change of air. A sea-voyage, therefore, or a journey attended with many incidents, and with some difficulties, has sometimes been found to be very serviceable. The wives of officers, delicate and hysterical in the languor of country quarters, have lost their complaints amidst the fatigues or dangers of a march. The ladies of Paris forgot their hysterical affections, we are told, in the French revolution; and the Irish ladies in the rebellion, although exposed to many and violent impressions. Cullen noticed similar effects in the ladies of Scotland in the civil war of 1745-46; and Dr. Rush, in a curious paper "On the Influence of the American Revolution on the Human Body," says that many hysterical women, who were much interested in the successful issue of the contest, "were restored to perfect health by the events of the time, change of place, occupation," &c. (Medical Inquiries and Observations, vol. i. Philadelphia and London, 1794.) Dr. Parry has recorded some remarkable instances illustrative of the same principle; (Posth. Works, vol. i. p. 368-9,) and Dr. Bright observes that a severe nurse in a ward will sometimes cause hysterical disorders to be less inveterate there than in other wards. (Op. cit.)

Ease and indulgence seem always to exasperate this disorder. The daughters of cottagers removed to the kitchens of people in comfortable circumstances, often become hysterical. The wives of merchants, Frank remarks, are affected with hysteria in flourishing times; but when reverses come, they "have no time to be ill." (Op. cit. cap. xiv.)

In both classes of cases the treatment of which has now been spoken of, periods occur in which neither the proper remedies for plethora, nor those usually suitable to states of mere debility, will do all that is required. The plethoric tendency may be controlled, and the susceptibility, the tendency to irregular and spasmodic actions, yet remain; and the same may be the case both where every thing has been done to counteract debility, and where the patient, although manifestly weak, cannot bear many of the usual means of restoring the strength. It is in these cases that a watchful practitioner will find periods in which anti-hysterical, or antispasmodic, stimulant, or sedative medicines may be prescribed with the happiest results. We do not here allude so much to opium, henbane, conium, and medicines of that description, which are generally only given with temporary advantage in cases of hysteria; but to assafoetida, musk, valerian, and other means which appear to be not only antispasmodic, but directly to decrease the morbid susceptibility of the nervous system. First in the list we should place the gummi resina assafoetida, the chief of those "fetid medicines" which, in the language of Sydenham, "are calculated to compose the tumultuary motion of the spirits," and were therefore anciently called *hysterics*. The assafoetida is, indeed, a medicine which we have found particularly useful; and, if the patient will submit to take a very nauseous mixture, the *mistura assafoetida* (the old *milk* of assafoetida) is

perhaps the most efficacious form in which it can be given. Each ounce of this mixture contains gr. xv. of the gum resin, and either $\mathfrak{z}\text{i}$ or $\mathfrak{z}\text{ss}$ may be given three or four times a day, in cases in which the patient is subject to very frequent attacks. It is, however, often necessary to give this disagreeable medicine in pills: in either form much confidence may be placed in it. If genuine musk could commonly be procured, its prescription in doses of gr. xv three times a day would probably be equally or even more efficacious: it is certainly a valuable medicine. The *mistura moschi* of the pharmacopœia, containing in each $\mathfrak{z}\text{ss}$ of aq. rosæ gr. xv of musk, is one of the most convenient formulæ for the use of the practitioner. The utility of both the *assafoetida* and the musk will be the most conspicuous in cases in which the surface is pale and the pulse languid. The *castoreum* has been much recommended; and the tincture, and still more the compound tincture of the Edinburgh pharmacopœia, in which it is combined with *assafoetida*, may be usefully added to other medicines in doses of one or two drachms. The effects of *valerian* are occasionally very striking. Idiosyncrasies seem to exist, which render different anti-hysterical medicines of paramount service in different cases; and in some of the forms of hysteria the *valerian* is a specific. As many patients cannot bear the powder, the *infusum valerianæ* of the pharmacopœia of Dublin may be conveniently prescribed; we are ourselves most familiar with its effects in the form of the *tinctura valerianæ ammoniata*; and particularly in the hysterical headach, to be presently spoken of. The *oleum succini* has sometimes been recommended in hysteria, but we do not think that either in its simple form, or in that of the *spiritus ammoniæ succinatus*, it is now much employed.

[*Dracontium* and *creasote* have likewise been used in the same cases; but they are not possessed of any powers, which should give them a preference over the articles already mentioned.]

Although we feel convinced that there are, as we have said, periods in almost all cases in which antispasmodics are most serviceable, there are no medicines which will more surely disappoint the practitioner who trusts entirely to them, or employs them indiscriminately. In many cases it must be remembered that the means of reducing vascular action, or, on the other hand, the means of improving the general strength, are the best antispasmodics, and more truly anti-hysterical than any specifics which can be employed.

The restless nights and various uneasy feelings of hysterical patients make it in many cases absolutely necessary to have recourse to anodynes. The extracts of *hyoscyamus* and *conium*, with camphor; the *tinctura opii*, or *tinctura camphoræ composita*; the acetate or muriate of morphia, the *liquor opii sedativus*, the Dover's powder, or opium alone, will be suitable in different circumstances: but the disposition of hysterical patients to continue the use of these medicines, and to take them in large quantities, should be carefully discouraged.

Treatment of cases dependent on uterine disorder.—Independently of all the parts of the general treatment of hysteria, these cases require especial attention, different according to the precise disorder existing in the uterus. If *amenorrhœa* is present, which we have stated that we consider

not a very common circumstance, the practitioner must have recourse to the proper treatment as described under that head. (See *AMENORRHŒA*.) If, as more frequently happens, there is too frequent or too copious menstruation, a form of disease in young females which is even more difficult to be managed, attention to the general health will be found the most important; although sometimes astringent medicines are decidedly useful. We have known marked advantage derived from taking six or eight grains of the *pulvis kino compositus* with a few grains of alum two or three times a day; but when medicines of this kind are given, the supervention of headach, with a hot and dry skin and feverishness, will sometimes compel their discontinuance. There is usually in such cases what may be termed an irritable state of the uterus, indicated by pain in the hypogastric region, in the sacrum, along the upper edge of the *ossa ilia*, and down the thighs; with *leucorrhœa*, and a quick and feeble pulse: the *os uteri* is tender to the touch, and there is a disposition to organic disease: the digestive organs are almost always in these instances considerably disturbed. Cupping on the loins, leeches to the epigastric region, or to the vagina or the *os uteri* itself, anodyne enemata, fomentations, rest in the horizontal position, the frequent use of the hip-bath, and temporary separation a marito, and a most careful avoidance of irritating purgatives, are among the measures most to be recommended in such cases. For the addition of anti-hysterical or tonic remedies no rules can be laid down; the judgment of the practitioner must entirely regulate their administration in each case: they will often be found necessary even when the uterine irritation is relieved.

Some of the French practitioners lay more stress than we are accustomed to do in this country on particular articles of diet, and substances introduced in enemata, in occasioning uterine excitement and hysteria. Crabs, mussels, onions, truffles, aromatic chocolate, vanilla, and cinnamon, are enumerated by M. Louyer Villermay as having these effects; and he adds *perhaps* strawberries and raspberries, but more certainly too nourishing, spiced, and heating aliments, wines, spirits, and every excess. He further mentions pastilles, into the composition of which the powder or tincture of *cantharides* enters; and also enemata of drastic, irritating, and poisonous plants, which he says have often caused nymphomania with convulsions, terminating in death. (*Dictionnaire de Médecine, Art. Hystérie.*)

Treatment of cases dependent on gastro-intestinal disorder.—These cases may require little more than the simple treatment of indigestion (for which we refer the reader to the article *INDIGESTION*) as preparatory to the administration of antispasmodic medicines. If there is much tension of the abdomen, with uneasiness, and some tenderness on pressure, the cure will be very much hastened by the application of from six to twelve leeches to the epigastrium. This practice, recommended by Dr. Wilson Philip in particular stages of indigestion, we have seen the immediate advantage of in innumerable instances; constantly observing the utility of medicines after such application, which had been fruitlessly persevered in before. If the lower part of the abdomen is tumid

and uneasy, the leeches may with more advantage be applied to the orifice of the rectum. But this tenderness is by no means constant in hysterical cases; and the distension of the abdomen is seldom permanent, but rather comes on and subsides with some suddenness, and is then shown by many symptoms to be dependent on flatus. Temporary relief may be obtained in the attacks from carminatives; as the compound tincture of cardamoms in aqua menthae piperitæ, aqua carui, or aqua cinnamomi, or a little spiritus ætheris aromatici in camphor mixture; or even a few drops of the oleum carui on sugar. The importance of giving relief in these attacks of flatus depends less on their severity, although that is considerable, than on their tendency to induce the hysterical paroxysm. The measures from which we have seen the most permanent efficacy are the administration of the warm gums and purgatives at night, or night and morning, and of bitter medicines with an alkali twice a day; with strict attention to diet and to clothing. Eight or ten grains of the pilulæ aloes et assafetidæ of Edinburgh, or equal parts of the compound extract of colocynth and of the pilulæ galbani compositæ, have seemed to be of essential service: the inactivity of the bowels often requires an aperient draught to be given in the morning; in which case the decoctum aloes compositum is preferable to salts and senna. Whytt recommends pills of assafetida, extract of aloes, and sulphate of iron: we have found pills of the sulphate of iron, extract of aloes, and extract of gentian, very beneficial: the tinctura muriatis ferri, or a draught of equal parts of infusum gentianæ compositum and aqua menthae, with the carbonate of potass or of soda, twice a day, are also useful. The state of the stomach and bowels is often improved by giving small alterative doses of the pilula hydrargyri; but the practitioner should never forget that although nervous patients are more than all others sensible of the immediate relief derived from taking a dose of the blue pill or of calomel, there are none on whom the penalties of taking these medicines too often or in excess, are more certainly and more painfully exacted, in the shape of increased nervous susceptibility, which may thus indeed be exasperated to the extremest sensitiveness, and even to madness.

External applications, in the form of emplastra, are perhaps too little regarded in modern practice; we are persuaded that much benefit is sometimes obtained by the application of a good-sized emplastrum galbani compositum to the abdomen, as well as occasionally by a mercurial plaster. A broad bandage of flannel is sometimes useful, and the daily use of the flesh-brush and friction. We have not found any form of bathing very serviceable in this description of cases.

Attention to the diet of these patients is of great importance: they generally find it necessary to avoid fluids and vegetables, except in small quantities. Moderate meals, at regular and sufficient intervals, should be recommended to them, rest in the horizontal position for an hour after eating, and afterwards exercise: a glass or two of sherry after dinner will generally be found useful to them, or small quantities of brandy and water. Porter, ale, and beer, seldom agree with them. One of the benefits of not drinking at

dinner, a rule in itself not warranted by natural instinct, is that it causes the patient to eat less: large draughts of beer or soda-water are decidedly improper.

If there is reason to suppose that the hysteria is almost wholly dependent on confined bowels, the continued use of the compound aloetic pills will perhaps be found more productive of relief than the most complicated treatment which can be devised. Large and unsuspected collections of fecal matter are frequently lodged in the colon, and remain or re-accumulate, unless the practitioner perseveres in the treatment calculated to remove them.

When the hysteria is connected with the presence of worms in the stomach or bowels, recourse may be had to anthelmintics: except in the case of tænia, however, against which the oleum terebinthinæ may almost be said to be infallible, the best vermifuges will be found in the means already detailed.

Among the complications of hysteria we have already mentioned that of the intestinal with uterine irritation; and the cases which we have just described will often be found to be considerably aggravated at the menstrual periods. We are convinced, however, that in many such examples the uterine irritation is neither first in order nor in importance. No sequence is, in fact, more familiar in pathology than that of irritation of other mucous membranes supervening on that of the intestinal canal.* The vehement pulsation of the aorta, which was also mentioned, sometimes depends on intestinal disorder.

Treatment of particular symptoms.—Concerning these it will not be necessary that much should be added to what has already been laid down respecting treatment; but the practitioner will be disappointed if he looks for the retreat of some of these troublesome complaints even when attacked according to all the rules of art. Theoretical writers, vain of their science, but unversed, as it would appear, in the perplexities of practice, are too ready to deride empirical modes of relief, and to believe that their general maxims are all-comprehensive. Thus M. Louyer Villermay, maintaining the uterine theory, disregards the condition of other organs; and M. Georget, treating the uterine theory with ridicule, asserts that as hysteria is a disease of the brain, it is idle to prescribe for the stomach, or the heart, or the lungs; and seriously advises "pills of crumbs of bread and other substances of like energy, and for drink, water and tisanes of equal virtue." Whoever sees much of hysteria will soon become satisfied that such practices would be singularly useless, and that even when every general means has been attended to, there are particular attentions which cannot be neglected without disadvantage.

The hysterical headach is best relieved by the tinctura valerianæ ammoniata in doses of ʒss, with an equal quantity of sp. æth. sulph. comp., or of sp. lavand. comp., or of the tincture of hyoscyamus, in camphor mixture. A drachm of the simple tincture of valerian, and ten or fifteen drops of acidum sulphuricum dilutum, taken twice

* The reader is referred for an illustration of this important principle to the article *ASTHMA*, vol. i. p. 216.

a day, with or without $\mathfrak{z}$ i of the tinctura cinchonæ, is also a useful medicine. The application of cold to the head, the frequent use of the shower-bath, and of pediluvia of warm water, may be resorted to with benefit. Although blisters behind the ears are in these instances, and in those of hysterical pains about the face, usually productive of much temporary irritation, their employment is often followed by relief. In very obstinate pains, as in nearly all obstinate chronic disorders, a gentle course of mercury has occasionally proved useful. (*Whytt.*)

For the relief of those cases in which the symptoms of phrenitis are simulated, rest, quietness, opiates, and, according to circumstances, purgatives, and the usual means of equalising the circulation, will generally be found efficacious; and stronger measures are not hastily to be resorted to.

In the hysterical asthma, in addition to the ordinary treatment of cases in which there is much nervous irritability, the patient may take pills of equal parts of ammoniacum and squill, or of ammoniacum and assafœtida. Dr. Whytt recommends equal parts of the two latter in aqua pulegii. We have seen evident relief from plasters of assafœtida and ammoniacum applied to the chest. These cases also often require particular attention at the monthly periods, when small doses of the sulphate of magnesia, with tincture of hyoscyamus, given in the mistura camphoræ, will sometimes be found to ward off threatening symptoms.

Of all forms of hysteria none are so obstinate as those attended with pain in the left side. We have not found it so constantly connected with tenderness of the spine, nor so uniformly dependent on uterine disorder, as Mr. Tate seems to have done. As regards all local treatment of the side itself, we believe it to be a mere waste of time; nor can we speak with much confidence of medicines. We have generally found it difficult, sometimes impossible, to produce proper counter-irritation in the side; but, on the whole, have seen more advantage gained from repeated applications of the tartar-emetic ointment to the spine than from any other means. After many trials, we prefer using ointment of the strength of a drachm of the antimonium tartarizatum to $\mathfrak{z}$ ii, or $\mathfrak{z}$ iii, of cerate; one application, the part being previously sponged with hot vinegar, being often sufficient to produce numerous small pustules, by the repeated evocation of which we have thought the patient much more benefited than by the same counter-irritant applied as a plaster or in any other degree of strength. In our experience, the advantage derived by the patient from the use of this ointment is not generally increased in proportion to the suffering it occasions. Leeches, and a succession of small blisters to the spine, are sometimes still more serviceable than the ointment.

These cases are very unsatisfactory. The patient sometimes continues an invalid for one or two years, and at length recovers without appearing to be under much obligation to medicine; or sinks into a state of atrophy, hardly able to take any nourishment, a prey to every morbid feeling, and a burden to herself and to all about her.*

* For an extreme example, see Dr. Bright's Reports of Cases, vol. ii.

The tenderness of the dorsal spine and the pain about the sacrum have been accurately pointed out by Mr. Tate, who has also given some very striking cases in which relief followed his practice in them. Dr. Darwall had previously called the attention of the profession to the tenderness and spinal irritation, and Mr. Griffin has published some interesting cases of it in the London Medical and Physical Journal. Mr. Tate apprehends that the accompanying pain in the side is seated in the intercostal nerve; although he says he has sometimes thought it must be situated in the nerves of the heart itself. The right side, however, is occasionally the seat of suffering; and we have not observed that the pain, even when in the left side, was often attended with palpitation: a sense of weight is very commonly complained of. We have proposed acupuncture with sanguine expectations of success, which have ended in disappointment. In one case we noticed complete relief ensuing on the coming out of a vesicular eruption in the situation of the pain, and in another on the appearance of an ovoid tumour, which subsequently subsided without suppuration. Dr. Whytt, to prove that "complaints of the nervous or hysterical kind often proceed from some morbid humour in the blood," adduces cases in which "an itching between the toes, red pustules appearing on the breast and belly, or some other cutaneous eruption," produced relief. (*Op. cit. chap. iv.*) Much of the difficulty in these peculiar cases arises from the morbid state of the patient's mind: she supposes that she cannot walk or move, or bear the shower-bath and other means; and the kind attentions which it would be inhumanity to withhold from such apparent afflictions seem to make them more intractable.

Hysterical palpitation is often almost instantaneously relieved by the valerian, or yields to its more continued use. The danger of repeated bleedings in these cases is extreme, or, at least, the mischief thus induced is incurable. The hysterical diabetes will probably be best treated by opium, blisters, or plasters to the loins, flannel worn next the skin, and other parts of the general treatment: spurious symptoms of calculus in the ureters will yield to anodynes and laxative enemata; and attention to the state of the bowels and surface will best keep off the attacks. The great violence of the pain in these cases sometimes leads the practitioner to use the lancet and other means, which are generally superfluous and often very detrimental to the patient.

In the mutable cases, in which various diseases seem to succeed to each other with rapidity, each new aspect of the malady may require new resources; but the general principles of treatment must be kept steadily in view.

We have not spoken in this article of electricity, galvanism, or electro-galvanism, agents which have occasionally been employed in the cure of hysteria; we fear that their application has hitherto done little more than prove the inveteracy of some forms of the disorder. (*See ELECTRICITY and GALVANISM.*)

It may here be observed that hysterical women are very generally disqualified for being good nurses. Sometimes the performance of that function may be serviceable to them, but they generally

perform it inefficiently; their liability to feel all impressions too keenly, and the violent agitations of feeling and temper which belong to them, operating unfavourably on the secretion of milk, and causing disturbance in the child's bowels, and perhaps in its nervous system.

No part of pathology or practice is more unsatisfactory in its present state, or at the same time more promising of future results, than that which relates to the conditions of the blood. If any cases of hysteria could be clearly traced to peculiar states of that fluid, productive of nervous irritation, the object of our treatment would of course be to effect an alteration in it. The means of doing so would be the regulation of diet, the improvement of the digestion, attention to any function obviously deranged, and a careful general regimen. The effects which have ensued in some recent experiments in which saline substances have been directly injected into the veins, would seem to point to very important results. And if the practitioners residing at watering-places had been less satisfied with general assertions of the universal virtues of the mineral waters of their respective localities, and more observant of the actual operation of these serviceable agents in chronic maladies, reasons might have been found for ascribing some part of the benefit derived from them to their effects on the circulating fluids rather than on the bowels, effects which have long been admitted in the case of the chalybeates, but hardly ever hinted at as regards the saline waters. We should desiderate, however, the perfect establishment of facts indicative of such advantage before we should be disposed to send hysterical, and fanciful, and susceptible patients to places resorted to by so many whose idleness and selfishness are their chief complaints. It is not in places devoted in an especial manner to every weak and luxurious indulgence, and in which the honours of medical science cede too often to a miserable waiting upon the caprices of spoiled adults, that we can expect hysterical females to acquire habits of bodily or of intellectual health.

Preventive treatment.—When a young lady has had an hysterical attack of some severity, much anxiety is commonly felt to prevent a recurrence of it; and this may in the generality of cases be thus early prevented by proper attention to the causes which appeared to bring on the attack, and to any peculiarity in the state of her health which has predisposed to it. Where there has been no severe and marked paroxysm, and yet many of the peculiarities of the hysterical temperament exist, the preventive treatment is too often neglected, whilst in the examples in which it assumes peculiar and embarrassing forms, the nature of the disorder is often misunderstood, or, after very insufficient trials, medical and moral means of relief are abandoned.

A careful education may undoubtedly prevent the increase of a susceptibility observed to be naturally too intense; but, although it would be easy to lay down regulations for the accomplishment of so desirable a purpose, it would manifest a great want of experience in the ways and weaknesses of mankind to expect such regulations to be followed with much perseverance. As regards schools, however, it is but just to acknowledge

that of late years much more attention has been paid to allowing hours for relaxation and exercise than formerly. Yet the exercises of ladies' schools are often absurdly enough ordered; the natural amusements of running, leaping, and playing at various active games in the open air being considered ungenteel, and, by a strange inconsistency, the rigid positions of the drill serjeant, the fixed distortion and torture of the feet in stocks, as inculcated by dancing mistresses, the difficult poises and attitudes of a system which is termed calisthenic, and sometimes the exercises of tumblers, the climbing of ropes, and the rubbing of tables, are among the approved means of avoiding at once both deformity and the vulgarity of rude and boisterous health. Meanwhile, the nature of their studies is such as hardly to merit the name of mental cultivation. Ostentatious efforts are made to crowd the elements of many accomplishments into a few years, and if the young lady is not afterwards *finished* by those who profess to instil taste as well as art, and who succeed in effacing all natural and simple tastes and traits of character, she commonly remains unskilled even in accomplishments; whilst the want of all love of literature or acquaintance with science, and consequently of all companionable qualities of a higher kind, diffuses an ennui over society that every one feels without thinking of its source, and by which the whole moveable community is driven about from one place of public resort to another, without useful objects, without attachments, without duties; leading to the habitual neglect of all self-government and the creation of much domestic wretchedness. After the confinement of school, the young female is introduced into fashionable life, and exposed to numerous causes of debilitated health. Returning for a few seasons to London blooming from the coast or the country, she leaves town in June the shadow of herself, often bearing in her countenance not only the marks of dissipation, but of expectations disappointed, wounded pride, and a disposition from which all the attractive frankness of youth has been carefully rooted out. Then, perhaps, ensue the mortifications of celibacy, and the misery of growing old without an active and contented mind. Concerning the evil effects of these and many other circumstances, the physician may feel a thorough conviction, but as the circumstances are not much within his control, it would be useless to dwell upon them in the present article. As causes of disease, and especially of hysterical and other various disorders, none will deny their wide and powerful influence but those who have paid no reflection to the operation of human passions in society. From the circles of nobility these follies flow to the families of the country gentry, and from them to the upper ranks of country towns, whose inferiors of every degree imitate them as well as their daily necessities will permit. The dictates of health, of reason, of happiness, are lost in the love of false greatness and over-refinement which hangs over empires devoted to decay. But against such habits it avails little to protest; the physician cannot obviate them, nor are they "curable by any herbs."

He may, however, often with more success devote some portion of his care to the preservation

of a healthy body. If every function is well performed, the nervous system will, it is probable, soon become freed from the morbid susceptibility which disposes the young female on receiving any slight impression to the irregular actions of hysteria. It has so often been found useful in chronic disorders of an obstinate nature to place the patient in new circumstances, and thus to change the whole series of impressions to which she is exposed, that this resource should not be overlooked. With this intention the hours of rising and taking food, the times of exercise and rest, the nature of the mental occupations and of the bodily exercises, should no longer be the same as customary. Change of scene, change of climate, change of manner of clothing, may all form parts of such a plan. So many of these changes are effected at once by a removal to a watering-place, or to the sea, that the advantage of such a change may overbalance all other considerations, and be advised with great propriety.

Nor should it be forgotten that the different parts of what is called an alterative treatment often induce most important changes by slow operations, seemingly effected in the actions or condition of the nervous or vascular systems, or wrought upon less obvious sources of continued malady, existing perhaps in the secretory processes. (See ALTERNATIVES.)

By the means now enumerated, numerous, as always happens in diseases little obedient to the healing art, and requiring consequently much discrimination in the practitioner who employs them, there is no doubt that many cases of hysteria may be completely cured, and that almost all cases may be more or less relieved. The constitutional susceptibility in some instances of the disorder is so great that relief is all that can be effected, and the protracted character of the malady often leads to its being too soon withdrawn from the care of the physician. Where this is not the case, we believe the failure of the treatment is generally to be ascribed to a want of patience, an insufficient employment of the various resources which we possess, or a want of conformity and perseverance on the part of the patient herself.

Even a palliative treatment, if nothing more can be immediately promised, should not be disregarded either by the patient or practitioner, it being unquestionably true, as Dr. Whytt has remarked, that "long-continued palliation may sometimes make a cure; for while the palliative remedies lessen the bad effects of this disorder of the nerves, nature, either by herself or with their assistance, at length expels or subdues the morbid cause." The practical wisdom of this observation may be remembered with advantage in the treatment of all chronic disease.

We have dwelt longer on the affections united under the name of hysteria than we should have done if we did not know that it is always a peculiar disadvantage to the practitioner to decide, or to be expected to decide, at once upon a plan of treatment of which the immediate effects are to be observable in each hysterical case. It seemed to us that their proper treatment might be facilitated by considering them with reference to their various origin and complications somewhat more closely than had before been done. The best chance of

effecting a perfect cure in any case will depend on the deliberation with which all the circumstances connected with it are considered: the origin, the causes, the duration of the malady, and the present state of the patient, well and duly reflected upon, will usually lead to means of eventual relief, to which hasty and presumptuous prescription can seldom or never attain.

J. CONOLLY.

ICHTHYOSIS, (*Syn.* *Lepra ichthyosis*, (*Saur.*;) *Lepidosis ichthyosis* (*Young, Good*;) (from *ἰχθῆς*, a fish,) *fishskin*, a cutaneous disease, named from its supposed resemblance to the skin of a fish. In our opinion, Willan and Bateman have erred in classing it in the order *Squamæ*, as it has a much nearer affinity to the papular than to the scaly eruptions. It is characterized by a harsh, papillary, or horny condition of the skin. In other instances, the papillæ are elongated into horny peduncles bearing a broad irregular top. Whatever be the cause of this morbid growth, it appears to have a close affinity to that state which produces the common wart. These excrescences frequently suffer partial exfoliation, which affords the scaly appearance that probably may have led to the present arrangement of the disease.

Instead of the division of the genus into the two species, *ichthyosis simplex* and *ichthyosis cornea*, it would be more consonant with experience to divide it into, 1. *ichthyosis fortuita*; and, 2. *ichthyosis innata*.

In both species of the disease the eruption sometimes appears on distinct portions of the body, whilst the rest of the skin retains its healthy appearance; sometimes it extends over the whole of the surface, except the hairy scalp; and although it is observed directly above and below the flexures of the joints, yet it seldom appears on or around the joints, or, as Dr. Bateman remarks, on the inner and upper parts of the thighs. It also rarely appears in the axillæ, upon the palms of the hands, or on the soles of the feet.

Species 1. *Ichthyosis fortuita*, (*ichthyosis simplex* of Willan and Bateman) not unfrequently affects only the extremities, and occasionally the face. The more extended form of the disease is common in children who come from India at rather a later period than usual. It rarely makes its appearance for the first time in adults, and appears to commence by a soiled appearance of the cuticle, followed by a thickened, papillary, and discoloured condition of the skin, which seems, to a casual observer, the effect of want of cleanliness. By degrees the hardness and roughness increase, so as to afford to the finger, when passed over the skin, the sensation caused by a rough file, or shagreen. The colour of the patches soon deepens to a dirty, brownish-black hue; and when carefully examined, they are found to be composed of small pedunculated horny excrescences, closely impinging upon one another; or, when the disease is general over the body, of conical horny excrescences, the apex of which are generally loose and separating, so as to give the appearance of being covered with dirty, coarse meal. In some instances these horny papillæ are crowded in various groups, following the variations of the cuticular lines: in other instances they form decided

patches, like incrustations upon the part; and when the peduncles are long, and the clothes press upon the parts, the papillæ overlay one another like scales; but in no case do they naturally assume an imbricated or scaly aspect. The patches are occasionally separated by whitish furrows; in some cases, when they are distinct, they terminate abruptly, in others they are gradually lost in the healthy skin. When the face is the seat of the disease, it is usually confined to the cheeks; but in a case mentioned by Dr. Bateman, (*Synopsis*, 7th edit. p. 80,) and another, in a young lady, which came under our own care, the patches on the cheeks communicated across the nose, so as to produce the appearance of a pair of large brown spectacles laid upon the face: (*Ibidem*, nota.) In some instances the mammæ in females have appeared completely encased in this horny covering. If the excrescences be picked off, or if they fall off when submitted to the action of the vapour of hot water, they rapidly grow again; but, in the interim, the skin does not bear any trace of inflammation; it appears in a healthy state until the papillæ re-assume their former horny aspect. In the case of the young lady referred to, the disease, which made its appearance about the age of puberty, was preceded by considerable constitutional disturbance, namely, headach, disordered bowels, cold feet, and flushings of the face; but in general no premonitory symptoms have been observed; nor is the eruption accompanied with itching, tingling, or any uncomfortable feelings. The whole skin, in the more extended form of the disease, is dry, and its perspiratory function apparently impeded; it has been suggested that the urine and the pulmonary exhalations balance the defective perspiration, and maintain the general health of the habit. (*Rayer*, *Maladies de la Peau*, tom. ii. p. 305.) Bielt mentions that in some instances the sound or uncovered parts of the skin perspire more than usual.

Few opportunities of ascertaining the condition of the constitution or that of the skin in this disease, have occurred to us; but the few which have presented themselves have confirmed the view we have given, namely, that it cannot be regarded as a scaly eruption. The chorion is found to be thicker than usual, and the furrows which traverse it are deeper than common; the horny papillæ are readily detached by maceration. But these investigations have shed very little light upon the nature of the disease.

Treatment.—The obstinate nature of this eruption has in many instances resisted every plan of treatment, both local and general. With the exception of the decoction of the root of *rumex obtusifolius*, no internal remedy appears to have at any time produced benefit. The decoction of this dock root, made with an ounce of the sliced root and a quart of water, boiled down to a pint, and taken in doses of a fluidounce and a half twice or three times a day, purges briskly, and clears the skin in ten or twelve days; but in cases of long continuance the eruption is likely to return. Dr. Willan strongly recommended pitch, made into pills with flour or some farinaceous matter; the dose being gradually increased until twenty or thirty of the pills are taken in the course of the day. The pitch seems to operate by stimulating

the capillary system, so as not only to enable the skin to throw off the patches of horny cuticle, but to restore the skin to its natural and healthy state.* Arsenic is sometimes useful on the same principle; but the experience of those who have had the best opportunities of seeing and treating the disease, affords little encouragement to prescribe it. The dock-root, the use of which was first recommended by the writer of this article, is certainly the most effectual remedy which has been hitherto employed: the only objection is its disposition to purge, which, however, can be moderated by the addition of ten or twelve drops of laudanum.

In old cases, when the eruption returns, and is successively removed by the decoction of the dock-root, the obstinacy of the case often depends upon a state of the skin which is sometimes only to be permanently relieved by the application of blisters over the whole of the diseased surface: this was the case in the instance of the young lady already mentioned.

With regard to external means, almost every stimulant and detersive plaster and ointment has been tried, and each in its turn declared nugatory. The scales have been picked or shaved off, and removed in various ways, but in the greater number of instances without any permanent advantage. Mr. Plumbe found the firm application of adhesive straps aid greatly the desquamation, if this term may be employed, of the patches; the diseased cuticle was softened, and might be scraped off without pain. "By persevering," says Mr. Plumbe, "in this plan, the skin gradually acquires a healthy texture." (*Practical Treatise on Diseases of the Skin*, 1st edit. p. 334.) Sulphur fumigating-baths have been found useful, and the benefit received is undoubtedly more permanent than when the common sulphureous baths of Harrowgate, or similar springs, are employed; but, nevertheless, in several instances in which we have seen the fumigating baths used, the eruption has returned after they were discontinued. Whatever applications are used, the daily employment of the warm bath, with friction whilst in the bath, and brisk exercise taken immediately afterwards, materially aids the restoration of the healthy condition of the skin. The bath should be used in the morning.

Species 2. Ichthyosis innata.—This congenital form of ichthyosis, although scarcely perceptible at birth, yet even at that period may be recognised by the skin being harsher and thicker than usual in infants, and rough when the finger is passed over it. By degrees, as the infant grows, the disease assumes its proper character. In almost every recorded instance the disease has been hereditary. As in the fortuitous species of the disease, the rigid and scaly state of the skin is sometimes partial, sometimes general, assuming the appearance as if the body was covered with a coat of mail. The case of the native of Suffolk, known by the name of the "Porcupine Man," and described by Mr. Baker in the forty-ninth volume of the *Philosophical Transactions*, is the

* Dr. Willan generally ordered at first three or four five-grain pills to be taken three times a day; and the number of pills to be gradually increased until a drachm of the pitch was taken for a dose.

best illustration of this form of the congenital disease. The face, the palms of the hands, and the soles of the feet, were the only parts free from the scaly covering. The disease appeared about two months after birth, and the scales regularly dropped off every winter and re-appeared in the spring. The individual enjoyed excellent health, and had six children, all of whom were covered with the same excrescences. Many other curious examples of congenital ichthyosis are to be found in the Royal Transactions and the memoirs of the various scientific societies throughout Europe; but as no means that have hitherto been tried have proved successful in restoring the healthy texture of the skin, it is unnecessary to refer to them.

The ichthyosis *cornea*, horny fish-skin of Willan and Bateman, the *cornua cutanea* of Plenck, (*Doctrina de morbis cutaneis*), the *appendices cornés* of Rayer, (*Maladies de la Peau*, tom. ii. p. 315,) has been improperly confounded with the congenital form of ichthyosis by Bateman and Rayer; but the horny appendages constituting this affection, which cannot be regarded as a species of ichthyosis, are rarely if ever congenital, and differ in every respect from the horny papillæ of ichthyosis. "They are," as Bateman expresses himself, "purely of cuticular growth, consisting of a laminated callous substance, contorted and irregular in form, and not unlike isinglass in appearance and texture." In every instance they are accidental, and generally connected with some diseased growth, such as wart; (*Morgagni*, de *Sedibus et Causis Morborum*, ep. 65, art. 2. *Avicenna*, canon. iv. fen. 7, tract. iii. cap. iv. *Lorry*, de *Morbis Cutaneis*, p. 519): or they arise in the cavity of encysted tumours of very slow growth. Their extirpation belongs to the province of surgery; the only effectual remedy being excision and the ample destruction of the surface secreting them, at an early period.

[Under the name *Ichthyosis sebacea*, Mr. E. Wilson (*A Practical and Theoretical Treatise on Diseases of the Skin*, Amer. edit. p. 276, Philad. 1843) describes a morbid condition in quality and quantity of the secretion from the sebaceous follicles of the skin, which spreads upon the surface of the epidermis, forming a thin layer that dries and hardens, and breaks, in the direction of the linear markings of the skin, into small polygonal portions. These concretions increase in thickness by the accumulation of fresh sebaceous secretions, and become discoloured from exposure to dust and dirt. The small masses have the appearance of scales closely adherent to the epidermis, are hard and dense in texture, and present various degrees of thickness.

The best method of treatment is to remove the scaly concretion by means of the warm bath or warm fomentations rendered moderately alkaline by subcarbonate of soda or potassa, several times repeated; after which the sebaceous glands may be excited to healthy action by frequent ablutions with warm or cold water, succeeded by brisk frictions with a rough towel, sea-bathing and astringent lotions or ointments, composed, for example, of sulphate of copper or sulphate of zinc. Mr. Wilson (*Op. cit.*) states, that in one case of the disease he obtained much benefit from the exhibi-

tion of milk of sulphur. The bowels must be kept open, and the diet be regulated.]

A. T. THOMSON.

ICTERUS. (See JAUNDICE.)

IDENTITY, PERSONAL.—The question of personal identity becomes not unfrequently a matter of vital importance in both civil and criminal investigations.

1. Thus it may be doubted whether a child claiming an inheritance is the same that he pretends or is pretended to be, as in the celebrated Douglas* or Anglesea (for the Anglesea trials see 17 and 18 Howel St. Tri. and Harg. St. Tri.) causes; or long absence of the owner of property may give rise to a similar doubt, as happened in the following instance related by Zacchias. (Quest. Med. Legal. Consilium 61.)

A noble Bolognese, named A. Casali, left his country at an early age and joined the army. He was supposed to have lost his life in the wars; but after an absence of thirty years he returned and claimed his property, which his heirs had already appropriated to themselves. Although there were some marks which appeared to identify him, yet the change in appearance was so great, that none who remembered the youth were willing to allow that this was the individual. He was arrested and imprisoned. The judges were in great doubt, and consulted Zacchias whether the human countenance could be so changed as to render it impossible to recognise the person. His opinion was in the affirmative; in consequence of which, and because the heirs could not prove the death of Casali, the judges restored to him his name and estates. (See also Foderé, vol. i. p. 109.)

Thus it might happen that the true heir would not be able to prove his right merely by failing to establish his identity; while, on the other hand, an impostor may succeed where he has no claim, merely by the force of resemblance. One of the most remarkable instances of such an occurrence is that of Martin Guerre, which came before the parliament of Toulouse in 1560.

Martin Guerre had been away only eight years, when a certain Arnould Dutille, depending on his likeness to the absent person, formed the design of taking his place, and actually took possession of the property and wife of the true Martin. Children were born of this union, and he lived in the family more than three years, with the four sisters and two brothers-in-law of Martin, without being suspected. At length, however, it became matter of trial, and three hundred witnesses were examined; thirty or forty of whom deposed that the new comer was really Martin Guerre, with whom they had been on habits of the closest intimacy. Nearly an equal number swore that he was Arnould Dutille; while the others were so perplexed by the resemblance between the parties that they would not venture to affirm whether the individual before them was the one or the other. The judges also were completely puzzled, and were on the point of deciding in favour of Dutille, when the arrival of the true Martin exposed the imposture; though to the last the effrontery and

* See Journals of the House of Lords, and also Speeches and Arguments, &c. of the Lords of Session of Scotland in the Douglas Trial. London, 1767.

impudence of Dutille led many to doubt, and even Martin himself appeared confounded; so that the judges were still more embarrassed than before his arrival. At last, however, he was fully identified and recognised by his wife and sisters. (From the *Causes Célèbres*.)

2. Secondly, in criminal prosecutions the question has very frequently arisen, whether a prisoner is actually the person who committed the offence with which he stands charged; or, where a prisoner after conviction escapes and is retaken, whether he is the same person that was convicted. The same question also applies in cases of return from banishment.

In connection with this branch of the subject, circumstances have frequently occurred evincing the vital importance of the accuracy which should furnish grounds of evidence; and the extreme caution by which witnesses or prosecutors should be guided in depositions. A few years since a gentleman coming into Dublin late in the evening, was stopped and robbed by a footpad. A man was arrested by the police under suspicious circumstances, and, being recognised by the gentleman, was committed to abide his trial, when he was identified by the prosecutor in the most positive manner; in consequence of which he was found guilty, but, owing to previous good character, recommended to mercy. In a very few days afterwards, the gentleman was surprised and horror-struck at meeting on the road the man who had really robbed him.

The mistake here appeared to arise from the imperfect light in which the robbery had taken place, and naturally suggests for our consideration a question which has given rise to some discussion, and appears to require notice here, viz. *the degree of light which may be necessary to enable an observer to distinguish the features, so that the person may be afterwards identified.*

In a case which occurred in France in 1809, of a person shot at night, it was stated that the flash of the pistol enabled the witness to identify the features of the assassin. The possibility of this was referred to the Institute, who reported against it. Foderé, on the other hand, believes that if the persons be at a small distance from each other, and the night very dark, such an event might be by no means impossible.

A case in point occurred in England in 1799. A man named Haines was indicted for maliciously and feloniously shooting at Edwards, Jones, and Dowson, Bow-street officers, on the highway. Edwards deposed that, in consequence of several robberies near Hounslow, he, together with Jones and Dowson, were employed to scour that neighbourhood; and that they accordingly set off in a post-chaise on an evening in November, when they were attacked near Bedfont by two persons on horseback, one of whom stationed himself at the head of the horses, and the other went to the side of the chaise. The night was dark; but he swore that, from the flash of the pistols, he could distinctly see that the man rode a dark-brown horse between thirteen and fourteen hands high, of a very remarkable shape, having a square head and very thick shoulders; and altogether such that he could pick him out of fifty horses: he had afterwards recognised the horse. He also per-

ceived, by the same flash of light, that the man at the chaise-door had on a rough-shag brown great coat.

A lady, a patient of the writer, lately told him that on one occasion, on her passage from India, she awoke in the middle of the night and heard some one stirring in her cabin, but could see nothing, it being quite dark; when suddenly the cabin was so completely illuminated by a flash of lightning, that she could see distinctly a man rummaging one of her trunks, and discerned his features so accurately that she identified him next morning; some of the stolen things were found upon him, and he subsequently acknowledged the fact.

We were once present at a trial when a witness swore that the prisoner at the bar was one of a party who attacked and burnt his house, and that he saw him, at a distance of more than ten yards, in the act of putting a burning coal into the thatch; the night being *so bright* that he could distinctly recognise his features at that distance. This occurred in the middle of December. Subsequently, a gentleman of undoubted veracity swore that he recollected the night of the attack, and that it was *so dark* that he could not see his horse's head as he rode along! On reference to the almanack, it was found that the moon was at the time in her last quarter.

The extraordinary resemblance which is occasionally observed between two individuals furnishes another ground for extreme caution in swearing to the identity of a prisoner not absolutely taken in ipso facto.

At the Old Bailey in 1822, Joseph Redman was indicted for assaulting and robbing Wm. Brown. The prosecutor, on his cross-examination, stated that he knew a man named Greenwood, who, with his hat on, so much resembled the prisoner that he should hardly know one from the other; Greenwood was in custody, and was brought to the bar, when the extreme similarity between the two men struck every one present with astonishment. Redman proved an alibi, and the jury returned a verdict of not guilty.

The case of the Perreaus was a remarkable illustration of this fact. Daniel and Robert Perreau were twin brothers, and in 1775 were tried and executed for a forgery on Mr. Adair. So great was the resemblance between them, that Mr. Watson, a money scrivener, who had drawn eight bonds by order of one or other of the brothers, hesitated to fix upon either; but being pressed to make a positive declaration, he at length fixed upon Daniel. The name of these unfortunate men is familiar to the public from the well-known exclamation of George III., when asked to pardon Dr. Dodd,—“If I save Dodd, I shall have murdered the Perreaus.”

A very remarkable instance of personal resemblance was for some years under our own observation in the sons of a poor peasant. They were twins, and so much alike, that one of them, who was very wild, used frequently to bribe his brother to change clothes with him, and go home to take a beating in his place; the father having no other means of distinguishing them except by their dress.

An individual was indicted and tried at New York in 1804 on a charge of bigamy, and the

whole evidence turned on the question of his identity. He was called Thomas Hoag by the public prosecutor, but stated himself to be Joseph Parker. Several witnesses swore that he was Thomas Hoag, among whom was a female that he had married and deserted. It was stated that Hoag had a scar on his forehead, a small mark on his neck, and that his speech was quick and lisping. All these peculiarities were found on the prisoner. Two witnesses deposed that Hoag had a scar under his foot, occasioned by his treading upon a drawing-knife, and that this scar was easy to be seen, and had been seen by them. On examining his feet in open court, *no scar was to be found on either of them*; and it was further proved, that at the time of his alleged courtship of his second wife in Westchester county, he was doing duty as a watchman in the city of New York. The jury acquitted him. (Beck's Medical Jurisprudence, p. 223.)

3. We must not omit to mention the necessity that occasionally occurs for identifying the dead, as in cases of murder, accidental death, exhumed bodies, &c., cases which not unfrequently present themselves under very embarrassing circumstances.

In January 1817, the body of a woman was found tied to a boat near Greenwich Hospital, and an inquest was accordingly held, but adjourned on account of vague evidence. At the second sitting an old man declared the deceased to be his daughter, who had been the wife of an out-pensioner, and between whom and her husband a fight had taken place with sharp instruments in his presence; that soon after both parties left his house, and he had not heard of them since. Other witnesses also supported the statement that it was the body of the old man's daughter. A second adjournment took place. The constables in the mean time had sought in vain for the husband, but *they found the wife alive*, and she was produced accordingly. The coroner reprimanded the witnesses, though the strong likeness between the living and the dead woman was allowed to be sufficient to impose on even better judges. (Smith's Principles of Forensic Medicine, p. 500.)

In swearing to the identity of a dead person, witnesses should be very cautious how they assume any except indelible marks as a means of recognition, because so complete an alteration takes place in the features and general appearance soon after death as to deceive even the nearest relatives. A trial took place some years ago in Edinburgh, which illustrates satisfactorily this part of our subject. A prosecution was instituted against four medical students for exhuming the body of a lady. The body was so disfigured that it could not be identified by the friends; the ovaries were, however, examined, and it was reported that there was found in one of them a perfect corpus luteum, which would be sufficient to prove that the remains were not those of the lady in question, who was a virgin, and advanced in years. On the trial there was a total contradiction between the medical witnesses as to the corpus luteum, but the body was afterwards identified by a dentist who produced a cast of the gums which he had taken before death.

Even under circumstances apparently less difficult, great doubt may exist as to identity. A resurrection man was lately tried before the high court of judicature in Edinburgh for raising the

body of a young woman from the church-yard of Stirling. Nine weeks after death, the body was discovered and identified by all the relations, not only by the features, but by a mark which they believed could not be mistaken, she being lame of the left leg, which was shorter than the right. There was a good deal of curious swearing as to the length of time after death that the body could be recognised, but the jury was convinced that the *libel was proven*, and gave a verdict accordingly. "Now, I am certain," adds the relater (see Beck's Elements of Medical Jurisprudence, p. 223, note, signed *Dunlop*.) of this case, "that this was not the body of the woman who was taken from the church-yard of Stirling, but one that, at least six weeks after the time libelled, was buried in the church-yard of Falkirk, from which she was taken by this man, who also had taken the other, for which he was tried; she also was lame of the left leg: thus, though guilty of the offence laid to his charge, he was found guilty by a mistake of the *corpus delicti*."

4. From the foregoing cases may be collected a general view of the facts or circumstances likely to engage the attention of a witness, or a court, in cases where the identity of an individual may be doubted or disputed, and of the circumspection necessary in giving testimony on such a subject; in doing which we ought always to keep in view the following considerations, at least.

Seeing the great resemblance that may exist between different persons, we should hardly ever, after a lapse of any considerable time, trust to our mere recollection of external form or peculiarity of features, except we are able to connect these with some indelible or unalterable mark, such as *nævi*, cicatrices produced by disease or operations, congenital malformations; with reference to which object it would be very desirable that medical men practising midwifery should in all cases note down along with the other circumstances of time of birth, &c., any bodily peculiarity of the infant by which it might afterwards be recognised. We once detected by this means an attempt at substitution of a child, which would otherwise have certainly succeeded.

We should remember and make allowance for the great alteration that may be made in the person and countenance by the mere lapse of time, especially at the season of life when youth is matured into manhood, and by altered habits. When the brethren of Joseph stood before him, "they knew him not." If to time be added the effects of a hot or very cold climate, or disease, the pressure of mental anxiety or bodily hardship, the effects are still more striking:

Danger, long travel, want or woe
Soon change the form that best we know;
For deadly fear can time outgo,
And blanch at once the hair;
Hard toil can roughen form and face,
And want can quench the eye's bright grace,
Nor does old age a wrinkle trace,
More deeply than despair.

SCOTT'S MARMION.

[My hair is grey, but not with years,
Nor grew it white in a single night,
As men's have grown from sudden fears.

BYRON.

The change in the colour of the hair thus referred to might give occasion to a question of

identity. It has likewise become a question, whether it is possible to change the colour of the hair by any physical agency. A case which occurred in Paris in 1832, gave occasion to some careful experiments by Orfila (*Traité de Méd. Lég.* i. 127, 142), and by Devergie (*Médecine Légale*, 2de édit. ii. 536, Paris, 1840,) in order to discover what changes could be induced in the hair by chemical agents: and they have given various methods by which a change from light to dark and conversely may be accomplished. (See, also, Guy, *Principles of Forensic Medicine*, Pt. I, p. 20, Lond. 1843.)]

The return of Ulysses, and his rejection from his own halls, unknown by all, and recognised by his faithful dog alone, although probably no more than a poet's fiction, has been realized in more instances than that of Casali.

In conclusion, it appears to us that in the case of a person seeking to establish a claim by proving his identity, a more certain mode of examination would be to question the person himself as to his knowledge of facts, however trifling in themselves, but of which he must have had cognizance if really the person he pretends.

W. F. MONTGOMERY.

[IDIOCY. (See INSANITY.)]

IMPETIGO, *humid or running letter*,* (from *impeto*, to infest,) is a non-contagious, pustular affection of the skin, terminating in thick lamellated scabs or thin scaly crusts. Willan and Bateman, who are followed by Bielt and Rayer, enumerate five species of impetigo; but in our opinion there are only two distinct species, the one unattended by febrile symptoms, the other preceded by them; the first three forms of impetigo may be ranked as varieties. We therefore propose the following arrangement:

Spec. 1. *Impetigo simplex*.

Var. a. *Impetigo figurata*.

b. *Impetigo sparsa*.

c. *Impetigo scabida*.

2. *Impetigo erysipelatodes*.

The first of these species (*impetigo simplex*) appears generally without any obvious premonitory symptoms, attacks chiefly the young, and those of a lymphatic temperament; and displays itself in clusters and groups of psudracious, or irregular, slightly elevated, small pustules, which, after discharging their contents, continue to exude a thin, acrid ichor, accompanied with much itching, or rather stinging, and a sensation of heat. This discharge concretes into thin, yellowish, semidiaphanous scabs, which turn up at the edges, so as to allow the discharge to ooze from under them. The disease is frequently chronic, or kept up by successive eruptions of the groups of pustules. The two first varieties of this species are founded on the manner in which these patches of eruption appear; whether large, circumscribed, oval, or some other regular figure; or small, disseminated, and assuming no peculiar form: the third variety is distinguished by forming one continuous crust over the affected part.

* *Syn.* *Lepra squamosa* (auctor var.); *kouba* (*Aicenna*); *ecpulysis impetigo* (*Good*); *phlysis impetigo* (*Young*); *dartre crustacée* (*Fr.*); *der Kleinausatz* (*German*); *cowrup* (*Javanese*); *herez* (*Arabic*).

Impetigo figurata. This variety of simple impetigo generally occupies the face, appearing most frequently on the cheeks, the chin, the sides of the nose and margin of the nostrils: the extremities, particularly the hands, are often the seat of the eruption; it occasionally, also, appears upon the trunk of the body. Although, in general, this variety occurs without any obvious diseased state of the general habit, yet it occasionally follows much mental anxiety, or other depressing affections of the mind, in which case it is accompanied with cardialgia and uneasiness of the stomach, with a sensation of weariness of the limbs, and other indications of low febrile disturbance. At first the patches are small, distinct, red spots, which itch considerably: in a short time, however, they enlarge and are covered with minute yellow psudracious pustules, closely crowded so as to be almost confluent, and surrounded by a red inflamed border. The pustules are flat, and are the source of much heat and stinging pains. In a few days they burst, and discharge their contents; the pus drying and changing into thin semi-transparent crusts, which characterize this species of impetigo; sometimes, however, the scab is thicker and not unlike "the exudation of gum on a cherry-tree." (*Rayer, Traité Théorique et Pratique*, tom. i. p. 474.) If the scabs fall or are rubbed off, the surface appears red, excoriated, shining as if stretched, and exhibiting minute pores from which an ichorous discharge exudes, which greatly augments the heat and smarting. On the margin of these diseased patches, unbroken psudracious pustules may be observed. When the disease is not perpetuated by successive eruptions, the crusts gradually dry, and remain nearly stationary for two or three weeks, the itching, heat, and smarting gradually diminishing; they then fall off, leaving the surface red, stretched and shining, and the cuticle so thin as to be liable to excoriation from the slightest friction. More frequently, however, the ichorous discharge is reproduced, accompanied with fresh crops of psudracious pustules; and the eruption is thus repeatedly renewed and runs its whole course; continuing for many months, sometimes for years. When the disease yields either spontaneously or to the influence of medicine, the amendment is first perceptible in the centre of the patches; and sometimes, even when this occurs, the border not only retains its diseased character, but fresh pustules show themselves: as the cure proceeds, however, these also gradually disappear, and the whole skin acquires its natural aspect, except that it is covered with minute scales, which are reproduced for an indefinite time, more or less protracted according to the severity of the previous disease.

This variety of impetigo simplex does not always preserve the uniform course which has been described. Sometimes the patches enlarge by successive marginal crops; this is particularly the case when they appear on the legs, which are thus often gradually covered from above the knee to the instep. In some instances, the pustules are intermixed with transparent vesicles, not unlike those of some of the varieties of herpes; indeed there seems to be some affinity between the causes of herpes and impetigo; as the two diseases occasionally appear simultaneously on the same in-

dividual. We have at present a case of severe herpes zona under treatment, in a man who has scarcely recovered from a protracted attack of impetigo sparsa. When these vesicles break, the ichor which they pour out is much more acrimonious than that of the pustules: wherever it touches the sound skin, inflammation and a crop of vesicles or psudracious pustules follows. The vesicles appear in tardy succession, and are slower in their progress than the psudracia: when broken, they are little disposed to heal; and the constant irritation of the ichor inflames the cuticle, thickens it, and covers it with small ulcers. In this state of the disease the burning sensation and itching are extremely distressing, and much increased by friction, or any source of irritation, or even any application, however emollient.

Impetigo sparsa differs from the former variety chiefly in the irregular and scattered distribution of the pustules: these appear in small groups, dispersed without any regular order in the extremities, about the neck and shoulders, and occasionally on the face, the ears, and scalp. They run the same course as those of impetigo figurata, but the scabs which succeed the bursting of the pustules are thicker, more friable, and do not form in so large plates as the former variety: the surrounding inflammation is, however, more extensive, and they oftener terminate in ulceration, interspersed with fissures, (See Atlas of Delineations of Cutaneous Eruptions, pl. xv.), and not unfrequently are accompanied with œdema.

Impetigo scabida of Willan and Bateman (Practical Synopsis, 7th edit. p. 222) is merely a more severe form of the last variety. It commonly appears on the legs; and the pustules are so numerous, and discharge so abundantly, that the greater part of the limb becomes incased in a yellow crust, variously divided by deep fissures, and not unlike the bark of a tree. When it extends over the joints, the movements of the limb become difficult and painful; and the heat, itching and tingling are greater than in either of the former varieties. When any portion of this crust spontaneously separates, or when it is removed, the vacuity is quickly filled up by the copious discharge poured out from the excoriated surface; the limb generally swells, and if the eruption extend to the toes, the nails drop off, and the new ones are thick, irregular in their form, and notched.

The causes of these varieties of the simple impetigo are very obscure. There seems to be a peculiar predisposition to the disease connected with the sanguine or the sanguineo-melancholic temperament, with a thin lax state of cuticle. We have already stated that impetigo figurata is sometimes preceded by gastric derangements, languor, and headach; and this is true of the other varieties; but more generally it cannot be traced to any derangement of the digestive function. In the predisposed, however, it has been observed to follow violent exercise, intemperance, or the use of tainted animal food; and, like some other cutaneous eruptions, it has been traced to mental agitation and to sudden causes of depression, such as disappointment, grief, and fear; (Med. Trans. vol. i. art. 2. Med. Obs. and Inq. vol. i. art. 19. Pract. Synopsis, 7th edit. p. 214, nota); and occasionally to exposure to cold. The first variety

in particular seems, also, to be connected with an irritable condition of the system, such as accompanies dentition in infants, and the appearance of the catamenia in women. The third variety does not appear to be influenced by the changes of season, but the first is liable to recur in the spring, and the second in the autumn, often continuing through the winter and disappearing in summer.

Some external irritants acting upon the skin produce pustular tetter closely resembling those of impetigo sparsa; in this way the eruptions termed grocer's and bricklayer's itch are produced; the former arising from the acrid stimulus of raw sugar, the latter from that of lime, acting on the hands and arms of those who are constantly handling these substances. In both cases the disease is readily distinguished from scabies; it is not contagious, and soon disappears when the sources of irritation are removed. Bateman regards the pustular eruption arising from the application of tartar-emetic, and various stimulating plasters to the skin, as displaying some affinity to impetigo; but the pustules are of a very different character, distinct, elevated, and seated on a hard inflamed base, which is never the case in any of the varieties of this eruption.

Diagnosis.—The foregoing varieties of impetigo may be confounded with several other cutaneous affections, but attention to two or three of the most obvious characters common to all the varieties furnishes us with the means of forming a correct diagnosis. Thus the nature of the crusts distinguishes impetigo from eczema, which is, besides, a vesicular disease; and from porrigo larvalis and favosa. Impetigo figurata appearing on the face may be recognised also by the character of the crusts, which are thick, soft, and cellular in porrigo, and do not discharge thin ichor, but thick glutinous pus. The hard inflamed base of the pustules of ecthyma prevents impetigo from being confounded with that eruption; and although, in its advanced stage, impetigo is frequently mistaken for lepra and psoriasis, yet the diagnosis is not obscure, if we discriminate between the scaly exfoliations of the latter and the laminated crusts of the former, or the ichorous discharge of the pustules of impetigo, and the complete absence of all fluid discharge in lepra and psoriasis. Between impetigo and scabies the diagnosis is not more difficult: the distribution of the eruption in patches; the copious discharge of ichor; the rough and fissured cuticle; and the heat and tingling which accompany the itching impetigo, are sufficient guides for recognizing the disease. It is more likely to be mistaken for some of the syphilitic scabby eruptions, especially when these appear on the face. A case of this kind is mentioned as having occurred under M. Bielt, in the hospital of Saint Louis, and having been treated for some time as impetigo figurata; but the nature of the scabs, which are large, black, thick, very adherent, resting upon a violet-coloured base, and when separated, leaving deep ulcerations, with the regular, circular form of the eruption, are generally sufficient to distinguish this syphilitic eruption from impetigo.

Prognosis.—The only circumstance to be attended to in the prognosis of impetigo is the disposition the eruption always shows to recur: it is

more likely to prove obstinate in old people, and in weakened states of the system, than in the young and robust; but under no circumstances can it be regarded as a fatal disease.

Treatment.—The same treatment is applicable to all the varieties of simple impetigo. The internal administration of sulphur, either alone or combined with soda, nitre, and the bi-tartrate of potassa, is strongly recommended by Willan and Bateman in the commencement of the disease; but our experience leads us to agree with MM. Cazenave and Schedel, that the preparations of sulphur have been too indiscriminately employed, and that they have frequently proved hurtful, aggravating the symptoms, and favouring the disposition of the eruption to re-appear. The sedative and cooling influence of conium in the common effervescing mixture, with the aid of emollient fomentations, or even of simple tepid water, constitute the best and most efficient means in the incipient stage of any of the three varieties which have been described. In cases of impetigo *figurata* extending over a considerable portion of the skin, particularly when it attacks the face, M. Bielt recommends moderate bloodletting, either local or general; we have never ordered either, and indeed cannot exactly conceive how the abstraction of blood is likely to prove useful. When fever accompanies the eruption, we have found no difficulty in controlling it by antimonials and calomel.

If simple impetigo proves obstinate, an alterative course of mercurials, either hydrargyrum cum cretâ or Plummer's pill, with sarsaparilla or decoction of cinchona bark, is generally supposed to be indispensable; but we have found the occasional administration of five or six grains of calomel at bed-time, followed by a brisk cathartic next morning, and the arsenical solution given in the decoction of elm-bark three times a day, more beneficial. In many habits, indeed, the skin is peculiarly sensitive to the stimulus of mercury, whether internally administered or applied to the surface; in these cases in particular, mercurial alteratives prove hurtful. Every description of local application has at one time or another been employed in impetigo; in some cases even the most soothing and emollient cannot be endured; in others the most stimulant have been applied with advantage. When the discharge is profuse, ointments prepared either with the oxide of zinc, or the white precipitate of mercury, or the sub-acetate of lead, have been found most useful in moderating the quantity of the discharge, and allaying the irritation. In a drier and less irritable state of the eruption, the ointment of the nitrate of mercury diluted with six or seven parts of lard or of simple ointment, or the tar ointment, will be found advantageous in securing a more healthy surface when the crusts separate. We have also seen an ointment formed by triturating two drachms of subnitrate of bismuth with an ounce of simple ointment very serviceable in this condition of the eruption. In the thickly encrusted state of the limbs, in impetigo *scabida*, no local application will prove beneficial until the incrustations are removed, which is best effected by poultices, or by exposing the limb to the vapour of hot water; after the crusts are removed, the surface should be covered with pledgets

of lint, thickly covered with any of the mild ointments above mentioned, or touching the whole with a solution of nitrate of silver.

In many instances the irritation is scarcely supportable: in such cases we suggested, some years ago, the use of the hydrocyanic acid, in the proportion of half a fluidrachm to two fluidounces of water, with half a drachm of alcohol, and two or three grains of acetate of lead, as a lotion which not only soothes the irritation, but disposes the skin to regain its healthy action: subsequent experience has sufficiently established the value of this application. It is proper, however, to mention that Mr. Plumbe met with two cases in which its application was followed by considerable intermission of the pulse, which ceased on discontinuing the use of the lotion; but in these cases both legs were affected, and the lotion was consequently most extensively applied, which may in some degree account for the effect it produced. We have never met with any unpleasant result, although we have most extensively employed this form of lotion.

In very obstinate chronic cases of impetigo, the baths of Harrogate, or the artificial sulphur fumigating baths, generally prove effectual, not only in clearing away the eruption, but likewise in preventing its return. With the same view the waters of Barèges, Enghien, Bonnes, and some other of the continental springs, and also the warm sea-water bath, followed by a course of sea-bathing, have proved highly beneficial. In every stage of the disease, the advantage to be anticipated from any plan of treatment depends much on the discrimination of the practitioner. In cases accompanied with much irritability of surface, the internal means should be of a sedative kind; and local applications, with the exception of tepid water, should be wholly abstained from, until some abatement of the irritability admits of the employment of the hydrocyanic acid lotion. In the opposite condition of the disease, the moderately stimulant ointments, with the internal employment of the arsenical solution, will be found the most effectual mode of treating these forms of this troublesome disease.

[A solution of creasote (f.ʒss. ad aquæ f.ʒv.) has been found successful; or an ointment of the same (f.ʒss. ad adipis ʒi.) may be used. (*Medicinisch. Zeitung*, Nov. 30, 1824, cited in the author's *New Remedies*, 4th edit. p. 217, Philad. 1843.)]

Under all circumstances the diet of the patient should be milk and farinaceous matters, with a very moderate proportion of animal food once a day; wine, spirits, and every description of fermented liquor, must be sedulously avoided.

Impetigo erysipelatodes, the second species of this eruptive disease, closely resembles, in its commencement, the ordinary appearances of erysipelas, with slight febrile symptoms, which are followed by a puffy swelling of the upper part of the face, accompanied with redness and an œdematous state of the eyelids. The inflamed surface, on close examination and running the finger over it, appears papular, and in a day or two it becomes covered with psudracious pustules, that break and discharge a hot acrid fluid, which irritates and often excoriates the sound surface on which it

flows. This state of the eruption, which often covers the greater part of the face, and extends to the neck and chest, is attended with the same heat, itching, and tingling, that accompanies the varieties of simple impetigo; it continues in this condition for some days, the discharge, as it diminishes, concreting and forming thin yellow scabs, in the interstices between which fresh pustules appear, and run the course already described. The disease continues for an uncertain period, sometimes for two or three months, and, in disappearing, it leaves the skin red, shining, and in the dry brittle state which follows the other varieties of impetigo.

This form of impetigo is liable to be confounded with *eczema impetiginodes* in the commencement, even by those acquainted with both diseases; in the advanced stage, however, the pustular form of the eruption sufficiently characterizes it. In some instances of the impetiginous eczema, a few psudracious pustules may be observed intermingled with its vesicles, but the latter greatly prevail.

Treatment.—The febrile symptoms which precede this eruption indicate the necessity of antiphlogistic measures in the commencement. Saline purgatives, with antimonials and nitre, generally alleviate the fever, after which decoction of cinchona bark, acidulated either with muriatic or diluted sulphuric acid, may be administered with advantage. When the after stage of the disease proves particularly troublesome, and runs on for two or three months, a slight alterative course with sarsaparilla generally succeeds in completing the cure; or when it can be obtained, much benefit is derived from sea-bathing, or a course of Harrogate water. As local applications, nothing farther is required than tepid ablution, and guarding the excoriated surfaces with the ointment of oxide of zinc.

[In some troublesome affections of the skin, especially of the hands, conjoining the characters of impetigo with erysipelatous redness and swelling, and inducing most intense suffering, the textures were speedily restored to a healthy condition by the external use of cod-liver oil—*oleum jecoris aselli*—after all other remedies had been tried in vain. (Dr. M. Hall, *Lond. Med. Gaz.*, Sept. 1832.)]

With respect to a supposed species of impetigo described by Willan and Bateman, under the title *impetigo rodens*, we have never seen the disease, and are rather disposed to regard it as a variety of malignant ulcer, complicated with psudracia.

A. T. THOMSON.

IMPOTENCE.—*Impotence* or the incapacity of sexual intercourse, and *sterility* or the inability of procreation without loss of the power of copulation, are subjects which require to be considered, first as physiological questions, involving the consideration of all the causes temporary as well as permanent from which these defects may arise; and secondly, as a medico-legal subject, forming disqualifications for the matrimonial state, or affording pleas in exculpation of alleged rape or affiliation.

Impotence may exist either in the male or female; it is, however, most commonly found in

the male, as from the nature and conformation of the genital organs in the female, physical impediments to coition more rarely occur, and she is generally enabled to admit the venereal congress at least in a passive manner. Sterility, on the other hand, is nearly confined to the female, for if the male be capable of accomplishing the act of coition, including of course the ejaculatio seminis, no farther question as to his virility can arise.

The causes of impotence may be divided into three classes: 1. organic; 2. functional; 3. moral.

In the human species, as in all the warm-blooded vertebrated animals, the procreation of the species is effected by a congress of the two sexes, and a variety of organs are provided, upon the integrity of which the due performance of this function mainly depends. The male is destined to furnish a peculiar fecundating secretion, which is to be deposited in the body of the female, and for this purpose he is furnished with glands which prepare this fluid, and also with a conduit by which it is conveyed to its proper destination; while the female, being the recipient, offers a cavity into which this secretion is received, and is, moreover, furnished with an organ where the embryo is originally produced by the specific action of the fluid from the male.

Without attempting to enter into an explanation of the process of generation, which has been rightly designated as "one of those mysteries which the present state of our knowledge does not enable us to explain or even to comprehend," (Bostock's *Physiology*, vol. 1, p. 72,) it may be admitted as the result of observation and experiment, that a failure in any part of this complicated apparatus is attended by impotence or sterility.

I. IMPOTENCE IN THE MALE.—In order to effect procreation he must possess all the organs of generation in a state capable of performing their respective functions, and this leads us to the first class of causes of impotence.

1. Organic.—Organic impotence may proceed from different sources; there may be, (a) deficiency of some of the organs of generation; (b) malformation of these organs; (c) diseases of some of them, or of the parts in their immediate neighbourhood, sufficient to impede the procreative function.

(a) *Deficiency* of the penis, whether natural or accidental, is an absolute cause of impotence. A congenital deficiency of this organ is very rare, but it has been observed. "J'ai traité et guéri," says Foderé, "d'une incontinence d'urine un jeune soldat plein de courage et de vigueur, qui, avec des testicules bien conformés, n'avait à la place de la verge qu'un bouton, comme un mamelon, par lequel se terminait l'uretère. Il m'assura avoir été toujours ainsi, et que ce bouton se renflait quelquefois en la présence des jeunes personnes du sexe, et qu'il en sortait par le frottement une humeur blanche." (*Médecine Légale*, tom. 1, p. 364.) Accidental deficiency of the penis is more common. This may arise from amputation or destruction by disease. In a subject lately procured for the purpose of dissection in the College of Surgeons, Dublin, the writer witnessed an instance of complete deficiency of the penis from operation. In this subject, which was a very old man, the amputation had been performed so long

before death that the cicatrix was nearly obliterated, and many who saw the case supposed it to have been one of congenital deficiency.

It is difficult to determine the extent to which the penis may be mutilated without destruction of the power of procreation. The glans has been frequently lost without being attended by impotence, and both corpora cavernosa have been destroyed, but the urethra being preserved, the individual retained his virility. (*Paris and Fonblanque*, Med. Jur. vol. 1, p. 205.) Frank also states an instance of a gun-shot wound of the penis which carried away so much of the organ that it remained curved after cicatrization, nevertheless it served the purpose of procreation. (*Deduct. Opusc. Medic.*, tom. iv. p. 313.) From these and numerous similar instances, as well as from the effects produced on the generative function by that malformation, to be presently considered, termed *hypospadias*, it would appear that in order to insure impotence there must be complete deprivation of the penis, as a remnant capable of entering the vagina is sufficient for impregnation.

That the testicle is the only essential organ concerned in the secretion of semen is now generally admitted, an opinion supported by comparative anatomy, as well as by the daily proofs we have in the castration of animals. A different opinion formerly prevailed, chiefly on the authority of Aristotle, who was led to deny the necessity for the existence of testicles, from having seen a bull capable of impregnating a female after castration. But he was led into error by not being aware that if copulation were performed immediately after castration, the quantity of semen retained in the vesiculæ seminales would confer fertility on the coitus. The complete absence of the testicles then, whether natural or accidental, must render the individual unfruitful.

Congenital deficiency of the testicles is a very rare occurrence, if it ever takes place. Foderé doubts that it does; and the case adduced by Cabrollo of a soldier addicted to sexual pleasures, in whose body no testicles were found, although the vesiculæ seminales were distended with semen, has been supposed by Portal to have been one of those instances in which the testicles are retained in the abdomen during the whole of life, and that they thus escaped observation. It is not to be inferred that an individual is impotent or sterile in whom no testicles are found in the scrotum. We know that in some instances these organs do not descend from the abdomen for some time after birth, and instances are not wanting in which this delay is prolonged through the whole period of existence. In order to distinguish if the absence of the testicles be real or not, it is necessary to inquire on the one hand into the previous history of the individual, and on the other into his present condition and general habit. The first may indicate the previous existence of these organs in the scrotum, and their removal by operation or accident, in which case the external marks of mutilation, such as cicatrices, will be apparent. We do not think, generally speaking, that an absolute congenital deficiency of testicles can take place without producing in the constitution the general phenomena by which the character of the male is obliterated, and that of the female simu-

lated. In these cases of apparent absence of testicles, therefore, if the usual general signs of virility are observed, if masculine activity and vigour, combined with a well-developed muscular system, a strong deep voice, with the usual covering of hair on the chin, breast, and pubis, and at the same time no cicatrix indicating castration, are present, we must be cautious in condemning the individual. However, it is necessary to be circumspect in inductions from the general habit. Marc knew a man in Paris whose features, thin beard, smallness of hands and feet, and voice altogether feminine, indicated a defect in genital organization, yet in whom none such existed; the testicles occupied their proper situation, and the man had many children. (*Dict. des Sciences Méd. Art. Impuissance*.) Foderé considered the retention of the testicles in the abdomen as a source of increased vigour and fecundating power. "Ces organes paraissent tirer du bain chaud ou il se trouvent plongés, plus d'aptitude à la sécrétion, que lorsqu'ils sont descendus au dehors dans leurs enveloppes ordinaires." (*Méd. Lég.* tom. 1, p. 370.) This is at variance with the opinion of Hunter, whose views on the subject seem more correct, as he considers the delay in the descent of the testicles to arise from imperfection in their development. However, this imperfection does not go the length of rendering the organ useless, and therefore, when the other signs of virility are present, we are not justified in taking the absence of the testicles from their usual situation as an absolute proof of impotence. "Nous avons vu en France, dit Voltaire, trois frères de la plus grande naissance, dont l'un possédoit trois testicules, l'autre n'en avoit qu'un seul, et le troisième n'en avoit point d'apparens; ce dernier étoit le plus vigoureux des trois." (*Mahon, Méd. Lég.* tom. 1.)

[The writer has met with a marked case of absence of testes in the scrotum, the individual possessing full virile powers. In this case the testis of one side presented at the internal abdominal ring, and gave occasion to great swelling and intense suffering, which passed away under appropriate treatment, the testes remaining in the abdomen. Cases of absence of the testes are, however, rare. Dr. Marshall states (*Hints to Young Medical Officers in the Army*, p. 83,) that on the examination of 800 recruits, he found 5 in whom the right, and 6 in whom the left testis was not apparent. He met with but one instance in which both testicles had not appeared. In certain cases the testes are drawn up against the abdominal ring, so as to encourage the idea that there are no testes in the scrotum; and Professor Gross (*Western Journal of Medicine and Surgery*, May 1841, p. 355) has given the cases of two boys—one 14, the other 11 years of age, who were said to have been castrated, and a medical practitioner deposed to the absence of testes, which, however, were found to be in the groin, a little below the external ring, whence, by a little traction, they could be easily forced down into the scrotum.]

Complete extirpation of the testicles, although it deprives the individual of the power of procreation, is yet not accompanied by total extinction of venereal desire, and it has been observed that

eunuchs of this description retain the power of copulation in an imperfect manner. This is so well known in the East, that the eunuchs who have charge of the seraglios are deprived of the penis as well as of the testicles. This power in the castrato is alluded to by Juvenal, (6th Satire,) and it is said that the unfortunate victims of avarice and bad taste in modern Italy are by no means deficient in capability of erection and penetration. However, this imperfect power of copulation does not remove such persons from the class of impotent, as the most important part of the function, the emissio seminis, is wanting. Monorchides, or persons with but one testicle, are not deprived of the power of procreation. This was at one time doubted, and in the year 1665 the parliament of Paris decided that such an imperfection rendered the matrimonial contract invalid. But numerous instances in man, as well as in the inferior animals, have completely disproved that opinion. It must be admitted, however, that if the remaining testicle be small, extenuated, and withered, and if a sufficient length of time has been passed in unfruitful matrimony, such a development must afford a strong probability of sterility.

[It has been a question whether procreation be practicable after the removal of the testes. As regards man, it is probable that the effect of the operation would prevent copulation until after the sperm contained in the vas deferens had been removed by absorption or otherwise; but in another work, (*Human Physiology*, 5th edit. ii. 327, Philad. 1844), the author has satisfactorily shown that it is possible in animals.]

(b) *Malformation.*—Impotence may be absolute when the genital organs exist, but are malformed or pathologically altered.

The penis varies from the natural formation in different ways that have been accounted causes of impotence. Mere diminutiveness of this organ, where the subject is otherwise vigorous, cannot be included under this head; and it would appear that the genital organs, although originally of diminutive size, are capable of considerable development even after the age of puberty. Of this the case related by Mr. Wilson is a good example. "I was," says he, "some years ago consulted by a gentleman on the point of marriage respecting the propriety of his entering that state, as his penis and testicles very little exceeded in size those of a youth of eight years of age. He was then six-and-twenty, but never had felt the desire for sexual intercourse until he became acquainted with his intended wife; since that period he had experienced repeated erections, attended with nocturnal emissions; he married, became the father of a family, and these parts, which at six-and-twenty years of age were so much smaller than usual, at twenty-eight had increased nearly to the usual size of those of an adult man." (*Lectures on the genital organs.*) But excessive size, more particularly excess in length, may be considered as a relative cause of impotence, from the contusion and laceration inflicted on the female at each attempt at intercourse. Such cases as these are very rare. P. Zacchias cites an instance in which the female was always thrown into syncope from this cause.

The orifice of the urethra is occasionally formed in an irregular manner, and this constitutes the most common malformation of the penis. It sometimes opens in the perineum, sometimes on the dorsum of the penis, constituting the malformation termed *epispadias*; but most frequently in the under surface of the penis; this defect is called *hypospadias*. This malformation was considered by Mahon, P. Zacchias, Faselius, and Haller, as an absolute cause of sterility, but certainly without sufficient foundation; for there are numerous instances recorded in which impregnation has been effected by individuals in whom the urethra opened in an unusual manner, provided the orifice was in that portion of the penis that entered the vagina. Kopp relates the case of a peasant at Hanau, in whom the urethra opened on the under surface of the penis at the distance of eleven lines and a half from the extremity of the glans, notwithstanding which he was the father of five children. (*Annales de Méd. Politique*, t. iii.) Simeons of Offenbach gives eight cases of hypospadias. The first and second were married and had children; the first six, and the second four. The third and fourth were brothers; the fifth and sixth were the sons of the first; the seventh was remarkable as having had an action for a divorce against him, and the eighth was an infant. (*Dict. des Sciences Méd.* t. 24.) Foderé quotes four cases of hypospadias, in all of which the power of impregnating was preserved, (*Méd. Lég.*, tom. i. p. 367); and Belloc states that he knew at Agen a man who had the orifice of the urethra at the base of the frenum of the glans, and who left four children perfectly resembling himself, two of whom had the same malformation. (*Cours de Méd. Légale*, p. 129.) From the cases on record in which impregnation has taken place without the possibility of intromission, it is clear that the emissio seminis in any portion of the vagina is sufficient for this purpose, and that it is not necessary that this fluid should be carried to the uterus, or to any great distance within the vagina. We shall have occasion to revert to these cases in speaking of female impotence, but at present we mention them as affording an explanation of the subject before us. It may, therefore, be assumed that malposition of the orifice of the urethra does not necessarily constitute a cause of impotence, unless the opening be situated in a part that cannot enter the vagina. Even in the latter case, impregnation may be effected by artificial means. The experiments of Spallanzani, (*Œuvres de Spallanzani*, t. iii. p. 224,) who succeeded in his attempt to impregnate animals by injecting semen into the uterus, led Mr. Hunter to adopt the same course in the case of a man by whom he was consulted in consequence of malformation of the urethra. (*Trans. Royal Soc.* 1799.) The orifice of the canal was in the perineum, through which the semen escaped during coition; and Mr. Hunter directed him to collect this fluid in a syringe and instantly inject it into the vagina. The experiment succeeded, impregnation took place, and the female was delivered of a child in nine months.

[The inference is, however, just, that if the semen be not projected far up in the vagina, and in the direction of the os uteri, impregnation is not likely to be accomplished;—a fact, which it

might be of moment to bear in mind, where the rapid succession of children is an evil of magnitude. The writer has elsewhere (*Op. cit.* ii. 368, Philad. 1844) referred to two cases, in which procreation appeared to be prevented by the existence of epispadias opposite the corona glandis.]

A contracted state of the prepuce, by which the emission of the seminal fluid is impeded, may be a cause of impotence, but this is easily removed by operation. A more serious case is that in which the prepuce adheres to the glans, and the orifice of the urethra itself is contracted. The writer has at present under his care a boy, eleven years of age, in whom a malformation of this kind exists. The reflected portion of the prepuce adheres universally to the glans, and is firmly attached to the orifice of the urethra, which opening is so contracted as scarcely to permit the passage of an eye-probe. The urine is, of course, voided in drops. If this case be permitted to go on to puberty without relief, there is strong reason to imagine that impotence would be the result.

Malformation of the excretory ducts of the testicle may also prove a source of impotence. Mr. Hunter (*Animal Econ.*, p. 47, plate 5,) represents a case in which the epididymis, instead of passing to a vas deferens, terminated in a cul-de-sac. A similar conformation sometimes occurs in the vesiculæ seminales, where, instead of entering the urethra, they terminate, after being joined by the vas deferentia, in shut sacs. It is evident that when such a disposition of parts exists on both sides, the semen, although secreted, cannot be ejaculated, and, therefore, the individual is rendered absolutely impotent.

(c) *Diseases.*—The diseases of the genital organs which cause impotence, may be divided into those affecting the penis, and those affecting the testicles. Of the former may be enumerated excess or defect of muscular or nervous energy, inducing priapism, or paralysis. Priapism gives rise to a temporary impotence when the erection is so vigorous as to close the urethra in such a manner that the semen cannot pass into it. Defect of energy in the vessels, nerves, or muscles of the genital organs, sometimes prevents the influx of blood to the corpora cavernosa in a quantity sufficient to cause erection, which produces a state of atony approaching to paralysis, constituting the anaphrodisia paralytica of Dr. Cullen. This is a disease not unfrequently met with. Instances of it are given by Chaptal, Gessner, Weicard, quoted by Foderé, (*Méd. Lég.* tom. i. p. 382,) and also by Mahon, (*Ibid.* tom. i. p. 58,) in which it was removed by local stimulants.

Strictures in the urethra, when the canal is greatly diminished, may oppose such a barrier to the exit of the semen as to render the individual impotent; but it is extremely difficult to ascertain to what extent a stricture may exist without producing this effect. We know that many persons in whom strictures in this canal are found, do not lose the procreative power, and therefore, unless in extreme cases, where the finest bougies are with difficulty passed, we should be cautious in assuming this as a cause of impotence. The opening of the conjoined ducts of the vesiculæ seminales and vasa deferentia may be closed by scirrhus

enlargement of the neck of the bladder, by enlargement of the prostate gland, a scirrhus state of the veru montanum, or by disease of the duct itself. Foderé alludes to the cases of two individuals mentioned in a French Journal, (*Journal de Médecine de Paris*, Ann. 1680,) who having full powers of copulation could never expel semen. On examination after death, the seminal ducts of one were found filled with matter of stony hardness; and in the other the extremity of these ducts was callous and blocked up. All these causes produce inability for procreation by obstructing the passage of the semen, although this fluid be duly secreted.

But the cause of impotence may lie in the secreting organ itself, the texture of which is so altered by disease as to interrupt the performance of its natural function. Thus scirrhus, cancer, scrofula, when they affect the entire substance of the testicle, produce such an obliteration of its intimate structure that the seminal fluid is no longer formed. The form of disease described by Andral must be considered as belonging to this class: "Un état d'induration grise ou blanche du parenchyme avec disparition des conduits séminifères; le testicule représente alors une masse homogène, dure, ou l'on ne trouve plus aucune trace de son organisation primitive." (*Anat. pathol.* tom. ii. part xi. p. 669.) But in order to constitute complete impotence, it is necessary that both testicles should be implicated, and that the disease pervade the entire organ; for a small portion of the gland remaining uninjured may be still capable of secreting semen in a quantity sufficient for impregnation. "In the first method adopted in the East for making eunuchs, we are informed that the masculine efficiency was destroyed by bruising the testes, (a method of castration still pursued in some places with regard to animals,) and destroying their functionary powers along with their organization. Instances of generating, however, seem to have occurred among eunuchs made in this manner, and are explained on the supposition that part of the testes remaining uninjured was still capable of preparing the necessary secretion, and furnishing it to a certain extent." (*Dr. J. G. Smith, Forensic Medicine*, p. 450.)

Local injury may be followed by atrophy of the testicle, and it is well known that a state of complete inaction, such as is observed in those who have maintained a strict monastic life, is often attended by a similar result. Elephantiasis is said to cause a wasting of the genitals and a loss of all sexual appetite, but this is denied by other authorities. (See ELEPHANTIASIS.) A species of idiopathic atrophy of the testicles is described by Baron Larrey, which affected many of the French troops on their return from Egypt. In these cases the organs became soft to the touch, and gradually diminished in size without any pain. Foderé mentions that he observed in some young deserters condemned to work at the canal of Arles, that the testicles melted away just as if they had never existed. (*Méd. Lég.* vol. i. p. 369.)

Diseases of the neighbouring parts may also prove a source of impotence by affording obstacles to the venereal congress. These are extraordinary obesity and very large scrotal hernia and hydrocele. Obesity, when extreme, must be considered a disease; of this, Martin, king of Aragon, furnishes

a striking example. "He is stated by historians to have been so corpulent that neither mechanical contrivances nor medical treatment could render him any assistance towards the accomplishment of venereal congress." (*Paris and Fonblanque*, Med. Jurispr. vol. i. p. 204.) Large scrotal hernia and hydrocele, by distension of the integuments, cause recession of the penis, and render coition impracticable. Besides, these tumours are considered by Foderé to impede the secretion of semen either by causing too great tension of the spermatic vessels, or by so compressing them that their diameter is obliterated. This effect, however, must be of rare occurrence.

2. Functional.—One of the most remarkable changes that take place in the transition from youth to manhood is the development of the sexual organs, and the new train of sensations by which it is accompanied. Puberty is the season of life in which the generative function is called into active operation, and unless impaired by excesses or disease, it usually continues in vigour until the sixty-fifth year. "The genital organs (says M. Virey) offer two states during life, in the young and old, which are the frozen zones of existence; the intermediate state is the torrid zone of life. The infant has nothing to give, the old has lost all." (Ryan's Med. Juris. p. 124.) This doctrine, however, must not be received without limitation; for instances of precocity, as well as of protracted generating power, are not wanting. Dr. Ryan (Loc. cit.) cites some examples of children precociously developed, even before the fourth year; and he alludes to a case of a boy described by M. Virey, who at seven years of age was as fully developed as an adult, and who made the most furious attacks on his female acquaintance, and absolutely deprived one of them of that which she could never regain. Instances of vigorous senectitude are also occasionally met with. Of these the case of the celebrated Thomas Parr is, perhaps, the most striking. He married at the age of one hundred and twenty, and was compelled to do penance for an amour in his hundred and fiftieth year. But looking on these as exceptions to the general rule, it may be said that extreme youth or old age is incompatible with the exercise of the generative function.

There are, moreover, certain states of the body in which, although the genital organs be perfect, impotence may nevertheless exist, in consequence of incapability of erection. This may arise from constitutional frigidity, or what may be termed the apathetic temperament. The offspring of infirm aged persons, of parents too young, or of those worn down by debauchery, often present examples of this condition. The appearance of persons of this temperament is thus described by a French writer: (*Dict. des Sciences Méd. art. Impuissance*.) "The hair is white, fair, and thin, no beard, countenance pale, flesh soft and without hair, voice clear, sharp, and piercing, the eyes sorrowful and dull, the form round, shoulders straight, perspiration acid, testicles small, withered, pendulous, and soft; the spermatic cords small, the scrotum flaccid, the gland of the testicles insensible, no capillary growth on the pubis, a moral apathy, pusillanimity and fear on the least occasion." Impotence arising from this cause is usually incurable.

A more common source of impotence is a par-

ticular weakness of the generative organs arising from too early coition, from abuse of venereal pleasures, or from indulgence in the pernicious crime of masturbation. In persons whose organs are debilitated by these causes, erection does not take place, although the mind be highly excited by lascivious ideas. The erector muscles have lost power from over-use, and are to a certain extent paralysed; and if semen escapes, it is clear, serous, without consistence, and consequently deprived of prolific virtue.

Among the causes of general debility capable of producing impotence, have been reckoned defect of nourishment, bad quality of food, and unwholesome regimen. But we would observe that these influences must be exerted to the very extreme before they can produce the effect described, for in this city (Dublin), where misery, poverty, and starvation exist to a degree perhaps unparalleled on the face of the globe, procreation proceeds with extraordinary rapidity; and it has fallen to the writer's lot, through his connection with the Coombe Lying-in Hospital, to witness the birth of numberless infants whose unfortunate parents had not for years partaken of a wholesome meal.

The habitual abuse of spirituous liquors, long watching, excessive evacuations of blood, bile, saliva, or fæces, as they tend materially to depress the powers of the constitution, may prove temporary causes of impotence. To this class Marc (*Dict. des Sciences Méd. art. Impuissance*) adds the sedative action of opium, hyoscyamus, and tobacco. The influence of the narcotic gases, in consequence of the sedative effects they produce on the sensitive system, sometimes gives rise to a temporary impotence. Of this the following case given by Foderé is a good example. "J'ai traité un homme âgé d'environ quarante ans, qui, ayant échappé à un état apoplectique occasioné par la vapeur du charbon, reste tellement impuissant pendant six mois, qu'il étoit absolument insensible à toutes les caresses que sa femme, qu'il aimoit jusqu'à la jalousie, mettoit en usage pour l'exciter. Il reprit complètement ensuite son état naturel." (*Méd. Lég. tom. i. p. 382*). Certain substances, as the nymphaea or water-lily, nitre, camphor, colchicum, and indeed most of the diuretics, have been supposed to exert directly sedative effects on the generative organs. That this specific action can cause impotence is probably too much to assert, although some writers have done so; but from the beneficial effects we have obtained from the use of nitre and camphor in cases of over-excitement of the generative apparatus, attended with nocturnal emissions, it would appear that these substances are possessed of properties that tend to moderate the venereal appetite. We have heard of a patient rebelling against the continuance of the use of colchicum, in consequence of its impairing his virility. Dr. Paris takes notice of a peculiar species of impotence arising from debility which deserves notice. "It depends," says he, "upon a want of consent between the immediate and secondary organs of generation; thus the penis acts without the testicles, and becomes erected when there is no semen to be evacuated; while the testicles secrete too quickly, and an evacuation takes place without any erection of the penis." (*Med. Jur. vol. i. p. 208*.)

We have already alluded to the effects of strict chastity on the testicles. In this state of decay impotence is the final result. There are some diseases which stimulate the generative organs, such as gout, rheumatism, hemorrhoids, calculus in the bladder or kidneys: in the latter disease the constant irritation propagated to the glans penis frequently urges the sufferer to coition even during the most severe pain. But there are others which extinguish venereal desire during their continuance. These are nervous and malignant fevers, which engage the sensorium from their commencement, and are accompanied with general weakness and prostration of excitability; and diseases of the brain and spinal cord, occasioned either by internal or external causes. Hennen (*Military Surgery*) mentions a case of a soldier who was rendered impotent by a blow on the occiput. With reference to the effect of diseases on the generative function, Foderé mentions a circumstance worth being remembered, which is, that it is possible that certain diseases may produce such an alteration in the constitution, that an impotent man may find himself cured of his impotency on their cessation. He adduces the instance of Avenyoes, who stated he had been without offspring during the whole of his youth, but became a father on recovering from a severe fever. Zacchias states a similar instance. An artisan lived twenty-four years with his wife without having children, when he was attacked by an acute disease, from which he recovered; the fruit of his convalescence was the birth of a son, after which he had many children. It is well known that persons recovering from acute diseases are often extremely salacious. Dr. Dunlop (*Beck's Med. Jur. by Dunlop*) gives an instance of this on the authority of a friend who visited the hospitals in New York, and who stated that patients recovering after the yellow fever exhibited most furious sexual passion, to the great inconvenience of the nurses and their assistants.

3. Moral.—We have already treated of those causes which produce permanent impotence, and of those disturbances of the constitution which during their continuance suspend the generative function: we have now to observe upon those causes which in a sound constitution, with perfect genital organs, are capable of suspending their action, but the cessation of which leaves them free to fulfil their office. These are strong mental emotions, such as too ardent desire, fear of not being loved or of being incapable, shame, timidity, surprise, jealousy, hatred, disgust, in short any thing by which the mind is forcibly arrested. A temporary impotence from this class of causes is by no means a rare occurrence. Of all the causes just mentioned, the fear of incompetence is most frequently productive of impotence. It was a knowledge of this fact that led Hunter to adopt the remarkable mode of treatment which proved so successful in a case of impotence. He prevailed on the person to promise on his honour to pass six nights in bed with a young woman without attempting sexual intercourse, and before the allotted time had expired, the patient's only fear was lest the force of desire should induce him to break his promise. Similar instances have occurred to most medical men, and have been cured

by the same means. The facility with which the most vigorous man is rendered impotent by this cause, led to the supposition that supernatural agents were concerned in effecting it, and the natural credulity of mankind soon confirmed the idea. This belief in the powers of enchantment, or, as the French term it, "*nouer l'aiguillette*," has prevailed in most ages and countries. We have accounts of it in the East, in Egypt, among the Greeks and Romans; and even some of the early fathers of the church, St. Jerome and St. Augustin, are said to have been imbued with it. Like other forms of enchantment, persons were found who made it their business to practise it, and even princes were subject to their dominion. Nero and Amasis were, at the suggestion of their concubines, rendered impotent by incantation. In this process there was always something to arrest the imagination; some drug was administered, some obscure and unintelligible words were pronounced, or written on paper with blood, and tied about the victim's neck; a lock of his hair was tied, with certain mysterious ceremonies, or some equally absurd practice pursued, no matter what, so that the proper impression was made upon the mind, and as long as this continued it had the power of preventing erection by the very fear of failure. The progress of knowledge has done for this species of witchcraft what it has done for others, and it is now confined to the lowest and most ignorant people.

II. IMPOTENCE AND STERILITY IN THE FEMALE.—It is necessary to distinguish between these two conditions in the female, as it is quite possible for a woman to be impotent and not sterile, and sterile but not impotent; in other words, there may exist a malformation of the genital organs of such a nature as to prevent intercourse, on the removal of which she becomes fruitful; and, on the other hand, she may be perfectly competent to copulation, yet never conceive. The latter is by much the most common, and is believed to occur more frequently in the female than impotence does in the male. Strictly speaking, impotence can only be said to exist in the female when the vagina is incapable of admitting the penis. By this incapacity, however, sterility is not always insured, as it will appear from cases to be presently alluded to, that impregnation has taken place when intromission was impossible. But laying aside these instances, as exceptions, it may be stated generally that an impervious vagina is attended with impotence. Such a condition of the female organs may be the result of various causes existing either in the hard or soft parts. It is rare to find the impediment originating in the former, but Foderé alludes to a malformation of the pelvis, such as considerable depression of the pubis, or exostosis, as capable of opposing the act of generation: we cannot, however, believe that deformity of the pelvis caused by approximation of the pubis and sacrum can offer such a barrier as he supposes; and we are strengthened in our disbelief by the many instances recorded, in which impregnation took place notwithstanding the highest degree of deformity. But an exostosis, when it attains a great magnitude, may very well prove an obstacle to coition. The cause of impotence is more frequently found in the soft

parts, and this may be either absence or occlusion of the vagina. Cases in which the vagina was altogether wanting are not numerous, but there are some recorded, and of these one of the most remarkable is detailed in the *Causes Célèbres*. (Tom. vii. and x., *Vingtième cause*.) We will not give the case at length, but the leading facts were the following. A young woman in Paris was married in her twenty-fifth year to a young man named La Hure. Six years were passed without consummation of the marriage; and then the woman was examined by a midwife, who declared all the external organs of generation wanting, and their place occupied by a solid body pierced by a small hole. The woman admitted that she had never menstruated; nevertheless she had always enjoyed good health. A surgeon, named Dejours, who saw the case at this time, supposing it one of simple occlusion of the vagina, proposed to divide the barrier, in hopes of reaching and laying open the cavity. He accordingly carried a scalpel to the depth of two fingers' breadth, but instead of reaching a vagina he was still opposed by solid resisting parts. Finding this, he judged that he had nothing to hope for in going further, and that he should run great risk of wounding the bladder or rectum. He therefore endeavoured to keep open the wound he had made by the introduction of tents, and this opening remained during life. Matters continued quiet for eight years more, when the husband, disgusted with his wife, demanded a divorce. The woman died at Lyons ten years afterwards, and on examination it was found that the place of the vagina and uterus was occupied by a hard compact substance, in which no cavity could be traced. Not long ago a case somewhat similar was exhibited to the Society of the Faculty in Paris, in which no uterus or vagina existed, and the perineus was pierced by a small hole, which was the termination of the urethra.

A more common case is that in which the calibre of the vagina is so diminished as to resist the intromission of the penis. Several instances of this malformation are to be found in writers on legal medicine and midwifery, one of which we may mention, as it affords a striking example of the manner in which nature accommodates parts to the offices they are called on to perform. A young girl, married at the age of sixteen, had the vagina so narrow, that a goose-quill could scarcely enter it. A young and vigorous husband had failed in all his attempts, and some of the faculty who were consulted declared copulation impracticable. Nevertheless, after eleven years this woman became pregnant without any increase in the dimensions of the vagina. Her friends of course despaired of the possibility of delivery, but about the fifth month of pregnancy the vagina began to dilate, and at the full time it had acquired a size sufficient to permit the passage of the infant. (*Mém. de l'Acad. des Sciences de Paris*, 1712.) In the celebrated Joan of Arc, the Maid of Orleans, according to the account of two physicians who were ordered to examine her, the vagina was found so contracted that coition must have been impracticable. Malformation of this kind is frequently removable by appropriate treatment. In a case that occurred to Benevoli, he employed emollient fomentations and tents, and by gradually

increasing the size of the latter, succeeded in removing the imperfection.

In those cases in which the uterus is divided longitudinally into two chambers, it sometimes happens that the septum is prolonged into the vagina, even to the vulva. (*Andral*.) In this condition of parts, if the intervening membrane be firm and rigid, it may oppose a barrier to coition. The vagina may be also too short and terminate abruptly in a cul de sac; this disposition of parts may be congenital, but it may be also the result of difficult labour. When congenital, it is usually attended by absence of the uterus.

The inflammation that sometimes follows difficult labours (particularly if instruments have been incautiously used) has been known to cause adhesion of the side of the vagina, and so cut off all communication with the uterus. The writer is acquainted with a very remarkable instance of this accident at present in the Coombe Lying-in Hospital, Dublin. The sufferer is a young healthy woman, in whom there is a fistulous opening between the bladder and the vagina, and just beyond the opening the sides of the vagina adhere firmly. She applied at the hospital in hopes of obtaining some relief from her miserable state, which she said was in consequence of a tedious labour, during which instruments of some sort were employed. It is remarkable in this case, that although the outlet for the menstrual discharge is closed, there is no indication that it is poured out by the uterus, for none of the signs of confined menses are present. We are therefore inclined to suppose that the cavity of the uterus itself has been obliterated by the inflammation, and consequently that an operation would not be attended with success.

The vagina is frequently found closed at its orifice: this may be caused in different ways. It is sometimes produced by neglected inflammation and excoriation of the labia in children, and even in adults; and this has extended in some cases to a complete closure of the canal, so that no passage has remained but a small one at the superior anterior part for the discharge of urine. Dr. Ryan (*Manual of Med. Jurisprudence*, p. 129) states that he has seen four cases of cohesion of the labia externa at the age of puberty, so complete that only a small probe could be introduced at the superior commissure. Dr. Merriman once met with an instance where the entire opening of the labia was so perfectly closed, in an infant of two years old, that there was not the smallest aperture through which the urine could escape. (*On Difficult Parturition*, 3d edit. p. 221.) We find in the works of Ambrose Paré, Ruysch, Fabricius Hildanus, Benevoli, and others, examples of complete obstruction of the vagina, either at its orifice or at a greater or less depth, by a membrane of such strength as to resist intromission. Dr. Merriman (*Loc. cit.*, p. 216) relates the case of a young woman whom he was called to attend in her first accouchement, and on proceeding to make an examination he found it impossible to introduce his finger into the vagina, that passage being closed by a membranous expansion about one-tenth of an inch in thickness. This membrane occupied the entire opening of the vagina, with the exception of a small aperture through which a pea could hardly have passed. It was finally

ruptured by the child's head, and delivery was safely accomplished. The same author gives another case related by Dr. Tucker, in which the obstruction was even more complete. "The labia pudendi were observed to have the usual situation and appearance; but being expanded, they were discovered to be connected to each other by a strong opaque membrane, nearly a finger's breadth, not distinguishable from their external skin in texture and appearance, which was stretched from the surface of the perineum (of whose outward skin it seemed likewise a continuation or production) over the longitudinal sulcus between the labia, and over the clitoris, quite to the pubis. About the middle of this membrane there was a circular aperture, with a strong ring, just large enough to admit a female catheter one-eighth of an inch in diameter." In this case the membrane was so strong that it resisted the forcible impulse of the child's head during several pains, and was at last divided artificially from the aperture to the frenum labiorum. These and many similar instances on record are the cases to which we referred in speaking of hypospadias, as confirmatory of the doctrine laid down there, viz., that an emissio seminis at the orifice of the vagina is sufficient for impregnation, and they afford instances of what may be considered paradoxical, that is, of women being impotent, yet conceiving. The following case from Foderé is so striking that we cannot omit to mention it. A young man had married a young woman, with whom, although he had frequently made the attempt, he could never consummate the marriage, "à son gré." At the end of three months he demanded a divorce, although she declared herself pregnant. She was now examined by many skilful surgeons, who found a hard callous membrane placed at the mouth of the vagina; this they divided, and the operation succeeded so well that the husband relinquished his claim for divorce. The woman was delivered, in six months after the operation, of a male infant at the full term, and of great vigour. From these cases it is plain that this hypertrophied state of the hymen, although it affords a barrier to copulation, is yet capable of removal by operation, and therefore it cannot be considered as a permanent cause of impotence.

Narrowness of the mouth of the vagina is sometimes accompanied with a communication between that canal and the bladder or rectum. Foderé states two cases of this description, in both of which sterility prevailed. Procidencia of the uterus might be supposed to create impotence, were it not that some very remarkable instances of the contrary are recorded. In the fourth volume of the London Medical and Surgical Journal, may be found a description of two cases of this disease, in both of which impregnation took place, although the natural orifice had been fixed without the vulva for years.

We now come to speak of sterility, or of those cases in which, the vagina being pervious, impregnation does not occur. This may depend upon imperfect development or total absence of the uterus, obliteration of its openings, diseases of this organ, obstruction or disease of the fallopian tubes, and absence or disease of the ovaria. That form of imperfection in the uterus in which one-half

of the organ is wanting, and which case is attended with but one ovarium and one fallopian tube, does not entail sterility. Chaussier relates a case of this kind in which seven children were born at the full time. (*Andral*.) But there is a variety sometimes found which must render the woman barren; in which the uterus is so small that it is with difficulty found in the pelvis, and the fallopian tubes appear to terminate in the extremity of the vagina. We have already said that unnatural shortness of the vagina is frequently connected with absence of the uterus. Columbus dissected a woman who had always complained of great pain in coitu, in whom he found the vagina very short, and no uterus at its termination. A similar case occurred to Dupuytren: (*Répertoire d'Anat. Pathol. t. v. p. 99*): the vagina was only one inch in length, the ovaria and fallopian tubes were well developed, but no uterus existed. Foderé states that this malformation may be discovered during life by the smallness of the breasts, &c.; but in the case mentioned by Dupuytren the breasts were well formed, the external genitals developed, and the whole appearance was feminine. It is plain that sterility must attend this defect.

The different orifices of the uterus may be obliterated, and thus impregnation will be prevented. The opening of the fallopian tubes has been found closed; and this may be owing to a simple continuation of the lining membrane of the uterus over it, or to the existence of a particular membrane blocking up the mouth of these tubes, or to an obliteration of the tube itself, which sometimes extends to the distance of some lines from the uterus. When both tubes are thus circumstanced, no utero-gestation can go forward, for obvious reasons. But the mouth of the uterus itself is occasionally obstructed either by an adventitious membrane stretched across, or by an agglutination of its sides; and when this is the case, sterility is the result.

Besides the closing of the uterine extremity of the fallopian tubes, these canals are sometimes impervious throughout their whole extent; sometimes the obstruction is situated about the middle, and at others the fimbriated extremities alone are blocked up; and this latter is frequently caused by an intimate adherence between them and the ovaria. (*Morgagni. Baillie. Richerand. Andral*.)

The ovaria are sometimes wanting. This deficiency may exist at but one side, a specimen of which is preserved in Dr. Hunter's museum; and Dr. Baillie takes notice of others in which these organs were deficient on both sides. Dr. Denman says he was shown two preparations by Dr. R. Hooper, in which the fallopian tubes terminated bluntly, and without any aperture, fimbriae, or ovaria. (*Denman's Midwifery, 6th edit. p. 42.*)

Besides these impediments to impregnation, there are certain diseases of the female genital organs, which, when they exist, are found to cause sterility. Polypus in utero is very generally considered to belong to this class; but although the opinion is generally correct, it is not universally true, for it has happened that conception took place notwithstanding the presence of a very large tumour in the uterus. Of this the late Dr. Beatty (*Trans. of the Association of Coll. of*

Phys. in Ireland, vol. 4) has described a very remarkable instance, which occurred in Dublin in the year 1820. The patient was a lady twenty-five years old, who, in consequence of the indisposition of her husband, had left his bed in May 1819, to which she did not return until August 1820. In the previous May she first perceived what she termed a "lump in her womb," attended with external swelling and soreness on pressure at the lower part of the abdomen. This swelling was not permanent, but was observed to disappear during the menstrual period. Finding an increase in her unpleasant symptoms, she applied to Dr. Beatty in September, and on the 28th of that month he made an examination per vaginam. The os uteri was found dilated to the size of a dollar, and in its opening was a large dense substance with a regular smooth surface. On the 10th of November, while out in her carriage, she had a moderate discharge of blood from the vagina, and upon examination the parts were found as they were a month before. At two o'clock the following morning she miscarried, the embryo was entire, the membranes not being ruptured: the contained fetus was about three months old—a period corresponding with the time at which the connubial intercourse had been resumed, and at which she had last menstruated; and just three months after she first experienced uterine uneasiness. The tumour was expelled in six days afterwards by pains resembling labour, the uterus was inverted by its descent, but on separation of the slight attachment between it and the tumour it was easily reduced. The weight of the tumour was found to be nearly four pounds. This lady was delivered of a healthy boy on the 10th of February, 1822. This was an instance of pregnancy during the existence of a tumour of considerable magnitude in the uterus; but we believe it to be an exception to what usually takes place.

Inflammation, suppuration, calculous depositions, cancer, cauliflower excrescence, corroding ulcer, the irritable uterus of Dr. Gooch, and any disease in which the texture of the uterus is much engaged, or with which the constitution sympathizes strongly, are so many obstacles to impregnation, as are diseases of the ovaria, in which the natural structure of these organs is obliterated, and both of them engaged. Leucorrhœa, when profuse, is very often also attended by barrenness; but this is by no means a constant effect, as we have known instances in which this disease existed to a great extent without preventing impregnation.

A question has arisen whether menstruation is necessary in order that a woman shall be prolific; and it is generally stated that women who do not menstruate cannot conceive. (*Paris and Fonblanque*, Med. Jur. vol. i. p. 214.) This is true when applied to those who have never menstruated, but is not in cases that have had even a single monthly discharge. Foderé (*Méd. Légale* vol. i. p. 397, ed. 2me) states that, in the first edition of his work, he had maintained that females who do not menstruate are sterile; but he afterwards was obliged to change his opinion, from having observed some patients under his own care enjoying good health without this evacuation, and bearing many children. One of them was a

woman thirty-five years old, the mother of five children, the last of which she was suckling. She was in good robust health, and had never menstruated but once at the age of seventeen years. It would appear that a single occurrence of this periodical evacuation is a sufficient indication of generative power; and although irregularity in subsequent years is frequently attended by sterility, it is not to be taken as an absolute cause of it. There is a form of dysmenorrhœa described by Dr. Denman (*Denman's Midwifery*, 6th edit. p. 90), and Dr. Dewees (*Dewees' Midwifery*, p. 154) of Philadelphia, which both these authors state to be productive of barrenness. The striking peculiarity in this disease is the formation of an adventitious membrane in the uterus, which is expelled after severe and protracted suffering at each menstrual period. This membrane is sometimes thrown off in pieces, and at others entire, at which time it bears the strongest resemblance to the decidua, so much so that, when it occurs in unmarried females, it may and sometimes does give rise to most painful suspicions. There is a preparation in the museum of the College of Surgeons, Dublin, of an entire membrane of this kind, which might deceive the most experienced eye. Morgagni relates a very remarkable instance in which pregnancy occurred during the existence of the habit just described, but it is probable that there was a suspension of the disease for a time in that case, when the capability of conceiving might exist.

It is well known that instances have happened in which persons have lived for years in unfruitful matrimony, and being after divorce remarried, have both had children. This is a fact which in the present state of our knowledge we are not able satisfactorily to explain, and we will not delay the reader by offering any speculative opinion upon it.

Treatment.—The treatment of impotence and sterility must be influenced by the causes from which they spring, some of which are incurable, whilst others may be removed by appropriate remedies. Those cases which depend upon congenital deficiency of the penis, testicles, vagina, uterus, Fallopian tubes, or ovaria, belong to the former; but we have seen that some of those arising from malformation and disease of these parts are susceptible of cure. Such are phymosis, adhesion of the prepuce to the glands with diminution of the orifice of the urethra, priapism, partial paralysis, strictures in the urethra, diseases of the neighbouring parts, contracted vagina, occlusion of the mouth of this canal by adhesion of the labia, or by a dense hymen, prolapsus and procidentia uteri, polypus in utero, leucorrhœa, dysmenorrhœa: all these are more or less capable of removal either by operation or general treatment. The cases of impotence which depend upon functional or moral causes are much more numerous than those just mentioned, and frequently become the subjects of medical treatment. If old age be the cause, there is little to be done; medicines are useless, and temporary stimulants are often worse. There have been instances of old debauchees, who, wishing to make a last attempt, have taken some of the nostrums, such as the Venetian pastilles, Italian lozenges, &c. and have perished without success in the very effort. Cases

arising from debility of the generative organs, from too early coition or the abuse of venereal pleasures, are not unfrequently met with, and indeed furnish the great mass of dupes to quackery. In the treatment of such cases there are many points that must be strictly attended to. We must be careful to remove from the imagination, or regimen, all that may excite the generative apparatus, while we endeavour to strengthen the system by mild nourishing diet and gentle tonics. We must combat on the one hand muscular weakness, and on the other nervous susceptibility, and so restore the equilibrium between the two systems. The local application of cold water has a great effect in allaying the excitable state of the generative organs, and should be had recourse to at least twice a day. If the impotence be owing to moral or physical irritation, the constitution must be lowered by spare diet, cooling acidulated drinks, exercise in the open air, and removal from all objects which excite venereal desires. This plan of treatment we think preferable to the employment of narcotics, which sometimes produce unpleasant effects, and are always hurtful to the digestive organs. In those cases which are purely the effect of atony of the generative organs, and do not arise from their over-excitement, a different line of conduct must be pursued. The diet should be full and generous, with a liberal allowance of spices and wine; and the exclusion of all objects of a nature to excite the senses need not here be recommended. Frictions to the loins, and the cold bath, will be found useful; sometimes it will be necessary to substitute the warm bath when the cold does not produce the healthy reaction we desire. (See BATHING.) If these means fail, we may then have recourse to stimulating applications to the loins, thighs, and pubis, and electricity may be used with advantage. (See ELECTRICITY.) In the year 1776, Dr. Graham opened an establishment in London, in which were a number of electrical beds, destined to awaken the dormant generative powers in cases such as we have described.

Modern systematic writers have discarded that class of medicines formerly grouped together under the name of aphrodisiacs, from their supposed power of exciting a desire for venery: it consisted of stomachics, aromatics, odoriferous gums, balsams, resins, essential and volatile oils, perfumes, particularly musk, phosphorus, opium and aromatics combined, and cantharides. These, with the exception perhaps of cantharides, seem to act only as general stimulants, and do not possess any specific powers over the organs of generation. Cantharides, as is well known, when administered in large doses, are sometimes capable of inducing a violent state of irritation of the urinary and genital organs, indicated by strangury, bloody urine, priapism, &c.; but this condition can never be induced without other violent constitutional symptoms being also brought on, to the great hazard of life, (Christison on Poisons, p. 456); and we are much inclined to doubt that a person labouring under these effects is disposed to venereal enjoyments. However, cantharides have been employed as an aphrodisiac, and for this purpose they entered into the composition of many secret remedies, such as the Venetian pastilles, Italian

lozenges, love potions of Italy and Turkey, &c. to the use of which we believe many have fallen victims. The "remède de magnanimité" of Kœmpfer, so called after its inventor, is composed of opium, musk, and ambergris, and is extensively employed in the East, where it is taken daily by the great for the purpose of exciting venereal desires.

From what has been said in commenting upon the different causes of impotence, it is unnecessary to prolong this article by any further notice of their medico-legal application; we will therefore conclude by deducing, in the words of Dr. Ryan from the preceding statements, the following general principles:—

"1. To declare either sex impotent, it is necessary that certain physical causes be permanent malformations or accidental lesions, and be evident to our senses, which art cannot remedy, and which prevent the faculty of exercising a fecundating coition.

"These causes, when rigorously examined, are few in number.

"The moral causes of impotence ought not to be taken into consideration, as they would serve for an excuse for an individual accused of impotence." (Ryan's Med. Jur. p. 133.)

THOMAS EDWARD BEATTY.

INCUBUS, (from *incubo*, to lie or sit upon,) *nightmare*: an affection coming on during sleep, and characterized especially by a sense of weight on the chest, with an inability to move, and sometimes even to speak. Various affections attacking a person during sleep produce sensations, often very uneasy, but insufficient to awake him completely; and although his eyes may be open, and he may be conscious of surrounding objects, he labours under the fancies of some horrible dream excited by the sensations in question. It is this state of imperfect possession of the faculties, and the absence of volition, which gives the peculiar character of the disease called incubus, or nightmare; and this circumstance would entitle it to be considered as much a mental as a bodily disorder. The causes of the sensations are, however, physical, and it is against these principally that treatment can be directed.

The usual and severe form is that in which the patient, in the midst of his sleep, generally in the first part of the night, becomes conscious of the sensation of a huge weight on his breast, which oppresses and impedes his breathing. This is accompanied by a feeling of inability to move, and often to speak, which greatly increases the discomfort; and the fancy, ever active, embodies these phenomena into some monster, overpowering and crushing the body. Hence the superstitious names, *nightmare*, *incubus*, *succubus*, *ephioltes*, &c. In many instances the feeling of weight or pressure is less defined; but there is a sense of general restraint and uneasiness which the mind converts into some imaginary danger, such as falling down a precipice, being pursued by an armed enemy or savage beasts, and the like, with a feeling of weight on the limbs, and an inability to escape; and this becoming so intense as to break the remaining tie of sleep, the person awakes with a

start, and under the temporary alarm of this imaginary evil.

Nightmare in all its varieties is, then, a disorder of the function of sleep, (if by such a name we may designate a suspension of other functions,) and it becomes an interesting matter of further inquiry, inasmuch as it in a degree presents an analysis of the state of sleep itself. The power of volition, both in mind and body, is that which is the most completely suspended in natural sleep. Sometimes the other mental faculties are equally so, but more generally there are trains of thought going on; and simple sensation, although blunted, is never entirely suspended. Dr. Alison has well established the opinion formerly entertained by Whytt, that respiration is an instinctive motion excited by the sensation of black blood in the lungs; and the movements and changes of posture unconsciously effected during sleep, seem to be of the same kind, and scarcely coming under the head of voluntary motions. When sleep is coming on, there is, first, an indisposition to perform voluntary acts, and if no awakening cause be applied, this soon amounts to inability. But the senses may still be awake, and although volition cannot shape or direct them, trains of ideas result from their impressions. When sleep becomes more perfect, however, the senses become more obtuse, and, unless excited by some considerable impression, incapable of influencing the other mental powers that may remain still in activity. Such an impression, when produced, if of the painful kind, and insufficient directly to awake the person, will not fail to excite some or other of the varieties of nightmare. The form which it assumes will depend on the nature of the bodily impression, and it will be sufficient to illustrate the subject by one or two examples.

In the case to which the term *incubus* or *nightmare* is commonly applied, that, namely, of a sense of weight and oppression on the chest, there is, we believe, an imperfect performance of the function of respiration, caused either by a constrained posture or distended stomach; or in some cases it may be by a slight attack of asthma, excited by acid or other crudities in the alimentary canal. Now such slight impediments during our waking hours are easily obviated by the supplementary aid which voluntary efforts can give to the respiratory process: we change our posture, draw our breath more deeply, relieve the stomach by eructation, &c.; and all this with scarcely a consciousness of the ailment, or of the act which relieves it. But during sleep these movements are not at our command; the respiratory act is more limited, and although sufficient for the natural state of the function, becomes inadequate when an embarrassment renders necessary an increased exertion or new movement. In event of this, therefore, black blood gradually accumulates in the lungs, with its consequent effects of congestion in the right cavities of the heart, and feeling of oppression and suffocation, which, after tormenting the mind for a time in some demoniacal form, at length reaches such an acme, as to break the spell of sleep, and awake the sufferer to the possession of those voluntary powers, by the exercise of which the bodily function is restored to its natural state. No sooner is he fully awake

than the bodily uneasiness is removed, and he is sensible only of the mental disquietude which his frightful dream has occasioned; and this, joined with the excitement of the restored circulation, may prevent him from readily composing himself to rest again. This we conceive to be a sufficient explanation of the phenomenon of nightmare; without resorting to hypothetical notions of pressure on the solar plexus or nerves of the stomach, which, if capable of producing an effect at all, should do so equally beyond the period of sleep. Incubus may, therefore, be justly placed in contrast with somnambulism, in which the power of voluntary motion continues, whilst the external senses are either suspended, or their impressions superseded by some internal train of ideas that engrosses the mind.

As causes of incubus, we have already named disordered digestion and constrained posture; and we may now add diseases of the heart, and whatever is capable of interrupting, during sleep, the due arterialization of the blood.

We pass on to notice some other causes which may produce effects of analogous character. Such are, pains of any kind, as tooth-ach, ear-ach, &c., which, when insufficient to prevent sleep, often become the demon of a dream, tormenting the sufferer in a thousand different shapes. Cold feet are another common cause of disordered sleep. There is, however, between these causes and that which produces nightmare, this difference; that in the case of these, the person awakes to a consciousness of the real cause, whereas the sensation of nightmare ceases with the return of voluntary movement.

Various impressions on the sense of touch may engender disturbances of somewhat similar character. On this subject some remarks by the most celebrated writer of our day are too philosophical to be omitted here. "There is one circumstance in which the sense of touch is very apt to betray its possessor into inaccuracy, in respect to the circumstances which it impresses on its owner. The case occurs during sleep, when the dreamer touches with his hand some other part of his own person. He is clearly, in this case, both the actor and the patient, both the proprietor of the member touching, and of that which is touched; while, to increase the complication, the hand is both toucher of the limb on which it rests, and receives an impression of touch from it; and the same is the case with the limb, which at one and the same time receives an impression from the hand, and conveys to the mind a report respecting the size, substance, and the like, of the member touching. Now, as during sleep the patient is unconscious that both limbs are his own identical property, his mind is apt to be much disturbed by the complication of sensations arising from two parts of his person being at once acted upon, and from their reciprocal re-action; and false impressions are thus received, which, accurately inquired into, would afford a clue to many puzzling phenomena in the theory of dreams. This peculiarity of the organ of touch, as also that it is confined to no particular organ, but is diffused over the whole person of the man, is noticed by Lucretius:—

* Ut si forte manu quam vis jam corporis ipse
* Tate tibi partem ferias, æque experiare.*

A remarkable instance of such an illusion was told me by a late nobleman. He had fallen asleep, with some uneasy feelings arising from indigestion. They operated in their usual course of visionary terrors. At length they were all summed up in the apprehension that the phantom of a dead man held the sleeper by the wrist and endeavoured to drag him out of bed. He awaked in horror, and still felt the cold dead grasp of a corpse's hand on his right wrist. It was a minute before he discovered that his own left hand was in a state of numbness, and with it he had accidentally encircled his right arm." (Sir Walter Scott's *Letters on Demonology*, p. 43.)

Another case, which Dr. Abercrombie in his interesting work "On the Intellectual Powers," cites from the late Dr. Gregory, is clearly one of the same character with nightmare, and well illustrates our explanation of its pathology. "Dr. Gregory mentions a gentleman, who, after sleeping in a damp place, was for a long time liable to a feeling of suffocation whenever he slept in a lying posture; and this was accompanied by a dream of a skeleton which grasped him violently by the throat. He could sleep in a sitting posture without any uneasy feeling; and after trying various expedients, he at last had a sentinel placed beside him, with orders to awake him whenever he sank down. On one occasion, he was attacked by the skeleton, and a severe and long struggle ensued before he awoke. On finding fault with his attendant for allowing him to lie so long in such a state of suffering, he was assured that he had not lain an instant, but had been awakened the moment he began to sink. The gentleman after a considerable time recovered from the affection." (Page 274.) In this case, we have little doubt that there was a real constriction or spasm in the glottis, or some of the air-passages, which became sensible only in the confined posture of recumbency, and during the low respiration of sleep.

We have little to say of the treatment of nightmare, as it must depend on the correction of its several causes. Of these, too much or undigested food is among the most common; hence the propriety of prolonging the period between the principal meal and the hour of rest, as well as of avoiding crude and indigestible articles of food. (See *INDIGESTION*.) The symptoms of acidity and flatulence are to be treated in the usual way, by magnesia or alkalies, and essential oils or other carminatives; and when these fail, ether will often succeed in relieving the stomach of wind, and the nervous palpitation which often follows an attack of nightmare. Nor is it unimportant to pursue measures to prevent the recurrence of this disorder; for besides that it

"— makes sleep a pain,
And turns its balm to wormwood,"

the disorder that it occasions in the circulation may, in those predisposed, bring on a fit of epilepsy or apoplexy, which not unfrequently occurs during the first sleep.

C. J. B. WILLIAMS.

INDIGESTION.—This word is synonymous with *dyspepsia*, (from *δυσπεψία*, to digest with difficulty: *Th. δύς* and *πέπω*;) and signifies in-

terrupted, laborious, or painful digestion; or, in other words, any derangement of that function by which the aliment, after having been received into the stomach, is converted into chyle.

The function of digestion is in its nature complex, consisting of the harmonious action of an apparatus of several organs, all mutually dependent upon the action of each other. These organs, singly, are liable to be disturbed by many different causes, which may each be again modified in their operation by a multitude of secondary and adventitious circumstances; and as every separate organ must perform its part healthily to complete the general function, so also the disorders of each individual organ may induce various derangements in the action of the whole apparatus. This view of the matter may give us some notion of the necessary diversity of the disorders of the function of digestion, and may serve to show us that, whatever common denomination we may employ to denote its general derangement, we must comprehend different disorders, having their seat in different organs, depending on different morbid conditions, presenting various forms, induced by various causes, and all necessarily demanding various corresponding methods of cure. For though the disorder of one of the subordinate processes may induce the interruption or the disorder of the whole function, and thus may seem to lead only to the same common disease, yet even under this supposition it is not immaterial to ascertain where and in what manner the faulty series has commenced, whether the impediment may have arisen in the stomach, the duodenum, the liver, or in any other organ; but it is also necessary to be acquainted with the particular modification of the function of either of these organs, for in this consists the nature or proximate cause of the disease: just as in the derangement of a watch, though the motion of the entire mechanism may be arrested by the disorder of some of its parts, the artist finds it necessary to discover in which the error lies, whether in the spring, the verge, or the balance, and whether the fault consists in excess or in deficiency of momentum or of matter.

That which physiology leads us to anticipate, observation fully confirms; for pursuing a contrary course of investigation, tracing effects up to their causes, we shall have still greater reason for admitting the diversity of the disorders of the function of digestion. Thus it would be contrary to all the common principles universally admitted in reasoning concerning natural phenomena, to suppose that the most opposite symptoms could arise from the same pathological state of the digestive organs,—that causes the most contrary could induce the same morbid condition, and that methods of treatment in direct opposition to each other could generally overcome one and the same disordered state. Thus,—that an impaired and fastidious, and a keen, craving, insatiable, nay, bulimious appetite; that an unquenchable thirst and a complete disrelish for liquids; that painful sensations of the stomach excited by the presence of food, and others relieved by the presence of food; that pain before eating and pain after eating; that an exalted sensibility of the organs rendering the patient painfully conscious of the whole process of digestion, and a diminished sensibility of the

stomach by which a patient, though suffering from, is altogether unaware of, any disorder of the digestive function; that the more easy digestion of solid food by some, and of liquids by others; the agreement of fat or oily substances with some, of albuminous with others; of saccharine matter with one, acidulous with another; that a deranged state of this function, constantly accompanied with a moist, pale, white, or coated tongue, or with a clean, dry, red, appearance of the tongue; with a clammy, moist, perspiring, or dry, shrivelled, impervious skin; with unhealthy, fetid, alvine discharges, or with evacuations which betray no sign of disorder; with a perfectly healthy state of the urine, and a highly unnatural state of that secretion; not to mention secondary and sympathetic affections, various, contrary, and incompatible with each other;—that all these discordant symptoms should emanate from one and the same morbid condition of the digestive organs, is a supposition altogether incomprehensible, and totally at variance with the acknowledged laws of order, constancy, and consistency, which regulate natural events.

In the same manner,—that fasts and surfeits; that repletion and starvation; that taking food too frequently and fasting too long; that the richest viands, the most refined preparations of food, and cold, crude, vegetable fare, without seasoning or condiment; that the varied repast of the most pampered, with every thing to whet and every thing to sate the appetite, and the simple scanty food, greedily devoured for very existence, (whether the potatoe of the poor Irish, the oaten cake of the Scot, or the salted and smoked fish of the Swedish peasant—all three well known to be equally great sufferers from dyspepsia); that wine-drinking and water-drinking; that dry diet and fluid diet; that excessive indulgence in sleep and overwatching; that inactivity of body and excessive fatigue; that indolence of mind and intense bent of thought; that the ennui of the fashionable idler, or the wearisomeness of the artisan; that the anxious cares of business, and the languor of inaction; that dwelling in dry, warm, badly ventilated apartments, and constant exposure to cold moist air; that the too frequent use of the warm bath, and the habitually squalid unwashed skin.—that all these ordinary causes of dyspepsia, so much at variance with each other in their nature and effects, should yet conspire in producing only one disease,—only one pathological condition of the digestive organs,—involves the absurd conclusion, that in the actions of the human body the most opposite causes have, in similar circumstances, the same identical effects.

And no less from the different nature of the means by which the disordered conditions may be corrected or removed, than from those by which they may be induced, shall we have reason to affirm that the derangements of the function of digestion are many and various: or we must suppose that a dry and a fluid diet; that a full diet and a scanty; that one of animal food and one of farinaceous; that a stimulating diet and a cooling; that distilled or fermented liquors and water; that alkalies and acids; that bitters and sweets; that tonics and demulcents; that stimulants and refrigerants; that repletion and depletion; that sipping brandy and sipping ices; that heat and cold;

that the warm-bath and the cold-bath;—that means so dissimilar and methods so repugnant to each other, have yet the same operation upon the living body.

From this diversity of symptoms, of causes, and of means of cure, it is more reasonable to infer a corresponding diversity in the morbid condition of the digestive organs, than to embrace the absurdity,—belied by all experience, and only consistent with our superficial learning in the language and grammar of the Book of Nature,—that the same things can have contrary signs, or that in similar circumstances opposite causes can produce the same effects.

It may seem that on this point,—the different nature of the disorders of the function of digestion, we have insisted too much; and indeed we should have thought it unnecessary to have pressed upon the attention of the profession a matter of such obvious importance, had we not occasion daily to observe the general tendency to apply to all these disorders the same method of treatment, as if they invariably constituted merely one and the same disease. The late Dr. Cullen, by affixing a general term to these disorders, may be justly charged with having in no inconsiderable degree promoted this error; but we are likewise not aware that any writer has felt more forcibly than himself its practical inconvenience. "We have established," says he, "a genus of disease under the title of Dyspepsia, and perhaps there was no avoiding it, but it is too general, and under this generality of little use. It comprehends every irregularity in the functions of the stomach; but these are certainly of great diversity in their nature and causes, and we want more accuracy and precision than we yet have." (First Lines, &c. Thomson's Edition.) In this circumstance of the great diversity of diseases comprehended under one common name, has originated the chief impediment to the successful medical treatment of dyspepsia; for it is self-evident that, as its different forms require to be met by corresponding methods of cure, the skill of the physician must mainly depend upon the power of distinguishing them, so as to be enabled to apply to each particular form of disorder its especial remedy, and also to adapt as nearly as possible the modification of the treatment to the modification of the disorder. The perfection of medical skill is most unquestionably the talent of applying to each individual case its precise, and, as it were, its individual cure,—an object which, though difficult of attainment, ought nevertheless to be the constant aim of the physician—the object which he ought unceasingly to pursue, and never rest until he has overtaken. Furthermore, we are very much inclined to suspect that a great part of the real secret of specific remedies lies in this, that they, being only applicable to diseases of one form and few specialties, are on this account alone so constant in their effects. In some degree in confirmation of this opinion, we may observe that when any specific disease, by complication or otherwise, assumes any remarkable deviation of character, then the specific remedy becomes dispossessed of its power. So that the success of these remedies does not so much depend upon any exclusively specific relation between the nature of the medicine and the

nature of the disease, (for we know that syphilis is to be cured by other medicines than by mercury; that psora is curable by hellebore as well as by sulphur; that agues may be arrested by arsenic as well as by quinine,) but upon the medicine having the power of curing a disease which is comparatively constant in its character, its operation not being liable to be frustrated by any peculiar modifying circumstances;—the disease thus specifying the remedy, not the remedy the disease.

This view of the matter should afford us reason to hope, that if in diseases less constant in their character and more variable in their accidents, we could meet the specialty of disease by its corresponding specialty of cure, we might also hope for an equal success, of which we have already some example and foretaste in the method of treating some diseases; as, for instance, in the plan of cure followed so successfully by the Pères de la Charité in colica pictorum. It should also teach us that, instead of ransacking every kingdom of nature for specific remedies,—a pursuit literally preposterous,—it is more reasonable, and would most certainly turn to better account, to seek for specific diseases, or by a proper specification, which is the very spirit and essence of practice, to endeavour to make them such. This is the object we have chiefly in view in the following article,—rather a sketch than a treatise of dyspepsia,—namely, to decompose the false and artificial genus comprehended under this term, to endeavour to establish a natural one in its stead, and by a proper classification of causes, symptoms, and methods of cure, to distinguish and define the different kinds of the disorders of the function of digestion,—*eorum tempora et causas in quibus medicinæ summa est, (Celsus)*,—so as to be able to establish a more close and accurate relation between each variety of disorder and its most appropriate remedy, in order that more certainty and more success may attend its application. “*Ideoque dubitandum non est, quin si medici, missis paulisper istis generalibus, naturæ obviam ire velint, compotes ejus fierent de quo ait poeta :*

“*Et quoniam variant morbi, variabimus artes ;
Mille mali species, mille salutis erunt.*”
(BACON, DE AUGMENTIS SCIENTIARUM.)

On reviewing the labours of our predecessors, we are confirmed in these opinions, for we find that the best observers have recognised great diversity in the disorders of the function of digestion, and that though, masking them each with his own particular theory, they have disguised them under particular names, there remains a remarkable coincidence in their observations and in their principles of distinguishing them. Thus we find that Hippocrates (Aphor. sect. iv. Aph. 17–20) made a distinction between gastric and intestinal dyspepsia, to which corresponded the *passio stomachica et ventriculosa* of the Methodists. (*Cælius Aurel.*) This distinction was revived by Hoffmann (De Duodeni morbis) and others, was insisted upon by Pinel, (Nosographie Philosoph.) and indicated by Ferriar (Med. Hist.), and Warren (Med. Transac. vol. iv.) but was never accurately and precisely laid down before the able and useful lecture of Dr. G. D. Yeats upon the diseases of the duodenum. (Id.

vol. vi.) Thus Celsus establishes several different disorders of the function of digestion, founded chiefly upon the different morbid conditions of the organs, to each disorder assigning its appropriate remedies.* In the different disorders of the digestive organs noticed by Celsus, not, however, to be all admitted as species really distinct, might no doubt be found most of those recognised by more modern writers; the simple dyspepsia of the solidists, the chylopoietic disorder of Mr. Abernethy, and the chronic gastritis of Broussais. In the disorders of the function of the stomach the Methodists acknowledged two principal divisions, *stomachica passio solutionis et stricturæ, (Cælius Aurelianus)* which were again by many of the sect variously subdivided. The former we shall find equivalent to the simple dyspepsia of the moderns, but in the latter may be found a strong resemblance to the dyspepsia from morbid sensibility and irritability of the stomach noticed by Cheyne, (English Malady); Whytt, (Nervous Diseases); and Pemberton, (Diseases of the Abdominal Viscera, &c.); but more insisted upon of late years by Barras (Traité sur les Gastralgies, &c.) and Dr. James Johnson. (On the Morbid Sensibility of the Stomach, &c.) Others, building upon shifting quicksands, founded the distinction of the different kinds of dyspepsia upon their symptoms; and thus Galen, who defined dyspepsia to be any deprivation of the alimentary mass in the stomach by which it was changed into something different from its natural product, distinguished dyspepsia into two species, *nidorous (κλινώδης)* and *acid (δξύδης)*, marking two of the most ordinary effects of indigestion. In this principle of distinction, Galen was followed by the symptomatic nosologists, who carried it to such a height, that the disorder was decomposed into all its various symptoms, each being made to constitute a distinct and independent disease.

To this error Cullen opposed another, still more pernicious, for he gathered together all the symptoms of disordered digestion, and thus formed his genus, *dyspepsia*; a genus illogically constructed, without species to support or sustain it, in which all previous distinctions were lost and confounded. Cullen, as we have already had occasion to remark, was himself more fully aware of the inconvenience of this arrangement than his followers; but it was not until—recovering the traces of the earliest physicians, and following the more recent examples of Dessault, Richter, Schmucker, and Scarpa,—after having incurred the just criticism of Fischer, a German, and having had the subject boldly unfolded to them by Halle,† a Frenchman, and when the attention of the medical profession of England had been fully concentrated on the disorders of the digestive organs by the writings of Dr. Hamilton (On Purgative Medicines) and

* Besides *cruditus* and *concoctio tarda*, which are repeated in several places, we have the following comprehensive passage: “*Faucibus subest stomachus; in quo plura longa vitia incidere consueverunt. Nam modò ingens calor, modò inflatio hunc, modò inflammatio, modò ulceratio afficit; interdum pituita, interdum bilis oritur; frequentissimumque est ejus malum, quo resolvitur; neque ulia re magis aut afficitur, aut corpus afficit.*” Lib. iv. cap. v.

† Reflexions sur le Traitement de la Manie atrabiliare comparé à celui de plusieurs autres Maladies chroniques, et sur les Avantages de la Méthode évacuante. Mem. de la Soc. Roy. de Méd. 1806, p. 310.

Mr. Abernethy (On the Constitutional Origin of Local Diseases,)—disappointed by the generic treatment and dissatisfied with the generic knowledge of dyspepsia, observant practitioners felt the want of better distinctions; and a spirit of specification commenced, which, still in progress, is yet, we hope, far from having reached its utmost limits. Of this spirit the earliest signs, we think, are to be found in Pemberton (Op. cit.), who was followed by Stone (On Diseases of the Stomach, 1806) and by Warren, (Med. Trans. vol. iv. p. 233.) It is to Dr. G. D. Yeats, (Med. Trans. vol. vi. p. 325,) however, that we are indebted for one of the most important contributions. About this time appeared Broussais, a bold reformer in physic, to whom the world is under deep obligations for subjecting the nature of dyspepsia to a searching analysis, but who in exposing one error plunged into the opposite, perhaps a greater one. With the same object in view, Dr. Wilson Philip, (On Indigestion, 1821,) an original observer, pointed out some valuable practical distinctions in these disorders; and though his work may fairly lay claim to be considered the most comprehensive and the most original which we possess upon the subject of indigestion, we are of opinion that, admitting only one primary form of dyspepsia, he laid too narrow a foundation for rearing a complete and correct classification of this disease. Other candidates have since appeared in the same field of inquiry, who have more or less helped towards the completion of this work. In chronological order, we find Dr. Ayre, (On Marasmus,) who has chiefly considered one form of the disease; our esteemed friend, Dr. Marshall Hall, (On the Mimoses, Lond. 1818—Commentaries on some Diseases of Females, 1827,) a physician of fine and distinguishing observation, who, under the term of *mimoses*, has treated the subject of symptomatic diseases with much judgment and discrimination; Mr. Law, (On the Digestive Organs,) who has made some original observations on the various kinds of costiveness; Dr. Paris, (On Diet,) who, from the physiology of the function of digestion, has deduced some valuable conclusions concerning its disorder: Dr. James Johnson, (Op. cit.,) who has checked and corrected the hasty generalization of Broussais and his adherents; our excellent friend Dr. Sir James Clark, (On the Influence of Climate, &c.,) an acute and a scrupulous observer, who has very accurately described two different species of these disorders; Mr. Cook, (On the Digestive Organs,) an able and observing practitioner, who has illustrated his distinctions of the disease with very interesting cases; and lastly, Dr. Mayo, (Essay on Indigestion, 1831,) who has called the attention of the profession to the importance of considering the influence of temperance in the treatment of indigestion. But it is due to the memory of Mr. Abernethy to state, that, though he did not co-operate in the task of distinguishing and specifying the disorders of the function of digestion, he looked forward to its accomplishment, (The Constitutional Origin of Local Diseases, &c. p. 17, 48,) and insisted on its importance. It is only matter of deep regret that he should have contented himself in his first position, instead of methodizing and digesting his ample

store of accumulated experience, and of thus advancing forward to the consummation of his enterprise.

Digestion, like any other function of the body, may be disordered in consequence of some morbid condition of its proper organs, or it may be disturbed in consequence of the morbid condition of the body in general, or of some organ in particular. This affords the leading division of dyspepsia into *idiopathic* or *primary*, and *deutero-pathic* or *secondary*, the most important practical distinction of every disease. But the disorder of a function may arise either from some change of action of the organ,—some new modification of its vitality,—or it may depend upon some lesion of structure; from this is naturally deduced the division of *primary* dyspepsia into *functional* and *organic*.

And as the disorder of a function may be either the effect of disease of the whole body, or of some particular organ or apparatus of organs, *secondary* dyspepsia may be conveniently divided into *symptomatic*, forming only a part of a more general disease, and *sympathetic*, the consequence of consent with the disorder of some other organ.

The disorder of the function of an apparatus of organs may either predominate in some particular organ, or may involve the whole apparatus; a consideration which, in the instance of dyspepsia, leads to the distribution of the previous divisions into four natural orders, according as the *stomach*, or *duodenum*, or *colon* is the exclusive or principal site of the disease, or as it involves more or fewer of these parts at the same time; whilst the different morbid conditions which any of the particular organs, or the whole apparatus may assume, afford an easy method of distinguishing these orders into different species. The morbid conditions by which the action of the organ may be modified, have been recognised by the best observers under the terms, *atonic*, *irritable*, *inflammatory*, and *follicular* or *pituitous*: in these morbid conditions, easily cognizable and perfectly capable of verification by the symptoms, consist the proximate causes of functional dyspepsia. Those in which the structure of the organ is altered, admit of being distributed according to the nature of the structural lesion, or as the function becomes disordered by change of capacity, sensibility, or in its secretory function. *Symptomatic* dyspepsia might be divided into species according to the constitutional disease in which it might originate, whether fever, plethora, anæmia, asthenia, or any other form of constitutional disorder; and *sympathetic* dyspepsia would admit of a convenient division according to the organ from whose disorder it took its rise, as the brain, the lungs, the skin, the kidneys, the uterus, or any other organ.

Such is our plan of a complete natural classification of the various disorders of the function of digestion, the result of close and continuous observation, combined with a methodical arrangement of cases; those being grouped together which coincided in causes, symptoms, and means of cure; and each group being denoted by the pathological derangement on which we supposed them to depend. Pursuing this course, it will be observed that we have arrived at distinctions nearly coinciding with those of our predecessors, a strong proof of their correctness, which, verifying our observation by that of the great masters of our art,

establishes these distinctions on a long line of uninterrupted experience. But before concluding this part of our subject, we must observe that, whatever objection may be taken to our pathology, to our opinions, or to the terms by which the different species are denoted, it will afford no ground for denying the existence of those species; for being founded on observation and formed inductively, they must survive any error of opinion; and the classification, being natural, has this advantage, that as any new species of disorder of the function of digestion, may be discovered and ascertained, (as no doubt, hereafter, many most certainly will be,) their place or niche will immediately be found without the necessity of the whole structure being broken down and rebuilt, as constantly happens with artificial classifications. The nature of the present work does not, however, admit of the possibility of following up the whole of this plan, and requires that we should confine ourselves to the first division of the subject, *idiopathic functional dyspepsia*; but we shall endeavour, by way of help, to avail ourselves of the corresponding facts of the other divisions, to confirm, explain, or illustrate any part of this. The following outline presents the plan of classification, and enumerates the several species to which we hope to be able to refer the greater part of the varieties of this disease.

IDIOPATHIC FUNCTIONAL DYSPEPSIA.

I. GASTRIC.

- a. *Atonic.*
- b. *Inflammatory.*
- c. *Irritable.*
- d. *Follicular.*

II. DUODENAL.

- a. *Atonic.*
- b. *Inflammatory.*
 - 1. *Strumous.*
- c. *Follicular.*

III. COLONIC.

- a. *Atonic.*
- b. *Inflammatory.*
- c. *Irritable.*
- d. *Follicular.*

IV. GASTRO-ENTERIC.

- A. *Enopathic.* The same morbid condition obtaining throughout the whole alimentary canal.
- B. *Polypathic.* Different morbid conditions existing in different parts of the alimentary canal.

I. GASTRIC DYSPEPSIA.

The disease consisting chiefly in disordered function of the stomach.

1.—ATONIC GASTRIC DYSPEPSIA.

Synonyms.—*Ἀπεψία, πλεσμονή, Hipp*; stomachi resolutio, *cruditās, Cels*; frigiditas stomachi, *Prosp. Alpin*; anorexia, plethorica, arthritica, paralytica; nausea a cacoehylia; vomitus a saburrâ; flatulentia, acida, nidorosa; cardialgia a saburrâ, paralytica; gastrodynia saburrâlis, *Sauvages*; dyspepsia idiopathica; anorexia atonica, *Cullen*; saburra materis mobilis, *Auctor. Var.*; indigestion, first stage of *W. Philip*; dyspepsie, apyrétique, asthé-

nique, *Broussais*; dyspepsie per asthénie de l'estomac, *Andral*; embarras gastrique.

General Character.—Loss of appetite, sometimes nausea and loathing of food, with occasional inclination to vomit, but seldom sufficient to provoke vomiting; thirst after eating, not after digestion; heartburn; acid, nidorous or putrescent eructations; sense of weight at the epigastrium after a meal; power of digestion more particularly impaired as regards oily, fatty, mucilaginous, saccharine, and acidulous substances; tongue pale, flabby, whitish or slimy, more or less coated; bowels generally confined; urine clear and copious, devoid of its natural smell, deficient of urea, sometimes albuminous, and then disposed to putrefy on standing; pulse somewhat weaker, generally slower than natural; temperature of the body lower than natural and unequally distributed; extremities cold, countenance pale, skin flaccid, eye dull; listlessness in expression, languor in motion; obtuseness of feeling, mind impaired in vigour, in all things a want of alacrity.

These symptoms depending chiefly on the morbid condition of the stomach, are subject to considerable variation from the presence of crudities, being different as the stomach is full or empty. But the general character of the symptoms is not destroyed by this cause of variation; for, as the different morbid conditions give rise to different symptoms, so the presence of crudities excites symptoms, subject and corresponding to each morbid condition.

The symptoms also vary as they may happen to be direct or indirect, as they emanate immediately, from the suffering state of the stomach, or, mediately, as the suffering of the stomach is felt and reflected in the sympathetic disorder of some other organ. The variation and diversity of the symptoms of atonic gastric dyspepsia arising from each of these sources, will be noticed in describing this disease according to the two forms under which it presents itself, as it takes place suddenly, or as the symptoms manifest themselves in a slow and gradual manner.

a. *Acute Form.*—In the first case, which might for the sake of distinction be termed *acute atonic gastric dyspepsia*, corresponding more precisely with the *ἀπεψία* of Hippocrates, the *cruditās* of Celsus, and the *embarras gastrique* of the French, the disorder comes on in distinct attacks or paroxysms, the patient enjoying in the intervals a comparatively healthy state of digestion. As the disease continues, these attacks are repeated at shorter intervals, whilst the interval itself becomes a state of less perfect health, and the disease, growing more and more habitual, at last arrives at that state in which disorder of the digestion is more or less constantly present, though in a degree less severe than during the intensity of the paroxysm.

These paroxysms vary in their duration from three or four to twenty-four hours or even longer, being shorter in young, and longer and more frequent in older persons and those most disposed to them. As the paroxysms are induced by accidental causes, their return is of course irregular; but, as has just been observed, the liability to them increasing with repetition, slighter causes are capable of inducing them, and they are therefore, *ceteris paribus*, more frequent in old than in young sub-

jects, some suffering a paroxysm every two or three days, others once in two or three weeks.

The patient may have been feeling dull or heavy, have been losing his usual relish for food, may have observed his bowels less regular, or have been complaining of that peculiar sensation at the root of the tongue, and sometimes through the whole length of the œsophagus, which constitutes what is called heartburn; but as it is generally during sleep that the paroxysm comes on, it is in the morning that the symptoms of indigestion are first distinctly pronounced. The patient awakes with headach, or feels heavy and languid, devoid of his wonted alacrity, and indisposed to leave his bed. There is rather flatness than lowness of spirits, with sometimes slight confusion or indistinctness of intellect. The tongue feels clammy, sometimes it is also dry; there is generally an insipid taste, but sometimes it is milky or sweetish, occasionally sourish. The appetite is impaired or entirely deficient, sometimes with nausea, amounting occasionally to a disposition to vomit, and when vomiting does occur, phlegm only is thrown up; or there is a capricious appetite, craving for some unaccustomed kinds of food, but which are seldom agreeable if presented. When the attack is slight, the symptoms are occasionally suspended by taking some grateful food, the action and sensibility of the stomach being revived and restored by being gently solicited. Generally there is an aversion to acids, sweets, or any thing insipid. There may be heartburn, eructations of acid, of oily or rancid matter, sometimes of hepatic gas, or a feeling of weight or load at the stomach, giving the sensation that the process of digestion is entirely at a stand. In other cases there is a sense of constriction of the fauces, with a watery secretion from the back part of the mouth. Sometimes the patient is suddenly awakened by a cramp in the legs, or violent spasmodic pain in the stomach, (*gastrodynia saburralis*;) accompanied frequently with violent retching. The face is pale, the countenance inexpressive, and the eye dull and heavy, with sometimes a dark discoloration or puffiness round the eyelids. The pulse is somewhat weaker, generally slower, usually soft, frequently languid and feeble, sometimes small and quick, occasionally intermitting. The skin is moist, clammy, and flaccid, and generally cold. The feet and hands are cold, with a general feeling of chilliness or creeping over the skin, sometimes amounting to rigors: sometimes there is a particular coldness, stiffness, or numbness of the fingers. The tongue is pale and flabby, generally moist, and covered with a loose slimy white coat, more or less thick. The bowels are constipated; sometimes there is a sensation of inaction or of dryness in them. In the commencement of the paroxysm the urine is pale and copious, less frequently it is deficient: but in its decline it becomes high-coloured and turbid, depositing a red sediment of lithic acid, or of lithate of ammonia, or the amorphous sediments of the lithates generally.

The above is an account of an attack of atonic dyspepsia connected with, or arising from, a state of repletion of the stomach; but the same state may arise from that organ being deprived of its accustomed stimulus or supply, as occurs to delicate people when they pass the hour of their

accustomed meal. They have a great sense of weakness, sometimes faintness and trembling; they lose their appetite, have a bitter taste, and a sensation of weight or sinking at the præcordia, their countenance becomes pale and wan, their eyes sunk; they lose their temper and their spirits; their urine becomes hot, scalding, and high-coloured; if they attempt to eat, they have no appetite or a disgust for food, and if they eat, all their symptoms are increased. They have a difficulty in getting to sleep, or are disturbed with dreams. Giddiness, headach, coldness, trembling, constant yawning, are common attendants of this state of the stomach.

The sympathetic affection most universally connected with this form of disordered digestion is headach, which, being generally associated with nausea, is well expressed by the common term *sick-headach*. (*Fothergill*, Med. Obs. and Inq. vol. vi.) It affects generally one particular part of the head, chiefly the forehead, or is seated over one or both eyebrows, and sometimes in the ball of the eye. The pain is heavy, dull, and overpowering, but seldom acute. With the headach, the whole nervous sensibility appears to be concentrated in the head, where it is much increased, being accompanied with intolerance of light and of noise. The headach begins sometimes to abate on a vomiting of bitter or acid matter, but sleep is the most constant harbinger of relief. As the headach abates, it leaves a general soreness or tenderness of the head, and the squeamishness and general uneasiness continue for some time after.

The other affections frequently observed, sympathetic of *acute atonic gastric dyspepsia*, are a sensation of mistiness before the eyes, indistinctness or obscurations of vision, sometimes amounting to temporary amaurosis, and more rarely, dilatation of the pupil, without any defect of vision; deafness, and sometimes unusual sounds in the ear; loss of smell or taste, or depravation of these senses, so that unnatural smells and flavours are perceived, when there is no external impression; in delicate and sensitive persons, fainting, and in women hysterical fits occur; trismus, convulsions, and, in those predisposed, a fit of epilepsy; loss of voice, paralysis, a fit of apoplexy; spasmodic cough, a fit of asthma or of angina pectoris; neuralgia and various local pains, temporary delirium, a fit of mania, urticaria, erysipelas, and some other cutaneous affections. But many of these complaints are more especially connected with one of the effects of this disorder, distension of the stomach, the direct symptoms of which are restlessness, a sense of oppression, and anxiety.

Causes.—This particular form of dyspepsia most frequently makes its first appearance in early and middle life, from puberty to the age of thirty, less commonly after forty. Women are more subject to it than men. It is more common in cold than in warm climates, in cold than in warm weather; but moist climates and moist weather, whether warm and moist or cold and moist, have a great influence in predisposing to it. The middle and upper stations of life are most exposed to it. The predisposition to this complaint is sometimes hereditary, the person inheriting a relaxed constitution, or one of exalted nervous sensibility,

but of weak powers; for it affects rather the cold plegmatic and the asthenic habits than the sanguine or bilious temperaments; and chiefly those of that peculiar relaxed constitution characterized by want of firmness, resistance, and elasticity, by a soft relaxed skin of a pale colour, by a tendency of the hands and feet to be cold, by a languid circulation, by the functions of the body being imperfectly performed, either less actively or irregularly, and by the secretions being rather disposed to be copious than scanty. But this particular constitution may be also acquired by certain habits and manner of living, as by want of exercise, by indolence of body, by indolence as well as by intense or long application of mind, disproportionate to the strength of the body; by effeminate habits and enervating excesses, by the too frequent use of the warm bath, by dwelling in close, warm, ill-ventilated apartments, by sleeping in hot soft beds, and by over-indulgence in sleep. The habits of certain trades and professions contribute considerably to this disease; the confinement to the desk, the sedentary occupations of sempstresses, milliners, mantua-makers, and tailors; those of the loom, of the tambour, of the stocking and lace-frame, and of laundresses who work much over a stove. For all these various reasons, this complaint prevails more in the town than in the country,* and is, as it were, endemic in the boarding-school, the boudoir, and in manufactories; at court, at college, and in prisons; and under the title of *asthenia* has been very well described by Dr. Willan in his account of the diseases of London. The habit which predisposes to this disease may also be a consequence of loss of blood, excessive suckling, seminal weaknesses, leucorrhœa, or any cause which exhausts or debilitates the system in general; of the habitual use of narcotics in excess, as tobacco, conium, or henbane, which injure the sensibility of the nervous system. But the cause which has the greatest influence in disposing to this disease above all others, is habitual incaution in diet, both in respect of kind and quantity of food; for it matters not whether the stomach be frequently offended by that which it cannot subdue, or morbidly distended, and thus rendered incapable of appropriating that which is wholesome. For this reason offences against quantity are not less injurious than offences against quality, and both are doubly baneful when the repast consists of many kinds indiscriminately mixed. To these may be added an irregularity in the times of taking food, the meals being sometimes too frequently repeated, or the intervals too long protracted.

Where the predisposition is strong, or the patient has suffered long, slight causes are sufficient to produce a paroxysm of this form of dyspepsia; but where even neither natural nor acquired predisposition exists, certain circumstances are capable of producing an accidental fit of dyspepsia, and of thus laying a foundation for its recurrence. Amongst such may be enumerated any sudden or unusual disproportion or want of due relation between the digestive organs and the ingesta, a neglected state of bowels, intense application or strong emotions of mind, especially soon after a

meal. A sudden fit of passion, or great joy, will sometimes instantly produce this affection. They will also sometimes remove it; "We have more than once," observes Pemberton, "known a necessity for a great exertion of mind to supersede the stomach affection, which has re-appeared on the necessity being withdrawn." Violent exertions or much fatigue of body, either immediately before or soon after a repast; any causes which induce sudden distension of the stomach, as a bulky meal of soft, sweet, pultaceous food, over-indulgence in fruit, large quantities of cold, iced, warm, acid, or sweet fluids suddenly swallowed, more particularly if the process of digestion is still in progress; a sudden change of diet from animal to vegetable food; mucilaginous drinks, &c.; eating hastily after fasting too long, missing the wonted meal, or taking it out of season; taking a cold or warm bath immediately before or soon after a meal; medicines, particularly calomel, conium, henbane, digitalis, ipecacuanha, especially administered at an improper period of digestion; venesection when performed soon after a meal, or leeches applied to the epigastrium under the same circumstances. In the delicate and predisposed, we have observed it excited by variable weather, by exposure to a cold and moist atmosphere, by the application of cold to the skin, particularly to the lower extremities, by sitting in a room of low temperature, so low as to cause a sensation of chilliness, by a change of wind, particularly from a north to a south-west gale.

b. Chronic form.—In this form of indigestion, which might be termed *chronic atonic gastric dyspepsia*, the *πλησμονή* of Hippocrates, the disorder creeps on in a slow insidious manner, and becomes scarcely apparent until it has existed for a considerable time. Some of the following symptoms, more or less grouped and combined together, afford indications of its approach: drowsiness in the day, particularly after a meal; sleep deep, heavy, prolonged beyond the usual hour; the sleep ceases to be refreshing and is disturbed with uncomfortable dreams, sometimes with incubus, and the patient awakes in the morning feeling fatigued, and having a disagreeable taste in his mouth;—less aptitude for exercise, frequent stretching and yawning, torpor or sluggishness in movements, which begin to require a greater effort; diminished activity of mind, mental occupations becoming laborious; diminished enjoyment of the natural appetites, less relish for food, by degrees diminished appetite, especially for breakfast; a sensation of heaviness in the head, of fulness or itchings in the forehead, of fulness or stuffing in the nostrils, particularly after a meal, with a frequent desire to emulge them; a feeling of huskiness in the throat, particularly in the morning, with expectoration of a grey, viscid phlegm, and sometimes an increased flow of saliva. A sensation of fatigue and weariness, sometimes amounting to pain, begins to be felt in the whole or in particular members of the body; a heavy dull pain in the head with drowsiness, a sensation of weight at the stomach, heartburn, or a sensation of internal heat after meals, more especially after breakfast; and the bowels begin to be habitually constipated. These symptoms are followed by distension after eating, by flatu-

* At imbecillis stomacho, quo in numero magna pars urbanorum.—Celsus.

lence when the stomach is empty, at first relieved but afterwards increased by eating; by eructations of the last meal, sometimes acid, sometimes putrescent; by change of complexion, paleness of the face, which is bloated; by deficient alvine evacuations, altogether disproportionate to the ingesta, sometimes by diarrhoea of liquid and undigested food, which affords temporary relief; or by perspiration on the slightest exertion. The disorder may continue for a considerable time in the degree manifested by these symptoms without producing any serious derangement of the health; and, by change of habits, of air, and of exercise, they may be entirely removed. But the long continuance of the disorder brings other derangements. The bowels become habitually confined, and there is a constant sense of fulness, distension, and dryness in them. The repasts cease to be pleasant or satisfactory, but are always followed by oppression; the extremities are generally cold, the power of exercise begins to diminish, the patient begins to lose flesh, and has a constant sensation of weakness, faintness, or trembling, or is troubled with vertigo or headach, with noise in the ears, throbbing of the temples, cough or fits of palpitation. The mouth feels clammy; the tongue is more or less furred, or has a whitish sodden appearance; sometimes the saliva runs from the mouth, and there is a viscid frothy secretion from the fauces, or there is frequent spitting. The skin is generally moist and clammy, sometimes cold; and perspiration is excited by the least exertion. The urine leaves a coating of lithic acid at the bottom of the utensil. The powers of the intellectual faculties, particularly of attention and memory, are remarkably diminished; the feelings are obtuse and little alive; the patient begins to feel flat, dull, and timid without reason, or sinks into a state of apathy or indifference, whilst the physical sensibility becomes morbidly increased, manifested by a remarkable sensitiveness of changes of weather, particularly of the approach of moist weather or storms.

The further course of the disease is generally very much influenced by the use of remedies, and by the different methods of treatment had recourse to; for if not properly administered, they are mainly instrumental in determining various forms of dyspepsia hereafter to be described. If the disease be allowed to follow its natural progress, it terminates by inducing a disordered state of the function of the duodenum and liver. More rarely the disease undergoes an entire change, which occasionally leads to a natural cure, in consequence of a fixed point of irritation becoming established in the intestines, the activity of the stomach is excited and increased, and the disease is transferred to the intestines in the form of diarrhoea, which, subsiding spontaneously or artificially, leads to a permanent relief of the primary disorder; but which continuing lays the foundation of a form of inflammatory dyspepsia to be treated of in the sequel of this article.

Causes.—This variety of atonic gastric dyspepsia, is, with some exceptions, the consequence of the same causes as those which give rise to the first variety. It is less the effect of hereditary disposition, and more the result of the remote causes of dyspepsia operating insidiously upon a healthy

constitution. In this way it is induced in people of regular and orderly lives, who seldom commit any offence against temperance or sobriety, and in people of sedentary, monotonous, indolent habits. It affects literary (*Omnesque pæne cupidi literarum—Celsus*), and professional people, clerks, shopkeepers, and is met with in all constitutions, but in men rather than in women: it occurs generally late in life, and prevails most in winter. A disproportion between food and exercise is the great cause of this disease; but indulgence in much warm liquid, as tea, pre-eminently the English breakfast, in relaxing slops, in meals too frequently repeated, deluging the stomach with tea whilst digestion is in progress, and the habitual use of malt liquor, are the most fertile sources of this disorder.

Pathology.—The morbid condition of the stomach, from which proceed the various symptoms of atonic dyspepsia, has been recognised by the very earliest physicians (*Ἀτονίη τοῦ πύλιντος*—*Aretæus*), under the term of *atony*, or some word of corresponding meaning, as *asthenia*, *relaxation*, *resolution*, or *debility*; and instead of this morbid condition of the stomach having been overlooked as the proximate cause of indigestion, it has, on the contrary, been too generally admitted, and the species of dyspepsia which is now under our consideration has accordingly been made to represent the whole genus, every symptom indicative of indigestion, every sign of chylopoietic disorder, having been attributed to debility or want of tone of the stomach.

A state of collapse, of deficient vital power or nervous energy, under various modifications and descriptions, has, as we have already observed, been universally admitted ever since the phenomena of life have been an object of observation. By the operation of certain causes, the whole body may be involved in this morbid condition; by their more partial application, particular parts or individual organs only may be placed under its influence. But as it is the nature of the body for a part to assume the state of the whole, and for the whole body to partake of the action of a part, whether the disorder be at first induced in the general system, or only in some particular part, in either case they both ultimately arrive at, and terminate in, the same condition. The digestive organs are not exempt from the operation of causes capable of inducing this morbid condition, and when the stomach, more especially, is placed under its influence, the disorder of the digestive function which we have just described is the consequence.

But by the term atony of the stomach we express a general and complex condition, resolvable into several subordinate or particular ones; for under it are included—1. a deficient innervation of the stomach, by which some unknown vital action is withdrawn, and the natural affinities of the constituent elements of the alimentary mass, instead of being directed and controlled, obey the laws of inorganic matter, rather than the special influence of organic life; 2. a depraved or deficient secretion of the gastric juice; 3. a diminution of the absorbing power of the stomach, by which the digestion of liquids is rendered more

difficult; and 4. a diminution of the contractile power of the muscular fibres of the stomach, by which this organ is prevented from compressing its contents, as in health, that the food and gastric juice being brought into contact may be exposed in successive and appropriate portions to each other's action.

It would not be difficult to trace the process by which the causes of dyspepsia induce the foregoing results. If we consider the nature of their operation, we shall find that they admit of a classification corresponding to the several morbid conditions just enumerated. Thus by sedentariness and repletion is destroyed the healthy equilibrium of waste and supply; for, as has been well observed, as, by virtue of the consent of every part of the living body, all the functions of assimilation can only be preserved in health so long as the stomach digests well, so on the other hand the stomach can only digest well so long as the different functions which convey and deposit the nutritious matter in the various tissues are healthily performed, which, however, cannot be the case when from indolence or similar causes there is both a deficient consumption of this nutritious matter, and a defective elimination of the effete and worn-out particles. The consequence is, that the whole process of nutrition languishes, and the stomach losing the stimulus of demand fails in its activity. This principle, recognised so early as Hippocrates in his famous dictum, *διότι οὐ δύναται ἰσθμὸν ἀνθρώπου βυβαίνειν, ἢ μὴ καὶ ποιεῖν*, explains the operation of many of the causes of dyspepsia, showing how they may induce a deficient innervation of the stomach; and this will be the result whether the equilibrium be destroyed from the consumption being deficient or the supply being excessive. Then we may again observe that some causes induce the same effect by destroying the corresponding and harmonious action of the different parts of the alimentary canal; others by diminishing the natural sensibility of the stomach, either directly, as narcotics, or indirectly, by concentrating the nervous energy in the head, by intense thought and application; whilst others arrive at the same result, diminishing the innervation of the stomach, by withholding or diverting from it a proper and sufficient supply of blood, from which results an unhealthy and insufficient supply of the gastric juice; very contrary to the opinion of Parry, who attributes idiopathic dyspepsia to a morbid fulness of the vessels of the villous coat of the stomach. Other causes act by diminishing the contractile power of the muscular coat of the stomach, either by producing a relaxed state of its fibres, or by sustaining them in a state of unnatural distension, by which they lose the power of resuming their natural state: others effect their deleterious influence by withdrawing from the stomach the healthy and accustomed stimulus which calls it into action, so that it not rarely happens that, after having been more or less stimulated, withdrawing suddenly every source of excitement, the stomach falls into the opposite state, one of perfect atony; and this frequently occurs, whether it be the body in general, or the stomach in particular, which is deprived of its wonted stimulus and excitement.

This view of the operation of the causes which

induce atonic gastric dyspepsia, and of the various morbid conditions which they produce, we shall find very much confirmed by considering the state of the body and of other organs in those cases in which this form of dyspepsia is secondary, whether symptomatic of general disorder, or sympathetic of the disorder of some particular organ; for we shall find that the dyspepsia of simple general plethora, (anorexia plethorica,) of asthenia or general debility, (Anorexia exhaustorum, cardialgia lactantium, *Sauvages*.—Dyspepsia paralytica, *Cullen*.) whether induced by venereal excess or weakening discharges, of general anæmia, (Dyspepsia menorrhagica, dyspepsia chlorotica,) whether from loss of blood, or disorder of the process of sanguification, (Halle, *vid. Anémie*, *Dict. des Sciences Méd.*.) and the dyspepsia of gout, (Anorexia arthritica, cardialgia arthritica.—*Sauvages*. Dyspepsia arthritica, —*Cullen*.) all belong to this form. In like manner we shall find that the dyspepsia sympathetic of cerebral irritation, (Vomitus cephalalgicus,) of hydrocephalus, of vertigo, (Nausea marina,) and nervous headach, from accidental injuries of the head, from the action of narcotics upon the nervous system, as tobacco, digitalis, hemlock; the dyspepsia which follows a fit of inebriety, (Dyspepsia inebriorum,) the dyspepsia of constipation, the dyspepsia of some forms of disordered uterine function, the dyspepsia of rigid continence, (Nausea a semine corrupto. —*Galen*.) and the dyspepsia which alternates with an atonic state of various other organs, (Gastrodynia metastica, —*Cullen*.) belong also to this form. The dyspepsia which is produced in animals by the division of the eighth pair of nerves, offers a strong analogical proof of the same position.

We may also find the view we have taken of the proximate causes of atonic gastric dyspepsia amply confirmed by examining cases of dyspepsia from organic lesion; for we shall find that, as the organic changes approach the morbid conditions of this form of dyspepsia, the symptoms of atonic gastric dyspepsia are present. Thus, when the stomach has been found unusually large and distended, with or without obstruction of the pylorus; (*Bonet. sep. iii. vi. 1. Lieutaud M. etc. Par. 1756, 223. Cardialgia paralytica.—Sauvages. Johnston, Med. Observ. and Inq. ii. 107. Richt. Chir. Bibl. iii. 78. Anderson, Med. Comm. Ed. ii. 294. Douglas, M. Med. Soc. Lond. iv. 395. Abercrombie, case v. p. 32, p. 70*;) thus also in induration and thickening of the coats of the stomach; (*Abercrombie, xvi. p. 59*;) in the early stage of diseases of the pylorus, or where there exists any obstruction to the egress of the chyme from the stomach; (*Abercrombie, xvii. p. 61. Bonet. sep. iii. vi. 2*;) in atrophy of the mucous and muscular coats of the stomach; or when the stomach has been found lined with a false membrane; in the softening or solution of the mucous membrane of the stomach, (*Ramollissement des Vieillards*.) to which we may add anæmia of the alimentary canal, which is always accompanied with more or less attenuation of the coats,—a pathological state not rarely presented to the anatomist, but chiefly observed in the bodies of those exhausted by chronic diseases, or who sink during the convalescence of a severe fever; (*Andral, Path. Anat.*.)

in all these cases the disorder of the function of digestion approaches the form of atonic gastric dyspepsia. But though approaching and resembling each other, the two disorders afford data of distinction; 1. by the absence of sympathetic affections; in the organic diseases of the stomach, the sympathetic headach and other disorders being never observed; 2. by the stomach being the seat of painful affections; 3. by the greater constancy and invariableness of the symptoms; and, 4. by the attendant emaciation.

Method of cure.—The treatment of *atonic gastric dyspepsia* is conveniently divided into the means of affording relief when the disorder is actually present, and the means of preventing its return.

1. The means of affording relief when the disorder is present consist in, 1. removing crudities or offensive substances directly from the stomach by vomiting; 2. in endeavouring to remove indigestible substances from the stomach, and restore its action by exciting that of the intestines; 3. by allowing the stomach to repose until its action begins to revive, and by soliciting its action as its sensibility returns; and, 4. by relieving the secondary affections which arise from the disordered function of the stomach.

1. Emetics afford the proper means of removing offending substances from the stomach. In the beginning of a fit of dyspepsia, in the earlier period of the disease, or in cases of accidental dyspepsia, an emetic frequently at once arrests the progress of the disorder, and we have known some persons subject all their lives to frequent paroxysms of the acute form of this disease, who have experienced more relief from emetics than from any other remedy. If, however, the paroxysm has continued long, or the disease has become habitual, they cease to bring their former relief, and, when unnecessarily administered, are always pernicious; (*Inutilis est gracilibus et imbecillum stomachum habentibus,—Celsus*); for vomiting, whether spontaneously occurring or artificially excited, becomes itself a frequent cause of stomach complaints. It was a remedy much used and abused by the Romans, affording them the means of indulging their gluttony; *qui quotidie ejicendo vorandi facultatem moluntur*: but it is a short-sighted compromise, granting no impunity; it changes but does not take away the penalty of the vice.

The immediate symptoms which more particularly indicate the administration of an emetic are nausea, a sense of weight at the præcordia, bitter eructations, the internal sensation of crudities, the mouth overflowing with saliva, and paleness of the countenance.

When vomiting is strongly indicated, it is easily excited. The gentlest means are therefore to be preferred, warm water, simple, or containing a little culinary salt, warm infusion of chamomile flowers, infusion of mustard-seed, and ipecacuanha, are means of different degrees of power which may be occasionally had recourse to; sometimes simply titillating the fauces answers every purpose. After vomiting, cold water is the best remedy for restoring the stomach; in summer, iced water; sometimes Seltzer water. These should be sipped in small quantities at a time. After a

proper interval, a small quantity of light palatable food may be taken.

2. By virtue of the sympathy which exists between different parts of the alimentary canal, the function of the stomach is frequently restored by exciting that of the bowels, and therefore, when the attack has continued beyond that state in which emetics promise relief, or when they have failed of relief, purgatives are to be had recourse to. They should consist of such as are warm in their nature and speedy in their operation, but neither stimulating nor drastic. Rhubarb is decidedly the best. It may be advantageously combined with, and modified in its action by, magnesia, by carbonate of soda, by tartarized potass or soda, in conjunction with some aromatic or carminative distilled water, with a small quantity of the tincture of rhubarb or compound decoction of aloes, and a little of the compound spirit of lavender, or aromatic spirit of ammonia, as the state of the stomach or accompanying circumstances may suggest or indicate. In this form of dyspepsia senna is not proper, and saline purgatives alone are injurious, as are also the mercurial purgatives.

It is generally necessary to continue to promote the action of the bowels during the decline of a fit of dyspepsia, and for some days afterwards. For this purpose a few grains of rhubarb, in combination with a little soda or carbonate of ammonia, taken an hour before the two principal meals, answers very well; or the following formula of Fothergill affords a remedy well suited to this intention:

R Alöes ʒi.

Rad. rhei, rad. glycirrh. aa ʒss.

Spirit. lavend. comp. ʒss.

Aq. calcis, ʒviii.

Infunde per horas xii et cola. Colaturæ coch. ʒ. duo bis terve die sumenda. On some occasions it suffices to relieve the bowels by clysmata, and when this method is found to answer, it is always to be preferred.

3. It would seem unnecessary to insist on the necessity of abstinence during a fit of dyspepsia; but it is not always superfluous, for the morbid sensations of the stomach sometimes imitate, and are readily construed into, that of hunger. They ought not, however, to be listened to, for abstinence is the chief remedy. The patient may drink, from time to time, a small cup of green tea, without sugar or milk, or a cup of coffee, moderately strong, with as little as possible of those ingredients; or he may take a small quantity of light pure-broth, sufficiently sapid to be agreeable, with a small quantity of stale bread or dry toast. As the natural sensibility of the stomach returns, it may be solicited by a little animal food, such as is palatable and easy of digestion. If the patient is accustomed to the use of wine, but not otherwise, it may be necessary to allow a moderate quantity with the meat: the red wines for this purpose are generally to be preferred. Farther than this the stomach is not to be excited. All such means of doing so, as brandy, capsicum, or food containing it; mustard, piquant sauces, curries, or high-flavoured dishes, are to be avoided. In this category we would also place bitters, and those medicines improperly termed stomachic. The action of the

stomach ought never to be hurried or forced by stimulants; it can only bear them when its function has been already to a certain degree restored. Before this period they only tend to fix the disease. The state of the tongue affords the best guide for the use of food and its quality; as it is moist and disposed to clean they are admissible, and as it is dry they are to be forbidden.

4. Besides the general treatment of a fit of dyspepsia, there are painful symptoms and sympathetic affections which ought not to be overlooked, and, indeed, the relief of which is not without its influence upon the primary disease. But in administering means of relief for such affections, it is important to take care that they do not oppose, but are made subservient to, the plan of general treatment.

Heartburn.—Dr. Fothergill's formula, mentioned above, affords a good corrective of this symptom; magnesia, liquor potassæ (gut. x. pro re natâ), ammoniæ subcarbonas (gr. v.), lime-water; sometimes alkalies combined with bitters. We have found Seltzer water a very excellent remedy; and at other times repeated small quantities of very cold or iced water, taken when the stomach is empty. Heartburn which is habitual or of long standing is sometimes more effectually relieved by acids than by alkalies. Pemberton mentions having seen it subdued by the juice of half-a-dozen lemons taken daily, and recurring on the remedy being left off; but we imagine that the heartburn here meant is not that which proceeds from acidity, but the burning sensation depending upon a heated state of stomach, a symptom of another form of dyspepsia. In heart-burn, nitric acid is also a useful remedy; five drops of the diluted acid may be taken every four hours. We have also used successfully the phosphoric acid with the same intention, and have found it more agreeable to the stomach.

Flatulence.—This symptom is best relieved by combining a carminative with the aperient. Equal parts of the pil. rhei comp. and pil. galbani comp. form a convenient remedy; carbonate of ammonia in mint-water; very hot water in small quantities after a meal, is sometimes found a very efficient corrective of this symptom.

Distension of the stomach from flatulence to an extreme degree, in old people, is often attended with alarming symptoms, sometimes convulsions, sometimes apoplexy. By extreme distension the muscular coat loses its contractility, and the mucous membrane its sensibility, and thus the usual remedies lose their power. In such cases mustard poultices applied to the pit of the stomach are of great service, whilst the internal means are put in use. The best of these are ammonia in infusion of horse-radish or of mustard-seed, and repeated draughts of water as hot as it can be taken. In extreme cases the use of the stomach-pump should not be omitted.

Nausea and Vomiting.—When these symptoms continue after the stomach and bowels have been satisfactorily relieved, effervescing saline draughts, especially those prepared from the subcarbonate of ammonia, are suitable remedies; to these, if the symptoms are urgent, may be added a little spirit of lavender, camphor julap, and, in case of necessity, one or two minims of the "black

drop." The hydrocyanic acid (gut. i. ad ii.) has been also used with considerable advantage; but we believe it to be more efficacious in the other forms of dyspepsia.

Headach.—When this symptom does not subside with the primary affection, it may be relieved by valerian (tr. valer. ammon. or infus. valer.) either alone, or combined with camphor; if attended with sleeplessness, a small dose of pulv. ipecacuanhæ comp. may be given in camphor mixture, or a saline draught; or if heartburn be present, may be combined with magnesia or liquor potassæ. But a warm pediluvium, containing mustard or culinary salt, or evaporating lotions of vinegar, spirits of lavender and rose-water, applied to the head, are sometimes more efficient than internal remedies.

It would be extending this article too far to enter into the treatment of the other various secondary affections of this disease; we must content ourselves with referring to the symptomatic form of each of these disorders.

II. Having afforded relief to the urgent state of indigestion, it is the duty of the physician to direct his attention to the means of obtaining a permanent cure, which consists more in prevention than in positive remedies. The object to be held in view in the prevention of a disease has been clearly and succinctly expressed by Celsus—"quod vel corporis vel loci, vel studii ratio detrahit, cura restituat." Guided by this general view, seeking if possible to avoid or remove, if not to counteract the causes of the disease, we shall endeavour to fulfil this intention by indications derived from the nature of the operation of the causes in which it originates, and from the morbid condition of the stomach in which it consists. These indications serving as principles to direct our prophylaxis, and applicable, with some small modification, to every form of dyspepsia, may be stated to be—1, to render the process of digestion as easy as possible by a selection of food of a quality suited to the nature of the disease, and by a proper adjustment of the quantity suited to the power of digestion; 2. to excite the function of nutrition by proper exercise of body and mind; 3. to correct the morbid condition of the stomach, the proximate cause of the disease.

1. This is beyond all comparison the most important point in prevention of this disease; the reducing the quantity of the food to the power of digesting and of appropriating it, instead of yielding to the cravings of a pampered appetite. The change ought to be brought about gradually, for in that way it is most agreeable to the habits of the body, and most likely to be persevered in; and if the diminution of diet is made with judgment and selection, it ought to be effected by withdrawing from it such articles of food as are difficult of digestion, and such as have a tendency to weaken the stomach. The object is best attained by confining the patient to a small spare diet of animal food, with considerable restriction in the use of fluids. It is in this form of dyspepsia that so much benefit has been obtained by strict adherence to a dry diet, and by avoiding a bulky meal. When the appetite flags, abstinence will be found a better whet than cordials, stomachics, or dainty fare. When the appetite does not fail, the patient

should finish his meal without waiting for the sensation of satiety, taking care that he be not deceived by a morbid craving, the offspring of disease and bad habit, not of health. When any doubt as to quantity may arise, he may be assured that it is safer to err by taking less than enough than more than enough—"nunquam utilis nimia satietas, sæpe inutilis nimia abstinencia."

For breakfast coffee is to be preferred to tea, and should be taken with as little milk and sugar as possible, and with a moderate quantity of bread, which, with a little fresh butter, should form the repast. It is necessary that the bread should be limited, for if taken in excess it is a common cause of heartburn after breakfast. The dinner should consist of the lean of animal food, chiefly mutton, poultry, venison, game, with the exception of hare. Roast meat is to be preferred to boiled. Vegetables are to be eaten sparingly, or entirely abstained from; mealy potatoes mixed with the gravy of the meat, asparagus, soft young summer turnips, cauliflower, or French beans, are the only kinds admissible. Rice mixed with the gravy of the meat will be found a good substitute for vegetables. Eggs lightly boiled may be occasionally used. The fruits the least offensive are strawberries, the morel cherry, and the mulberry; but they should be eaten in the early part of the day, and never after dinner. Fluids must at all times be taken with the greatest moderation; the patient should not yield to every slight sensation of thirst; they should be taken slowly, a small quantity at a time, and should follow, never precede the meal. If the weakness of digestion or habit demand a stimulus, port wine and water or sherry and water are the best; malt liquors are to be particularly avoided. Three moderate meals is the best general rule for the periods of eating, taking care to eat nothing in the intervals, and avoiding suppers. It may be stated also as a general rule, that the food and drink in this form of dyspepsia should be taken decidedly hot or cold, not tepid; that twice dressed meat should be scrupulously avoided; and that the meat should be eaten slowly, and thoroughly masticated.

It may not be easy to say strictly what kinds of food are wholesome and what are unwholesome, but there are some so decidedly so, that there can be no dispute about them. Dr. Mandeville's definition of wholesome, "what you like and does one no harm," allows a deceitful latitude to dyspeptics. The admonition of Celsus carries a stronger impress of wisdom and experience; "*non quicquid boni succi est, protinus stomacho convenire, neque quicquid stomacho convenit, protinus boni succi est.*"

The kinds of food most decidedly injurious in this form of dyspepsia, and therefore to be avoided, —fluid food, more especially that which is sweet, mucilaginous, or acid, such as contains much milk; all pultaceous diet, puddings or compound dishes, particularly meat pies or meat puddings; new bread, particularly with butter; heavy unfermented bread; hard-boiled compact fat dumplings; all preparations of milks, whether custards, creams, curds, or cheeses; all fat meat, particularly pork or bacon; all young meat, and all the gelatinous parts of meat; all salted or smoked meat; strong broths, gelatinous soups, or highly concentrated

dishes; fish; melted butter, oil, sauces, spices, condiments, and pickles; all vegetables, more especially roots, with few exceptions,* particularly peas, beans, cabbages, waxy potatoes, cucumbers, and pot-herbs generally; fruit in general, whether fresh or preserved, jellies of fruits, figs, dried as well as green, currants, gooseberries, pears, apples, plums, apricots, melons, and all kinds of nuts or kernels; mushrooms, truffles, and morels; treacle and honey; malt liquor, particularly ale; perry, home-made wines, punch, shrub.

2. In the early stage of dyspepsia an increase of exercise admits of greater latitude of diet; when more advanced, it affords no exemption from strictness of regimen. But by exercise we do not mean those nominal kinds in which half of the body only is exercised, as a quiet sauntering walk or the passive exercise of a carriage;—we understand active exercises, in which every part of the body is more or less in motion, sometimes one, sometimes the other. In persons of weak digestion the ancient physicians used to insist upon the exercise of the superior extremities, and we fully understand the nature of their advice.† It is impossible to lay down any precise rule for the extent of exercise, which must be proportioned to the strength and even the habits of the patients; but it should be continued for at least two hours daily, and be sufficient in degree to produce gentle perspiration.‡ The patient should by degrees overcome his habits of sedentariness, commencing by taking gentle exercise on foot and horseback between breakfast and dinner; he should then extend the period of his exercise, and, if possible, rise in the morning so as to allow of a little before breakfast; but this should always be the least fatiguing. As his strength increases, he may proceed to more active exercises, strong enough to excite perspiration, but not fatigue; such as walking over unequal ground instead of plain, climbing ascents, rowing, digging in a garden, cutting and clearing wood, drawing weights over a pulley, turning a heavy windlass, as in grinding malt; military exercises, drilling, or the gymnastic exercises; or such amusements as field-sports, as coursing, fox-hunting; swimming; or such active games as cricket, fives, racket, bowling, foot-ball, fencing, the broad-sword, or single-stick, or playing at quoits. Sometimes it is necessary to impart interest to exercise. In such cases gardening, agricultural occupations, the practical study of botany, geology, entomology, have been found of eminent service. On this subject Dr. Cullen says, "as a bodily exercise I can say that walking has good effects. I have always thought it necessary to continue other amusements or business; and there are several instances of persons, who have long laboured under weakness of the stomach, being cured by watching the concerns of their farm, which obliges them to be much

* The abstinence from vegetable food, which is a painful privation to most persons, might possibly be obviated by using a digester, by which the vegetables might be submitted to a temperature considerably higher than that of boiling water. The ancients considered the cabbage race of vegetables as rendered more wholesome by boiling them in two waters.

† Maximeque quæ superiores partes moveat, quod genus in omnibus stomachi vitiis aptissimum est.—Celsus.

‡ Exercitationes autem plerumque finis esse debet sudor, aut certe lassitudo quæ citra fatigationem est; idque ipsum modo minus, modo majus.—Celsus.

in the open air, and in constant gentle exertion. I have cured weak stomachs by engaging the persons in the study of botany, and particularly in the investigation of our native plants, and in other gentle and long-continued amusements, such as our game of golf." (Op. cit.) It was observed during the late war, that many of our tradesmen who joined the volunteer corps, were, by their regular military exercises, entirely cured of their dyspepsia. When the weather does not admit of exercise in the open air, reading aloud, reciting, singing, flute-playing, the dumb-bells, battledoor, dancing, skipping, and such-like, afford useful substitutes.

Exercise should always precede a meal, and never follow it; neither should the patient sit down to eat in a state of fatigue or exhaustion. A little interval between exercise and eating is on that account desirable; and this interval would be advantageously employed in gentle friction with a flannel glove, (made best of a piece of coarse blanket,) or the flesh-brush. No active exercise should be used for at least two hours after eating.

It is an old rule of philosophy as well as of physic, that the body cannot be properly exercised without the mind, nor the mind without the body. This rule emanates from the twofold function of the nervous system, which not only supplies the vital energy or power by which the entire process of organization is carried on, but also that by which the more distinctive offices of animal life, intelligence and voluntary motion, are performed. If the power of the body be occupied exclusively in either of these, the other languishes. Many familiar illustrations of the truth of this position will readily present themselves. Long-continued or intense application of the mind does not derange the function of digestion negatively, by interfering with the opportunities of exercise, but positively by withdrawing a portion of the power by which it is carried on. Indolence of mind, on the other hand, does not interfere with the function of digestion by withdrawing the power, but by withdrawing the stimulus, the pleasurable enjoyment which well-regulated occupation of the mind imparts to the whole functions of life. The functions of digestion may be deranged by three different states, obtaining between the exercise of the body and the occupation of the mind: 1st, the most usual, a total inaction and inertia of the body may coincide with a fatigued and exhausted state of mind; 2dly, a state of indolence and sluggishness of mind, with inertia of the body; or, 3dly, a fatigued and exhausted state of body may coincide with a wearied and worn state of mind. The two first cases only apply to the present form of dyspepsia, and the indications deducible from them readily suggest themselves. The studious should, therefore, relax from their application, nor urge and overstrain the attention too long and too far; and though entire repose may not be allowed, their studies may be varied, that the different faculties of the mind being exercised* may relieve each other. It was a correct observation of a learned physician, that indigestion follows learning as close as the shadow follows the body, "*Omnesque pæne cupidi literarum*" Celsus considers the most

constant sufferers from dyspepsia; and Aretæus has painted with his most vivid colours the painful sufferings which await a devotion to science and letters, *Διὸς μὲν μαθήσεος πόθος*, when ill regulated and unrestrained. If study cannot be dispensed with, at least all application soon after a meal may be abstained from.† The indolent, on the other hand, should seek occupation, and thus avoid the pains of inertia. But in making these changes, care is to be taken to avoid running into the opposite extreme. Fatigue of body discomposes the sedentary, vacuity of mind is irksome and oppressive to the learned and to the man of business, and much study or business overcomes the indolent. Let them seek, then, occupations in which exercise, amusement, and interest may be happily combined, for they may rest assured it is a policy both narrow and short-sighted, which does not allow some hours a day to the care of their health. "*Quem interdiu vel domestica vel civilia officia tenuerunt, huic tempus aliquod servandum curationi corporis sui est.*" (Celsus.)

3. This indication, correcting the morbid condition upon which the disease depends, according to our pathology, subdivides itself into (a) endeavouring to restore the harmonious action of the different parts of the alimentary canal; (b) restoring or increasing the activity of the excretory organs, and (c) restoring the tone, or improving the innervation of the stomach.

a. To restore the corresponding and harmonious action of the different parts of the alimentary canal. In health there exists a sympathetic relation and corresponding action between the different portions of the alimentary canal. Whilst some are in action, others are in repose, or the action of one part induces that of another. This relation is most remarkable between the stomach and larger bowels; and it is frequently one of the first effects of the operation of the causes producing dyspepsia to destroy or derange this relation; either by the patient not lending a ready obedience to the calls of nature, by losing the habit of it, or, by the sensibility of the stomach becoming altered, the natural intimation ceases to be transmitted to the bowels, and then the parts lose their correspondence. This state is to be corrected by endeavouring to restore the habit of a daily evacuation after the first meal, which is natural to most people in health. For this purpose the water-closet is to be visited even when there is no call from nature. When this does not succeed, the patient may relieve the bowels every second morning by a lavement of warm water. He should only have recourse to aperients when neither of these means succeed, but which will seldom be the case if he has observed those rules of diet, exercise, and occupation pointed out in the first indication; and whatever artificial means he may have recourse to, he should every now and then afford nature an opportunity of righting herself. Another method in common use, that of resorting to vegetables and fruit and coarse bread, seldom succeeds in this form of dyspepsia, or does so only temporarily; a mild aperient is on the whole more expedient and less pernicious. The best form of aperient with which we are acquainted is the pulv. aloes comp. (gr. v.)

* *Levet quoque lassitudinem etiam laboris mutatio: cumque quem novum genus ejusdem laboris pressit, id, quod in consuetudinem est, reficit.*—Celsus.

† *Sin lucubrandum est, non post cibum id facere, sed post concoctionem.*—Celsus.

or the following:—*R.* Pulv. aloes spic., pulv. rhei, pulv. g. guaiaci aa $\mathfrak{z}$ i. Pulv. ipecacuanhæ gr. iv. Ft. pil. xii. Una vel binæ pro re natâ sumendæ. The pil. galban. comp., the pil. scillæ comp. may be sometimes advantageously substituted for the guaiacum. From five to ten grains of the inspissated residuum of the evaporated decoct. aloes comp. prepared with carbonate of soda instead of potass, or of the baume de vie, affords a mild and easy aperient.

The physician should be economical of his means, and not expend his resources unnecessarily. By this precaution he will both spare the power of the organ and of the remedy. If the habitual use of aperients is established, their power must be increased, and at last even strong remedies fail in their effect. The limitation of Celsus, with regard to aperients, is consistent with his wonted prudence; “dum et modo et non nisi quum opus est adhibeatur;” and his reason in accordance with daily observation, “assuecit enim non ali corpus, et ob hoc infirmum erit.” This morbid condition will be also corrected by the means used for invigorating the function of the stomach itself. The restoration, however, of the natural relation of the stomach and bowels often suffices to restore the healthy action of the stomach and of the whole function of digestion.

b. The equilibrium of supply and waste of the body may become deranged through inactivity of the excretory organs, a common effect of sedentary and indolent habits, and not always removed upon changing them. The bowels, the skin, and the kidneys may become torpid in their action; the effete parts not being carried off, the process of nutrition flags, and the digestion fails; a stagnation takes place in the extreme vessels, the whole reproductive processes go on sluggishly, or are entirely at a stand, and the stomach in this way loses its stimulus and impulse. This state is to be corrected by giving activity to the excretory organs; and it is a method of restoring the equilibrium often had recourse to, but ought only to be used when the foregoing methods fail; for it is neither so safe, so salutary, nor so permanent as increased exercise and diminished diet. We have frequent instances of its efficacy in the use of alterative remedies, as is shown in the vigour of nutrition which sometimes follows a course of mercury, or a course of alterative mineral waters. When expedient to be used, a continued source of alterative saline purging affords the best means of effecting it, and most efficiently the mineral waters of Carlsbad or Marienbad.

Besides these means of restoring the desired healthy equilibrium of supply and waste, it has been observed that the same may be temporarily obtained by diminishing the volume of the circulating fluid; and on this principle many cases of this form of dyspepsia, originating in a bloated or plethoric state of the system, have received considerable relief by letting blood. It is a plan well to know, but seldom to be followed.

c. The morbid condition of the stomach which constitutes *atonic gastric dyspepsia*, may be corrected, and the tone of the organ restored, either directly by means applied to the stomach, or indirectly by means acting upon the system at large.

1. Of the direct means which have the power

of rousing and invigorating the stomach, in our opinion wine in moderate quantity is not only the most grateful but the most useful. The dry wines are to be preferred, as pale old sherry, diluted with equal parts of water, or old port wine and water, good claret, or white hermitage, sauterne, or hock. Some persons find a little brandy and water agree better than any kind of wine. It is sometimes of advantage to administer these stimulants very cold or very warm, but never of a tepid temperature.

The medicines comprehended in the list of bitters, tonics, and astringents, have also, in a certain degree, the power of correcting the relaxed state of the stomach. But their power in this respect has been very much overrated, which has led to their abuse, and to the exclusion of more rational and successful means. According to our experience the following are the medicines of this nature best suited to this disease:—lime-water, alone or mixed with some aromatic or carminative water (the distilled water of orange flowers best conceals its taste); the infusions of calumba, chamomile, cascarrilla, orange-peel, or wormwood, alone, or in combination with carbonate of soda, or ammonia; camphor julap, mineral acids, the acid. sulphur. aromat., the diluted sulphuric acid combined with tincture of hops, or tincture of cardamoms; the phosphoric acid in the same way; the metallic tonics, as the tr. muriatis ferri alone, or in infusion of quassia, the subnitrate of bismuth, or the sulphate of zinc.

Of all the remedies of this description the best are the carbonated chalybeate waters, as those of Spa, Pyrmont, Schwalbach, and Eger, on the continent, or their imitations so accurately and scientifically prepared by Dr. Struve at Brighton; or those of Tunbridge Wells. In administering these remedies, it ought not to be forgotten that they are contra-indicated if any derangement of the biliary secretion be present.

The intention of this indication is sometimes more safely and completely fulfilled by combining tonics with aperients, as the powder of calumba with rhubarb and carbonate of soda, sulphate of iron with extract of aloes, subnitrate of bismuth with rhubarb and aloes, the sulphate of quinine with aloes, or extract of colocynth.

The stomach may also be acted upon by external local applications, as by warm stimulating plasters, but more efficiently by the cold douche to the region of the stomach. The ancients held this remedy, to which they gave the name of *cataclysmus*, in high estimation.* They used chiefly the cold douche, either of sea-water or mineral springs. Those of Cutilla, Simbruinum, and Nepete, were most in repute, now almost unknown; for the modern Italians prefer the indulgence of the thermal springs, which they use in precisely the same manner.

2. The indirect means of restoring the tone of the stomach consist in avoiding all the causes which tend to weaken, enervate, or exhaust the body or mind, as over-indulgence in sleep, and hot beds, lustful excesses, hot and ill-ventilated apart-

* Hinc perfundi frigidâ, atque in eadem natâre, canalibus ejusdem subicere stomachum ipsum, et magis etiam a scapulis, id quod contra stomachum est.—Celsus. Ægrotante maritimæ natatione exercendi atque cataclysmo, hoc est, aquarum illusione, suppositis partibus.—Cels. Aur.

ments, moist climates, the too frequent use of the warm bath; and correcting or removing those habits or states of body which have the same effect, as leucorrhœa, or other weakening discharges; habitual venesections, chlorosis, and such-like diseases. The hours of sleep should be diminished; the patient should retire to bed early, and should rise in the morning soon after waking; he should sleep upon a mattress, in a bed without curtains, and should be careful that his chamber is well ventilated and dry.

The clothing of the body should be rather cool than warm, but sufficient to prevent the feeling of coldness; without being oppressive, it should be sufficient to protect the patient from the inclemencies of the weather. It will be at all times desirable that the lower extremities should be kept in a state agreeably warm.

If the patient have the power, he should select for his residence a dry climate, either cold or mild, such as is found in England at Brighton, Tunbridge Wells, Clifton or Malvern; in Switzerland, at Berne or Lausanne; in the south of Europe, at Nice, Genoa, and Naples. He should inhabit airy and well exposed apartments fronting the south-east, so as to have the forenoon sun, and should be cautious not to dwell near rivers and marshes.*

Much of the baneful effects of prisons, manufactories, and places of a like kind, might be corrected by proper ventilation, by the use of the *cheminée d'appel* and similar expedients.
