CYCLOPÆDIA

OF

PRACTICAL MEDICINE.

REFRIGERANTS (from *refrigere*, to grow cold), may be defined, medicines which diminish the *morbid* heat of the body. Their influence is generally admitted, but the theory of their operation is not well understood; and, consequently, many and very opposite hypotheses have been advanced upon the subject. The first of these which deserve notice is that of Cullen, based upon a doctrine of Needham; it forms a remarkable instance of the obscurity into which hypothesis leads men otherwise distinguished for the perspicuity and soundness of their reasoning. This hypothesis supposes "that there is every where, in nature, an expansive and a resisting power; and that, particularly under a certain degree of heat, the expansive power appears in all the parts of organized bodies, in consequence of which they show a singular vegetating power; while, at the same time, there is, in other bodies, a power resisting and preventing the action of this vegetating power, and, at least, of diminishing its force." And it is assumed that this power is found in those substances which are usually employed as refrigerants. (Mat. Med. ii. 121.) It is unnecessary to comment upon these opinions; indeed, their obscurity is such as to render them scarcely intelligible.

A later theory is that of Dr. John Murray, whose habit of reasoning upon chemical principles led him to call in the aid of these to explain the operation of refrigerants. He founds his opinion on the presumption of the truth of the theory of Dr. Crawford, that, in the process of respiration, the arteries in the lungs absorb the caloric liberated there; and, owing to the great capacity of arterial blood for caloric, they instantly render it latent, in which state it remains until the subsequent conversion of the arterial into venous blood, when it is liberated equally through the system. Now, Dr. Murray considers that the consumption of oxygen in the lungs, supplying the caloric to the arterial blood, is greatly influenced by the nature of the food and other ingesta received into the stomach. He supposes that when these substances contain a small proportion of oxygen, the demand for that component of the air, and its consumption by the lungs, are augmented; and, consequently, the animal temperature is elevated; whereas an opposite effect takes place when the ingesta contain much oxygen, more especially if it exist in a loose state of combination. According to this theory, therefore, all substances containing much oxygen capable of being extricated by the powers of the stomach, should possess a refrigerant influence. Plausible as this theory appears to be, its accuracy is very questionable; but, in order to reason correctly upon its merit, it is necessary to take a cursory view of the theory of animal heat upon which it is founded; for if the difference of capacity of arterial and venous blood for caloric be insufficient to account for the temperature of the living body, Dr. Murray's theory of the changes produced by refrigerants must necessarily fall to the ground.

Dr. Crawford's object was to prove, as already stated, that arterial blood has a greater capacity for caloric than venous blood; and this is also the case in reference to common or atmospherical air and carbonic acid gas. The latter fact explains the augmentation of temperature arising from the change which the air undergoes in the lungs when carbonic acid is present in them; but as the caloric thus evolved is absorbed by the arterial blood, and rendered latent, the sensible temperature of the blood is not augmented; and it only becomes so as the arterial blood changes to venous in the course of its circulation. By this evolution of caloric the loss of temperature which the body sustains is compensated. Respiration, therefore, and the greater capacity of the arterial than the venous blood, are, according to this theory, the true sources of the peculiar temperature of the living body.

Many facts might be mentioned as favouring the truth of Dr. Crawford's hypothesis; for example, the greater the comparative size of the lungs, and the greater the quantity of blood which passes through them, the higher is the temperature of the animal. Thus, the capacity of the lungs is greatest in birds, which have the highest temperature among animals; and it is a well-known fact, that whatever lessens the free action of the lungs and diminishes the consumption of oxygen, reduces the temperature of the animal. Individuals who labour under a malformation of the heart sufficient to prevent the arterialization of the blood, are always of a temperature below the natural standard. In hybernating animals, also, the temperature falls as the respiration is suspended; and it rises with the return and the progress of respiration: and, farther, M. Gallois ascertained, by experiment, that the temperature of the body falls exactly in the ratio of any diminished quantityof oxygen consumed in respiration. These opinions are strengthened by some experiments of Dr. Wil-

son Philip; and, upon the whole, it is tolerably well ascertained that the temperature of the body sinks, if it be not maintained by the chemical changes which occur in respiration.

But, notwithstanding the support thus given to Dr. Crawford's opinion, many and as strong facts have been advanced in support of that view of the subject which regards nervous energy as the source of animal heat. The most important experiments on this side of the question are those of Mr. [Sir B.] Brodie. He found that, by maintaining the action of the heart by artificial respiration after the brain is removed, although the blood undergoes its ordinary changes, yet that the temperature of the animal thus treated is rapidly lowered. Sir B. Brodie's experiments were made on rabbits, in which the functions of the brain were suspended by dividing the spinal marrow: the blood, in both systems, underwent no change different from that which occurs in natural respiration. "It may perhaps be urged," says Sir B. Brodie, "that, in these experiments, the secretions had nearly, if not entirely, ceased: it is probable that the other changes which take place in the capillary vessels had ceased also, and that, although the action of the air on the blood might have been the same as under ordinary circumstances, yet there might not have been the same alteration in the specific heat of the fluid as it flowed from the arteries into the veins. But, on this supposition, if the theory of Dr. Crawford be admitted as correct, there must have been a gradual but enormous accumulation of latent heat in the blood, which we cannot suppose to have taken place without its nature having been entirely altered. If the blood undergo the usual change in the capillary system of the lungs, it is probable that it must undergo the usual change in the capillary system of the greater circulation also, since these changes are obviously dependent on and connected with each other." From the experiments of Sir B. Brodie it appears that, when the functions of the brain are suspended, the power of generating animal heat is also suspended; although the same quantity of oxygen be consumed as in natural respiration under ordinary circumstances. It is, nevertheless, proper to mention here the opinion of M. Le Gallois, that, owing to the nature of artificial respiration, upon which Sir B. Brodie's conclusions are founded, the temperature may fall, and the animal be killed by cold, although every part remain uninjured. The air in artificial respiration does not enter the pulmonary cells in the same manner as in natural respiration, but is forcibly propelled into them; a large formation of frothy mucus occurs, which both prevents the air coming in contact with the lining membrane of the air-cells, and by its evaporation tends to cool the body.

Many other facts concur, also, to prove that the temperature of the body is regulated by the nervous energy. It is true that these demonstrate its effect chiefly in maintaining the heat of parts; but if its influence on parts be admitted, it is not easy to conceive on what grounds its power over the entire system can be denied. Sir Everard Home divided the nerves going to the growing antler of a stag, and found that the temperature almost immediately fell; and although, after a few days, it rose again higher than before, yet this may have originated from the reunion of the divided nerves: at all events it does not invalidate the fact that the temperature fell on the division of the nerves, and, consequently, was regulated by their condition. In paralyzed limbs the temperature sinks, although in many cases the circulation in the limb is unaffected, and the paralysis is confined to the sensibility of the member. In a case recorded by Mr. Earle, in which the axillary plexus of nerves on one side was crushed, the paralyzed limb of that side was of a lower temperature than the opposite limb: indeed, in general we find that increased nervous action, whether depending on affections of the mind or on other causes, augments the heat of the body; whilst the effect of depressing passions, which diminish nervous energy, is followed by either general chilliness, or coldness of the extremities.

These facts undoubtedly go far to prove that animal heat is a vital principle closely connected with the integrity of the nervous system; but at the same time, as the stimulus of arterial blood is requisite for the excitement of the brain and nerves, and arterialization is the result of respiration, the influence of respiration in the production of animal heat must be so far admitted; for without the function of the lungs the brain would lose its energy, and the temperature of the system be necessarily greatly lowered. This opinion receives also considerable support from some experiments of Dulong to ascertain whether the quantity of caloric, developed by the consumption of oxygen in respiration, be equivalent to the quantity given out by the body. He found that in carnivorous animals the proportion is equal to forty-nine and fifty-five parts in one hundred of the heat generated by the whole body during the same interval of time; and, in phytivorous animals, to betwixt sixty-five and seventy-five parts; and that the whole quantity of caloric and water together is equivalent to sixty and eighty parts only; so that the animal heat is greater than can be accounted for by the fixation of oxygen during respiration. Upon the whole, the examination of both sides of the question leads us to conclude that both opinions are to a certain extent true; that animal heat is influenced chiefly by the state of the nervous system, but partly, also, by the chemical changes which take place in the lungs during respiration. [See, on all this subject, the physiological works of Müller, Carpenter or Dunglison.]

If this view of the sources of animal heat be correct, it presents a considerable obstacle to the admission of Dr. Murray's explanation of refrigerants, which can only be regarded in the light of an ingenious hypothesis. The subject, therefore, remains as he found it; and the question presents itself—can no rational explanation of the operation of refrigerants be suggested? The writer of this article, although he does not venture to offer a theory likely to be generally adopted, yet conceives that some approach to a rational explanation may be attained by ascertaining how far the action of refrigerants taken into the stomach resembles that produced on the skin by similar substances.

In abstracting caloric from the surface of the

body, or, in other words, cooling the skin, whatever agent be employed, whether diluted acids, salts in a state of solution, cold air, or cold water or ice, the activity of the capillaries of the part is immediately diminished; and as their action cannot be materially lessened without the whole vascular system being more or less influenced, the vigour of the heart and arteries is also materially depressed. The consequence of this diminished vascular action is immediately felt on the respiration; the blood does not undergo its necessary change; venous blood is conveyed to the brain, the function of which being impeded from defect of stimulus, a state somewhat resembling paralysis of the nervous system ensues, so that torpor of every organ, the function of which depends on the energy of the brain and nerves, must necessarily follow. The effect of the abstraction of caloric on the nerves is strikingly illustrated by the numbness and insensibility which follow the exposure of the hands, in many individuals, in cold weather; a result which is more likely to arise from the direct influence of cold on the nerves themselves, than from the diminished supply of blood to the parts. Indeed, as in this case the effect on the nerves is partial, we can scarcely imagine any other cause of the diminished action of the capillaries than the depression of the nervous energy. Now if we suppose,—and the supposition is far from being unreasonable,—that an effect resembling that produced on the surface takes place in the stomach when refrigerant agents are introduced into it, we may readily admit that the effect on the capillaries of that organ is extended by sympathy over the system. The possibility of such a result is equally probable in the one case as in the other. This opinion receives some support from the fact that nitrate of potassa operates as a powerful general refrigerant when it is swallowed at the instant of its solution; but it acts as an excitant when it is not taken into the stomach until after it have been some time dissolved. The sensation of cold which the nitre, during solution, causes in the stomach, is evidently owing to a partial abstraction of stimulus, and the effect of this being extended through the nerves to the heart and larger branches of the arterial system, a general reduction of action is produced, and this is followed by a sensation of cold over the whole body. Let us now inquire how far this theory is borne out by the known effects of refrigerants upon the functions of the stomach, the lungs, and other organs.

1. In the healthy condition of the *stomach*, refrigerants exert little perceptible influence upon it; but when it is either in an irritable state, or affected with inflammation, the continued use of refrigerants, particularly cold and iced water and lemonades, allays the sensation of heat, nausea, and general uneasiness. Even when no local inflammation exists, cold water and other cold, bland fluids, received into the stomach, moderate general excitement and control febrile action; an effect which can only be explained by the influence of the refrigerants on the nervous energy. The same results follow the administration of refrigerants in enteritis.

2. Refrigerants exert no evident influence on the *circulating* and *respiratory* organs, in the state of health; although in some individuals, owing to idiosyncrasy, acidulated fluids cannot be taken without so powerfully affecting the larynx as to cause a temporary loss of voice; but in a diseased state of these organs the influence of refrigerants is well marked.

In an excited state of the vascular system, when the pulse is both quicker and stronger than natural, acidulated drinks reduce both states, both moderating the action, and relaxing the tension of the pulse; nor is their effect on the capillaries less manifest; and it is to their influence on these that we must attribute the diminished temperature which follows their administration. It is surely unnecessary to say how intimately this is connected with their impression on the nerves of the stomach. In the febrile state, the effects of refrigerants on the circulation are necessarily communicated to the lungs; but besides this sympathetic influence, some of this class of medicines, in particular, acids, seem to operate directly on the pulmonary tissue. In acute inflammation of the air-tubes, or even of the pleura, acid fluids greatly augment the cough and oppress the breathing, when administered before the excitement be subdued; and after this is effected, we still perceive the evidence of their action on the mucous membrane by the aid which they afford to expectoration.

3. But the most decisive illustration of the extent to which the nervous system is influenced by refrigerants, is observed in the effects which acidulated fluids produce on those who are labouring under diseased conditions of the spinal cord. The author had an opportunity of witnessing this in a gentleman who was labouring under subacute inflammation of the spinal theca. Whenever he swallowed a spoonful of lemonade, or even an ordinary effervescing draught, a sensation of pricking was felt over the surface, the skin became so sensitive as scarcely to admit of being touched, and the whole system restless and uneasy. Hypochondriacal and hysterical persons, not unfrequently, suffer in a similar manner from the internal use of acids; and, as this effect is not confined to particular individuals, it cannot be ascribed to idiosyncrasy.

Upon the whole, it is evident that refrigerants operate to a certain extent as sedatives; diminishing the force and rapidity of the pulse, depressing morbid temperature, and calming, generally, the disturbance which always attends acute diseases.

The substances employed as refrigerants operate either on the organic functions or on the sensibility of the body in a state of disease.

1. The refrigerants operating on the organic functions are chiefly vegetable acids. The influence of *acetic acid*, in its diluted impure state or as vinegar, in cooling the body labouring under disease, was very early known. In its undiluted state it is a powerful stimulant; and when daily taken in large doses into the stomach in its diluted form, it produces great uneasiness, cramps, and colic, and gradually destroys so effectually the texture of the organ and its digestive function, as to cause emaciation of the body. When it is only occasionally taken, largely diluted with water and moderately sweetened, it displays decided soothing and refrigerant properties, and is em-

ployed with advantage in inflammatory and bilious fevers, for quenching thirst, calming the vascular excitement, re-establishing the perspiratory function of the skin, and restoring the action of the kidneys. In inflammatory affections of the lungs, however, it increases the cough, and augments the morbid sensibility of the mucous membrane in the same manner as all other acids; and, therefore, it is contra-indicated in such diseases, even as an expectorant, until the excitement be subdued.

The refrigerant influence of diluted vinegar on the surface is undoubted; it not only diminishes heat but allays pain. In hemorrhagic affections, the cold feeling which it produces on the skin is extended to the whole system; hence the benefit derived from it in internal hemorrhages, and in the inflammation of cavities; as, for instance, in uterine hemorrhages applied to the thighs and abdomen; and in acute meningitis applied as a lotion to the shaved scalp. In general fever, sponging the body with vinegar and water is applicable to every case in which the skin is preternaturally hot, when no idiosyncrasy stands in the way.

When diluted acetic acid is internally administered, if opium be prescribed at the same time, it should be recollected that it decomposes the meconate of morphia of the opium and forms an acetate, which is a more powerful narcotic than the meconate. The combination of this acid with ammonia, in the preparation known by the name *liquor ammoniæ acetatis*, possesses refrigerant powers nearly equal to those of the diluted acid, acting at the same time as a diaphoretic; and it is more generally employed than the acid in modern practice. The salts procured by the combination of acetic acid with the other alkalies operate chiefly on the kidneys.

The *citric acid* is more frequently employed than the acetic as a refrigerant; but chiefly in its combined state as prepared by the hand of nature, in the juice of the lemon, the orange, and other fruits. It is more grateful in its combined than in its uncombined state; a fact which is quickly perceived by patients in fever, when it is ordered to form the common effervescing draught for checking nausea and vomiting. When simply diluted with water, in the proportion of the juice of two moderately-sized lemons to a pint of water, and slightly sweetened, forming lemonade, citric acid constitutes a most serviceable and agreeable beverage in fevers; and in those of a typhoid character this is rendered more grateful and beneficial by using water impregnated with carbonic acid gas instead of common water. In the ordinary condition of the stomach, citric acid, either pure or combined, does not weaken the stomach; and in some irritable states of that organ, characterized by a sensation of heat, painful digestion, an unpleasant taste in the mouth, and a disgust of food, it removes these symptoms and proves decidedly beneficial: but on the other hand, when the stomach is highly irritable, and its nervous susceptibility great, lemon-juice, or the citric acid, even when largely diluted, causes heat, uneasiness, and pain, and not unfrequently obstinate vomiting. Nevertheless, as M. Broussais has remarked, (Phlegmas. Chron. t. iii. p. 254,) the citric acid is that which the stomach supports best when suffering under inflammation.

The citrates of potassa and of ammonia are also refrigerant: the citrate of soda, which is not an officinal preparation, operates as a purgative.

The above remarks are applicable to the juice of the orange, the apple, the currant, and the gooseberry, all of which owe much of their acidity to the citric acid.

The *tartaric acid*, except as it is contained in the tamarind, is much less frequently prescribed than the citric as a refrigerant, being more apt to disorder the digestive organs, to produce colic and to purge; and its morbid influence on those labouring under affections of the spine is more constant and evident than that occasionally resulting from the employment of citric acid: indeed, so obvious is this, that patients sometimes refuse to continue taking it on account of the nervous agitation which it causes. Its combination in the form of the *bitartrate* is more frequently employed; and in small doses at moderate intervals, it does not operate as a purgative, but as a simple acidulous refrigerant. It is best administered in the form of whey, or of cream-of-tartar beverage; it moderates febrile heat and softens the skin; but when its employment is followed by a red and dry tongue, it ought to be discontinued. Both the acid and the bitartrate are incompatible in mixtures with the nitrate of potassa, which it decomposes, and, uniting with its alkaline base, forms either a bitartrate or a tartrate.

The *oxalic acid* in the form of the binoxalate, as found in the oxalis *acetosella* and rumex *acetosa*, was formerly much prescribed as a refrigerant; but these plants, and, indeed, the oxalic acid in any form, are now rarely employed.

Nitrate of potassa, in small doses, is a well-known refrigerant: it produces a powerful sympathetic effect on the nervous system, depressing the strength and diminishing the frequency of the pulse, and lowering the animal heat: the skin becomes pale, and a sensation of languor is felt. To obtain the full refrigerant effect of nitre, the salt must not only be administered in small doses at short intervals, but it should not be dissolved until the instant in which it is to be administered. As a refrigerant, the dose should not exceed a scruple, or, at the utmost, half a drachm.

The *bicarbonate of soda*, although seldom prescribed as a general refrigerant in this country, yet is frequently administered in inflammatory febrile affections on the continent. It is, however, better calculated for operating as a local than as a general refrigerant.

2. The refrigerants operating on the sensibility of the body are few; but they are more directly refrigerant than those which have been already noticed. *Cool air*, the first of these, is so agreeable to the feelings in a heated state of the body, that observation alone might have led to its early employment as a remedial agent; and nothing marks more strikingly the perversity of mankind than the opposition of physicians, at one period, to the indulgence of the instinctive desire for this remedy in fever patients. Its utility in moderating high vascular action and operating as a sedative refrigerant is now generally acknowledged; and

consequently its admission to the apartments of the sick, in febrile diseases, is almost universal.

If cool air be beneficial in the above-mentioned conditions of the body, *cold water* and *ice* are still more so; and their application is extensive. For an account of the effects of cold water and ice in reducing the temperature of the body in its healthy condition, we must refer our readers to the articles Bathing and Cold. When cold water and ice are employed as curative agents, their influence may be obtained either by their internal administration or by their application to the surface; in both cases their effects are extended by sympathy over the system; but they are modified by the manner in which these agents are used. If the body be immersed in the *cold bath*, the most striking effect is the shock or nervous impression which produces the vascular reaction so beneficial when cold bathing is used as a tonic; an effect, however, which must be avoided as much as possible when the refrigerant influence only of the bath is required. To insure simple refrigeration, the water should be of a temperature not much below that of the skin; but as, even at such a degree of heat, the sudden immersion of the body is likely to cause more reaction than would be safe in cases requiring mere refrigeration, the cold bath is rarely or never employed in this country for producing that effect. The shock and reaction caused by dashing cold water over the body, constituting the *cold affusion* as it is termed, is as considerable as when the cold bath is used, but it is more transitory, and therefore it is a more useful refrigerant. *Sponging* the body with cold water, as far as a simple refrigerant effect is desired, is preferable to either the cold bath or the cold affusion: there is no shock; the fluid, being left to evaporate, merely cools the surface; and by persevering in the process, the cooling effect is fully obtained, and rendered permanent. One great advantage of sponging the surface with cold water is the facility of limiting the extent of the effect according to the feelings of the patient: in general it may be continued until the sensation of chilliness comes over the body, when the patient should be dried and placed in bed. The more simultaneously the influence of cold water is extended over the surface, the better; the process of sponging should, therefore, be performed by several attendants with large sponges on the different parts of the body at the same time. In ordinary cases the temperature of the water may be regulated by the feelings of the patient, as the beneficial effect depends on the evaporation, which may be aided by the addition of vinegar or alcohol. *Evaporating lotions* applied to a part, operate locally in the same manner as general sponging; the sedative and refrigerant influence is not confined to the part, but extends to other parts of the body, even to the interior, as, for instance, to the brain, the contents of the abdomen, and to joints. The sedative effect is still more powerful when a small stream of cold water is directed upon the part: the author of this article has seen this most strikingly exemplified in burns; the mere immersion of the part in cold water, or the application of cloths dipped in cold or even iced water, is much inferior in its effect to this method of employing cold water. It is scarcely necessary to comment on the influence of the local application of *ice*, which operates exactly in the same manner as evaporating lotions, but more effectively, owing to the steady continuation of the same low temperature to the parts.

The foregoing remarks lead to this conclusion—the utility of refrigerants as curative agents is more limited than that of most other classes of remedies. They are chiefly employed to depress inordinate vascular action, and thereby to lower temperature; consequently, it is in inflammation, active hemorrhages, and febrile affections that they are found beneficial; and in such cases they are, undoubtedly, most valuable remedies.

In local inflammations on the surface of the body, cold water and evaporating lotions prove highly serviceable; whilst in those more deeply seated, as, for instance, inflammation of the brain and its membranes, ice applied to the scalp is to be preferred: the steady abstraction of caloric which it effects, operates not only upon the vessels and nerves of the integuments, but, by diminishing action in the carotids and large vessels, it produces the most decisive benefit in reducing the vascular action within the cranium. These applications have been lately recommended in other internal inflammations, even those of the thorax and abdomen, and under proper circumstances have been found highly beneficial.

Hemorrhage arising from increased action, or accompanied by it, is frequently checked by the sedative influence of refrigerants. When the bleeding is internal, the degree of cold should be such as to operate sympathetically on the whole system; and to lessen not only the action of the vessels of the part, but to restrain, to a certain degree, that of the heart. Thus in hæmoptysis, not only should the patient be freely exposed to cold air, but ice and cold acidulous fluids should be freely administered; indeed, the temperature may be with safety, and even with advantage, diminished so much as to be uncomfortable to the feelings of the patient. In such a case, the low degree of temperature is accompanied with an evident diminution of the irritability of the contractile fibres of the whole vascular system, and, consequently, aids greatly in checking the flow of blood. The liquids administered as drink should be cooled down to 32°, either by ice or by a freezing mixture, and slowly swallowed. The influence of nitre has long been regarded as considerable in such cases; and much of the benefit received has been attributed to a chemical change effected on the blood; but if the opinions advanced in this article be correct, it is unnecessary to assert that this explanation of the operation of nitre must fall to the ground.

[The notion of nitrate of potassa being refrigerant has probably arisen from the coldness which it occasions whilst undergoing solution in water. Indeed, as elsewhere stated, (*General Therapeutics*, Philad. 1836, and *General Therapeutics and Materia Medica*, ii. 206, Philad. 1843,) all internal refrigerants probably act wholly by their being comparatively of low temperature, and thus reducing the heat of the stomach. A recent writer, Dr. Spillan, (*Manual of General Therapeutics*, p. 185, London, 1841,) after citing the published opinion of writers on this subject, states that

"the refrigerant effects of nitrate of potassa as a sedative, when given dissolved in even tepid drinks, such as whey, are known to every one." They certainly are not known to the writer; yet he has watched most carefully for them; nor have others been more fortunate. Dr. A. T. Thomson says, that "the dose of the salt should not be dissolved until the instant in which it is to be swallowed," (*Elements of Mat. Med. and Therap.*, 2d edit. Lond. 1835); and Dr. Pereira (*Elements of Mat. Med. and Therap.*, Amer. edit. i. 438,) accords with him; whilst Dr. Christison (*Dispensatory*, p. 741, Edinb. 1842,) expresses himself in a manner that still more strongly corroborates the views of the writer:—"Its refrigerant action, generally admitted by systematic writers on materia medica and by many practitioners, is of doubtful existence, having probably been inferred rather from the coldness it occasions while dissolving in water, than from actual evidence of its effects in disease. The sedative action ascribed by some to it has been probably inferred from its supposed refrigerant property, and not from observation."]

In hæmatemesis occurring in young and vigorous perons, the same assiduous employment of refrigerants is requisite as in hæmoptysis; and when the bleeding is so violent as to threaten quickly serious consequences, the other refrigerant plans may be aided by injecting iced water into the rectum, and by the local application of cold to the epigastrium. In no species of hemorrhage is the sympathetic influence of refrigerants more strikingly obvious than in epistaxis. Thus dashing cold water on the genitals has sometimes instantaneously suppressed bleeding at the nose; and on the same principle is explained, what it is scarcely necessary to notice, the popular remedy of applying a large cold key or a piece of metal between the shoulders under the clothes.

It is superfluous to say that, however useful refrigerants may prove in all cases of active hemorrhages, their employment in the passive is to be most carefully avoided.

But it is in fevers that refrigerants under every form are to be regarded as the most valuable set of therapeutical agents. In continued fever, the vegetable acids largely diluted are internally administered, especially those found in fruits; and not unfrequently nothing is more grateful to fever patients than cold water slightly acidulated with either the sulphuric or the nitric acid. It is, however, the general application of cold to the surface which proves the most useful refrigerant in continued fever. In those forms of the disease which assume a typhoid type, ventilation and the free admission of cool air into the apartments of the sick are absolutely necessary: irritation is allayed, debility obviated, and the whole complexion of the disease often changed in a few hours, by the removal of the patient into a cool and well-ventilated, from a close and filthy apartment. The most direct and effective refrigerant, however, in continued fevers is the cold affusion; but its employment requires certain cautions, without attention to which much mischief may be incurred. In the first place, the exact temperature of the body must be carefully ascertained. In this country, in the severest attacks of fever, it has rarely exceeded 108° Fah.; but in tropical climates it rises sometimes to 112°; the higher the temperature of the patient, the more benefit may be anticipated from the cold affusion. The temperature of the water should vary according to the season of the year and the feelings of the patient, the average range being from 40° to 70° Fah. The effect is to diminish the morbid heat of skin, to lower the force and retard the rapidity of the pulse, and to induce perspiration and sleep; and when such results follow, the cold affusion proves beneficial in any form of fever.

The thermometer is employed to determine the temperature of the patient; but if he feel cold when that instrument indicates an augmented morbid temperature; or if he feel hot when the thermometer demonstrates that the heat of the body is below that of the natural standard; then in neither case should this form of refrigerant be resorted to. It is also improper when the skin is bedewed with perspiration; or if the patient dread greatly its use; nor is it less so during menstruation, and in the latter months of pregnancy. In the advanced stages of fever, refrigerants of any kind are injurious.

With respect to the kinds of continued fever in which refrigerants are indicated, we may enumerate six.

1. In inflammatory fever, (*synocha*,) a rare disease when unaccompanied with topical inflammation, the advantages to be derived from refrigerants are well understood. The cold affusion is admirably adapted for rapidly abstracting the stimulus of heat, diminishing general excitement, and operating as a powerful sedative. In the more advanced stages of the disease, cool sponging is often substituted for the affusion; but when the patient can bear the fatigue of the affusion, it is always to be preferred. The greater frequency of this form of fever among the ancients than the moderns explains their constant employment of cold drinks and cold bathing in continued fever.

2. In fevers of a typhoid type, the disease has been cut short by the cold affusion; but in this case more perhaps is to be attributed to the shock and the reaction which follows, than to the refrigerant influence of the affusion.

3. In synochus or inflammatory fever, gradually assuming the typhoid character, refrigerants in general, but more especially the cold affusion, are chiefly applicable to the early stages of the disease; and, indeed, no form of remedy is more advantageous when there are no local determinations; but when these exist, particularly if the lungs be affected, much caution is required.

4. In remittent fevers, especially those of warm climates, and in their more intense and excited variety, the cold affusion may be employed with great benefit. In severe attacks, also, much advantage is derived from the application of ice or cold water to the scalp; in the remissions, however, the application of cold in any form must be suspended. In yellow fever, the safety of the patient frequently depends solely on the early application of the cold affusion.

5. If hectic be symptomatic of pulmonary affections, or determination to internal organs, the cold affusion is decidedly contra-indicated; but even in such cases much benefit is often obtained by sponging the trunk of the body with cold

water mixed with vinegar, whilst the lower extremities are kept warm in bed. We must, nevertheless, bear in mind that, under any form of hectic, although general refrigerants are useful auxiliaries, yet the cold affusion can scarcely be regarded as admissible.

6. In most eruptive fevers, except measles, the body should be freely exposed to cool air; and even the cold affusion may be safely and advantageously prescribed, should the state of the surface require it, nor should the presence of the eruption operate as a reason against its employment. The Hindoo physicians plunge their patients, during the eruption of small-pox, into cold water, and with the best results. It diminishes the fever, lessens the number of the pustules, and is said to prevent pitting. The writer of this article has long been in the habit of employing the cold affusion in scarlatina during the height of the eruption, and has seen the severity of the disease instantly checked by it.

In intermittent fevers, when the skin is dry and parched, and the general heat greatly augmented, cold in every form applied to the surface, and cold acidulated fluids taken into the stomach, are of the same value as in continued fever, and greatly favour the accession of the sweating stage. The affusion should be used in the hot stage of the paroxysm, and continued until the temperature of the body of the patient be reduced to the natural standard.

It is unnecessary to discuss the nature of the various diseases, besides idiopathic fevers, in which refrigerants are indicated: in all, much depends on the degree of the attendant fever, and the existence of local affections. In one local disease, phrenitis, however, their advantageous effects are very conspicuous: the most furious delirium is quickly subdued by allowing cold water to drop on the vertex, whilst the rest of the scalp is covered with cloths moistened with vinegar and water. The degree of collapse, indeed, which is thus produced, is often so great as to require most active measures to counteract it; when such occurs, the state of sinking is to be treated exactly in the same manner as when extreme debility suddenly appears from other causes: external warmth, particularly the application of bladders of hot water to the scrobiculus cordis, friction, electricity, and sometimes artificial respiration, are the means to be employed to restore animation; and when the power of deglutition returns, the administration of excitants, especially aromatics and ammonia, is to be resorted to.

From the foregoing remarks, it is evident that, although, as we have already said, refrigerants constitute a class of medicines of limited application, yet they are of much value in a few important diseases. Like every other class of therapeutical agents, their utility will be more or less obvious as the discrimination, the judgment, and the observation of the practitioner are properly exercised, in determining the exact condition of the body which demands their employment.

A. T. Thomson.

RHEUMATISM, from ῥεῦμα, *a defluxion*. This term, originally adopted when diseases accompanied with swelling were usually attributed to the flow of some special humour to the part affected, has been used for ages to designate an affection which has so much of distinct character as to justify its being considered a special disease. So loosely, however, has the term been applied, that a host of ailments, with no character in common save that of pain, have been classed under it, and much both of false experience and of bad practice has thence resulted. Diseases called rheumatic have been relieved by stimulant remedies, which from the character thus acquired have been empirically resorted to in states of constitution for which they were utterly unsuited. In acute rheumatism, a disease intensely inflammatory, we have known the use of the most powerful stimulants confidently urged by well-meaning but misguided friends, who in support of their prescription have pleaded the wonderful cures which they had seen their favourite specific perform in what they assumed to have been rheumatism; thus misled by a name to recommend in active inflammation what could have benefited only in a totally opposite state of the system. As many affections really rheumatic present an equivocal character which to superficial observation too often appears to justify the use of stimulants, it is very necessary to discriminate the real disease, so as to distinguish it from those diseases with which it is liable to be confounded; and however difficult it may be to class the latter, it is better to leave their place in nosology unassigned, than, by ranging them under the head of rheumatism, to beget confusion where clearness and precision are of the first importance.

In the investigation of rheumatism, the best mode, similar to what was followed in treating of gout, is to consider, first, the simple disease in its most perfect form; and then, with the lights thus supplied, to elucidate the more complex conditions which the larger portion of rheumatic affections present. So contradictory, and, we may add, so ineffectual are the means ordinarily used in treating the latter, that no greater benefit could be conferred both on patients and practitioners, than to divest the treatment of perplexing confusion and inconsistency by reducing it to fixed principles, and bringing it within the pale of rational and scientific practice.

In determining the diseased condition to which the name of rheumatism should be specially assigned, it is expedient to examine the representations given of it by the systematic nosologists. Sauvages describes rheumatism as "dolor diuturnus in parte carnosa artuum," and places it in the class *Dolores*, order *Vagi*, of his nosology. According to Linnæus, it is "musculorum dolor ad motum, a tunica cellulosa injecta;" class *Dolores*, order *Extrinseci*." Vogel places it in class *Dolores*, as merely "cutis et musculorum dolor." It would be difficult to recognise in these brief and meagre specifications the ordinary disease of rheumatism, such as we daily witness it.

Sagar is both more copious and more precise. He describes two diseases, a chronic one ranged in the class *Dolores*, order *Vagi*; and an acute under the specific name of myositis, in the class *Phlegmasiæ*, order *Phlegmasiæ musculosæ*, giving respectively the following definitions. "*Rheumatismus.* Dolor Diuturnus in parte carnosa

tendinosa artuum, vagabundus, sæpius sine coryza, rheumate, catarrho, erysipelete, et sine febre notabili; (acutus rheumatismus facit genus inter Phlegmasias, myositin a me dictum;) sanguis missus rheumatismo laborantium, est gelatinosa crusta tectus, et urina sæpe ad sulphureum colorem tendit." "*Myositis.* Febris acuta inflammatoria, dolores in diversis musculis artuum, eorundemque involucris, diu noctuque discruciantes, motum vetantes fere omnem, ad noctem exacerbantes; sanguis missus est tectus crusta inflammatoria subgelatinosa, vel pelli tenui tenaci: hic morbus vulgo audit rheumatismus acutus." It is worthy of remark that Sagar notices the blood drawn in chronic rheumatism as exhibiting a buffy crust. Cullen considers acute rheumatism alone as a special disease, regarding the chronic form as only a sequel of it. He places it in the class *Pyrexiæ*, order *Phlegmasiæ*, and gives the following definitions. "*Rheumatismus.* Morbus ab externa et plerumque et evidente causa; pyrexia; dolor circa articulos musculorum tractum sequens, genua et reliquos majores, potius quam pedum vel manuum articulos infestans, calore externo euctus." "Rheumatismi sequela est, *Arthrodynia.* Post rheumatismum, nisum violentem vel subluxationem, dolores artuum vel musculorum, sub motu præsertim aucti, plus minusve fugaces, calore lecti vel alio externo levati; artus debiles rigidi, facile et sæpe sponte frigescentes; pyrexia nulla; tumor plerumque nullus. Rheumatismus chronicus auctorum."

I. — Acute Rheumatism.

This disease is often designated by the trivial name of rheumatic fever, a term which implies a constitutional disturbance as well as a local. The ordinary phenomena which characterize it are so familiarly known, that a very brief account of its accession and progress will here suffice. That given by Sydenham, derived as it was from actual observation, and marked by his wonted truth and accuracy, presents in few words as clear a description of the early seizure as can well be rendered.

"This disease happens at any time, but especially in autumn, and chiefly affects such as are in the prime of life. It is generally occasioned by exposing the body to the cold air immediately after having heated it by violent exercise, or some other way. It begins with chilliness and shivering, which are soon succeeded by heat, restlessness, thirst, and the other concomitants of fever. In a day or two, and sometimes sooner, there arises an acute pain in some one or other of the limbs, especially in the wrists, shoulders, knees; which shifting between whiles, affects these parts alternately, leaving a redness and swelling in the part last affected. In the beginning of the illness the fever and the above-mentioned symptoms do sometimes come together, but the fever goes off gradually, while the pain continues, and sometimes increases."

The latter circumstance Sydenham, in conformity with the pathology then prevalent, attributes to the "derivation of the febrile matter to the limbs," which he conceives to be sufficiently shown "by the frequent return of fever from the repulsion of morbific matter by external remedies." The theory here propounded may be questionable as resting on hypothesis, but the facts with which it is connected are not the less valuable.

It appears, then, that acute rheumatism presents a state of active fever accompanied with local inflammation of one or more joints. And here one of the most important questions respecting rheumatism arises—whether the local inflammation be the cause of the fever, or only its attendant? On the solution of this, much both of the pathology and treatment of rheumatism must depend, and accordingly its elucidation will form a prominent part of the present article.

In the foregoing description of Sydenham, it appears that the state of febrile excitement precedes the local inflammation. In theoretic speculations this fact seems generally recognised, yet it does not appear to have been kept steadily in view either by speculative or practical writers. The term symptomatic fever, so often applied to the constitutional disturbance, implies that this was regarded rather as a contingent result of the local inflammation, than as a precursor or cause of it. To determine this point is of much importance, for by the decision must the whole course of treatment be influenced. If the local inflammation, whether seated in the *muscular*, though more frequently in the *fibrous* tissue of the affected parts, be the cause of fever, as implied by the term symptomatic, the reduction of local inflammation by the most direct means would be the best and most effectual relief; and this being duly attended to, the contingent fever might, according to the familiar axiom, *sublata causa tollitur effectus*, be little regarded. On the contrary, if the state of fever, or rather that condition of the habit which gives rise to fever, be the real source of rheumatic seizure, then should the constitutional state be chiefly attended to, and local treatment be only subsidiary to that by which the derangements of the constitution are rectified. We hope clearly to show that the constitutional state is that which chiefly claims our regard in the treatment of rheumatism.

When acute rheumatism occurs in its most active state, so intense is the inflammatory fever attendant, that whatever theory of the disease be entertained, the fever claims its full portion of attention, and is met by adequate activity of treatment. Bleeding, purging, and other means of reducing fever are promptly and freely employed, the more so as experience has shown this treatment to be indispensable for abating the local inflammation. This being the case, then, it may be asked, of what importance is it to decide whether the local or constitutional affection is to be regarded as the primary disturbance, inasmuch as the same treatment relieves both? It would be sufficient to answer that truth ought always to be ascertained, for it can never be unimportant. Were acute rheumatism in its more active state to be alone considered, the importance of the decision might be less, both the local and constitutional disturbance demanding the vigorous employment of corresponding means. But when the minor degrees of the same disease, constituting what is termed chronic rheumatism, come to be investigated, it will be seen that their essential character involves the point at issue; and that unless this be determined as truth and reason dictate, the

practice in a malady which is more prevalent, causes more suffering, and leads to more decrepitude than almost any other, must be vacillating, imperfect, and unsuccessful.

It will materially abridge the present article to refer to certain general principles of pathology already detailed in the articles Gout and Plethora. These principles apply directly to rheumatism, and through them alone can its pathology be adequately unfolded, or its treatment rationally explained.

Acute rheumatism principally attacks the young and vigorous. The period of life most subject is said to be from puberty to thirty-five years. Though no age is exempt, it yet more rarely occurs in the very young, or in advanced life. This circumstance alone would seem to indicate some connection between rheumatism and fulness of habit, or that approximation to plethora which was formerly noticed as exuberance of health; and if rheumatic seizures be duly scrutinized, they will be found to take place in those who from plethora, whether absolute or relative, are prone to fever or inflammation on any exciting cause being applied. The extraordinary health so often remarked by patients as having immediately preceded the rheumatic attack is sufficiently intelligible. But direct evidence of the state of constitution in which attacks of rheumatism occur is amply shown in those who, having had the disease, are liable to its recurrence, and on this account compelled to watch the premonitory indications of an attack. In these, constitutional disturbance of a febrile kind, marked by all the phenomena formerly detailed as denoting the transition of plethora into febrile excitement, will be invariably found to exist for a sensible time before the disease presents its full character by the establishment of a local inflammation. And to these premonitory indications should the earliest attention be given, for it is in this stage that relief can be most speedily and effectually afforded. By reducing plethora and subduing febrile action in this stage, the local inflammation may be wholly averted, and thus may be prevented not only the injury which the joints, when affected, are liable to sustain, but also the susceptibility to impression from slight causes which reiterated attacks of rheumatic inflammation never fail to leave.

The local inflammation of acute rheumatism undergoes a change during its progress which seems to have escaped observation. It exhibits at different stages two conditions, which may be conveniently distinguished as primary and secondary. The former is the immediate result of the rheumatic seizure, and must be attributed to the specific cause, whatever it may be, from which the disease derives its distinctive character. It differs from common inflammation in being more transient, for it is capable of rapid subsidence without any trace of its attack remaining. When this inflammation migrates from joint to joint, the occurrence of a fresh inflammation is oftentimes followed by a quick subsidence of that which immediately preceded. Still more signally does this rapid subsidence take place if active treatment for the relief of the constitutional inflammation be resorted to immediately on the attack occurring, and before the secondary inflammation has had time to supervene. In this respect the primary or specific inflammation of rheumatism has a close analogy with that of gout, from which it differs, however, in having a stronger tendency to pass into inflammation of a more ordinary and permanent kind. This specific inflammation is promptly relievable by constitutional treatment, no local applications being at all needed.

When from the severity of the attacks, or from neglect or delay in having recourse to suitable discipline, the specific inflammation lingers in a joint, a secondary inflammation results, more permanent in its nature, which does not immediately subside on the constitutional inflammation being subdued, and which generally leaves some traces of its existence, in effusion into the cellular membrane or bursæ mucosæ, or in more or less thickening and rigidity of the ligaments and other membranes surrounding the joints. The distinction here noticed is important, because it has a sensible influence on the local treatment of rheumatism, both acute and chronic.

Causes of acute Rheumatism.—The chief, if not the only exciting cause, is the application of cold to the body when unusually heated. Cold is more liable to produce this effect when combined with moisture, whence a cold and humid atmosphere, and wet or damp clothes, are the most frequent sources to which rheumatism can be traced. Partial cold, as when parts of the body are subjected to currents of cold air, is very apt to give rise to rheumatism. When the body is predisposed, a very transitory exposure of this kind will suffice to bring on an attack; if the current be sustained for any time, few will wholly escape some contingent suffering. Of the fact that rheumatism is so excited there can be no doubt. When it is reflected, however, that for every instance of rheumatism so induced, numbers continually endure a much or greater exposure to the alleged cause without any disease ensuing, too much importance should not be attached to it.

[Other causes have been enumerated, such as the repercussion of eruptions, the stoppage of an accustomed flux, &c. These may exert an influence, if a predisposition exist; but such influence is not easily appreciable. Recently, it has been affirmed by Messrs. Maddock and Sigmond, that where there is a disposition to acute rheumatism, the use of copaiba may develop it.]

Of far greater moment is it to regard the predisposition, without the concurrence of which either no rheumatism will take place, or it will be slight and partial, exhibiting none of the constitutional disturbance and febrile excitement which characterize acute rheumatism. A predisposition is said to be given by many circumstances, as age, temperament, climate, season of the year. Even hereditary liability has been classed among the predisposing causes, and possibly with reason, [and it is affirmed by Dr. R. B. Todd, (*Practical Remarks on Gout, Rheumatic Fever*, &c. Lond. 1843,) that the children of gouty parents are more liable to the disease than those who have not laboured under the gouty diathesis.] Each of these merits attention, but the circumstance common to all of them, and that which has most influence in pro-

ducing the disease, is a state of general constitution, which from the prevalence of plethora, either absolute or relative, is prone to be aroused by any excitement into febrile or inflammatory action. This subject having been fully discussed in its proper place, (see PLETHORA,) it will suffice on the present occasion to apply to the consideration of rheumatism the doctrines already explained. It furnishes a presumption, at least, of these doctrines having some foundation in truth, that corresponding principles have been advocated by one of the most enlightened pathologists of the present day. M. Andral, in various parts of his luminous Treatise on Pathological Anatomy, traces a variety of structural lesions, as well as the inflammatory actions which induce them, to a redundancy of nutritive matter in the blood, supporting his views with a copiousness of illustration, matured experience, clear discernment, and sound judgment, which claim the respect and confidence of every intelligent mind. These views, too, are so reiterated throughout the work as to show that they were not a mere transient conception, but a deliberate conviction deeply impressed.

A few extracts will evince that in these assertions we do not misrepresent this acute and philosophic writer. In discussing the effects of hyperæmia, or excess of blood, on particular tissues, he says: — "The hyperæmia, instead of being confined to a simple organ, may exist at the same time in every organ of the body. The general capillary system is thus overloaded with blood, and the whole system is said to be in a state of plethora or polyæmia. I shall not enter into a detail of the circumstances which characterize this state, the essential character of which seems to consist in the formation of a greater quantity of blood than is necessary for the purposes of nutrition and secretion. There are some individuals who, according to common observation, naturally make a greater quantity of blood than others. In general, those persons who live high, and make but little exertion, mental or corporeal, are most liable to this affection. It has been said, but without the slightest proof being adduced in support of the assertion, that an appearance of plethora has been produced in some individuals by an inordinate expansibility of the blood. When the blood-vessels contain a greater proportion of the nutritive fluid than is necessary to supply the demands of the different organs, the superabundant quantity becomes a permanent source of excitation to the solids, and at the same time the blood has a remarkable tendency to accumulate in different organs; so that, in such case, the whole system is in a general state of excitation, and some of the organs may become the seats of local congestions of various degrees of duration and intensity. Indeed, the phenomena which result from the plethoric diathesis, cannot properly be termed morbid unless when some local congestion is formed. Sometimes the brain is the seat of the congestion, and then follow the various symptoms of the cerebral disease, giddiness, headach, drowsiness, alteration of the sensorial and intellectual faculties, &c. which may be so violent as to induce death, and yet leave no trace of disease except a little more blood than usual in the cerebral vessels. Sometimes the congestion more particularly affects the pulmonary organs. The dyspnœa which accompanies this form of the disease arises from an unusual quantity of blood transmitted through the lungs, which necessarily requires a corresponding quantity of air to fit it for the purposes of the general circulation. It is this want of proportion between the blood which requires to be aerated, and the quantity of air inspired for that purpose, which produces the dyspnœa. In other cases the complication of palpitation with various degrees of dyspnœa proves that the heart has become the seat of congestion."

Corresponding effects are traced through other organs and tissues, and due notice is taken of the constitutional derangements resulting from polyæmia when no organ more especially suffers, as well as of the prostration of strength or false adynamia, as it is expressively called, which so generally attends this state. The section closes with remarks which are too apposite to our present purpose to be omitted, however reluctant we may be to indulge in lengthened quotations:—"The morbid state which I have now described, and to which may be referred some of the species of continued fever described by the older nosologists, may terminate in recovery or death. When the termination is favourable, the symptoms gradually improve as the superabundant quantity of blood, the original source of all the accidents, is diminished by abstinence and bloodletting. When death ensues, the post-mortem examination generally exhibits traces of well-marked inflammation of one or more organs. This inflammation seems to have taken place subsequently to the commencement of the febrile paroxysm; at least the symptoms would lead us to this conclusion. But on other occasions no trace of inflammation can be discovered, and the only morbid appearance consists in a simple accumulation of blood in the capillaries of the different organs, their textures remaining perfectly unaltered. These slight congestions affecting simultaneously several organs, may, by the various morbid sympathies which they excite, produce as violent and formidable symptoms as the most serious organic lesion of any individual organ. In such case, where are we to assign the origin of the disease?—Wherever the blood is distributed, there derangement of function is found. In the blood, then, indisputably resides the first cause of the disease; the lesion of the solids is only a secondary affection, but may, notwithstanding, become, during the progress of the disease, the prominent affection, and give rise to many and formidable accidents.

In noticing fevers, he particularises one class which he refers specially to excess of fibrine in the blood. "Lastly, the third class of fevers appears to be more particularly connected with alterations of the blood. On this head I can but refer to what I have already said, when treating of the diseases that may arise from that source. I shall content myself at present with repeating that the fever termed inflammatory seems to me often to arise from no other source than the blood being too rich in fibrine." Again, in considering the lesions of the blood, he refers the occurrence of inflammatory fever, not only to a general hyperæmia or excess in quantity of the circulating fluid, but more particularly to an altered condition

of its quality arising from redundancy of fibrine. "I have already established the fact that, under the influence of a state of general hyperæmia, every organ becomes excited; that death may result from such excitation; and that a superabundance of blood is found all over the body, but in no part is there any serious lesion, any alteration of texture. In such cases there exists that state of pyrexia, termed by nosologists inflammatory fever. But if, instead of being simply in excess, the blood contains more fibrine than ordinary, its exciting power will be still greater, and what it did in the former case merely by its increased quantity, it will now do by its alteration of quality." In fine, he applies the doctrines thus propounded to the particular disease which is the subject of the present essay. "Now if we mark the symptoms and progress of acute rheumatism, we find that very often a well-marked febrile action with a strong reaction, but without any symptom whatever of local affection, precedes the pain. In a word, there is first an inflammatory fever, and then rheumatism. Next observe the extreme mobility of the rheumatic pains. They run along in a manner wherever the blood is distributed; the application of leeches often removes the pain from one part, but it soon shifts to another, and not unfrequently it quits the articulating tissues and fixes on different internal organs, producing, by the derangement of their functions, symptoms more or less severe. It often happens that bleeding from a large orifice puts an end to the disease, as if by diminishing the mass of blood it proportionally diminished the stimulus that promoted all these shifting irritations."

The doctrines here advanced we believe to be founded in truth, and capable of furnishing much valuable guidance in the investigation and treatment of disease. In such copious extracts we may appear to have made too free with the pages of an author whose works are so generally known, but we could not resist the temptation of fortifying, by the authority of so distinguished a pathologist, principles which we have long maintained, and which we have endeavoured already to illustrate in the articles Gout and Plethora. They will suffice, we trust, to justify the assertion lately made, that whatever importance may attach to the exciting cause of acute rheumatism, the predisposition induced by a plethoric state of constitution is far more entitled to the practitioner's attention.

[As stated, however, in the article Plethora, M. Andral has pointed out the marked difference between the condition of the blood in it and in inflammation, and has shown that the increase of fibrin in it obeys the same laws as in the ordinary phlegmasiæ. He analyzed the blood of forty-three bleedings: in one of which the fibrin marked four, —the healthy proportion being three in 1000; in six, it marked five; in fifteen, six; in thirteen, seven; in three, eight; in three, nine; and in two, ten. When, however, the rheumatism was sub-acute, it oscillated between four and five; and when decidedly chronic, it did not exceed the healthy proportion. A recent writer, Dr. R. B. Todd, (*op. cit.*) regards both acute rheumatism and gout to be diseases of the blood, the phenomena of which are due to the presence of a morbid element in it, generated under the influence of particular causes, "by an abnormal chemical action of the blood itself."

It does not often happen that opportunities occur for examining the textures around the joints, whilst the rheumatic affection is active in them. As the disease rarely proves fatal, except by the supervention of inflammation in some of the fibrous or muscular tissues, seated internally, the mischief there is generally so predominant, that, for some time before death, the joints cease to be the source of suffering. Under these circumstances, it is not surprising that pathologists should differ as to the precise seat of acute rheumatism of the joints. It has been already remarked, that it invades every muscular and fibrous tissue, and that alternately the serous membranes may be implicated. Such may be the case in the articulations,—the synovial, which is a serous membrane, becoming affected last. On dissection, no decisive appearances may be met with. At times, the veins around the joints have been found gorged with blood; the ligaments, periosteum, and synovial membrane being injected, and thickened, with small collections of matter in the surrounding cellular tissue, and accumulations of pus or serum in the cavity of the synovial membrane. (Ferrus, art. *Rhumatisme*, in *Dict. de Méd.* 2de. édit. xxvii. 567, Paris, 1843.)

It is clear, that the hyperæmia of acute rheumatism—active as it is—can scarcely occasion any great organic changes, inasmuch as, in the course of a few hours, it shifts its seat, and leaves behind no evidences of its previous existence. This mobility has, indeed, given rise to the opinion, amongst many, that the disease is essentially seated in the nervous system; that the sanguiferous system is affected secondarily, and that it is very probable the nervous filaments of the diseased parts are more considerably involved than any other tissue. Dr. Mackintosh, (*Principles of Pathology*, &c. 2d Amer. edit. ii. 461, Philad. 1837,) who supports this view, remarks, however, that he has seen cases, which presented symptoms similar to those of rheumatism, in which, after death, the lymphatics of the limb were found inflamed, and filled with a puriform fluid. Some, again, have considered acute rheumatism to be nothing more than acute inflammation of the lining membrane of the arteries. The whole disease is certainly peculiar, and appears to be more neuropathic than ordinary inflammation. Its extremely changeable character sanctions this idea, and the remedies are not always those which we should think of prescribing in ordinary active phlegmasia.]

Diagnosis of acute Rheumatism. — This may be briefly disposed of. The only disease with which it is liable to be confounded is gout, in treating of which the distinctive character of each malady has been sufficiently noticed. Formerly discrimination in this respect was deemed of high importance, the prevailing theories of gout demanding a course of treatment very different from that to which rheumatism was subjected. In the present day a juster pathology of gout assimilates the treatment of both diseases sufficiently to render extreme accuracy of discrimination of very slight moment.

Prognosis of acute Rheumatism. — The

prognosis is so dependent on the promptitude with which suitable treatment is resorted to, that any remarks on the natural course or duration of the disease are of little worth. Generally speaking, there is little immediate danger to life, there being no inflammatory disease of equal intensity which so little deranges the vital functions. This, most probably, is owing to the disease expending its violence on the joints and other external parts, and being little prone to attack the viscera. The peculiar character of the inflammatory action too, and the little liability which it has to pass into suppuration, or undergo the other changes consequent to phlegmonous inflammation, may account for the safety with which even the metastasis of rheumatism to internal parts is borne. It is certain that such metastasis is not attended with so much danger as the severity of the symptoms would seem to denote. In early life we were often appalled by the metastasis of rheumatism from the joints to the heart, an organ more peculiarly liable to this transition than any other. More extended experience abated such fears, by showing that the immediate danger was by no means commensurate with the suffering experienced.

[Still, the pericarditis and endocarditis of acute rheumatism must be regarded as most dangerous complications—if they may be so termed—of the disease; for even if the patient recovers, which is often the case, from the immediate attack, cardiac lesions are apt to remain, which may lay the foundation for disease afterwards. M. Bouillaud (*Traité Clinique du Rhumatisme articulaire*, Paris, 1840,) has affirmed, that about one half of those who suffer under acute articular rheumatism are affected with pericarditis; and we know that endocarditis is a common accompaniment. One of the most important points, therefore, in the management of acute rheumatism is to watch the supervention of the morbid action in the fibro-serous tissues of the heart. It is not necessary to repeat here the symptoms of pericarditis and endocarditis (See PERICARDITIS); but the occurrence of dyspnœa, with more or less anxiety, jerking, or feeble and rapid pulse, and tumultuous action of the heart, ought to direct the attention of the practitioner to that viscus, and if he discover, by the physical signs and functional phenomena, the existence of inflammatory action there, it must be treated as if the disease were unconnected with rheumatism; for nothing is better established, according to M. Andral, (*Cours de Pathologie Interne*,) than that, although primary rheumatism, seated in the fibrous and muscular tissues around the joints, is remarkable for its great and rapid change of seat; secondary rheumatism—if it may be so termed—loses this mobility when it fixes upon a serous membrane.

Dr. Graves (*Clinical Lectures*, Amer. edit. Philad. 1842,) states, that rheumatic fever may exist without the affection of the joints; and that pericarditis may occur as a primary symptom before the appearance of the articular swelling. This is probable. The writer has certainly seen many cases in which the signs of pericarditis were amongst the earliest phenomena.]

If an attack of rheumatism be treated at the onset with due activity and discrimination, it may be relieved in a very few days without the affected joints sustaining any injury. But both with respect to time and local ravages, much will depend on suitable discipline being resorted to and adequately pursued, ere the specific inflammation of the joints becomes complicated with that which we have termed secondary. The specific inflammation we have repeatedly seen subside in twenty-four hours, leaving behind but little trace of its accession. When secondary inflammation, however, has been suffered to supervene, the case is materially altered, and greater obstinacy of local affection may be expected. It might be laid down almost as an axiom, that the severity and duration of the disease are proportionate to the degree of plethora present, the activity of inflammation, and the length of time during which the morbid actions are suffered to prevail unrestrained. If the plethora be great, inflammation high, and much delay take place in resorting to efficient means for correcting the constitutional derangements, then would it be difficult to assign limits either to the constitutional disturbance or local ravages, both of which may continue, though with abated force, for months or years, to undermine health and cripple the limbs; in other words, acute rheumatism may then pass into chronic of the most inveterate and intractable kind. Thus, though acute rheumatism rarely destroys life by its immediate seizure, however violent, this furnishes no excuse for supineness or inactivity in the treatment; for if not radically relieved in its early stage, the disease, even when of no extraordinary violence, may become so confirmed as to yield afterwards with difficulty to the most active and judicious use of remedies, while progressive disorganization of joints may entail protracted suffering and lasting decrepitude.

It is true that a slight rheumatic seizure may, like a gouty paroxysm, pass away without medical interference, the efforts of the constitution sufficing for relief. But this is not its general character; and to rely on such a contingency would be in the highest degree rash and inexcusable. Whenever an attack of acute rhematism occurs, the constitution must need some relief, which enlightened practice will never withhold. To neglect of this principle may be ascribed a very large proportion of the decrepitude which the victims of rheumatism so continually present. There is no truth of which we are more thoroughly persuaded, than that if rheumatism were at its onset treated as its real nature demands, and if due care were afterwards taken to guard against its recurrence by prophylactic measures judiciously directed and adequately pursued, there need not from this malady be one case of disorganized and crippled joints for every hundred that are so afflicted. The effects of the earlier treatment will, therefore, in general, decide the prognosis. There is inflammatory fever to subdue, local inflammation to remove. If early bloodletting in subduing the fever make prompt impression on the local affection, so that both pain and swelling quickly subside, thus marking the local inflammation as still retaining its specific character unmixed with secondary effects, speedy and effectual relief may be con-

fidently predicted, medical treatment judiciously conducted being fully capable of ensuring it. When febrile action is inveterate, and it is oftentimes very obstinate, though chiefly so when the earlier periods of disease have been neglected or inadequately treated, a tedious progress may be expected, for so long as fever remains unsubdued are the local inflammations incapable of removal, either keeping their ground unmitigated, or if abated by topical remedies, continually recurring. Again, when abatement of fever is not followed by quick subsidence of local swellings, in consequence of the latter having passed into the secondary stage, and especially when effusion and organic changes have already taken place in the affected joints, then is the restoration of the joints much more tedious, though great local derangements will admit both of speedy and decisive relief, provided the local mischief be not rendered inveterate, or continually renewed by unsubdued fever.

Much, too, depends on the state of constitution in which acute rheumatism occurs. In a healthy subject, capable of bearing the depletory and other treatment required for relief, great reliance may be placed on the efficacy and certainty of the curative process. When the constitution is depraved by long-continued relative plethora, with its attendant febrile excitement, and especially if the feebleness, natural or acquired, be such as to render caution necessary in carrying bloodletting and other remedial processes to the requisite extent, more protracted disease and more tedious recovery must be the natural and inevitable consequence.

It is said that rheumatic inflammation does not tend to suppuration or gangrene, and the remark is generally true. Yet we have seen abscess of the cellular membrane supervene on rheumatic inflammation, and we have also witnessed sloughing ensue when leeches have been applied to a highly inflamed joint without adequate constitutional treatment being conjoined. The most frequent consequences are, gelatinous effusion into the bursæ, thickening and rigidity of the ligaments and other membranes surrounding the joints, contractions of the limbs, and wasting of the muscles, all of which will come under consideration in the latter part of this essay, where it treats of chronic rheumatism.

Treatment of acute Rheumatism.—The indications are here to subdue fever and remove inflammation. It has been already shown that the former claims the first consideration. The promptitude with which the local inflammation in its earliest stage yields to the treatment by which a plethoric state of constitution is corrected, and febrile action allayed,—and the obstinacy of the local ailments, whenever the constitutional state is overlooked or inadequately treated, furnish the best proofs of the correctness of this pathology. In its simplest form and early stage, acute rheumatism is speedily and effectually relieved by antiphlogistic treatment, properly directed and adequately pursued. Bleeding, purging, salines with antimony, diluents, and abstinence, suffice both for subduing the general fever and removing the local inflammation. It continually happens, however, that these means, however actively or perseveringly employed, will not succeed in re-establishing health; a lurking fever remaining unsubdued, the blood retaining its buffy crust even when the crassamentum is reduced far below its natural and healthful proportions, and the local inflammation maintaining its hold of the affected joints. Further means are then required, which will be noticed in their proper place. The treatment of the simple and more manageable form must be first discussed.

One of the earliest practical writers on this complaint was Sydenham; and so direct and judicious was his practice, that we cannot do better than to make it the text on which to comment in treating this part of the subject. Sydenham's theories of disease often involved the pathological fantasies prevalent in his day; but it is his signal merit that he never suffered them to mislead him from the path which his clear discernment and practical experience enjoined him to follow. He attributed the local affection to "the derivation of the febrile matter to the limbs," which, as he observes, "the frequent return of the fever from the repulsion of the morbific matter by external remedies sufficiently shows." But we cannot perceive that he was influenced by this hypothetical principle, further than to adduce it in explanation of facts which his experience had taught him. He had witnessed the inefficacy of local treatment, and also the increase of constitutional disturbance which resulted when this alone was trusted to, and he wisely abstained from repellent applications. Having described the disease with some of its modifications, he gives the following concise instructions for its cure. "Since both kinds of this disease seem to arise from inflammation, as appears from the concomitants just mentioned, and especially by the colour of the blood taken away, which exactly resembles that of persons in pleurisy, which is universally allowed to be an inflammatory disease, so I judge that the cure ought to be attempted only by bleeding, the heat of the blood being in the mean time abated by cooling and thickening remedies along with a proper regimen. Accordingly, as soon as I am called I order ten ounces of blood to be immediately taken away from the arm of the side affected, and prescribe a cooling and incrassating julep. To ease the pain I order a cataplasm prepared of the crumb of white bread and milk tinged with saffron, or a cabbage-leaf to be applied to the part affected, and frequently renewed. With respect to diet I enjoin a total abstinence from flesh, and even from the thinnest flesh broths, substituting in the place barley-broth, water-gruel, panada, and the like. I allow only small-beer for drink, or, what is more proper, a ptisan prepared of pearl-barley, liquorice, sorrel-roots, &c. boiled in a sufficient quantity of water, and I allow the patient to sit up some hours every day, because the heat which arises from lying always in bed promotes and increases the disease. The next day I repeat the bleeding to the same quantity, and in a day or two after, as the strength will allow, I bleed again. Then interposing three or four days, as the strength, age, constitution of the patient, and other circumstances indicate, I bleed a fourth time, which is generally the last, unless too hot a regimen has preceded, or heating remedies have been exhibited without necessity. But the use

of opiates requires more copious bleeding; and, therefore, though the pain be ever so violent during the whole course of the disease, yet when I intend to effect the cure solely by bleeding, I judge it highly necessary to refrain from opiates, because the disease is fixed thereby, and does not yield so readily to bleeding; so when such medicines are given too frequently, bleeding must in consequence be oftener repeated than is otherwise necessary. Besides, in the height of the disease, they do not answer the expectations we have conceived of them. Whilst the above-mentioned remedies and regimen are carefully continued, I inject glysters made of milk and sugar, between times on the intermediate days of bleeding, earnestly recommending the exact observance of these directions for at least eight days after the last bleeding; and then I prescribe a gentle purging potion to be taken in the morning, and in the evening a large dose of the syrup of white poppies in cowslip flower-water, whereby a check is put to the tumultuary motion of the blood which might otherwise occasion a relapse. This being done, I allow the patient to return by degrees to his customary way of living in relation to diet, exercise, and air; but, at the same time, caution him to refrain for a considerable time from wine and all spirituous liquors, salt or high-seasoned flesh, and, in general, from all food of difficult digestion. After having repeated bleeding as above specified, the pain greatly abates, though it does not go quite off; but as soon as the strength returns, which bleeding had greatly impaired, the symptoms will vanish, and the patient perfectly recover."

In the simplicity, fitness, and activity of the foregoing course of treatment, there is much to admire. It comprises the more essential articles of antiphlogistic discipline, bleeding and abstinence; it discourages the premature use of narcotics, which, when employed too early, or in substitution of depletory measures, only mask the symptoms even when they allay pain, while they too often exasperate the disease, rendering it both more violent and more obstinate. It also inculcates a salutary reserve in the return to animal food and fermented liquors. That under this simple treatment many would pass safely through the disease, there can be no doubt, although recovery would certainly be slower than it might be rendered. But cases continually occur in which this treatment would be utterly inadequate, the febrile action maintaining its ground, and the local inflammation migrating from joint to joint, notwithstanding the diligent employment of all the means which Sydenham's practice in the disease comprises. In this practice one great deficiency is observable, the use of purgatives in aid of bloodletting not being at all enjoined. For regulation of the bowels, clysters of milk and sugar are trusted to, and not until eight days after the last bleeding is a gentle purging potion prescribed. In this and other respects, later experience has added much to our means of combating acute rheumatism.

When this disease occurs in its most active state, the means suited for reducing plethora, abating fever, and checking the progress of inflammation, must be promptly and adequately employed; full bloodletting and active purging, with the united powers of colchicum and antimony, being required to lower the circulation and arrest the evils which inflammatory action when unrestrained is sure to occasion. The first procedure in respect both of time and importance is bloodletting. In many instances the use of this directed by Sydenham would suffice, but in many it would fail. As a rule of practice, therefore, Sydenham's directions in this respect are defective, as not embracing conditions of disease which are of frequent occurrence, and for which the depletion directed by him would prove utterly inadequate. Indeed, no express rule in this respect could be laid down, both the amount and frequency of venesection being in every instance dependent on the degree of plethora existing, the activity of fever and inflammation present, and the natural powers of the constitution to be acted on. The pathology of inflammation, and the use of bloodletting most effectual for subduing it, have been so amply discussed in the articles Gout and Plethora, that to recapitulate what has been already advanced on these points must be needless. We shall proceed, therefore, on the presumption of the principles inculcated in those articles being clearly comprehended, and in conformity with these principles state practically how the lancet can be most successfully used. In ordinary cases the loss of twelve, sixteen, or twenty ounces of blood may suffice to check disease and prepare the way for the subsidiary treatment. But if absolute plethora be considerable, inflammatory action high, and the constitution robust, blood must be drawn to much greater extent if adequate impression is to be made on disease. In such case the rule should be not to abstract any assigned quantity, but to carry the bloodletting to the extent of making a sensible impression on the force of circulation. Thirty or forty ounces of blood may require to flow ere this is effected, and so essential is the impression alluded to, that even large bleedings, if not carried to this extent, will fail to produce their full effect in restraining inflammatory action. It continually happens in cases of active inflammation, that notwithstanding the loss of thirty or forty ounces of blood, the pulse does not yield, but maintains its hardness, while the abstraction of a few ounces more, by inducing a disposition to syncope, completely checks the inflammatory action and abates the violence of the disease. By making the constitutional powers the measure of the depletion, less bleeding on the whole is needed; thus by this mode blood is virtually saved and unnecessary exhaustion prevented, a single venesection carried to the necessary extent being far more effectual than reiterated bleedings to a far greater aggregate amount, if these be respectively of insufficient extent. Bleeding to actual syncope is not desirable, but if inflammation be high, some impression on the pulse should be manifested. If this begin to falter, while nausea is felt, the lips grow pale, and perspiration begin to bedew the forehead, such bloodletting may be relied on for accomplishing all that this remedy is capable of effecting. This use of the lancet, however, can only be required where severity of symptoms with vigorous habit demands such active treatment. In a large pro-

portion of cases much more moderate depletion will suffice. From twelve to twenty-four ounces of blood may be regarded as the ordinary limits, and many repetitions are never advisable; for when bloodletting to such extent, assisted by purging and other febrifuge treatment, does not make sensible impression on disease, other more adequate means of arresting its progress must be resorted to. Blood may be drained away until the body is blanched and the crassamentum reduced to a tithe of its just proportions, yet febrile action will continue, inflammation be unsubdued, and the blood drawn be still buffed and cupped.

It is right to mention here, that although a full and hard pulse is generally attendant on acute rheumatism, yet the absence of hardness is no evidence of active inflammation not being present, or of bloodletting not being needed. If the general symptoms concur to indicate inflammatory action, then, though the pulse be soft and compressible, bloodletting is nevertheless essential, the blood drawn in such case being almost uniformly buffed and cupped, the pulse rising after venesections, and disease more rapidly subsiding.

[Of late years, the profession have been startled by the extent to which bloodletting has been recommended by M. Bouillaud (*Op. cit.*); bleeding *coup sur coup*, with the view of "strangling" the disease, to use his own expression. The writer has had recourse to it in what appeared favourable cases; but the results have not been equally happy; and it has seemed to him, that the too vigorous use of the lancet has occasionally rather favoured the shifting of seat, which has been so much dreaded. It can, of course, only be admissible in vigorous individuals, and even in them, a more sparing use of the lancet, with the agents to be mentioned presently, appears to be less liable to objection. There are cases in private practice, and most of those that are seen in our eleemosynary institutions, in which any abstraction of blood from the general system could not fail to prove injurious.

As an adjunct to general bloodletting, the tartrate of antimony and potassa has been highly extolled of late years, and there are cases in which its sedative influence has been highly advantageous. The writer has frequently prescribed it under the restrictions and inculcations mentioned under another head (See Pneumonia), and occasionally with the best effects. It has seemed to him, however, that the antimony has acted most beneficially when it produced nausea, and the nausea was kept up two or three days in succession.]

The next measure is to purge freely the stomach and bowels; and here again we must refer to what was formerly advanced on this subject in illustration of the necessity of suitable and adequate purging being employed in aid of bloodletting. As soon as may be after bloodletting, a full dose of calomel combined with antimony (either James's powder or tartarized antimony) should be given, and in a few hours after a cathartic draught. The bowels being well evacuated, diaphoretic salines with antimony and colchicum contribute much to allay fever, quieting the pulse, and promoting the several excretions.

One of the best forms of saline for this purpose is a combination of acetate of ammonia, camphor mixture, antimonial wine, and wine of the colchicum seeds, as in the following formula:

R. Liquor. ammon. acet.
Mist. camphoræ, āā f.℥ss.
Vin. sem. colch.
Vin. ant. tart. āā *m.* xx.
Syrup. aurant. f.℥i. *m.* fiat haustus quartis vel sextis horis sumendus.

The properties of colchicum and the best modes of administering it have already been so fully discussed in the article Gout, that to avoid needless repetition, we shall refer to what is there stated. It is only necessary to remark that the effect of colchicum on the bowels requires to be watched, for when it irritates them so as to excite active purging, its use must be discontinued. In our early trials of colchicum in gout and rheumatism, we were accustomed to give it in full doses, but, for reasons already explained, we have for many years discontinued them, the salutary effect of the remedy being fully attainable from the more moderate exhibition of it which has just been prescribed. When the use of it irritates the bowels, producing frequent watery stools, discontinuing the colchicum suffices in general for the relief of this disturbance; but should it continue troublesome, moderate doses of Dover's powder are sure to allay it. It has been surmised that the use of colchicum has through irritation of bowels led to ulceration of their mucous membrane, but this effect we altogether distrust. It must be a very rash use of the remedy which could produce any such effect, and where it has appeared to result, our persuasion is, that the membrane was in an advanced stage of subacute inflammation ere the colchicum was exhibited. We have given colchicum freely and extensively for many years, with caution certainly, though not greater than is required in the administration of every active drug, yet a single instance has never occurred to us in which we could trace any injury to its use, while its medicinal properties have rendered valuable aid, not only in gout and rheumatism, but in many other inflammatory diseases.

[Aconitia, delphinia, and veratria, have been used both internally and externally; and cimicifuga carried to the extent of producing catharsis, and even slight narcosis, has likewise been of service. Of the different revellents, cupping on the back, strongly recommended by Dr. J. K. Mitchell, has appeared to be most frequently attended with happy results. An idea has been entertained that this has been owing to the depletion and revulsion effected near the origin of the nerves that are concerned in the articular inflammation. Whatsoever view may be entertained as to this matter, it is unquestionable that the highly sensitive integument of the back is an excellent locality for revulsion in many diseases; and it is not necessary that the mischief should be directly or indirectly connected with the spinal marrow, or its sheath, to explain this. The writer has seen the intense suffering in the joints as effectively relieved by cupping over the loins as by any other agency.]

As the extent and repetition of bloodletting must depend on the activity of disease and vigour of constitution, so must the use of purgatives be regulated by the condition of the bowels, and the necessity for purging which the stools may evince.

So long as these are dark, slimy, fetid, and otherwise unhealthy, must purgatives be used; and the most effectual are those by which the morbid secretions of the alimentary canal are evacuated. Pills of colocynth, calomel, and tartarized antimony should be given at intervals, and, if necessary, cathartic draughts should be interposed. When fever declines, and the stools present a more healthy appearance, milder aperients will suffice. Under such treatment low diet and a cooling regimen are indispensable. Barley-water or toast-water is quite sufficient during the inflammatory stage. Animal food and fermented liquors of every kind are prejudicial, and should be carefully withheld.

The several means now pointed out will in many instances suffice to allay fevers, remove inflammation, and restore health. But cases occur in which neither fever nor inflammation can be thus subdued. If active treatment be not resorted to on the first accession of disease, or if it be not urged to the requisite extent, inflammatory action acquires an inveteracy which simple antiphlogistic treatment is quite unable to correct. In such circumstances bloodletting may be pursued until the patient become nearly exanguious, yet the blood will still be buffed and cupped, febrile action will remain unsubdued, and local inflammation continue to disorganize and cripple the joints.

Even in milder cases of this kind, although permanent injury may be averted, and perfect recovery ultimately ensue, yet the successive migrations of local inflammations prove harassing to both patient and practitioner. We have seen such inflammation traverse almost every joint of the body, attacking several a second and a third time before the disease yielded. When the progress is favourable, each successive inflammation becomes slighter, until towards the close a mere blush of redness marks the morbid effort.

But this course of proceeding is at best tedious and unsatisfactory, even where an issue so favourable as has just been mentioned is attained. Such result, however, is not to be relied on; for in the form of disease now considered, it will more frequently happen that unsubdued fever will exhaust the general powers, and inflammation inflict its ravages on the joints, producing effusion, thickening of ligaments, with enlargement, rigidity, or contraction. When, therefore, one or two full bloodlettings, assisted by purging, abstinence, and other means, fail to make adequate impression on the disease, it becomes necessary to call in other aids in order to prevent the exhaustion and other ills which repeated bloodletting would occasion. And fortunately one exists which is worthy of our fullest confidence. This is mercury, which, when judiciously administered and made subsidiary to bleeding and purging, is capable of subduing rheumatic inflammation with as much certainty as attaches to the operation of any remedy in any disease. The practice of arresting the progress of rheumatism by mercury has been before the public sufficiently to have made it more generally known and more justly appreciated than it appears to have been. It originated with Dr. Robert Hamilton of Lynn Regis, who published, in the Medical Commentaries of the year 1783, an interesting account of the success with which he had administered calomel and opium in the treatment of several inflammatory diseases. So far back as the year 1764 he had been induced to employ calomel for the cure of hepatitis. Its efficacy in the disease and in several other inflammatory affections led him to extend his views of its applicability, and to conceive that it was a suitable remedy for inflammation in whatever viscus or tissue this might be situated. He accordingly employed its aid with the best effects in inflammations of every part, and particularly in acute rheumatism. His practice in the latter was to take blood in proportion to the violence of the inflammatory symptoms and to the age and constitution of the patient; after which he exhibited calomel and opium at suitable intervals until the disease yielded, or until the influence of the remedy on the constitution was evinced by increased secretions from the salivary glands, bowels, or skin. If in twenty-four hours after the use of mercury was commenced, relief did not ensue, or if inflammatory symptoms continued unabated, he bled again, and gave the calomel more frequently. Salines, antimony, camphor, and other auxiliaries were combined with bleeding and mercury, and through their united agency he found disease subside with a promptitude which no other mode of treatment could command. When this treatment was employed early in the disease, recovery was soon accomplished; if postponed to a later period, its effects were more tedious and uncertain. His experience also taught him that the curative process was most favourable when the salivary glands became affected by the medicine. This brief account of Dr. Hamilton's rational and effective practice in rheumatism embraces so many essential points of the treatment of this disease, that we shall have little to add save the detailed instructions which the young practitioner may need for conducting that treatment with discrimination and effect. In confirmation of the truth and accuracy of Dr. Hamilton's views, we may here remark, that having for five-and-twenty years pursued the practice and applied the principles which he inculcates, our faith in them has never wavered, and that with ample opportunities for subjecting them to the test of experience, we can truly say that we know of no fact in medicine better established than the power which mercury possesses of subduing inflammations, when used as subsidiary to bleeding and purging.

Every case of acute rheumatism does not require mercury for its cure. Bleeding, purging, abstinence, and salines, with antimony and colchicum, will frequently suffice. But if, after twenty-four hours, the early discipline has not produced sensible effect on the disease; if after this period fever continues unabated, inflammation unallayed, and further bloodletting be required; as obstinacy of disease is here sufficiently announced, it is expedient to lose no more time, but to resort to the only means by which an adequate check can be given to the malady.

Profuse use of mercury is not needed; both the amount of dose and frequency of exhibition must be determined by the circumstances of the particular case. Although it is desirable to obtain evidence of the constitution being affected by the remedy, so far as tenderness of gums indicates, it is not expedient to produce this effect very speedily,

and there are many reasons for enjoining caution in the administration of this medicine. It is not necessary to urge on its full operation, for the curative effect commences ere the specific action on the salivary glands appears. Unless the plethoric state of constitution, too, be adequately relieved by depletion, there is considerable risk of pressing the use of mercury. On this subject we must once more refer to what has been already advanced respecting it in the article PLETHORA. The susceptibility of impression from mercury, too, varies greatly in different persons, so much so, that while some cannot be salivated by any quantity, a few grains of calomel will in others induce severe ptyalism, with inordinate swelling of the jaws and extensive sloughing. On every account, then, it is advisable to incline to the minimum quantity capable of acting on the disease. The expediency of combining opium with calomel, when exhibited for this purpose, admits not of question. When thus conjoined, it allays pain, abates irritability, prevents the calomel passing off too quickly by the bowels, and promotes its more certain absorption. In general, two grains of calomel and a quarter of a grain of opium is a sufficient dose, and the frequency of its exhibition will be best guided by the severity and threatened obstinacy of the attack to be combated. In severe cases it is beneficial to commence with five grains of calomel, one of opium, and one of tartarised antimony at bedtime, and to pursue the course the next day with the smaller dose. In mild cases it may suffice to give this night and morning; to administer it thrice a day is no inactive practice, and by this use the gums will in general soon become affected. Given every six hours, so that, in the four-and-twenty, four doses are taken, is perhaps the frequency that will most commonly be needed. We have never had occasion to enlarge the dose, nor to exhibit it oftener than every four hours; but to this extent we have been occasionally compelled to employ it. The cases, however, requiring the active use of it are rare. The circumstances to guide its use are the curative effects on the constitutional and local symptoms, and its specific effects on the salivary glands, bowels, and skin: if any of these be signally induced, the use of it should abate, and the intervals of its exhibition be lengthened. Unless active salivation take place suddenly, and unexpectedly, it is never expedient to withdraw it wholly so long as fever lurks or inflammation keeps its ground. The best practice is to lengthen the interval, and to do this progressively by reducing the employment from four times a day to three, then to twice, and finally to continue a single dose daily for a short time. By this cautious proceeding, if bloodletting be adequately practised, the bowels freely purged, and no error in diet committed, the beneficial effects of mercury may be ensured without any risk of injury and scarcely of inconvenience. Should salivation chance to advance beyond what would be wished, the evil is but a slight counterbalance to the benefit which mercury confers in the case of this most painful and disorganizing malady. When the mouth becomes painfully affected, we may here remark that saline purges abate the distress, and that gargles of chloride of soda or of nitrate of silver have considerable power in allaying the morbid sensibility of the gums and tongue which is sometimes experienced. There are constitutions on which mercury acts so unfavourably, producing great derangement of the nervous system, that its use cannot be borne. When such sinister effects occur, its use must of course be abandoned; but such instances are not common, and when they do occur, we strongly suspect that neglect of early depletion is more in fault than any idiosyncrasy inimical to the remedy.

While mercury is exhibited in the way directed, the salines formerly prescribed should be continued, and occasional purges should be interposed. The use of the latter should be regulated by the degree of fever and the state of the stools. If fever continues high, with a dry tongue and costive bowels, or if the stools be very dark and slimy, purgatives must be the more freely used. When the bowels are unusually torpid, it is often expedient to substitute for the diaphoretic saline a solution of sulphate of magnesia in rose infusion, giving this at such intervals as shall keep the bowels free. It is generally conceived that purgatives impede the constitutional operation of mercury, and in consequence, when this operation is the object in view, purgatives are usually withheld. Without discussing this point, we shall merely observe that if the degree of fever or the foulness of bowels demands purging, it should be carried to the full extent required, without regard to its supposed interference with the effects of mercury. Under such circumstances greater injury would result from the neglect of purging, than even the unimpeded action of mercury would compensate.

There are cases in which it is not expedient to combine opium with the calomel, but they are rare. If headach prevail,—if the tongue, instead of becoming moist and clean, grow parched and dark, and the skin be hot and dry,—opium should be withheld, and the calomel given either alone or conjoined with James's powder.

[Opium has not unfrequently been given in acute rheumatism, with the view of inducing narcosis, and of establishing a new impression and action on the nervous system. Care must, of course, be taken not to push the remedy too far, and yet to keep the patient clearly under its influence. With this view, any of the preparations of opium may be prescribed; but the soft pill is as efficacious as any other; or the acetate or the sulphate of morphia or the pulvis ipecacuanhæ compositus; but the last can be seldom given in quantity sufficient for the opium to produce its narcotic action, without the ipecacuanha disordering the stomach.]

The progress of recovery and the experience of a few cases thus treated will readily guide the practitioner in that adaptation of remedies to the exigencies of each case which no specific rules could prescribe. He who possesses himself of the principles on which the treatment here directed is founded, will commit no error in the extent or duration to which he may carry it.

There is a period, however, in the progress of rheumatism, even when actively and judiciously treated, which calls for something more than has yet been enjoined. In a large proportion of cases, the treatment now prescribed will fully suffice. It will subdue fever, remove local inflammation, pre-

vent disorganization of joints, and restore the patient in moderate time to health and the free exercise of limbs. But it occasionally happens that notwithstanding the full employment of all the means directed, a certain degree of fever lingers, the skin continues dry with some morbid heat, the tongue too white, and pains of acute character are still felt in the joints. When this state first met our view, so completely did the assemblage of symptoms simulate active inflammation, that we hesitated whether there was not an actual relapse of disease, and a necessity for reverting to active remedies. But the indecision was of short duration; for assured by the treatment already pursued, and the effects produced by it, that inflammation had been successfully combated, we could not regard the supervening state as corresponding in its nature to that which we had already corrected, and instead of recurring to bleeding and mercury, we made trial of bark as a preferable agent, and with such benefit, that we have seen it remove, in twenty-four hours, the whole train of symptoms which we have just mentioned. Half a drachm of bark with ten grains of nitre is the combination on which we most rely, giving this twice or thrice a day; and so effectually does it answer the purpose that we are slow to change it. What we have now stated may serve to explain the confidence with which some writers have advocated the use of bark as almost a specific in rheumatism. There is undoubtedly a stage of the disease in which it may be beneficially given, but in the acute stage, to which we have hitherto chiefly referred, we at least would not compromise the patient's safety by trusting to bark, while bleeding, purging, and mercury were applicable; and even in what is called chronic rheumatism we would as little rely on it so long as plethora was unrelieved, the pulse high, the bowels loaded, and active fever predominant. When the general state of constitution is restored to the proper balance of its several functions, should some febrile indications linger, and pains continue to infest the joints or muscles, bark furnishes then a valuable and unexceptionable means of correcting the slight remnant of disease, but not before.

[The writer has had frequent opportunities for witnessing the exclusive use of both modes of treatment, antiphlogistic and tonic, and it is but proper to say, that he does not recollect to have seen the symptoms in any case aggravated, under the prudent employment of either. In the mass of cases that occur, except in very active, vigorous habits,—and it is generally applicable even to them,—a combination of the two modes of treatment has appeared as advantageous as any other,—treating the disease during the early period, by the ordinary antiphlogistics, and afterwards endeavouring to remedy the neuropathic condition by the cautious employment of tonics, as the sulphate of quinia. Dr. D. Davis, late Professor in the London University, has expressed a confident belief, that cinchona "is the most powerful remedy that can be employed even in an incipient case of acute rheumatism, and affirms, that he does not remember a case in which the disease was not happily subdued. "I have often recommended it," he adds, "in cases of pure arthritic rheumatism during its acutest stage, and the disease has always yielded to the remedy; and I have also recommended it in violent pains of the joints, accompanied by alarming complications; but never in any one case injuriously to the interest of my patient. I have, therefore, no difficulty in recommending its adoption to my medical brethren, and especially to those who are most frequently favoured with opportunities of seeing acute rheumatism in its earlier stages." Dr. Davis prescribes the cinchona in the dose of from a scruple to half a drachm, repeated three or four times daily. He always, however, premises the free abstraction of blood. (See, also, Popham, *Dublin Journal of Medical Science*, Sept. 1844, p. 50.) M. Briquet, and others, have advised large doses of the sulphate of quinia—from ʒi to ʒiss in the course of the 24 hours; and, they affirm, with unusual success. M. Briquet considers, from his observation, that the sulphate is a powerful sedative, diminishing nervous excitability, retarding the pulse, and lowering the temperature. It has been objected by M. Devergie to this plan, that it is apt to cause serious disturbance in the functions of the brain and organs of sense; but care in regulating the dose may prevent this.]

The cure of rheumatism by profuse perspiration has fallen so much into disuse that it can hardly be necessary to notice it. Yet it was held in high estimation not many years back, and very generally deemed the most effectual mode of treatment. The late Dr. Gregory, in his lectures, used to represent sweating as the evacuation most to be relied on for the cure of rheumatism, and to bear his testimony to its efficacy. He gave a caution, however, against resorting to it until the pyrexia had been abated by bloodletting, and stated that his test was, never to employ it until the pulse was reduced to 100. The chief agent was Dover's powder, given in doses of ten grains every two or three hours, assisted by warm covering and copious diluents, the latter to be used only when the perspiration commenced. To be effectual, this required to be kept up for forty-eight hours. This practice has, we believe, been very generally, and, as we think, judiciously, laid aside, the treatment recommended in the foregoing pages being far more certain and effectual, producing less exhaustion, and leaving less susceptibility to recurrence of disease.

[Recently, iodide of potassium has been recommended both internally and externally, and the treatment by large doses of nitrate of potassa, so highly advised in the last century by Dr. Brocklesby, has been revived, and, it is said, with much success,—from a quarter of an ounce to an ounce being given dissolved in a large quantity of gruel in the twenty-four hours.]

We have hitherto treated chiefly of constitutional disorder, and have considered the local inflammation only so far as it was connected with or dependent on the constitutional state. It is necessary, however, to scrutinize the local affections still further. So directly is the local disturbance dependent on the constitutional in the incipient stage, that if the latter be promptly and vigorously treated, the former will very speedily subside without any local treatment being needed. We have seen the local inflammation thus subside in rheumatism equally as in a first attack of

mild gout, leaving as little trace of its visitation. It must be admitted, however, that such speedy decline is not the general character of this local affection. Notwithstanding the abatement of fever, some pain, heat, and swelling will continue to affect the joint for a longer or shorter time; and in order to understand the treatment which this requires, it is necessary to bear in mind what was formerly stated respecting the change of character in the local inflammation. If on fever becoming subdued by the means directed, the local inflammation declines, no topical treatment whatever is needed, nor is it expedient that any should be resorted to. Decline of inflammation thus obtained affords conclusive evidence of disease being arrested at its source, and relapse need not here be apprehended; while, if the local inflammation be checked by topical remedies, its abatement affords no such assurance, and if the constitutional derangement be not thoroughly rectified, repeated renewal of the local inflammation with successive migrations from joint to joint will most probably ensue. But independently of this consideration there are other objections to the early use of topical remedies which ought not to be overlooked. Repellent applications may remove inflammation from any particular part; but only to transfer it to some other, if not to the heart, stomach, or other internal organ. Local bloodletting would beget less danger of this kind, but neither is it free from objection. The inflamed part is ill suited to sustain the operations by which blood can be abstracted. We have seen leeches when applied to a rheumatic joint prematurely and without sufficient regard to the constitutional state, exasperate every symptom, and cause increase of inflammation both in the skin and cellular membrane, ending in extensive sloughing, with troublesome ulceration, and followed by thickening of the ligaments with rigidity and contractions of unusually obstinate kind. So long as it is possible, therefore, to procure decline of local inflammation by the constitutional treatment, we consider it the better practice to abstain from topical remedies.

When inflammation continues in the joint, however, after fever has been sufficiently subdued, thus manifesting its having passed into what we have distinguished as the secondary state, it then becomes necessary to regard it as a local disease, and by appropriate topical treatment to avert those ravages which its continuance would occasion. The means are cupping, leeches, warm fomentations, poultices, cold lotions, modified according to the degree of inflammation, the sensations of the patient, and the effects produced. By such means, the local inflammation in this its secondary state may be so corrected as to prevent organic lesion, and preserve unimpaired the mobility of the joint.

[The application of methodical compression around the affected joints by means of a flannel bandage is often productive of great relief. It was advised many years ago, and has been revived. (See the writer's *New Remedies*, 4th edit. p. 183, Philad. 1843.) It is especially serviceable where there is great effusion. It has been recommended, that the compression should be made by means of compresses covered with mercurial cerate; and that a position and attitude should be given to the limb that would be most favourable to resolution. An elevated position would certainly tend to prevent the engorgement of the parts. The writer has seen good effects from compression where it could be borne, and a simple flannel bandage is all-sufficient.]

We would here impress, as we formerly did when treating of gout, the importance of an early renewal of motion in the affected joints, as indispensable for re-establishing their health and preserving their flexibility and power. From neglect of this, much protracted confinement and ultimate decrepitude continually result. On the subsidence of inflammation, the parts so lately disturbed are indisposed to motion, and some pain attends the early attempts at its removal. Yet leaving them at rest is not the means by which the power of motion is best restored. Exercise of the parts is necessary not only to restore those which have been morbidly affected to their healthy functions, but to preserve in due energy and activity the muscular apparatus by which they are moved. By exercise healthy circulation is maintained, effusion prevented, absorption promoted and flexibility preserved. By it, too, the muscles subservient to the motions of the joint are kept in a healthy and efficient condition. When, from too great apprehension of exciting pain or renewing inflammation, quiescence is too long continued, the ligaments and other parts surrounding the joints become rigid; if these be kept bent, contractions take place, and the mobility of the part becomes permanently impaired; while the several muscles, from want of exercise essential to the maintenance of their nutritive and healthy actions, progressively waste and lose power. This latter contingency is, we are persuaded, much more frequently owing to the continued inactivity to which the muscles are consigned than to any morbid action induced in them by the disease; and as we before observed, so satisfied are we of the mischiefs resulting from long-continued rest after rheumatic inflammation, that we would in our own person much rather hazard any renewal of inflammatory attack, than suffer those derangements to proceed which spring from a state of inaction too long continued.

[Capsular Rheumatism. — When rheumatism is seated in the lining membrane of the joints, and bursæ of the tendons, it is termed *capsular*. The parts most liable to its attacks are the feet and hands. It is recognised by the enlargement of the joints, which is circumscribed, owing to the distension of the synovial capsule with fluid; and is thus distinguishable from the smaller and more diffused swelling of ordinary rheumatic fever. In its history, too, it differs generally, as Dr. Macleod (*On Rheumatism, &c.*, London, 1842) has observed — affecting several joints, but commonly becoming more especially fixed in a limited number, and ultimately localized, and, in some cases, inducing permanent changes of structure, or disorganization. When death occurs in the acute stage, the joints are found to contain an increased quantity of synovia: when the disease has been more prolonged, distensions and nodosities are seen, similar to what occur in gout. Deposits are often formed in such cases on the cartilages of the joint,—which

Dr. Macleod found to be of urate of soda, as in gout. In cases of old synovial rheumatism, however, Dr. Chambers found them to consist of carbonate of lime. At times, suppuration has been observed in the joint; but these cases are rare.

Partial rheumatism of the joints, when of great intensity, is almost always of the capsular kind.

This form of rheumatism is said to occur generally in persons of feeble or debilitated constitution; or in the robust, after great and protracted mental or corporeal exertion. It is said, also, to supervene on gonorrhœa and other venereal affections, but in the latter case almost exclusively, according to Dr. Macleod, "where long-continued courses of mercury have been adopted." It is very rare for metastasis to take place to internal organs, and when it does, it usually passes to the pleura or membranes of the brain, and proves fatal in a very high ratio. Of 81 cases of capsular rheumatism, recorded by Dr. Macleod, 47 occurred in men, and 34 in women. These were much more equally diffused over the different periods of adult age than acute rheumatism, and much more prone to affect persons under forty than genuine gout; at the same time, it appeared to be more the disease of middle life than either rheumatic fever or muscular rheumatism; — from forty to forty-five years of age giving twenty-two out of eighty-one cases, or rather more than one-fourth, which is a much larger proportion than holds good with respect to either of the two others."

The average duration of capsular rheumatism was found to be more than twice that of acute rheumatism.

The general treatment, both internal and external, is that recommended under Rheumatism and Gout.]

What remains to be said respecting acute rheumatism, and the sequelæ occasionally left by it, will be more properly noticed in the division of the subject which treats of the chronic form of the disease, to the consideration of which we shall now proceed.

II. Chronic Rheumatism.

It would simplify the consideration of this form of the disease, if it were limited to that morbid condition to which analogy with the acute affection discussed in the foregoing pages would justify the name of rheumatism being applied. So many and various, however, are the derangements loosely classed under this generic term, that to give any history of the disease which should comprise the whole, would present a mass of confusion, if indeed it were not utterly impracticable. It has been too much the practice to pronounce as rheumatic every chronic pain of which the nature is obscure, or to which no other specific character is assigned. Practical writers have not overlooked this tendency; it is noticed by Heberden in the following very expressive passage: "Multi dolores quibus nomina nondum propria imposita sunt, quanquam inter se distent, ex causis longe diversis orti, tamen ad rheumatismum pariter referuntur." In order to ensure as much clearness as possible in the following observation, it will be expedient to commence with that modification of disease which, presenting all the essential characters of rheumatism, differs from the acute affection already treated of only in being less violent in its symptoms, and of longer duration.

The distinctive characters of this malady are a febrile state of the general system, with more or less of pain and swelling in certain tissues and joints. And in this, precisely as in acute rheumatism, the continuance of febrile action undermines the general health, while the local inflammation, however indolent, disorganizes the joints, occasioning eventual decrepitude. The pain and swelling of joints with progressive thickening of the ligaments, and effusion in the several bursæ, sufficiently evince the morbid actions from which such effects result. But, coincident with these will generally be found in the instances now referred to, evidences of constitutional derangement sufficiently marked to denote that a plethoric and febrile state of the circulation is also present. A quickened pulse, some increased heat of skin, and a furred tongue, are in greater or less degree the invariable attendants of chronic rheumatism of the joints so long as the disease in them continues to advance. It, no doubt, occasionally happens that in the course of time all febrile symptoms disappear, and the morbid action in the joints ceases to make further ravage. In such cases there is no longer rheumatism, but only the disorganization produced by it; and the distinction is important, for where such ravages alone remain, so far as they are concerned, constitutional remedies can be of no avail, and any treatment, to be effectual, must have special reference to the local lesions by which the free motion of the limbs is impeded. In the larger proportion of cases, however, the disease is strictly rheumatic, that is, it consists of a constitutional derangement having a febrile character, and of a local inflammation seated in the joints. This condition may be, and frequently is, the sequela of acute rheumatism; but it may be fully formed without any particular acute attack having preceded. Cullen regarded it in the former light, as appears from his definition of arthrodynia being introduced as "rheumatismi sequela." In the definition itself he somewhat incongruously represents this as ensuing to violent sprains and luxations, though why the pains resulting from such accidents should be deemed rheumatic it is difficult to imagine. In this definition, too, which ought to embrace every form in which chronic rheumatism presents itself, he states somewhat too positively the absence of fever and of swelling, — "pyrexia nulla, tumor plerumque nullus;" characters which do not apply generally to the disease, and which seem to have been introduced as an antithesis to the definition of acute rheumatism. This imperfection obliged him, when treating of chronic rheumatism, to enter into explanations rather at variance with his own definition, and in the following passage he describes more correctly and intelligibly the transition of the acute into the chronic stage. "The limits between the acute and chronic rheumatism are not always exactly marked. When the pains are still ready to shift their place, — when they are especially severe in the night time, —when at the same time they are attended with some degree of pyrexia, and with some swelling, and especially with some redness of the joints, the disease is to be considered as still partaking the nature of acute rheumatism. But when there is no degree of pyrexia remaining, — when the

pained joints are without redness, when they are cold and stiff,—when they cannot easily be made to sweat, or when, while a free and warm sweat is brought out on the rest of the body, it is only clammy and cold on the joints,—and when especially the pains of these joints are increased by cold and relieved by heat applied to them, the case is to be considered as that of purely chronic rheumatism." If the character of chronic rheumatism is to be derived from the most numerous and predominant instances, then we would say that the former of these descriptions is far more applicable to the disease, as generally met with, than the latter; for though all the phenomena recited as indicating the continuance of febrile and inflammatory action may not attend, it rarely happens that some or other of them are not present. As the former condition is capable of indefinite duration, for it may endure for years, and is hence strictly entitled to be called chronic,—it could not, where any distinction were made, be classed with the acute disease lately treated of; while, if it constitute any part of the chronic malady, a definition professing to characterize this ought assuredly to embrace it. Perhaps the more perfect representation of the disease, if it be necessary or beneficial to make any such distinction, would be to include both descriptions under arthrodynia, subdividing this into sthenic and asthenic. In this view the sthenic arthrodynia is by far the most frequent form in which the disease presents itself; and, what is no less important, it is that which, if unrelieved or improperly treated, is productive of the greatest mischief and of most distressing results; for under it the disease both local and constitutional, however indolent it may appear, is yet sufficiently active to continue and extend its peculiar ravages, deranging the general health, enfeebling and crippling the body through progressive disorganization of joints, and consequent wasting of muscles. In the asthenic form, the mischief is already done, and, however the body may suffer under the ravages sustained, there is no longer the active constitutional derangement inflicting further injury, which forms so essential a part of rheumatism. In the latter form there is little to do but support the general health, and remedy, as far as may be, the local lesions. But sthenic arthrodynia both admits of and demands more corrective treatment, the judicious, discriminating, and persevering use of suitable remedies being capable of accomplishing much, both in renovating health, and restoring power of motion to the still inflamed though rigid and contracted joints. With the consideration of this form we shall now proceed.

[The chronic form of rheumatism is often described as being frequently the sequel to the acute. This does not accord, however, with the experience of the writer. So far as his observation has gone, the subjects of acute rheumatism rarely suffer from the chronic form; and, on the other hand, persons who are constantly more or less crippled by chronic rheumatism may pass through life without suffering from the acute.]

It is a prevailing impression that a chronic disease cannot be inflammatory. How this originated it is needless to conjecture; but, however the misconception arose, it is a familiar truth that the term chronic conveys to most minds not the simple idea of duration, which alone it expresses, but something the opposite of inflammatory; some state to which the treatment proper for inflammation cannot be applicable. The pure chronic rheumatism of Cullen as described in the foregoing extract, is unquestionably of this latter character; but as the disease comprises, in addition to this, the subacute or sthenic condition also noticed by him, it is necessary to understand the term chronic, when its application is thus extended, in that restricted sense alone which rightly belongs to it.

Practitioners who are accustomed to regard chronic rheumatism as asthenic, and to treat it accordingly, are little aware of how long a decidedly inflammatory character may attach to it. Years may elapse, yet a distinctly febrile state, indicated by its appropriate phenomena, prevail, accompanied with evidences of disorganizing inflammatory action on the joints. And so long as this state endures, is there progressive deterioration of general health, and increasing structural derangement of joints. It gratifies the writer of this article to see this fact unequivocally stated by Dr. Elliotson, in his excellent clinical lectures delivered at St. Thomas's Hospital. He acknowledges the inflammatory character, and also the great length of time for which this may be retained, specifying this form of rheumatism as active in contradistinction to the term acute, which in its strict sense could not apply to it. The same character was long ago indirectly recognised by Sagar, when, in his definition of chronic rheumatism, he stated the blood drawn to exhibit a buffy crust. In this form, however subdued the symptoms may be, the characteristics of rheumatism, as they have been exhibited in the acute disease, are distinctly traceable. There is a febrile state of the general constitution, and more or less of inflammatory action in the joints; and the principles of treatment are precisely similar, though they require to be modified in their application so as to adapt this to the derangements, both constitutional and local, which need relief. It will assist in comprehending the real nature of this form of the disease to bear in mind what was formerly stated in treating of relative plethora. Certain delusive appearances were then noticed, as misleading practitioners from a right conception of the state of circulation or condition of health existing; and to similar delusions has it been owing that the febrile character of active or sthenic arthrodynia has been so frequently overlooked. An apparently feeble and compressible pulse induces the persuasion of debility; the enfeebled powers of the body sanction the conclusion; and relief is sought from a class of remedies which, in such case, cannot give other than transient relief, if, indeed, they do not aggravate every symptom. Were we sure that the doctrines of plethora formerly illustrated were rightly understood, we could at once close the discussion of the constitutional state prevailing in sthenic arthrodynia, by representing it briefly as that of relative plethora. It differs from the condition formerly described as relative plethora, only in having the local inflammations with their consequences superadded. In order to determine accurately this state of constitution, it is necessary

to judge, not from any one indication, but from that assemblage of evidences which, when collectively present, cannot mislead. The pulse, if alone trusted to, may deceive, at least where the practitioner is not on his guard against the delusive lowness of pulse which belongs to incipient plethora, or is unacquainted with the peculiar changes which the pulse undergoes when the congestive state is passing into that of febrile action. Though apparently low in force, it yet evinces some resistance to pressure, and is more or less quickened; the skin, too, is hotter than natural, and the tongue is white and furred. The gastro-intestinal membrane will also be found charged with redundant mucus, such as it generally secretes under febrile action. When all these phenomena are present, and especially when they are accompanied by evidences of local inflammation in the joints, no doubt need be entertained either of the nature of the disease, or of the principles of treatment. In this form of disease, then, it is obvious that the indications of cure are in no respect different from those which have been already shown as applying to acute rheumatism, namely, to subdue fever, and remove local inflammation. And the rationale of the practice suited for fulfilling these indications will be clearly perceived by those who have taken the trouble to comprehend the doctrines respecting the pathology of the circulation advanced in the article PLETHORA.

The constitutional state of sthenic arthrodynia bears the same relation to relative plethora that the acute form does to absolute; and in the principles of treatment laid down for the correction of relative plethora, with its concomitant disturbances, will be found the best guidance for conducting with precision and effect that of active chronic rheumatism. On the same principle as in acute rheumatism, it is the constitutional state which demands the first attention; for, unless this be radically corrected, all efforts to cure permanently the local ailments must fail, or be only of transient effect. In treating the constitutional disturbance, it is necessary to bear in mind that it is connected with relative rather than absolute plethora; that, consequently, the derangements existing are more complex, and that the practice must hence embrace considerations which it was not necessary to insist on particularly in discussing the acute disease. In acute rheumatism, active bloodletting was directed; the object being not only to reduce plethora, but to make speedy impression on febrile action, in order to arrest promptly the injuries which unrestrained continuance of this would occasion. In the more chronic form it is necessary to diminish plethora, but not equally so to make so speedy impression on febrile action. This latter requires to be regulated, but not extinguished; for some increased energies of circulation are absolutely necessary for correcting the concomitant derangements of function produced by defective capillary circulation. To restore the impeded circulation of the capillaries, and renew the secretory and excretory processes of which they are the agents, seems to be the final cause for which febrile action is instituted; it is assuredly the end which it often attains, and hence, when natural fever fails to accomplish it, we are accustomed to institute an artificial fever through the operation of mercury to effect the purpose. This, however, is not to be forced; it requires time for safe and salutary progress: minute vessels long obstructed cannot be all at once rendered pervious and efficient for the discharge of functions long disused; and hence, in treating the febrile state of chronic rheumatism, the practice, though corresponding in principle with that of acute, must be much less energetic. Bleedings must be of smaller amount and at longer intervals; a free state of excretion must be moderately but steadily maintained; and mercury must be employed for that renewal of function in the capillary vessels and their secerning extremities, which the powers of the constitution, unaided by mercury, are inadequate to accomplish.

It will be recollected that in relative plethora the redundancy of blood results more from its imperfect appropriation than from absolute excess; and that correction of this state requires, not only that the larger vessels be relieved from the load which oppresses them, but that the aggregate capacity of vessels be enlarged by renewal of the suspended activity of the capillaries, and also by promoting the natural expenditure of blood through the several secretions and excretions. These are the curative effects of febrile action; they constitute also the beneficial operation of mercury on the system, and on regulating them conformably with the views here displayed will the success of medical practice in a great measure depend, not only in this but in many other diseases. In the diseased state now under consideration, the first object should be to relieve the oppressed circulation, and thus arouse the energies of the system by taking away some blood; and in conducting this part of the treatment, judgment and discrimination are so requisite, that, even at the hazard of being deemed unnecessarily minute, we must dwell on the several circumstances from which any guidance can be derived.

If, with the general evidences of plethoric oppression and febrile action, the powers of the constitution be very low, and the pulse very feeble, it may be advisable to suspend for a while direct depletion, and to trust to purgatives. It may, in such case, be even expedient to employ gentle stimulants in order to arouse the dormant energies, and enable them to bear direct bloodletting; this being the end to which the use of stimulants should in this stage be directed. The necessity for this degree of caution, however, is not of most frequent occurrence. Much more generally may the curative treatment commence with small bleedings; and in these it should never be forgotten that the object is not to make impression on the moving powers, but to withdraw a portion of the circulating mass, and this with a view of arousing the natural powers to the discharge of functions required for the re-establishment of health. Small bleedings here suffice; and the extent of six or eight ounces will best answer the end designed. According as power increases, larger bleedings will be borne; but beyond twelve ounces it is rarely necessary to carry them. In general, even the first portions of blood drawn will be buffed, if not cupped; and under such circumstances the pulse, if previously low, will be found to rise

under bleeding. As was before remarked, a soft pulse is no contra-indication of bloodletting; for we continually find buffy blood and increase of power after venesection, where the previous softness and feebleness of pulse would, to unreflecting observers, appear to prohibit all direct depletion. This deceptive character of pulse is too often allowed to influence the practice even in acute rheumatism; yet it has been so often the subject of remark, that practitioners ought to be fully aware of it. Dr. Gregory, who in the treatment of acute rheumatism did not employ bloodletting indiscriminately, nor deem it essentially necessary, but who trusted rather to sweating as the preferable evacuation, used to acknowledge that he had been obliged to have recourse to bleeding after several weeks' duration of disease, where he had at first been apprehensive of employing it from the smallness and apparent debility of the pulse; and that after bleeding, the pulse rose and disease subsided. This is not peculiar to rheumatism, but a general fact connected with derangement of circulation, and worthy of attention in many diseases. The explanation of it has been fully and clearly given in the article PLETHORA; and if the principles there inculcated be duly regarded and discriminately applied, there will be little hazard either of bloodletting being withheld where it is needed, or of its being carried to any injurious extent.

Next to bloodletting, the most important evacuation is purging, which requires to be regulated both according to the degree of febrile action present, and to the state of the bowels as manifested by the stools. In proportion as fever is active will the free use of purgatives be required, and saline cathartics be needed in aid of those which more peculiarly deterge the mucous membrane of its morbid secretions; but so long as these continue dark, slimy, and unnatural, must suitable purgatives be assiduously employed. Pills of calomel, colocynth, and antimony, with occasional doses of sulphate of magnesia and senna, are the most effectual means of adequate purgation. According as active fever prevails, as evinced by a quick pulse, hot skin, and white or furred tongue, salines with antimony and colchicum, assisted by antiphlogistic regimen, should also be conjoined.

If under this treatment febrile action does not speedily abate, and local inflammation subside, mercury will be required, and for purposes similar to those for which its use was directed in acute rheumatism. According as fever is active will calomel and opium be necessary, for the proper administration of which no further instruction can be here needed, it being only necessary to observe, that as the morbid actions requiring correction yield more slowly than in acute rheumatism, a more slow and cautious administration of the remedy is here expedient. The direct agency of the medicine is to excite freer circulation in the capillary vessels, by which the larger vessels become relieved, both through the increased capacity thus given to the vessels through which the mass of blood circulates, and the increased expenditure of blood in the several secretions and excretions thus promoted. Whoever bears these facts and principles in mind, will experience no difficulty in regulating the administration of mercury in this or any other disease.

In many cases, however, febrile action, though sufficiently manifested by its appropriate phenomena, is less developed than in those just referred to. The pulse is feeble and irregular, the several secretory and excretory functions are inactive, and the whole frame displays a deficiency of power. Here stimulants are needed, and the most effectual for arousing the dormant energies is mercury. The milder preparations in small doses, repeated at intervals, are what should here be employed. The compound calomel pill, blue pill, hydrargyrum cum cretâ, are the remedies chiefly in use where a slowly alterative effect is desired. In old and obstinate cases minute doses of the oxymuriate have effect when other preparations fail. When the latter is resorted to, decoction of sarsaparilla is beneficially combined. Whenever mercury is employed for such purposes, it is highly necessary to watch closely the state both of the circulation and of the bowels. If under its use the arterial system becomes excited, and the pulse rises, becoming full, hard, or resisting, blood should be taken; and as mercury, when so administered, promotes the intestinal excretions, these should be assiduously evacuated by suitable purges, which in such case serve the double purposes of removing from the intestines a source of irritation, and of maintaining the excretories in an active exercise of those functions which so materially assist the curative process.

Under the foregoing treatment part of the local inflammation will subside without any topical remedies being applied. But as these inflammations have long reached the secondary stage, and as local derangements, such as were formerly noticed, have become more or less established, the local treatment suited to the special circumstances of each case is here indispensable. According as the local inflammation presents an active character, cupping or leeches will be required; and by these, with fomentations, or with cooling and sedative lotions, much impression may be made. Blisters, too, in time, are of much effect, especially where the bursæ are loaded with glairy effusion, the ligaments thickened and rigid, and the whole joint enlarged. To these changes all the joints are liable; they peculiarly occur in the wrists, where they materially impede the motions of the hands, rendering the patients very helpless. These swellings, when accompanied with heat and redness, require leeching and cold lotions; otherwise, repeated blisters are the means by which the enlargement can be best reduced, the effusions absorbed, the ligaments attenuated, and the flexibility of the articulations restored. In the intervals of blistering, stimulant embrocations are very serviceable; and frictions, especially the kind of manipulation termed shampooing, are of much avail.

In the inveterate cases which continually occur in practice, it is not any one remedy that can be relied on. The combined agency of all is required, and they should be assiduously employed in such succession and alternation as enlightened judgment may direct. By a judicious and steady use of them many a case, apparently hopeless,

may be restored to the enjoyment of good general health, and to considerable freedom of the affected limbs. Throughout the whole course of treatment warm bathing is signally beneficial, as is largely attested by the records and daily experience of the noble institution to which the writer of this essay is indebted for much practical knowledge—the Bath Hospital. It cooperates with the constitutional treatment to improve general health, promoting a free circulation in all the capillary vessels, and calling into renewed activity the highly important excretory functions of the skin, while its special effect on the pained and crippled joints is eminently salutary. For the latter purpose, pumping on the limbs, as it is termed, that is, directing against those affected a stream of tepid water, impelled with such force as to exert a mechanical influence on the part, is oftentimes a very powerful auxiliary. Even when general warm bathing is not admissible, this partial application of warm water may be used with much advantage for the relief of local ailments.

Subsidiary to these several means, one of the most effectual aids for restoring motion to rigid or contracted joints is the persevering endeavour to render them flexible by assiduous exercise; and the more this can be promoted through the appropriate muscles of the affected joints, the greater will be the benefit resulting; for the muscles previously wasted will thus recover bulk and strength, and through renewal of exertion will prove a most valuable instrument both in preserving and extending any power of motion that may be gained. Frictions and shampooing are a sort of passive exercise, and through this, as well as by promoting absorption and inducing a freer circulation in the extreme vessels, their effect on enlarged or rigid joints is considerable.

But even where, from great rigidity and extreme muscular feebleness, the joints are incapable of being exercised by their own proper muscles, the advantage derivable from passive exercise is not to be despised. Frictions and shampooing may lessen rigidity, so as to give more effect to the feeble muscles in their languid efforts. When the wrist and finger joints are affected, the parties may materially benefit themselves by moderate but continually renewed attempts to move the joints of each hand by means of the other. The joints may resist for a long time, but this should not discourage, and the slightest renewal of mobility should be hailed as the sure harbinger of further improvement. It is needless to urge this further. The principles are obvious, the effects proved by ample experience; and at all events perseverance in such endeavours, however little it may in extreme cases accomplish, holds out to the rheumatic cripple the only hope of recovering mobility in joints rendered inflexible by the effects of rheumatic inflammation. Attempts to restore mobility in such cases by internal medicines alone, is worse than fruitless. They may correct constitutional derangements where these coexist, and, by restoring general health, prevent further mischief; but they can have no effect in renewing either mobility or power to limbs so affected.

It has been shown that the secondary inflammation of acute rheumatism may survive the cause in which it originated. In like manner the local inflammation of chronic rheumatism may continue, although the febrile state which nurtured and aggravated it may have wholly subsided; and, further, the ravages of rheumatism in the joints may remain when all fever, as well as local inflammation, whether primary or secondary, has ceased to exist. Chronic rheumatism, therefore, may be said to present three conditions which deserve to be practically distinguished; — active fever with local inflammation;—inflammation unaccompanied with fever;—and structural derangements of joints unattended by either fever or local inflammation. Each of these conditions requires to be treated on principles applicable to its peculiar state; and any treatment adopted merely on account of its being specifically suited for rheumatism, must, if indiscriminately applied, be productive of much mischief.

There is another diseased condition often consequent to rheumatism, namely, a loss of nervous energy, which constitutes a modification of paralysis; but this demands a separate consideration, which belongs rather to paralysis than to the present subject.

The first condition of chronic rheumatism, or that which comprises both active fever and local inflammation, has been sufficiently discussed. The next in order is where the local inflammation, with the attendant pains and other derangements, endures after fever has subsided. This form also is of frequent occurrence, and it differs from the former in not requiring general bloodletting for its cure. Local depletion and occasional blisters constitute the principal topical treatment; and mercury with sarsaparilla and other such auxiliaries, is the chief agent for inciting the constitutional energies to cooperate in the cure. It is this form of the disease that has misled even intelligent practitioners into pronouncing that general bloodletting is not necessary in chronic rheumatism. Dr. Elliotson in his admirable clinical lectures has expressed himself of this opinion, and declared that he has relinquished general bleeding in active rheumatism, unless when some internal inflammation coexists. That in many such cases the treatment recommended by him, namely, local bleeding, colchicum, and mercury, will succeed without general bleeding, we were well aware; but we are no less assured that in very many it would prove very tedious, if not wholly fail. We consider, therefore, that Dr. Elliotson has stated this opinion somewhat too broadly; and that on reconsideration he will himself admit that the criterion for employing the lancet should be, not the presence of an internal inflammation, but such degree of plethora and febrile excitement as in itself demands direct depletion, independently of all coexisting local derangements. Topical bleeding, low diet, colchicum, and mercury, form a combination of influences which has great power in subduing febrile and inflammatory action; but if plethora exist to a certain extent, even their united agency will be insufficient, unless direct depletion be conjoined. And in such case it requires to be borne in mind, that, as has been already explained, the operation of mercury is not devoid of danger. When there is local inflammation without plethora or fever, the treatment recommended by Dr. Elliotson cannot be improved.

Even where plethora and fever exist only in slight degree, it may also succeed, although the progress will be slower than when venesection is conjoined. But when plethora and fever exist to any extent, then, even though there be no internal inflammation, general bleeding ought unquestionably to form part of the treatment.

Chronic rheumatism has been sometimes distinguished into hot and cold,—the hot being the active rheumatism of Elliotson, the cold the arthrodynia of Cullen. In the last, various stimulants are of much avail, and for the relief of such disease they should undoubtedly be resorted to. It is to be hoped, however, that their misapplication to acute or to any active rheumatism as the appropriate remedies, has passed away, or is confined only to ignorant empirics. It illustrates the difficulty of adapting treatment explicitly to the name of a disease, or even to special degrees of it, that there are modifications of active rheumatism in which even stimulants, cautiously administered, are not only safe but beneficial; and this circumstance confirms the necessity of all medical treatment being regulated, not by express rules, but by those principles from which all rules ought to emanate, and to which they ought to be subservient.

It would be vain to enumerate the various stimulants which have obtained character for the cure of cold rheumatism. The principal are essential oils drawn from resinous substances, such as turpentine; various balsams and gum-resins; the latter either in substance or in simple or ammoniated tinctures; sudorific decoctions; electricity. Any of these may benefit according as the general constitution is prepared for their operation, or as the special ailments may require. If there be no plethoric or febrile state present, their use will at least be harmless, if not beneficial; but should the case be such as to need depletory treatment and the operation of mercury, then must the use of such stimulants as are now named be watched with great caution.

Warm bathing and active exercise are among the unexceptionable and most powerful means of relieving chronic rheumatism. The local treatment formerly directed for the sequelæ of acute rheumatism also requires to be assiduously employed.

There are some affections generally regarded as rheumatic, which, however connected with rheumatism, seem to depend chiefly on a morbid condition of particular nerves. Of this kind are *sciatica* and *lumbago*, both of which differ so much in their symptoms from acute rheumatism, as scarcely to admit of their being classed under it. A mere error of arrangement, however, is of little consequence, as the same principles of treatment apply to all. If the state of constitution be such as to require for its correction bleeding, purging, colchicum, and mercury, these remedies must be employed, else the local affection will not readily yield. That sciatica arises from some lesion of the sciatic nerve or its investments, most practitioners are agreed. That this lesion results from a primary congestion or inflammatory action, seems evidenced both by the whole train of symptoms, and by the treatment most successful in giving relief.

When there is only the local affection to treat, repeated cupping or leeching, and blistering, with the warm bath, and a cautious return to exercise, will do much to effect restoration. Stimulant and sedative embrocations too, are occasionally of service.

In lumbago, though the spinal nerves affected are less distinctly indicated, yet the character of the pain marks it as more neuralgic than rheumatic. Free cupping and the general treatment of acute rheumatism will best succeed in relieving this disease.

But there is a form of neuralgia occasionally attendant on rheumatism which causes much suffering, and which does not seem to be generally understood. It occurs in paroxysms of great intensity, attended with a severity of pain which few can patiently endure. This may arise ere the febrile state has thoroughly subsided; and this circumstance is apt to mislead, for a continuance or removal of inflammation is thus apprehended, and depletory treatment is pursued, under which the disease is aggravated instead of relieved. The character of this affection is best denoted by the suddenness of the painful accessions. The nature of the pain, too, so different from that which attends inflammation, seems to distinguish it. For this affection the most certain and effectual remedy is iron; but it must be largely used, and assisted, if necessary, by full doses of opium. The carbonate is the best preparation, and this should be given in doses of two drachms three or four times a day. By administering it with equal parts of treacle, as directed by Dr. Elliotson, its constipating effects are obviated. Should opium be required, it should be given in full doses, and the best preparation for the purpose is Battley's sedative solution, of which from thirty to ninety minims may be given at bed-time without any sinister effect resulting. Under this treatment it may be necessary to purge occasionally with the common senna draught, which is sensibly improved by the addition of half a drachm of spirit of ammonia.

In the progress of rheumatism the chest is apt to become affected with pain and great dyspnœa, the distress being referred to the lower part of the chest, and described as if the point of the sternum were drawn back to the spine. This arises from the extension or translation of rheumatism to the diaphragm. The means of relief are bleeding, purging, and colchicum, with calomel and opium. So soon as the gums are touched, the distress finally ceases.

One of the most important affections connected with rheumatism is that in which the heart or its investments becomes the seat of rheumatic inflammation. This inflammation may be of the most acute kind, constituting complete carditis or pericarditis; or it may be only such increased action of blood-vessels as ultimately leads to hypertrophy. For the acute attack the most active treatment is required; full bloodletting, purging, antimony and colchicum, but above all the early and decisive operation of calomel and opium. If the latter be not speedily and effectually obtained in subserviency to bloodletting, this will be required to such extent as to render recovery extremely doubtful, sink greatly the powers of life, and occasion a very tedious convalescence. Some interesting cases of

rheumatic pericarditis have been recently published by Dr. Davis, the senior physician of the Bath hospital. He seems, however, to have trusted to general antiphlogistic regimen, without calling in the aid of mercury. The principles advocated in this article display the merits of mercury as an adjuvant; and the experience of the writer fully confirms their truth and practical utility. But independently of this acute seizure there is continually found in connection with rheumatism inordinate action of the heart, with evidences of actual enlargement or hypertrophy of that organ. The treatment of this affection, we can from much experience say, is best conducted on the principles inculcated in this article. Moderate bleedings are indispensable, the blood being almost invariably buffed and cupped. In judging of the state of circulation, the pulse at the wrist would mislead, for it may be soft and compressible even when the action of the heart is tumultuous. The carotid should here be examined as furnishing a more certain criterion. Free bowels and antiphlogistic discipline are indicated by the same necessity which calls for abstraction of blood. Mercury with opium is also required to produce its specific effects, by which alone the morbid action can be effectually or permanently subdued. The use of this requires to be cautiously conducted, for its slowest operation is that which is here most beneficial. The morbid condition is generally of slow formation; the changes wrought are not of a nature to be suddenly rectified; and attempts to accelerate the case beyond what nature permits, would beget mischief and lead only to disappointment. Cupping and leeching over the heart are valuable auxiliaries, and blisters are occasionally needed.

In fine, when inflammation both general and local is allayed, and the action of the heart still continues inordinate, or is too easily excited, the application of belladonna to the side, in the form of plaster, affords a valuable means of quieting the heart's motions, and of procuring rest from a disturbance which is always distressing.

[In this as well as in every form of rheumatism, the iodide of potassium, given in large doses, has been greatly extolled. (*New Remedies*, 4th edit. p. 396, Philad. 1843.)]

By the cautious adaptation of such means, and steady perseverance in their use, the disturbance of heart here treated of may in time be effectually relieved. Time, however, is required, for the disease yields slowly; and though impression be made on it by the early procedures, months may elapse ere perfect tranquillity of circulation can be restored. The patience, however, which can await this result, and pursue steadily the means of accomplishing it, will be amply rewarded.

There is one more form of rheumatism which requires to be noticed, namely, that which is called *rheumatic gout*; and so far as a name is concerned, this appellation, though only a popular term, is not misapplied. So much has this disease in common both with gout and with rheumatism, that it is scarcely possible to regard it otherwise than as a hybrid malady, in which the elements of both these diseases coexist. Its accession corresponds most with rheumatism; its ravages have a greater resemblance to those of gout. The enlargement of joints to which it is so prone presents much more of the character of gout than of rheumatism. Dr. Haygarth has described this disease, and proposed to denominate it *nodosity of the joints*. Of its history and treatment there is little to be said beyond what has been already advanced under the heads of gout and of rheumatism. It is more frequent in women than in men. Its commencement is often marked by active fever, and in proportion as this is disregarded or inadequately treated, are its ravages more severe and inveterate. But in many it advances by a slow and insidious progress, disorganizing the joints without materially deranging the general health. The local swellings long retain the character of active inflammation, being hot, red, and painful. They in general surround the whole joint, and, so far as mere touch can determine, they seem to arise from a general enlargement of all the structures constituting the joint. It seems strange that the structures actually enlarged have not been long since ascertained by actual dissection; yet we are not aware of any account of them, founded on anatomical examination, having been published. In 1805 Dr. Haygarth had not met with any such account, as appears from the following paragraph of his treatise: "In this disease the ends of the bones, the periosteum, capsules, or ligaments which form the joint, gradually increase. These nodes are not separate tumours, but feel as if they were an enlargement of the bones themselves. *This point might be anatomically ascertained without any difficulty or doubt.*" The disease, according to Dr. Haygarth, does not appear to shorten life; the first patient whom he saw so affected reached the age of ninety-three.

As to treatment, this must be regulated according to the state of constitution and local symptoms, and on the principles inculcated in this article. By local treatment much relief may be rendered. Frequent leeching has much effect in abating heat, swelling, and pain. In the purely chronic stage, successive blisters contribute much to reduce swelling and restore flexibility. As the hands particularly suffer from this malady, it becomes necessary to blister each finger separately, and even each joint; a process, which, however irksome, is yet ultimately recompensed by the increased power of using the hands which may be thus obtained.

[Under the name *Rheumatic Dermalgia*, Mr. Beau (*Note sur la Dermalgie*, in *Archiv. général. de Méd.* x. ii. 120, Paris, 1840) has described an affection characterized by the following symptoms. The head and lower extremities are the parts most usually attacked, but the pain does not remain in one place, often changing its seat gradually, and wandering from place to place. Two kinds of pain are experienced, the one enduring, the other intermittent and severe, resembling the prick of a pin or an electric shock, and recurring about every half minute. The enduring pain is often little more than an exaltation of the natural sensibility of the skin. Friction of the part with the finger, or with the patient's dress, always augments the pain; and if there be hair on the affected part, very severe suffering may be produced by passing the hand over the hair.

Rheumatism of the skin commonly alternates

with that form of the disease, which affects the muscular and fibrous tissues. Its usual duration is a day or two, after which it gradually subsides. It is said to be a more frequent occurrence among men than women, to be induced by damp, cold, and the ordinary causes of rheumatism, and, in general, not to require much treatment.]

[Robley Dunglison.]

RICKETS.—Rhachitis, Rachitis. The term *rhachitis* was derived by Glisson from the Greek ῥάχις (spine), because this disease affects, in an especial manner, the spinal column; but he acknowledges that he was induced to adopt this term from its near resemblance to *rickets*, a word by which the malady was commonly known in England even before his time.* The work of Whistler, and the remarkably clear and full account of rickets afterwards given by Glisson and his associates Bate and Regemorter, have procured a currency for their opinion that the disease made its first appearance in the western parts of England towards the middle of the seventeenth century, and have obtained for rickets among continental writers the designation of the *English malady*, (Morbus Anglicus, Maladie Anglaise, Englische Krankheit.) That rickets was never distinctly described by any medical author before the times of Whistler and Glisson, we readily admit; but that it was of such recent origin as the period stated above, we conceive to be quite inconsistent with the several terms in the Greek and Latin languages denoting deformity and decrepitude of the human body, and with the instances recorded in ancient history of persons so afflicted who were distinguished in various departments of letters and even in arms.

The essential characteristic of rickets is a softening of the bones; but the exact change which takes place in their structure, and the general symptoms by which this alteration is attended, are considerably different at different periods of life. Taking the term rhachitis in this extended sense, to which perhaps *osteomalakia* would be more properly applied, the disease may be divided into two species;—1st, softening of the bones of children, or common rickets; 2d, that of adults, mollities ossium, or osteo-sarcosis. Softening of the bones, like scrofula, is not unfrequently met with among the inferior animals. Thus Lordat dissected a rickety monkey; Bicherod found softening of the ribs of an ox (Act. Maris Balthici, 1707); Dupuy describes the skeleton of a rickety horse (Dupuy, De l'Affection Tuberculeuse); Mason Good (Study of Medicine, vol. v. p. 327) asserts that rickets occurs in the lion; and Comber has written a dissertation on the disease as it appears in sheep. (Letter on the Rickets in Sheep. Lond. 1772.) But to descend from the researches of the learned to the information of those who are observant of the manners and diseases of our domestic animals, curvature of the bones and swelling at the joints are not unfrequently seen in whole broods of young geese and ducks, when they have been continually exposed to cold and wet. The same affection is met with in young pointers, and more frequently in greyhound puppies, when kept in confined and cold damp kennels. In pigs, the same disease is in some places named krinckets; its causes are cold and moisture, and bad nourishment; and for its cure baths of hot grains are used, oily frictions, nutritious food, and removal to a warm and dry place.

* *David Whistler*, Dissertat. Inaugur. de Morbo Puerili Anglor. dicto "The Rickets." Lugdun. Batavor. 1645. This work, which preceded that of Glisson, is now exceedingly rare: a copy still exists in the Bodleian Library.

I. Rickets of Children.

1. **History.**—This disease rarely appears before the seventh month, and most commonly does not declare itself until the child first begins his attempts to walk, or until he suffers from the severity of the first dentition. Rickets has also been observed at birth, and in the fœtus: of the former Glisson (De Rachitide, p. 178), Henckel (Abhandl. Chirurg. Oper. Th. ii. p. 14), Klein, and Lepelletier (Maladie Scrofuleuse, Paris, 1830), have given examples; and of the latter Bordenave (Mém. de Mathemat. et Physique, tom. iv. p. 545), and Pinel.†

[Of 346 rickety children observed by M. Guérin, (*Gazette Médicale de Paris*, pp. 433, 449, 481, Paris, 1839,) 209 had been attacked with the disease at from one to three years old; three cases only had occurred before birth; and 34 at from four to twelve years of age. Girls appeared to be more liable to it than boys. Of the 346 individuals referred to above, 198 were females, and 148 males. (Guersant, art. *Rachitisme*, in *Dict. de Med.*, 2de édit. xxxii. 155, Paris, 1843.)]

When a child is about to be affected with rickets, he becomes dull and languid, the appetite is variable and capricious, the bowels are irregular, the stools unhealthy and usually pale. Constitutional disturbance now arises, and a febrile state is soon established: the limbs become emaciated, the belly tumid, the face full, and the head disproportionately large, the forehead projecting, and the sutures of the cranium remaining open or perhaps expanding slightly. The extremities of the long bones which are least concealed by muscle, as those of the wrists and ankles, and the sternal ends of the ribs, particularly these last, are swelled out into knobs. Some have doubted the tumefaction of the extremities of the bones in rickets, ascribing the appearance of swelling to the emaciation of the limbs; but an attentive examination of rickety cases has convinced us of the correctness of the former opinion. The firm texture of the bony framework of the body now begins to yield, and its increasing softness becomes apparent by the change of form which takes place. The sides of the chest are approximated by the combined operation or the pressure of the child's arms, the weight of the

† In Fourcroy's Journal, La Médecine eclairée par les Sciences Phys. tom. i. p. 111. This was the case of a rickety fœtus of eight months, in which the distortion was chiefly confined to the lower extremities. Farther illustrations of fœtal and congenital rickets will be found by referring to the following authorities.

body when laid on its side, and the mode in which children are usually carried; and thus the sternum is made to project like that of a bird, or like the keel of a boat. The lower extremities bend under the weight of the body, while they yield at the same time to the action of the most powerful muscles: the knees are usually bent inwards and the feet thrown out, so that the patient when he walks rests on the inside rather than on the sole of the foot. At other times the whole of each lower extremity forms an irregular curve with its convexity looking outwards, and thus the knees, instead of knocking against each other, stand far apart. Among some of the native tribes of North America, this particular form of the limbs is esteemed handsome: and the utmost care is taken in early infancy to mould them by continued pressure into the admired shape, which, therefore, must not be regarded as any proof of the previous existence of rickets. In this disease the natural convexity of the thigh-bone is often so much increased as to form an elbow; and the angle between the neck and the shaft is converted from an obtuse to a right angle, or even to an acute one. The pelvis is usually deformed in the reverse direction of the chest, the pubes approaching to the sacrum; but in all cases where the pelvis suffers, its cavity is diminished, which to the female in after-life is necessarily attended with more or less dangerous consequences in the event of pregnancy. The vertebral column exhibits in a remarkable manner the effects of rickets in retarding the completion of the bones, and softening their texture: the spinous processes of the last dorsal and of the lumbar vertebræ are sometimes deficient, and the natural form of the spine is variously changed; its uppermost portion is often bent backwards, while the dorsal part projects into a hump, the loins fall in, and the extremity of the sacrum is unnaturally protruded: thus the gait of the hunchback, who has survived the severity of the disease, is stiff and formal, and the face directed upwards. The distortion of the arms of rickety children is usually outwards at the upper part of the humerus from the action of the deltoid, and in other parts also it is chiefly determined by the operation of the most powerful muscles; but much will depend on the positions in which the limbs may chance to be placed at the time when the bones are recovering their strength and firmness. Rickets is considered by some to produce little or no change on the bones of the cranium, face, hands, and feet. Those of the two last, we believe, are little affected; but the vertex in rickety children is, with few exceptions, unnaturally flattened, the centres of the parietals are expanded, and the forehead is prominent from an enlargement of the frontal sinuses: the bones of the face also appear in most cases to undergo some change of form, indicated by the shortness of visage and elongated under-jaw usually observed in those who have suffered from general rickets. In such children the process of dentition is protracted, and the teeth soon decay: the enamel of the permanent teeth is often craggy and worm-eaten, showing its imperfect formation, though sufficiently hard; but the fang during the progress of the disease has been found somewhat softer than natural. (*Wilson*, Lectures on the Human Skeleton.)

The rapidity with which the bones are softened by rickets is sometimes altogether extraordinary. Brunninghaüsen observed the whole of the bones in one instance become soft in the short space of six weeks, and the case proving fatal, he preserved the skeleton.

As the disease proceeds, the bones are readily fractured when even a slight force is applied, and it is remarkable that, softened as they are, they usually reunite: at length they become completely pliant. We have seen those of the fore-arm of a child of four years as flexible as a piece of soft gristle, bending with the weight of the hand whichever way it was turned. The muscles grow more and more flabby, the abdomen more tumid, the appetite becomes keen, and the bowels sluggish. The urine in rickets is rarely healthy, sometimes clear, but more frequently turbid, depositing a copious whitish or light brown sediment, indicating the very disordered condition of the digestive organs, and consisting in all probability of lithate of ammonia, with a large admixture of the phosphates. During the continued progress of rickets, the febrile excitement abates until its latter stages, when at length a regular hectic is established, and contributes by its perspirations and diarrhœa to exhaust and destroy the patient.

The intellect of the subjects of rickets generally possesses a degree of development far beyond what is usual in healthy children of the same age; the children exhibiting a quickness of perception and a fluency of language sometimes astonishing. In other instances, though much more rarely, they are taciturn and stupid, or even verge to a state of idiotcy. The frequent precocity of understanding has been ascribed to the expansion of the skull, and the earlier development of the brain consequent on that determination of blood to the head which appears always to exist at least in the first stages of rickets; but when this disease does not occur until the sutures of the cranium have closed, the same circumstance of an increased flow of blood acting on a part no longer capable of yielding has been assigned as the cause of the mental torpor or fatuity occasionally met with.

Almost all those who become rickety soon after birth perish, but many in whom the disease has appeared later recover before their fifth or sixth year; the general health gradually improving, the tumefaction of the abdomen subsiding, and the bones acquiring firmness, though retaining, with scarcely an exception, a certain degree of deformity. The head remains disproportionately large, the child preserving its acuteness and vivacity. At other times recovery takes place after smart febrile reaction, which is occasionally accompanied by the appearance of a cutaneous eruption. Sometimes the child at the approach of convalescence exhibits an extraordinary liking to particular articles of food. We have known the desire for common salt so strong that the little patient would devour it as others do sweetmeats. The quantity taken in one instance was very great, and to the parents it seemed as if the salt had proved the means of cure.

After the cessation of the disease, the bones acquire a degree of solidity and strength even greater than natural, and many persons whose form proves

that they were rickety in early years, are in after-life distinguished for robustness and activity. The deficiency of earthy salts in the bones, which existed during rickets, is succeeded by their excessive deposition; and that state is induced which has been named hyperostosis: the long bones become more rounded and massy; and the sutures of the cranium are often obliterated, and the lines of junction raised into flattened ridges. In some instances rickets has been followed after some interval by a remarkable tendency to the production of bony growths. There is related by the Bishop of Cork, in the Philosophical Transactions for 1740, 1741, the case of a man who had been so rickety in his youth that almost every bone in his body was distorted. At the age of eighteen he began to grow stiff, and at length, having lost all use of his limbs, he became like a statue: he survived till his sixty-first year, and at his death his skeleton was found to be one continuous bone from the top of his head to his knees. Many osseous growths, some of them of the most grotesque forms, branched from his head, back, and haunches; and a portion of fully-formed bone was also found imbedded within one of the large muscles.

Should the disease not yield before the seventh or eighth year, the individuals, if they survive, are condemned to a life of infirmity, which is seldom prolonged beyond middle age. Such persons suffer exceedingly from the unnatural pressure and displacement to which the organs of the chest, and even the most important of those of the abdomen, are more or less subjected. The stomach in these cases is frequently pushed as low as the umbilicus, and even the urinary functions have been disordered by a projecting vertebra pressing upon the kidney. These unfortunate individuals are remarkable for their shrill voice, dilated nostrils, and panting respiration; and life is generally cut short by one of those attacks of pulmonary inflammation to which they are peculiarly prone; at other times they are destroyed by the development of tubercular disease, and occasionally by dropsy.

In rickets, as in most chronic disorders, the change which takes place at puberty is productive of amendment, or of an increase of the disease. Ravaton has detailed a remarkable case, which serves well to illustrate this influence. A girl, whose legs were so deformed that at thirteen years she was only three feet high, was seized with continued fever; the catamenia appeared, the limbs then gradually straightened, and in less than three months her height was five feet one inch.

The progress of rickets is accelerated by confinement and exposure to cold and damp, by bad clothing, imperfect nourishment, and careless nursing; and retarded by circumstances the reverse of these: hence it may be that the disease is now of less frequent occurrence than in former times, and that it has been observed to make less progress in spring and summer, and to advance most quickly in winter and autumn. But the progress of rickets often varies without any obvious cause; it sometimes appears to be arrested as if recovery were at hand, then revive, and proceed with more rapidity than before. As the disease advances to a fatal termination, the little sufferer cannot bear even to be moved in bed, and the attempt is often productive of the fracture of some bone: hectic fever is now established, with its attendant colliquative perspirations and diarrhœa. At this period also, a variety of nervous symptoms sometimes present themselves; such as temporary deafness, or blindness, irritation of the bladder or inability to expel the urine, or paroxysms of epilepsy, or convulsions. Should these last not prove the cause of death, the patient at length sinks under debility, and dies exhausted.

On examining the bodies of those who have died while still labouring under rickets, the brain is found disproportionately large, but often in other respects quite natural; in some instances the ventricles are filled, or perhaps considerably dilated with a liquid fluid; and a similar fluid is also found in the basis of the skull and within the canal of the vertebræ. The cavities of the thorax and abdomen likewise sometimes contain serous or bloody liquid; the lungs are compressed and occasionally displaced by the alteration in the form of the thorax; marks of inflammation are often apparent in the pleura and pulmonary substance, which last is sometimes hepatized, and at other times contains numerous tubercles in various stages of advancement. It is remarkable that in some cases of rickety children from one to ten years old, the thymus gland has been found much enlarged, and the upper part of the sternum bulging out, so as to form a concavity, within which the overgrown organ was lodged. (*Lobstein*, Anatomie Patholog. t. i. p. 54.) The heart is not found diseased where death occurs during the active progress of rickets; but in those who have survived with deformity of the chest, the obstacle thus occasioned to the circulation, especially through the lungs, rarely fails to produce in the end hypertrophy of that organ. (*Hope*, on Diseases of the Heart, p. 194.) The liver and spleen of rickety subjects are almost in every case enlarged, the former in particular. The mesenteric glands are usually enlarged, and often filled with tuberculous matter; and the other absorbent glands, both within the abdomen and externally, present similar alterations.

In the soft parts little or no adipose substance is found; the muscles are pale, flabby, and wasted; and the rigidity of death is rarely met with in such subjects. The bones, during the active stage of rickets, are found to resemble very vascular cartilage; the medullary cavities are filled with a bloody gelatinous-like substance in place of marrow; and the osseous texture presents every where, even in the cortex, numerous minute cells, from which a thin bloody fluid can be pressed. The appearance of rickety bones has been well compared to that of a healthy bone deprived of its earthy materials by immersion in a weak acid; but there is this difference, that the rickety bone is much more vascular, and that the cartilage of which it consists is of so loose a texture, that it is soluble in the same acid which will deprive common bone of its earthy constituents. We are not acquainted with any analysis of recent bone affected with infantile rickets; and the examination of those which have been dried cannot afford much accurate information respecting the constituents of parts which obviously contain so unnaturally large a proportion of fluid and

easily destructible ingredients. Nothing, indeed, has tended so much to obscure the pathology of the bones as the almost exclusive practice of macerating and preserving them in a dry state. When the bones of those who have recovered from rickets are examined, their texture is found to be more dense, in consequence of a morbidly increased deposition of the earthy salts; even small exostoses and bony spiculæ are sometimes observed; and in cases where the spine is deformed, the bodies of many of the vertebræ are found united by new osseous substance. The bones of the cranium are observed to be much heavier and thicker than natural, the sutures often obliterated, and the grooves formed by the meningeal arteries greatly deeper than common. Wherever the bones have been bent during their yielding state, a larger deposition of earthy salts is observed in the interior of the curve where its weakness had been the greatest; and to such an extent does the deposit of osseous matter sometimes take place, that the bone at the point of curvature has been converted into a solid substance, the medullary cavity being wholly obliterated. (*Stanley*, Lond. Medico-Chir. Trans. vol. vii. See also Wilson's Lectures on the Human Skeleton.) Perhaps to some it may appear sufficient to say that the earthy salts are thus deposited, because they are most wanted at the weakest point of the bony shaft; but the real cause of this arrangement seems to be that the bending of the bone has compressed into the interior of the curve a larger quantity of cartilaginous substance, which is afterwards filled with an earthy deposit; while it stretches and attenuates that on the exterior of the arch, and so diminishes there the matrix for the reception of earthy materials. It may be observed also, that the effect of bending the pliant bone is to bring its opposite sides into closer approximation, and thus to prepare the way for that ossification throughout its whole diameter to which allusion has already been made. Bones which are distorted are commonly named rickety, whether in the active stage of that disease or after its cure, when they have acquired an unnatural density from hyperostosis: hence some confusion has arisen in stating the composition of rickety bones; and the assertion has been hazarded that a deficiency of phosphate of lime is not an essential, but merely an adventitious circumstance in rickets. Dr. John Davy found 100 parts of the dry tibia of a healthy subject of fifteen to yield 46.4 of animal matter, and 53.6 of earthy; while the same quantity of the dry tibia of a rickety child contained 74 parts of animal and 26 of earthy substance. (*Monro*, Elements of Anatomy, vol. i. p. 27.)

2. **Causes.** — Rickets appears under very different circumstances, and therefore may be supposed to derive its origin from a diversity of causes. It is met with among the children of the affluent, enjoying every advantage of careful nursing, warm clothing, nutritious food, and airy apartments; and it is found likewise in the damp unwholesome dwellings of the artisan and labourer, where the child is neglected, scantily clothed, and poorly fed. In the former of these classes it is almost always a hereditary disease, or if not, it exists in connection with a scrofulous habit transmitted from the parent: in the latter it may also arise from hereditary influence; but it seems more generally to originate from those unfavourable circumstances in the rearing of the child which have just been enumerated. Some writers have endeavoured to trace a connection between rickets and gout, syphilis, and scurvy; but it has not been satisfactorily shown that any of these diseases, either in parent or child, can operate as causes of rickets excepting by the debility which they may induce, and the predisposition to the malady which may thus be occasioned. Of scrofula, on the other hand, we would speak in very different terms; for the connection of this disease with rickets appears to be very intimate; although we are far from agreeing with Dr. Thomas Young in the propriety of classing rickets as a mere species of scrofula, *scrofula rhachitis*. (Introduction to Medical Literature.)

Rickets rarely occurs excepting in delicate and sickly children: instances are occasionally met with where robust children, born of healthy parents, have been attacked with the disease; but it may be questioned whether such cases were truly rickety, or if the yielding of the bones had not rather arisen from the great weight of the infant's body, and from too early endeavours to make him walk.

Many cases have occurred which prove the close connection which exists between rhachitic disease and affections of the encephalon, such as hydrocephalus and convulsions. Büchner (De Rhachitide in Haller. Disput. Medicæ, tom. vi.) relates that he saw almost the whole of a family of eleven brothers affected with rickets. Most of them died of the disease in an advanced stage, while the rest were carried off by convulsions.

Rickets has been observed to prevail in particular localities, probably from their unhealthiness, and the indigence and misery of their inhabitants. Hence it may be regarded as occasionally an endemic disease; it is so described by Glisson in reference to England, (De Rachitide, p. 3. Lugd. Batav. 12mo. 1761,) and instances are recorded where it assumed the same character in different parts of Germany. (Acta Nat. Curios. vol. ii. obs. 153. Ephemerid. Nat. Curios. cent. i. et ii. append. p. 23.)

3. **Treatment.**—During the existence of the acute febrile symptoms of rickets, it will be proper to administer moderate doses of antimonials, to employ the tepid bath, and in some instances even to apply leeches to the forehead or nape of the neck, according to the urgency of the case and the strength of the little patient. The impaired appetite, morbid stools, and disordered urine require the use of small doses of calomel or hydrargyrum cum cretâ; followed by magnesia and rhubarb, or rhubarb and soda, with an occasional dose of a more active aperient, such as castor oil or senna. If the disease have occurred at a very early age, it may be advisable to try the effect of changing the wet-nurse; and in general it will be proper to wean the child about the end of the ninth month, for protracted suckling is certainly one of the debilitating causes which dispose to rickets. While the child continues at the breast, the diet of the nurse ought to be carefully attended to, in order that her milk may prove

nutritious and easy of digestion: or its powers may be assisted by allowing the infant, in addition, small quantities of isinglass-jelly, beef-tea, or yolk of egg, provided the absence of febrile excitement will permit. After the child has been weaned, the diet must be suited to the degree of constitutional irritation which exists; but one leading principle should be to support the strength as much as possible without quickening the circulation or oppressing the stomach. Farinaceous food has been condemned by many writers as injurious to rickety patients, from its inferior nutrient properties; yet it will not be denied that, during the existence of febrile symptoms, the various preparations of starch will be found to yield a mild and appropriate nourishment. Whenever the state of irritation has so far subsided that a more substantial diet can be borne, it ought to be given freely, and even a little wine or sound ale may be allowed as long as it causes no morbid excitement.

In the second stage of the disease our principal objects in selecting the means of cure are, to give tone to the system, and improve its nutrient and reparative powers; and for these purposes the cold plunge-bath, the affusion of cold water with salt, careful friction of the whole body, and the employment of tonic medicines, will be found very useful. Among the tonics best adapted for cases of rickets may be enumerated sulphate of quinia, gentian, calumba, oxide of zinc, and various preparations of iron, of which, perhaps, the wine and carbonate are to be preferred. With many of these it will be found highly advantageous to combine the alkalies and alkaline earths, the choice of some of them being determined by the state of the bowels and the rapidity or languor of the circulation; carbonate of soda being preferable when the bowels are relaxed, and carbonate of ammonia when the action of the heart is languid. In rickety cases, where the nervous energy appears defective, it may be proper, in addition to the means of invigorating the frame already enumerated, to employ electricity or galvanism, but in a very cautious manner.

The clothing of the child ought to be warm, and great care should be taken to preserve it free from damp. The apartment in which he sleeps should be dry and well ventilated, and his residence should be in a pure temperate atmosphere, either in the country or on the sea-coast; and when the weather permits, he should be carried about in the open air as much as possible. When the rickety child is carried, it should be alternately in either arm; and when placed in a chair or laid in bed, his position should be such in regard to the various objects of attraction around him, that he shall not incline continually to one side only; or so varied from day to day, that the formation of any fixed deformity may if possible be prevented. His bed should be smooth and comfortably firm, and the head but little elevated; the bed-clothes light, yet sufficiently warm. As soon as the constitution appears to be rallying, and the bones acquiring renewed strength and firmness, attempts should be made to restore them to their natural shape by well-directed manipulations, and the employment of such mechanical contrivances as will give support without injurious confinement. Considerable success is known to have attended the treatment practised by the Baron Dupuytren (Répertoire générale d'Anat. et de Phys. Patholog. tom. v. p. 198,) in deformity of the chest. His plan is to place the child with his back against the knee or a wall, and make moderate and gradually increasing pressure with the palm of the hand on the sternum, so as to diminish the antero-posterior diameter of the chest, and force out the ribs towards their natural convexity. This practice is repeated day after day very frequently, and at suitable intervals, with increasing force and for a longer time, augmenting and relaxing the pressure so as to suit the movements of respiration; until at length, after long and careful perseverance, the natural shape of the thorax is to a certain extent restored.

II. Rickets of Adults.—*Mollities ossium.*

1. **History.**—The softening of the bones which is met with in persons of adult or advanced age, presents itself in various degrees of severity. Sometimes it is merely a protracted form of infantile rickets, which has continued with numerous checks and interruptions, and successive revivals and increase of symptoms, even to advanced life. On other occasions, and these are not rare, softening of the bones occurs during pregnancy or follows parturition, and increases in severity during each successive gestation. The parts of the osseous system chiefly affected in these cases are the spine and the pelvis; hence the difficulties of childbirth are usually augmented at every succeeding confinement. But the disease has been observed in its most aggravated form among males as well as females, although certainly more often among the latter. Several notices of this intense form of mollities ossium are to be met with among the early historians and biographers of modern times: thus Abbon, the monk, who lived in the ninth century, relates an extraordinary instance where a very large man was reduced by it to the diminutive size of a child. (Guerres de Paris.) And Abulfedda asserts that the body of the prophet Gatleb was without bones, so that his limbs could be folded up like a garment. (Vita Mohammed.) Perhaps the first medical writer who has made mention of mollities ossium is Hollerius (De Morbis Internis. Rara Quædam, No. 7. 4to. Paris 1609): he states briefly that there was a woman in Paris whose whole body was soft and flexible, and without solid bones. The next case on record, and it is a well-marked and interesting one, is that detailed by Abraham Bauda, which occurred at Sedan in 1650. (Microcosmus Mirabilis. Sedan, 1665.) Since that period many instances of mollities ossium have been published in different countries, references to the most important of which will be found in the present article.

The softening of the bones in this disease is preceded by severe and long-continued pains, which are usually confounded with rheumatism, and have sometimes been supposed to arise from syphilis: a gradually increasing debility seizes the limbs, the nervous system acquires an excessive morbid irritability, the patient walks with the utmost fearfulness, and the slightest jar or con-

cussion of the body causes agony.* Some bone now suffers fracture, which all the efforts of the surgeon are perhaps unable to unite; the patient being constantly confined to bed, the bones soften more and more, assume the most strangely distorted forms, and before death have in some cases been so completely disorganized that the extremities were as limber as a rag. (*Bevan*, in Philos. Trans. v. 42.) The patient lies coiled up in bed, sometimes scarcely preserving, except in countenance, the semblance of a human being; the limbs appearing more deformed, and the stature much more shortened than they are actually found to be after death. Every attempt to alter the position of the patient produces agonizing pain, and perhaps new fractures, if the bones be not already too much softened to snap asunder. In such circumstances it is truly astonishing to observe how little the general health suffers, the appetite, digestion, and excretions remaining unimpaired till within a few weeks of death, and the mind continuing calm and intelligent, almost to the last. The urine in such cases is frequently turbid, depositing a copious white sediment; and in some instances small urinary calculi have been voided. But this morbid state of the urine is not constant, for it becomes clear and then again turbid, and occasionally clear for weeks before death. At length hectic fever comes on, sometimes with a feeling of intense burning heat, such that the patient can bear with difficulty the thinnest covering, and requires the windows to be kept open even in the middle of winter.† Diarrhœa and perspirations now exhaust the patient, and death at length, after years of protracted suffering, comes to his relief.

The appearances on inspection after death from mollities ossium differ considerably from those which are observed in the bodies of rickety children. The bones, instead of presenting the appearance of cartilage, as in rickets, are reduced to a mere shell resembling the rind of cheese, and are sometimes described as soft and membranous, and of the thickness of the peritoneum; in one instance the form of some of the bones seems to have been preserved merely by the periosteum;‡ and in the case related by Saviard, (*Saviard*, Nouv. Recueil d'Observat. Chirurg. p. 276,) the remnants of the bones are described as crumbling between the fingers like the rotten bark of a tree. The cavity within the changed and wasted bone has been found filled with a soft red or liver-coloured substance, which in the living body has been ascertained to be devoid of sensibility, (*Thomson*, Med. Observ. and Inquiries, vol. v. p. 259); at other times the contents have been a reddish fluid of the consistence of thick honey, and free from any disagreeable odour. (*Bevan*, Phil. Trans. vol. xlii. p. 488.) In Mr. Howship's case (Edin. Med. Chir. Trans. vol. ii.) the contents of the wasted bony shell were various in their appearance: one mass resembled coagulated blood, another gorged liver, a third light fibrinous matter, and a fourth was like compact fleshy substance. The last portions of the long bones which undergo these remarkable transformations are the extremities; and the remnants of osseous substance which they present are found softened and honey-combed with numerous irregular apertures, appearing, when macerated, like a thin piece of ice when partly melted; thus affording unequivocal evidence of the powerful action of the absorbent vessels to which the osseous tissue had been subjected. The cartilaginous coverings of the articular extremities of the bones have sometimes been found entire, at other times attenuated, but the surface polished and raised into eminences; the cavities of the joints sound; and even when unused for six years, filled with healthy synovia. (Case by Thomson, Med. Obs. and Inquiries, vol. v.)

Although fractures of the bones have not appeared during the life of the patient to have united, yet after death a callus has occasionally been found to have formed, sometimes only within the cavity of the disorganized bone, occupying it completely at the point of fracture; at others it has appeared externally as a prominent ring, and formed within a solid osseous partition, (*Planck*, de Osteosarcosi Comment); thus proving that the solution of continuity had served to restore to the part its ossific powers while they were everywhere else deficient. The muscles, in cases of mollities ossium, are found pale, and in general totally altered in their appearance, so that it would be quite impossible from their adhesions and displacement to unfold them by dissection. The viscera of those who have died of this disease have sometimes been found quite healthy, (*Saviard*, Rec. des Observ. p. 276. — *Howship*, Ed. Medico-Chir. Trans. v. ii.); and in most of the cases they are not stated to have suffered much serious alteration; in one instance indeed the liver was enlarged, (*Bevan*, Phil. Trans.); in another the gall-bladder was contracted, and contained no bile, but many minute black calculi. (*Thomson*, Med. Ob. and Inq.) It is obvious, however, from the histories of other cases, that the lungs and mucous membrane of the bowels must in these instances, if carefully examined, have presented abundant traces of active disease.

2. The **Causes** of mollities ossium are exceedingly obscure: syphilis, gout, rheumatism, and scurvy, have all been accused as the sources of this singular disorganization of the solid framework of the body. The sagacious Saviard observes that syphilis produces caries; but this is a softening and melting down of a totally different nature: as to the other diseases named above, they possess nothing in common with that now under consideration, excepting pain, languor, and debility. In well-marked and extreme cases of syphilis, gout, rheumatism, and scurvy, where death has been the result, we do not meet with mollities ossium as a concomitant, yet authors gravely tell us that softening of the bones arises from the diseases now enumerated lying hid in the constitution and tainting the habit. This

* See a very interesting case by Mr. Howship, Ed. Med. Chir. Trans. v. ii.

† *Planck*, de Osteosarcosi Commentatio, 4to. Tubing. 1782. This writer has been quoted as an authority on osteosarcoma, but his essay refers wholly to mollities ossium, of which it contains a very interesting case with an able and learned commentary.

‡ Case of Madame Supiol, *Moraud*, in Mem. de l'Acad. R. des Sciences, 1755.—*Hosty*, in Phil. Trans. 1753, 54. — *Bromfield*, Surgical Cases, vol. ii. p. 35. Here she is called Queriot, her maiden name. The skeleton of Madame Supiol is still preserved in the Museum at the Jardin des Plantes in Paris.

affection appears to be closely connected with an enfeebled and relaxed state of the system. Long confinement to bed, after acute diseases in young persons, is often productive of some degree of softening of the ligaments and bones, and consequent deformity; we have seen the pelvis in a delicate boy, after tedious convalescence from measles, elongated diagonally, producing great deformity and lameness; in old age, we have known a lady, who was long bed-ridden, fracture her clavicle by the mere effort of attempting to raise herself in bed by the help of a cord. Indeed, the progressive alteration which the bones naturally undergo in advanced life is itself an approximation to decay, the cortical part becoming thin, and the medullary cavity enlarging; but the former still preserves its hardness of texture. A careful examination of the bones, after a long period of inaction, shows that their healthy state is almost as much dependent on the due exercise of the muscles as that of the muscles themselves. In the vegetable kingdom we see the effect of exercise remarkably exemplified by the increase which it occasions in the bulk and density of the woody fibre. The wood of forest-trees which have stood alone, and exposed to the full force of the blast, is much closer in its texture and more durable than timber raised in natural groves or crowded plantations; and the size and strength of the roots of trees is always much greater in the side which stands exposed to the prevailing wind.

Females are much more liable to mollities ossium than males; and pregnancy and parturition favour in a remarkable manner the progress of the disease. Under such circumstances, the weight to be supported, the drain of nourishment for the supply of the fœtus, and the distending throes and exhausting consequences of labour, must all prove powerful causes of relaxing the connections of the bones and lowering the strength of the system. Softening of the bones is observed to occur most frequently in persons of a strumous habit; and this peculiarity of constitution may be fairly regarded as forming at least a strong auxiliary cause in the development of the disease.

3. **Treatment.**—Mollities ossium, unlike the rickets of children, occurs at a period of life when the reparative powers of the system have lost their early vigour, or perhaps when they are already in a state of decay: hence a cure of this disease very rarely or never takes place; but it may proceed with greater or less rapidity, and may be checked in its progress by judicious management. We have been unable to discover any case of mollities ossium in which a satisfactory cure has resulted, either from the unassisted efforts of nature or from medical treatment; but instances of the milder form are known to us, where the disease has proceeded slowly for years, and some of the individuals have attained even an advanced age. The influence which pregnancy has been observed to exert in accelerating the progress of mollities ossium, renders it necessary that the patient should live as in a state of celibacy; and every thing which tends in any degree to weaken the frame ought to be carefully avoided. Frictions of the whole body, gestation in the open air, nutritious diet, mild tonics, great attention to the state of the digestive organs, and removal to a dry, warm, and pure atmosphere, are the principal points to be attended to in our endeavours to arrest the progress of this disease. Benefit is likely to be derived, also, from sponging the body with sea-water, or the strong acetic acid obtained from wood; and if the strength be not too far reduced, the cold shower-bath, or sudden immersion in sea-water, may be tried with caution.

Before concluding our account of the several species of softening of the bones, it is proper that we should say a few words on the subject of lateral curvature of the spine, which of late years has engaged so large a share of the attention of medical men of both branches of the profession. In rickets, the curve assumed by the spine is, with few exceptions, confined nearly to the mesial line; and in mollities it is sometimes so, and sometimes lateral; but a very large proportion of the cases of lateral curvature of the spine are wholly independent of both rickets and mollities ossium, and arise from debility or habitual malposition of the body, such as are too often induced by the restraints and fatigues to which young persons are subjected in the course of education. (*Shaw*, Essay on the Nature and Treatment of Distortions of the Spine and Chest.) Hence arise sinking of the spinal column into the flexures naturally assumed under feelings of languor and exhaustion, and twisting of a part of the vertebræ upon their axes: after a time they remain stationary in their new situations, both the ligaments and muscles being so changed that the latter are no longer capable of restoring the bones to their proper positions. Thus, lateral curvature becomes established, and the figure of the patient is permanently deformed.

On examining after death the individual bones of the spine in such cases, we often find them quite healthy and natural in their form, but more or less twisted upon their axes: in some instances we have seen traces of inflammation, and new bone formed uniting them to each other; and, more rarely, we have observed the bodies of the distorted vertebræ somewhat attenuated and expanded in the interior of the curve where they were most exposed to pressure—a change which was probably the effect rather than the original cause of the deformity.

The treatment of lateral curvature of the spine falls chiefly within the province of the surgeon; but it will be the business of the physician to direct the application of those means which tend to restore the general health of the patient, and thus render effectual the exercises and training, the manual efforts and mechanical contrivances of the surgeon, which would otherwise prove unavailing or injurious. A carefully regulated diet, strict attention to the bowels, mild alteratives and tonics, relief from the restraints of education, and removal to a pure air, friction of the body, gentle exercise in a carriage or on foot, sea-bathing, or the cold shower or plunge-bath, or tepid or warm bathing according to the circumstances of the case, constitute the principal remedies by which the physician is enabled to lend effectual assistance in the treatment of lateral curvature of the spine.

W. Cumin.

ROSEOLA.—This term is applied to a cutaneous efflorescence of a rose colour, not sensibly prominent, usually preceded and accompanied by mild febrile symptoms. In some cases the rash is diffused generally over the skin, but frequently it is partial or limited to certain regions of the body, as the face, neck, trunk, or extremities; in which situations it occurs in patches variously figured, and of more or less extent. It has not unfrequently, especially by the older writers, been mistaken for measles or scarlatina; hence, probably, originated the notion, which many entertain, that scarlatina, unlike other exanthematous fevers, may occur more than once in the same individual.

Roseola is generally preceded by smart feverish symptoms—irregular chills alternating with heat of skin—pain in the head and limbs—languor and lassitude—and sensation of faintness. After these symptoms have continued for a few days, the rash appears first on the face and neck, spreading in a day or two afterwards over the whole body, and is generally attended by tingling or itching. When it first comes out, the eruption is of a bright red, but it soon assumes its characteristic rose colour. It begins to decline about the third day, and on the fourth, a few dark red specks are only perceptible, which wholly disappear on the fifth, at which period the whole disorder in general terminates.

From the redness and sensation of roughness in the throat, it would appear that the efflorescence extends over the mucous membrane of the mouth and fauces; and this circumstance tends to render the diagnosis between roseola and scarlatina more obscure.

The efflorescence is not always so generally diffused over the skin; in many cases it is partial, appearing only in patches on the face, neck, breasts, or shoulders: it frequently recedes and comes out again, its recession being followed by symptoms of gastric disturbance, which cease when the rash re-appears. The recession and reappearance of the rash cannot often be traced to any evident cause, though in many instances irregularities in diet and other indiscretions have been supposed to be powerful agents.

Though roseola may occur at any season of the year, it is more frequently observed in summer, (*Roseola Æstiva*,) and is usually attended by smart feverish symptoms. On the first day the eruption is very liable to be mistaken for measles; but the peculiar character of the eruptive fever, the absence of the catarrhal symptoms, and the form, colour, progress, and duration of the rash, are sufficient to distinguish the two diseases. The rash, which is accompanied by sensation of itching or tingling, is observed first on the face and neck, and in the course of twenty-four to forty-eight hours spreads over the whole body. The spots are distinct and scarcely prominent, of a circular or oval form and deep rose colour, the intervening portions of the skin preserving their natural appearance. The patches are at first very small, but gradually increase in size. The duration of this form of roseola is from three to four days, unless, as sometimes happens, the rash reappears at irregular intervals, and then its course may be protracted indefinitely. It generally disappears without sensible desquamation of the cuticle.

A similar form of roseola is occasionally observed in autumn (*Roseola Autumnalis*). It differs from the preceding in being unattended by itching or tingling, or feverish indisposition, and in the eruption appearing chiefly if not exclusively on the arms.

Another variety of roseola has been described by Willan (*Roseola Annulata*), in which rose-coloured rings, with central areas of the natural colour of the skin, appear on almost every part of the body, attended with sensation of heat, pricking, and tingling, especially during the night. The eruption, which is preceded by symptoms of acute fever, rigors, headach, flushing of the face, nausea, and pain of limbs, may last four or five days, and disappear as the feverishness abates; or, as now and then happens, it may be unattended with fever, and be of much longer duration. In these latter instances the eruption generally appears most vivid in the evening, or when the individual becomes warm in bed, and continues till morning, when it fades. It is sometimes also sensibly elevated, and very often, more especially when the eruption suddenly recedes, attended with considerable gastric disturbance.

Though roseola is not confined to any period of life, it is a frequent cutaneous disorder of infants, more especially during dentition, derangement of the bowels, and various infantile diseases attended with fever (*Roseola Infantilis*). Dr. Willan states that this efflorescence continues in some instances for a night; in other cases it appears and disappears for several successive days, being attended with symptoms of violent irritation. He has seen, even in infants but a few days old, an efflorescence on different parts, in numerous coalescing patches, rounded, though not exactly circular, of about the size of a sixpence, and of a strong red colour. These continue five, six, or eight days, with a slight elevation of the cuticle, and terminate by desquamation, but are not always attended with constitutional disorder. Occasionally during the first stage of dentition, a single patch of efflorescence appears on one arm or on the neck: it remains three or four days, then disappears, and is in a short time succeeded by another, perhaps on the opposite arm. This fades and disappears in about the same period, when a fresh patch arises in another place, and thus the eruption may be continued two or three weeks.

Roseola occasionally occurs also previous to the eruption of both the natural and inoculated small-pox, but seldom in the former; and when it does occur in connection with the natural small-pox, it always indicates a severe and often fatal disease, though some inoculators deemed it an indication of a favourable variolous eruption. The early writers on small-pox observed this roseolous efflorescence, which they regarded as measles converted into small-pox. Dr. Willan, who applied the term *Roseola Variolosa* to the rash when it occurred in connection with small-pox, states that it appears in about one case of fifteen in the inoculated small-pox, on the second day of the eruptive fever, which is generally the ninth or tenth after inoculation. The rash is first observed on the face, breast, and arms, and on the following day spreads over the trunk and lower extremities. It sometimes assumes the form of oblong irregular patches; in other cases it is diffused with nu-

merous interstices; and occasionally it extends over the whole body, so that the skin presents a continuous redness, with slight elevation in some places. The rash continues about three days, on the second or last day of which the small-pox pustules make their appearance, and may be distinguished in the general redness by their prominence and hardness.

A similar efflorescence, but appearing generally in a congeries of dots and small patches, and slightly elevated, takes place in some children about the ninth or tenth day of vaccination, and about the same time that the areola forms around the vesicle. To this rash, which spreads irregularly over the surface of the body, Dr. Willan gave the name *Roseola Vaccina*. It is generally attended with slight febrile indisposition, though from the statement of Dr. Jenner it would appear to be seldom observed, as his notes did not furnish him with a single instance of it, nor did he recollect in any case more than one or two slight patches of redness, which very soon disappeared.

Lastly, roseola sometimes appears in connection with various acute disorders—miliaria, various forms of continued fever, acute rheumatism and with gout. When it occurs under such circumstances, it is to be regarded merely as an accidental complication or concomitant.

Though attention to the appearance of the efflorescence and the constitutional symptoms by which roseola is accompanied will seldom leave any doubt as to its nature, there are some acute eruptive disorders which it resembles in some particulars, and from which it must be distinguished.

Measles may be discriminated by the catarrhal symptoms which precede and accompany the eruption, which generally appears on the fourth day of the eruptive fever, and declines about the seventh or eighth; by the crescentic form and vivid red colour of the rash; by the tendency to bronchial or pulmonary inflammation during the course of the disease, and by its being propagated by contagion. In roseola, the patches are larger, more irregular, and more varied in their form; the eruption disappears after four or five days' febrile indisposition, is not preceded nor followed by any peculiar local inflammation, and is never communicated by contagion.

In scarlatina, the bright red or scarlet colour of the eruption, which is more generally diffused, and more evident about the flexure of the joints; its appearing on the second day of the eruptive fever; the peculiar appearance of the tongue; the affection of the throat when it exists; the desquamation of the skin at the decline of the rash, and its propagation by contagion, will seldom fail to distinguish it from roseola.

It is scarcely possible to mistake roseola for erythema, in which the diffused or continuous redness of the skin without any distinguishable efflorescence, the trifling amount or total absence of constitutional disturbance, and its being generally symptomatic of some other affection, render the discrimination sufficiently easy. (See ERYTHEMA.)

The treatment of roseola includes the adoption of an antiphlogistic regimen modified according to circumstances. The little constitutional disturbance with which it is usually accompanied, and the comparatively slight irritation which it in general induces, render any active measures unnecessary. All that in the majority of instances is required, is to keep the patient cool, to prescribe light diet and acidulated drinks, to administer from time to time a mild aperient; and as the mineral acids have been found useful, they may be ordered according to the feelings of the practitioner. Dr. Bateman was of opinion that the decline of roseola was expedited by the use of sulphuric acid in the infusion of roses, or the infusion of gentian, in combination with small doses of sulphate of magnesia. The occasional employment of the warm or tepid bath may be conjoined with these measures.

When roseola occurs as a complication of some internal disorder, the treatment must be directed to the removal of the disease of which it is merely symptomatic.

A. TWEEDIE.

RUBEOLA, *Measles*, derived from rubio, *red*. This word appears to be of Spanish origin, and probably emanated from the school of Cordova: it was formerly written *rubiola*, or *rubiolo*. Another term by which this affection has been designated is *morbilli*, or the minor plague, being the diminutive of *il morbo*, as the Italians called the plague. The restriction now adopted in the application of the term rubeola is of rather modern date, and owes its establishment to Sauvages, before whose time great confusion prevailed in the naming of several of the exanthemata: rubeola, in particular, was used to signify equally scarlet fever and measles. A similar inaccuracy was to be found among the French writers also, for the word *rougeole*, their common name for measles, meant at one time *scarlatina*, and that so decidedly, that when it was thought necessary to apply distinct names to the two diseases, in consequence of the difference between them becoming fully understood, Chevenan informs us that the Marsellois used the word rougeole to signify scarlatina, and distinguished measles by the name of senapion. (Obs. Med. 454.) In our own country, Morton maintained the identity of these two exanthemata, and considered the relation existing between them the same as that between distinct and confluent small-pox. (De Morbillis et Scarlatina, Exercitat. iii.) Even so recently as 1769, Sir William Watson confounded these two diseases, (Med. Obs. and Enq. vol. iv. p. 132,) the correct diagnosis between which ought probably to be referred to the time of publishing the second edition of Dr. Withering's Essay on Scarlet Fever in 1793. But this was by no means the only or the most remarkable inaccuracy which in former days prevailed on this subject, since we find Sennertus, in the middle of the seventeenth century, discussing the question "why the disease in some constitutions assumed the form of small-pox, and in others that of measles," (Medicin. Prac. lib. iv. cap. 12); and in a posthumous work of Diemerbroeck, published in 1687, it is laid down that small-pox and measles are only different degrees of the same affection; "Differunt (morbilli) a variolis accidentaliter, vel quod magis et minus." (Tract. de variolis et Morbillis, cap. xiv.) The same doctrine was still more recently maintained by Lange, a professor at

Leipsic: "Præterea tam morbilli quam variolæ sunt eruptiones in eo duntaxat discrepantes, quod vel minus vel magis appareant," &c. (Miscell. Med. Curios. § xxxiv.)

Later and more accurate investigations have very clearly shown the distinction that exists between these diseases, not only in their essential characters, but also in the treatment which they require; so that we no longer hesitate in separating them, or feel doubtful as to the elements of a correct diagnosis between them.

By the term rubeola, or measles, in modern times is understood a contagious inflammatory disease, affecting at once the skin and gastro-pulmonary mucous membrane, in which, after catarrhal fever has continued about three days, a rash appears on the skin, at first in small stigmatized dots, not unlike flea-bites, which presently coalescing, form patches of a crescentic or semilunar figure, first on the face, and thence spreading gradually downwards over the whole of the body and limbs, at the end of four days disappear by desquamation of the cuticle.

Rubeola occurs at every period of life, but infants and persons of advanced age are less frequently affected by it than those of the intermediate stage. In childhood and adolescence, however, the disease is most common. It is asserted by Rosen, Vogel, and others, that infants have been born with the traces of measles. Guersent mentions (Dict. de Méd. tom. xviii. p. 513) having seen an infant born with measles on it, having taken the disease from the mother; but we presume such instances must be of exceedingly rare occurrence.

Measles are not unfrequently epidemic; they generally prevail from the beginning of spring to the vernal equinox, and decline about the summer solstice, though this is only a general observation to which numerous exceptions occur. It has been frequently observed that whenever measles rage as an epidemic, small-pox prevails at the same time; and generally speaking, the rubeolous contagion, if received into the system previous to that of variola, has the power of suspending the variolous action till the measles have run their course. This has not, however, been invariably the case, for instances have occurred in which both diseases proceeded together; "this," we are informed by Dr. M'Bride, "was observed particularly in the Foundling Hospital of Dublin in 1769. A number of the children having been inoculated for small-pox, in the meanwhile were seized with the measles, and both species of eruption were perfectly distinct; they nevertheless all recovered;" (Practice of Physic, vol. ii. p. 112;) and Mr. Russell has described two cases in which the two eruptions ran their course together in the same individuals, when these diseases were epidemic at Aleppo in 1765.*

The general law with regard to measles, in common with others of the exanthemata, is, that they affect the system but once, and this peculiarity is maintained with much greater strictness and fewer exceptions than the statements we are accustomed to hear in society would lead us to believe; very many indeed of the cases of secondary measles so reported, originated merely in the parties having confounded roseola or some other cutaneous efflorescence with rubeola. Of this we have detected several instances, and almost invariably it has been acknowledged that the former disease had not been seen by any competent judge: that exceptions have occurred, however, in this disease, as in scarlatina and small-pox, cannot be denied, but that they have been very rare is proved by the few instances which have been recorded. Guersent mentions having seen children affected with the disease twice in the course of the same year; in one child he observed two very regular eruptions of measles in six weeks, and in the interval between their first and second appearance the child had a variety of small-pox. (Dict. de Médecine, tom. xviii. p. 512.) The cases of this kind related by Dr. Baillie (Trans. of Soc. for Improving Med. and Chir. Knowledge, vol. iii. pp. 258 and 263) are not only the most decisive of which we are aware, but also the most remarkable, as showing not merely an individual but a family susceptibility. In the first instance five brothers and sisters had it in succession a second time, four of them after an interval of six months, and the fifth after a lapse of twenty-one years. In the other instance two sisters had a return of the disease after four months. An observation of Dr. Burns (Principles of Midwifery, p. 546, ed. 7.) deserves to be noticed here: he observed that "When the measles were epidemic, it was not uncommon to find those who had formerly had the disease affected sometimes with catarrh without any eruption, sometimes with an eruption preceded by little or no fever and without any catarrh: this was very distinctly observed during every season when the measles were prevalent;" but he is doubtful as to the exact nature of the eruption. Frank (tom. ii. p. 367) says that a second attack of measles is more common than of variola, an opinion which appears to be at variance with general experience, and decidedly with our own. It is also a well-ascertained fact that the imperfect form of measles, generally denominated *rubeola sine catarrho*, does not afford any protection against a recurrence of the disease.

[Mr. Erasmus Wilson, however, (*Treatise on Diseases of the Skin*, Amer. edit. p. 71, Philad. 1843,) affirms that one point of difference between measles and scarlatina is, that the former "frequently (?) attacks the same person twice," whilst the latter rarely does.]

The contagious nature of measles is, we believe, universally acknowledged, and there is even reason to believe that it is infectious before the appearance of the eruption (See Rust's Magazine, Feb. 1827); but, as in other contagious diseases, there is a great difference in the susceptibility of different individuals equally exposed. We very lately attended a young lady with this complaint, whose younger sister slept with her during the whole of the eruptive fever, and for two nights after the eruption made its appearance, and yet escaped the disorder. Heberden mentions that an infant who sucked a nurse till the measles appeared on her was not affected.

* Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, vol. ii. p. 90. See Frank, tom. ii. p. 367, French ed. See, also, a "Case of the Simultaneous Occurrence of Small-Pox and Measles," Med. Chir. Trans. vol. xiii. p. 163.

[The communicability of measles was denied by Dr. Dewees, (*Practice of Physic*, Philad. 1830,) but, evidently, on insufficient grounds.]

With regard to the latent period of measles, our own observation would lead us to fix it at about nine or ten days, but this is a point difficult to determine: after inoculation, the symptoms of fever appeared about the seventh day. Dr. Burns (Principles of Midwifery, &c. p. 642) states the latent period to be about twelve or fourteen days; Heberden (Commentaries on Diseases, p. 322) from ten to fourteen days; Dr. Gregory (Elements of Practice of Physic, p. 127, ed. 3) from eight to fourteen days; Dr. Elliotson (Medical Gazette, Oct. 1832, p. 99) from five days to a fortnight. Dr. Willan says he knew a person who passed through the measles and became convalescent, whose clothes infected a child in the country; this child had the eruption sixteen days after being exposed to the fomites.

[According to MM. Rilliet and Barthez, (*Traité Clinique et Pratique des Maladies des Enfants*, ii. 747, Paris, 1843,) it generally required an exposure of from five to twenty-five days in the wards before children exhibited the eruptive fever.]

Progress of the Disease. — The symptoms of the antecedent fever are not usually such as to excite much attention. The child appears at first not so well as usual, is less active, and out of spirits; the appetite is impaired, and the sleep is disturbed: this derangement of the system is presently explained by the patient exhibiting symptoms of catarrh, — frequent cough, sneezing, running from the nose and eyes, which are tender and generally itchy, so that the child frequently rubs the eyes, and picks the nose: the skin is hot and dry, with occasional chills; and the pulse is quickened. When these symptoms have continued about three days, the child feels on the fourth still more decidedly sick, and is unwilling to leave its bed. Sometimes the precursory symptoms are so slight as scarcely to be felt by the patient or noticed by others. We had lately under our care a young lady of seventeen, who was in constant attendance on her sister in measles, and the first notice we had of her having caught the disease was the appearance of the rash on her face. (See also Heberden, Comment. p. 317.) In other instances the precursory symptoms are very severe: there is high fever, with violent catarrhal symptoms, rigors, total loss of appetite, intense thirst, burning headach, suffused eyes, intolerance of light, constant somnolence, but little or no sleep, or if the patient happens to fall asleep, he starts from it as if frightened; the pulse is rapid and sharp, the throat sore, and the cough incessant, with pain or soreness in the chest. There is an evident exacerbation of these symptoms towards evening, accompanied often by difficulty of breathing, and not unfrequently by nocturnal delirium.

When the rash appears, which it usually does on the fourth day, it is not in general productive of much relief of the precursory symptoms, which are, indeed, more frequently somewhat increased: it is first perceived in general about the roots of the hair, on the upper parts of the forehead, and on the chin, in the form of small red spots somewhat resembling flea-bites, which are at first distinct, but soon coalesce and form patches of an irregular crescentic or semicircular figure, of a dull red colour, slightly elevated, and having between them portions of the skin retaining its natural appearance. If the finger be passed over the surface, the patches of eruption are felt slightly prominent and rough;* this roughness is frequently stated to be perceptible only on the face, but we have repeatedly found it most remarkable on the arms. In a case which we very lately attended, the elevation of the patches on the latter parts attracted our particular attention. In the course of the fourth day the eruption spreads over the face; spots also may be observed on the palate and fauces of a dark red colour, which are still more distinct after another day, the inflammation attending which causes a sensation of dryness and roughness in the pharynx, and increases the hoarseness. On the next day (the fifth) the eruption extends over the neck, breast, and upper parts of the trunk; it is now very vivid on the face, which is not unfrequently so much swelled, especially the eyelids, that the eyes are quite closed up as in small-pox, while the other features are from the same cause greatly altered. Towards the close of the same day, the eruption begins to appear on the arms, and spreads over the lower part of the trunk. On the sixth day the eruption is vivid on the trunk and arms, and appears on the lower extremities about as far as the knees, while it is declining or nearly faded on the face. On the seventh day it is fully out on the legs and feet, and on the hands, while on the body it is fading, which it does in the same order as to parts as it appeared on them. On the eighth day the rash is fading from the parts last invaded, so that on the ninth it is hardly perceptible, and by the tenth it has in general entirely disappeared. While the fading proceeds, the elevations of the cuticle drop off in the form of little scales, so that the surface of the body appears as if it had been sprinkled over with fine bran.

Such is the usual course of the disease in its simple and regular form; but we occasionally meet with deviations or peculiarities requiring to be noticed. Thus the eruption, sometimes anticipating the usual time of its appearance, comes out on the third or even the second day of the eruptive fever, while in other instances it has been delayed many days beyond the ordinary period. Buchobz gives an instance of its not appearing till the twenty-first day, and Dr. Elliotson in his description of the disease says, "these catarrhal symptoms will sometimes last two days, sometimes twenty, before the appearance of the eruption: in some instances the disease is ushered in by severe vomiting, and occasionally, though rarely, free salivation takes place." Heberden (Commentaries, p. 317; see also Frank, tom. 2, p. 370,) tells us of a patient who on the first day of the eruption "was seized with a spitting which continued to tease him for forty-eight hours, without suffering him to rest at all by day, or to sleep by night; the cough in the mean time al-

* It appears very singular that Rayer should describe the patches of eruption as not arising above the surface; his words are, "ces taches ne donnent pas sous le doigt la sensation d'une surface inégale et prominente."— Maladies de la Peau, tom. i. p. 18.

most ceased, and all the other symptoms were as mild as in a favourable sort of the measles." Convulsions also have occasionally preceded the attack, as happens sometimes in small-pox; and one person is mentioned by Heberden, who had a most excruciating pain in the back, which continued for a day or two after the eruption. In some instances the spots have appeared first on the body instead of the face, and in a few rare cases the rash has not spread to the arms during the whole course of the disease. Sometimes the eruption is not followed by desquamation. In many the rash is accompanied and intermixed with a very full crop of miliary vesicles of such size and distinctness as to lead to a suspicion of the approaching disease being small-pox. The production of these vesicles has been ascribed by some writers to an unusual intensity in the inflammatory action attending the disease, but this is certainly incorrect, as we have seen them very numerous in perfectly mild cases. It has happened, but we believe very rarely, that the eruption has broken out anew: Dr. Conolly (see article HYSTERIA in this work, vol. ii. p. 568,) relates the case of a young lady at school, who became the subject of a very singular hysterical affection a few months after having had rubeola in an unusual form; the eruption came out and seemed to be disappearing at the usual period, when it suddenly broke out afresh, and to such an excessive degree as to make it impossible to recognise the features of her face: very nearly the same thing was observed in a case detailed by Frank. (Tom. ii. p. 377.)

[In his examinations of the blood in measles, M. Andral (*Pathologie Hématologique*, Paris, 1843, or Amer. Translation, 1844,) found the proportion of fibrin to be the same as in health—3 parts in 1000. In many adults it was not more than from 2½ to 3½. This mean persists at the commencement of the disease; but after the eruption, and especially in the adynamic form of the disease, there is a tendency to the diminution of this principle. The proportion of the blood corpuscles is, however, augmented from their normal proportion, which is 127 in 1000. M. Andral has seen them raised to 137, 140 and 146. These modifications of the blood are very different from those seen in the phlegmasiæ, in which there is augmentation of the fibrin, which may exceed 10 in 1000, without any increase of the proportion of globules. So far, therefore, as the state of the blood affords an element for discrimination, measles is properly classed with the pyrexiæ or general fevers. (Guersant and Blache, art. *Rougeole*, in *Dict. de Méd.* xxvii. 676, Paris, 1843.)]

Treatment.—The treatment of measles in its ordinary and simple form may be comprised in very few directions. The patient should be kept in bed, with so much covering only as will secure comfort, avoiding equally too much heat or exposure to cold; on these points we almost always have to contend against one or other of two prejudices, the most common of which is, that a breath of cool air is most pernicious to a patient in measles, and in consequence of this belief the individual is kept constantly enveloped in a smothering heap of bed-clothes with drawn curtains and the room well heated by fire, by which means the fever and all its concomitant dangers are greatly augmented; others again, who have had children in the small-pox, insist upon the advantages of cold, not being able to discriminate between the widely different natures of the fevers accompanying the two diseases. The patient should be kept free from disturbance or noise, and, on account of the tenderness of the eyes, a subdued light only admitted into the chamber; he should be liberally supplied with mild mucilaginous drinks, and little or no food, and whatever is taken should be of the simplest kind; he should be solicited to inhale watery vapour by inclining the face over a basin of warm water or of chamomile infusion, by which means the tender eyes have at the same time the advantage of the soothing effect of the vapour; sponging the face, chest, arms, and hands with the same infusion, or with vinegar and warm water, is productive of great comfort by removing the heat, dryness, and itching of the skin, which are often distressing; for a similar reason mild diaphoretics should be given, which may be advantageously combined with gentle aperients in such quantity as the state of the bowels absolutely requires, active purgation being neither useful nor safe. In the opinion of some the administration of an emetic should form part of the treatment, but the propriety of such a remedy has always appeared to us doubtful, and we think we have had reason to be satisfied that its effects were often decidedly injurious by exciting disorder of the alimentary canal.

However favourable may be the condition of the case, we should guard against being lulled into security as to the event. There is no disease in which a change of symptoms occurs more suddenly, or danger more quickly takes the place of safety; we must therefore at every visit carefully ascertain the state of the head, chest, and abdomen; since from these, and especially the two latter, are likely to arise those dangers which may compromise the life of the patient. Thus the discovery, at any period of the disease, of severe headach, with pain piercing through the temples, and perhaps accompanied by delirium and suffused eyes, to which the least ray of light is torture, with a rapid hard pulse, is calculated to excite great apprehension, and demands the immediate adoption of very active measures. The state of the lungs should most particularly engage our attention, as being the organs most constantly and most severely affected in this disease. The period at which danger may generally be apprehended from this source is about the decline of the eruption, that is, from the seventh to the ninth day; but we should be equally on the watch at all times to detect the first symptom of inflammation within the chest, and for this purpose we would strongly inculcate the necessity, where there can be the slightest doubt, of always determining the point by auscultation, instead of trusting to the ordinary symptoms to be collected from the state of the pulse and respiration, or the expression of the countenance, all of which, under the peculiar circumstances of this disease, are but little likely to afford satisfactory information. When once we have satisfied ourselves of the presence of inflammation, our sheet-anchor is bloodletting. We should bleed at once; and if the symptoms are

not subdued bleed again ;* we would even say, if there be doubt bleed, but of course very cautiously, —carefully watching the effect, which, in ninety-nine cases out of a hundred, will be decidedly beneficial. Heberden (see Commentaries, p. 321), Cullen (Practice of Physic, vol. ii. p. 180 and 181), and others of our most celebrated physicians, appear to have considered bloodletting as an essential part of the treatment in almost all cases, and to have practised it in every stage of the disease. Mead (Medical Works, p. 261. Edit. 1767.) makes no exception, but directs it in every instance. We should, however, be very far from recommending an indiscriminate adoption of such a practice, which under the ordinary circumstances of the disease is not required, and might often be injurious. Bloodletting is seldom necessary during the eruptive fever; and when the rash has appeared we must take care not to fall into the error of mistaking the hurried and labouring respiration and quick pulse which accompany the disease during the height of the eruption, for proofs of pulmonary inflammation, these conditions being merely symptomatic, and subsiding after a day or two without any morbid condition of the lungs coexisting, as may be ascertained by the careful application of the stethoscope. Should the character of a prevailing epidemic or of a particular case be low, typhoid, or putrescent, the abstraction of blood would be altogether inadmissible; we must also bear in mind that a great majority of our patients are of tender years, and must be treated accordingly. In most cases all we desire may be accomplished by the application of a few leeches, which should always be applied over a part where there is a solid resistance to pressure, should it become necessary to restrain the bleeding; in general the back of the foot is preferred for this purpose in most of the diseases of children. If the object be to relieve the head, the leeches may be applied to the temples, or still more advantageously behind the ears. Whenever we find the patient harassed with an incessant hacking cough, complaining of pain or soreness within the chest, with a sensation of tightness or constriction across that cavity, increased by a full respiration, and with a full hard pulse, we should not hesitate to bleed, even though we may not be able fully to satisfy ourselves of the absolute existence of thoracic inflammation, the effects of which we shall too probably have to lament if we postpone the application of the most effectual remedy for its control.

We do not propose to enter here into the details of the treatment of pneumonia, bronchitis, or pleuritis, which may be consulted in full under their respective titles in other parts of this work: we will only here observe, that the remedial agents on which our reliance must be placed for subduing the inflammations incident to this disease are — bloodletting, leeches, blisters, or vesicating liniments, calomel, ipecacuan, tartar-emetic, and the warm bath. Vesicating liniments will often be found preferable to the common blister in treating this and other diseases of children, from the much greater quickness with which they may be made to act, and their not being nearly so apt to produce ugly sloughing sores,—an effect which is too often found to follow the action of the common blister, especially in measles; besides we can very conveniently regulate the degree of activity by altering the relative proportion of their components. A very eligible formula for such an application, the efficacy of which we have repeatedly proved, is three or four parts of linim. camph. comp. or linim. ammoniæ with one part of ol. terebinth. If this liniment be applied warm to the skin, by sopping it in a fold or two of lint of whatever size and shape may be thought necessary, it will produce vesication generally within twenty minutes. M. Luroth has recently recommended frictions with strong tartar-emetic ointment over the chest and epigastrium in this disease; but when we consider the extreme irritability of the skin in children, it would require a strong conviction of the indispensable necessity for such an application before we should venture to resort to it. Cold affusion has been recommended (see Bateman's Synopsis, p. 61, and Edin. Med. and Surg. Journ. April, 1814), and in a few instances adopted in the treatment of measles, and it is said successfully. Kœmpfer assures us that at Java the children die of measles if they are not washed with cold water; and Guersent says he would not hesitate to use it where there was pure debility free from disease in the chest. (Dict. de Méd. tom. xviii. p. 516.) We have never witnessed the adoption of this practice, and we confess that it appears to us so hazardous and so unnecessary, that it would be difficult to induce us to venture on the experiment.

It sometimes happens that the rash comes out imperfectly, or having appeared properly, suddenly retrocedes and disappears: under such circumstances the nurse will almost certainly, if not well watched, give the child a good dose of sulphur in diluted spirit, or a glass of punch containing saffron, which are considered specifics for helping to bring out the eruption. The pernicious results of such remedies it is unnecessary to point out, especially when we consider that in almost every such instance the retrocession is the effect of some internal disorder which is generally inflammatory, or of too high a degree of fever, the reduction of which should be the primary object of our treatment. If the retrocession have been caused by exposure to cold, the use of the warm bath, diaphoretics, and warm or perhaps slightly stimulating drinks, are all that will be required. Should debility appear to have been the cause, a stimulating plan must be adopted, not only because the rash has receded, but because it has done so in consequence of a condition of the system which, if allowed to continue, might place the patient in danger. The improper use of active cathartics may have been the source of the evil, or it may have arisen from a spontaneous diarrhœa setting in from the commencement; if so, the state of the alimentary canal claims our particular care. Should there be tenderness and other evidence of inflammation, we must bleed, or apply leeches,

* "I have with great success ordered even the tenderest infants to be blooded in the arm, in such quantity as their age and strength indicated. And sometimes also, when the disease (pneumonia) has been urgent, I have not feared to repeat the operation; and in reality, by bleeding, I have snatched abundance of children from imminent death. This disorder attacks children upon the departure of the measles, and proves so fatal, that it may justly be esteemed one of the principal ministers of death, destroying greater numbers than the small-pox."—*Sydenham*, p. 177-8.

and use the warm bath; if the discharges are ill-coloured and of very foul odour, we should give calomel, or mercury with chalk and rhubarb; afterwards an anodyne injection may be advisable. These observations apply to the treatment of diarrhœa when it comes on at the termination of the disease: Sydenham says, "Bleeding, also, cures the looseness which succeeds the measles;" (Works by Swan, p. 178;) but we must observe that we cannot always venture to bleed when there is tenderness present, which may exist without any other evidence of inflammation. On the contrary, there may be much debility; and here we must have recourse to blisters, irritating liniments, the warm bath, opiates, astringents, and a rice diet, with removal into the country to complete the cure.

Varieties of Rubeola. — 1. *Rubeola sine catarrho* is a form of the affection in which the eruption appears unaccompanied by the usual symptoms of fever and catarrh, and its invasion does not protect the individual against a second attack. This variety has been called by the German writers *rubeola spuria*, and by Dr. Good *rubeola incocta*. Rayer denies the existence of this form of measles, and maintains that such cases are merely roseola mistaken for measles; but the descriptions of Willan, Heberden, and many other very accurate observers, leave no room for doubt on the subject. The most satisfactory example the writer ever saw of it was in one of his own children; the rash was perfect, but the catarrhal symptoms were entirely absent. There is nothing peculiar in the management of this variety, but we should warn the parents that they may expect the occurrence of the disease in its usual form. Frank, in his general observations (tom. ii. p. 216, French edit.) on the exanthemata, maintains that as "there is no exanthem which does not occasionally exist without its peculiar fever, so on the other hand there is not one of the exanthematous fevers which does not in certain cases pursue its course without any cutaneous eruption, and *with the same consequences as in other cases*." This appears in some measure supported by the observation of Dr. Burns already quoted, but we confess that our own experience has made us very sceptical on the point. Rayer is of opinion that the cases which have been supposed *rougeole sans éruption* were neither more nor less than *catarrhes sans rougeole*; and it is to be remarked that Frank himself, speaking of measles, declares "he never met with the fever of measles without the eruption (febris morbillosa sine morbillis), and doubts its existence until it shall have been proved by inoculation that persons who have had such a fever are not susceptible of taking measles." (Tom. ii. p. 370.)

2. *Rubeola nigra*.—This designation is applied to a peculiar appearance which the rash occasionally assumes about the seventh or eighth day, the spots becoming of a livid colour, or, more properly, of a brownish hue, inclining to yellow. It is generally accompanied by languor and a quick pulse, but seldom lasts more than a week or two. Guersent, (Dict. de Méd. tom. xviii. p. 509,) however, met with a case in which it continued for more than five weeks; he thinks it ought to be distinguished from measles. Practically it is not a matter of much importance, as it is not productive of any bad consequence, the patient recovering quickly under the use of tonics, of which Dr. Willan preferred mineral acids, which may be very conveniently and advantageously given in combination with sulphate of quinine. It is to be recollected that this is a condition totally distinct from the presence of petechiæ, which mark a debilitated and broken-down state of the system, likely to occasion great danger.

3. *Rubeola putrida vel maligna*. — This distinction has been made to designate a class of cases in which the concomitant symptoms are such as accompany the low form of typhous fever, with a tendency to putrescency throughout the system. The form of disease described by Sir William Watson (Med. Obs. and Enq. vol. iv. p. 132,) as prevailing in the Foundling Hospital in 1769, which proved very fatal, was evidently scarlatina in its malignant form, and not measles. At that time the two diseases were confounded, and Dr. Watson was one of those who even thought that the term scarlatina might be altogether dispensed with.

This variety of the disease is said to have prevailed at Plymouth in 1745, in London in 1763, and at Edinburgh in 1816. (See Edinb. Med. and Surg. Journ. Jan. 1817.) In these epidemics the symptoms of the eruptive stage were particularly violent: the patients were early seized with extreme debility, restlessness, sometimes with coma; the tongue became dry, hard, and black; the fauces were of a deep red colour, accompanied with great irritability of the stomach; the eruption did not exhibit its usual characters; it frequently receded very soon after it made its appearance, was less elevated than it ought to be, and of a dark or livid colour. A large majority of these cases died, and on examination there were found well-marked evidence of inflammations within the thorax. In Edinburgh the retrocession of the eruption was almost always a fatal symptom. Such a form of the disease we believe to be extremely rare in this country, at least we have never met with it. At the same time, however, it is not to be doubted that in particular constitutions, or under certain contingencies, the complaint may assume these characters. Thus Dr. Perceval mentions that in a charity-school where measles prevailed, typhous infection was introduced, and a corresponding change was immediately observed in the character of the measles. Dr. Thompson saw a case in which the languor and state of the pulse were alarming, and the skin rubbed off like a moist cobweb, but the patient recovered by the use of wine and cordials, the administration of which, with the addition of some of the preparations of bark and ammonia, with the warm bath, constitute the chief remedial agents suited to such a condition of the system.

4. *Morbilli variolosi* is a variety mentioned by Dr. M'Bride, (Practice of Physic, vol. ii. p. 116,) in which he says "the eruption is prominent, the face swells greatly, and many pustules actually suppurate like those in the small-pox;" and he adds, "the cough and other catarrhal symptoms are the things which distinguish this from the small-pox." Such a disease as that here described

we have never seen, except it should be merely what we have already alluded to,—measles accompanied by a great number of miliary vesicles, some of which occasionally suppurate, but bear no resemblance whatever to small-pox: the occasional conjunction of the two diseases has been already spoken of.

Inoculation.—Some time about the middle of the last century it was proposed to adopt inoculation of measles for the purpose of rendering the disease milder; and Dr. Home (Clinical Facts and Experiments, 1758,) of Edinburgh performed several experiments on the subject, inoculating with a little blood drawn from one of the exanthematous patches. The result does not appear to have been either very decisive or satisfactory; nor has the eligibility of the practice been at all proved by subsequent trials, many of which failed altogether; and even where they succeeded in producing the disease, the operation did not always ensure a mild form of the complaint; on the contrary, many of the cases so produced were as severe as those arising naturally. On this point we have no evidence to offer from our own experience, never having seen the practice put to the test; and we can only find that authorities of equal weight are completely at variance on the subject. Theurmen and Tellegen, as we learn from Rayer, inoculated five infants without any other result than the production of slightly inflamed spots where the punctures were made. The same want of success attended the trials made by Dewees and Chapman at the Philadelphia Dispensary in 1801. The most recent trials of which we are aware are those made by Professor Speranza of Mantua: he inoculated in the first instance six individuals, and afterwards himself, with blood taken from a vivid patch of the eruption: in a few days the measles appeared, and proceeded mildly and regularly; in consequence of this he made further experiments, and he says they were all successful. Dr. Elliotson thinks it "likely that the vesicles which occasionally accompany the eruption may contain the contagion itself in a concentrated form."

Prognosis.—The prognosis in simple measles is almost always favourable; but nothing is more certain than that the mildest form may be speedily converted into the most dangerous; a sudden change taking place in the symptoms which could not have been foreseen, or produced by improper treatment, such as the administration of stimulants, by too much heat, or by exposure to cold. It is to be recollected that it is not the eruption or the mere disease which endangers the safety of the patient, but the internal inflammation which may accompany or follow it; and hence the great necessity for ascertaining exactly the degree of their development by a most careful examination of the organs of respiration and digestion, to enable us to form a correct opinion as to the probable result. There is a very general impression that adults are in greater danger from measles than younger subjects; but as far as our experience enables us to judge, we should pronounce exactly a contrary opinion, supposing each to be in an equally good state of health at the time of being attacked. Of course, if an adult encounters the disease with a constitution naturally delicate or previously broken up by intemperate habits, or with some old pulmonary complaint, such a patient would be in great danger; but as a general rule, young children are most likely to suffer severely, because they are most disposed to severe attacks of pulmonary inflammation; so that, in our opinion, the younger the subject the greater the danger. Pregnant women are known to bear all the exanthematous diseases badly, and especially small-pox; this might, *à priori*, be expected, because their system is already in a state very unfavourable for the reception of an inflammatory disease. Rayer considers measles under such circumstances peculiarly dangerous. The cases which the writer has seen have done well; and Heberden (Commentaries, p. 322,) expressly mentions that he "attended several who were greatly harassed by the violence of all the usual symptoms in this illness, but never knew it make one woman miscarry, or be in more danger on account of the pregnancy."

The character of a prevailing epidemic should always be taken into account: thus that of 1670, described by Sydenham, was particularly mild, while that of 1674 was remarkable for the frequency of pneumonia.* The season of the year also has no inconsiderable influence on the progress and issue of the complaint, which is likely to proceed more favourably and safely in mildly warm and temperate weather than when there prevails either extreme of heat or cold. When measles and some other disease are conjoined, as for instance variola or pertussis, or when measles follow close upon the subsidence of some other ailment, especially if that has affected the lungs, the danger to be apprehended will be greatly increased: the same may be said when this disease attacks persons of a scrofulous or a plethoric habit. The following may be considered as the general circumstances which should forewarn us of danger: great violence in the symptoms of the eruptive fever; the eruption appearing too soon or too late; the approach of pulmonary or abdominal inflammation; severe headache with delirium, suffused eyes, or coma; a hacking cough, with a hard pulse; extreme dyspnœa; retrocession of the eruption, which is generally owing to some serious internal derangement; the accession of typhoid symptoms; the appearance of petechiæ; profuse hemorrhages, inducing prostration of strength:† while, on the other hand, a favourable case may be known by the regularity with which the eruption appears and proceeds, and its equal distribution on the different parts of the body successively; by the absence or slightness of the symptoms of thoracic or abdominal inflammation; freedom from headach; the soft state of the pulse; the naturally moist condition of the skin; and the patient obtaining a sufficiency of refreshing sleep. From the London bills of mortality, it

* The number of deaths from measles that year amounted to 795; while for the three preceding years, taken together, they amounted only to 140.

† When females, especially girls, are the subjects of measles, it very frequently happens that during the eruptive stage of the disease the catamenia make their appearance perhaps a week or two before their natural period, and sometimes much more profusely than is natural; this we have repeatedly observed to happen, not only without injury, but we have thought with advantage.

appears that there died, from December to October 1831, of measles 532, of small-pox 436, and during the same period in 1832 the number of deaths were, of measles 508, of small-pox 532; making a total of measles 1040, of small-pox 968. Morton has given a very highly exaggerated account (Append. ad Exer. de Morb. Acutis, p. 427,) of the mortality during the epidemic of 1672, when he says the deaths from measles were *three hundred every week*; whereas it appears, from the public bills of mortality, that the whole number of deaths for that year by measles amounted only to 118. (See paper by Dr. Dickson in Med. Obs. and Enq. vol. iv. p. 256.)

Sequelæ.—Measles are very frequently followed by a train of symptoms indicative of serious pulmonary lesions, very generally by a distressing and tedious cough, by chronic bronchitis, chronic pleuritis, pneumonia,* tubercles and phthisis; chronic diarrhœa, generally of an inflammatory character, sometimes harasses and exhausts the patient; ophthalmia, ear-ach, and running of the ears, occasionally also supervene. There are several cutaneous affections apt to appear after measles; amongst them is a very troublesome eruption of inflamed pustules, sometimes terminating in ulceration. In a few instances gangrene of the inside of the cheeks, gums, and lips, in the horrid form of *cancrum oris*, has been observed; in other instances the mortification has affected the vulva. Anasarca has been known to appear after measles, as it very often does after scarlatina; but this is so rare an occurrence, that where anasarca is found, and said to have been preceded by measles, there is much reason to suspect that the previous disease was scarlatina. (Frank, tom. ii. p. 372, op. cit. Guersent, Dict de Méd. art. *Rougeole*.) Dr. Harty, who has had extensive opportunities of observing this disease, informed the writer that he has very frequently found during convalescence from measles that the pulse became unusually slow, about forty or fifty beats in a minute; but it did not appear to be connected with any thing unfavourable in the condition of the patients, whose recovery was uninterrupted.

WILLIAM F. MONTGOMERY.

RUPIA, from *ῥύπος*, *sordes*, may be characterized as an eruption of flattened and scattered bullæ, each surrounded with an inflamed areola; the bullæ filled with serous, purulent, sanious or dark bloody fluid, and succeeded by thick dark-coloured scabs covering unhealthy ulcerations. Bateman and Biett describe the varieties of rupia under three species or heads, viz. rupia *simplex*, rupia *prominens*, and rupia *escharotica*. The last of these, rupia escharotica, being the same disease as gangrenous or infantile *pemphigus*, and as such already fully described in the article PEMPHIGUS; the other two species, rupia simplex and rupia prominens, alone demand a place here: moreover, as these differ from one another merely in degree of severity, they may be comprised under one general description.

The bullæ of rupia are observed most often on the lower extremities, but are also frequently seen on the loins, the upper extremities, and about the shoulders. They are always few in number, and are generally scattered at some distance from one another. In the mild form, (rupia simplex,) one or more oval bullæ arise with little or no premonitory redness of the skin. These bullæ are flattened, and are filled with a sero-purulent fluid, and seldom exceed a sixpence in size. After the lapse of a few hours from their formation, they become partially flaccid; the contained fluid grows muddy and puriform, and dries into a dark-brown scab, thick in the centre, and thin towards the circumference. Around the scab there is a dusky red areola, the cuticle covering which is slightly raised or separated from the true skin, and continues all round with the thin edges of the scab. The latter is in general easily removed, or falls after a few days, leaving an unhealthy-looking ulceration of the skin, which either becomes crusted with a fresh succession of scabs, or heals, leaving a dark purple mark. In the aggravated degree of the disease, (rupia prominens,) a circumscribed inflammatory redness precedes the formation of the bullæ. The bullæ rise slowly, and, instead of serous fluid, contain purulent matter or a mixture of purulent matter and blood, which constitutes the blackish fluid already mentioned as sometimes found in the bullæ. The contained fluid dries into a very dark-coloured scab, which covers a deeper ulceration, and is surrounded by a wider inflammatory areola than in rupia simplex, and as the ulcerated surface is continually secreting pus, and at the same time enlarging in circumference, the scab is increased by successive layers, each wider than the preceding, and at length, at the termination of ten or twelve days, acquires a conical shape similar to a limpet-shell, sometimes extending at the base to the size of a dollar in area, and protruding in the centre an inch above the surface of the skin: hence the name of this variety of the disease — rupia prominens. This scab is superficial, and if removed is either replaced by a fresh scab, or leaves exposed a pale unhealthy spreading ulcer, bleeding on the slightest touch, of a depth proportionate to the duration of the scab, with livid swollen borders, and in old persons often very difficult to heal and even when healed leaving a dark-coloured cicatrix.

Diagnosis.—Rupia may be confounded with pemphigus, ecthyma, and venereal pustular eruption, but the bullæ of pemphigus are large, full, and very prominent, and generally contain a serous fluid, while the bullæ of rupia are small, flattened, quickly become flaccid, and contain a fluid, which, if not sanious or purulent from the commencement, very quickly becomes so. Gangrenous pemphigus pours out a sanious fluid, but does not form scales like rupia. The ulcerations of rupia are deep and indented, while those of pemphigus are superficial, resembling excoriations. The shape of the scab in rupia prominens at once distinguishes this variety from pemphigus. Rupia is frequently found in conjunction with ecthyma luridum and cachecticum, and Plumbe has classed rupia and ecthyma together. The two diseases

* Laennec thinks that the suffocating orthopnœa which sometimes very suddenly carries off young children after measles is produced by an idiopathic œdoma of the lungs. In the greater number of cases examined after death by the writer, the morbid alteration existing was the condensation of the pulmonary structure ordinarily found as the effect of pneumonia.

are, however, very distinct in their pathology and appearance. Ecthyma commences as a pustule, rupia as a bulla. The scab of rupia is generally easily removed; the scab of ecthyma is strongly adherent. Around the circumference of the scab of ecthyma there is deep-seated inflammatory hardness, extending into the subcutaneous cellular tissue; around the scab of rupia there is only a superficial red areola, the cuticle over which can be traced in continuation with the surface of the scab. The scab formed on some of the pustular venereal eruptions bears a very close resemblance to the scab of rupia; and as both diseases are likely to occur in the same broken-down constitutions, there is risk of confounding them. The venereal scab and pustule are, however, found to proceed from pustules with hardened bases, not from bullæ as in rupia, and they are generally surrounded with the peculiar syphilitic copper-coloured areolæ. These characters, with the presence of some of the usual constitutional symptoms of syphilis, will suffice to distinguish the two diseases. Plumbe speaks of having seen evil result from mercury being administered for rupia, under the mistaken supposition of its being a venereal affection. Few practitioners, however, in the present day, after the clear and lucid views laid down for the treatment of venereal affections by Mr. Carmichael, (an Essay on Venereal Diseases, and the Use and Abuse of Mercury in their Treatment, by Richard Carmichael, M. R. I. A., &c.), would push mercury to any extent for such appearances, even admitting them to be of venereal origin.

Prognosis.—The duration of rupia is very uncertain, running through its course in a few days, or extending to months. The disease is severe in proportion to the age of the patient, or weakness of the constitution. The slowly-healing ulcerations often keep up a low fever in the system, and thus injure the health, but rupia is scarcely if ever a fatal disease.

Causes.—Rupia may be considered as altogether a constitutional affection, being only seen in the aged, or in the debilitated from any cause, but particularly from intemperance, abuse of mercury, or want. Acute diseases affecting the skin, and leaving much debility after them, predispose to it; thus it appears as a sequela of small-pox and scarlatina. The scrofulous are peculiarly subject to it, and it is most prevalent during the winter season among the poor who are badly fed and clothed.

Treatment.—From what has been just stated relative to the causes of rupia, its treatment is easily anticipated. The remedies are a light nutritious diet, cleanliness, the warm bath, attention to the state of the bowels, and sarsaparilla or cinchona, with the mineral acids. Dr. A. T. Thomson, in his edition of Bateman, says that slight mercurial courses carried so far as to affect the mouth are sometimes necessary. Mercury, when used in this disease, should according to the best observers be used only as an alterative, and in its mildest forms, as in Plummer's pill. As to local applications, the scabs should be removed by a poultice, and the raw surfaces, if painful, are to be stuped with decoction of bran and poppy-heads. Relaxing or emollient applications, however, should be used only for a short time; the surfaces of the ulcers very soon require stimulating applications, and the strength of these must vary, according to the relaxed state of the ulcers, from a weak solution of nitrate of silver to the application of the solid nitrate, the strong nitric or muriatic acid, or ointment of red precipitate of mercury. Rayer recommends the ulcers to be dressed with saturine cerate, pledgets of lint to be placed over this dressing, and all to be confined with a bandage which shall keep up a moderate compression. He recommends the ulcers when indolent to be dusted with powdered supertartrate of potass, or a solution of it to be used as a lotion. In this, as in all skin diseases where there is ulceration attended with low irritative fever, internal opiates given at bed-time to procure sleep form an essential requisite in the treatment.

D. J. Corrigan.

[SALIVATION, See Ptyalism.]

SCABIES.—This is the classical word now universally used to designate the well-known contagious vesicular disease of the skin, called popularly, in English, *itch*, French, *gale*, German, *Krätze*, Italian, *rogna*, &c. These vulgar appellations, except the French, (the etymology of which is doubtful,) are derived from the property which our English expresses, the intense itching and irresistible scratching which it excites. Scabies is the word by which the Latins rendered the ψώρα of the Greeks, a term under which the latter comprehended a number of papular and squamous affections, although they at length appropriated it to the disease which we now denominate psoriasis. The confusion which for a long time attached to ψώρα necessarily involved its synonym scabies, and prevented it from becoming definite in its signification, until they were divorced by Celsus, who restricted the Greek term to scaly diseases, and excluded these from the comprehension of the Latin scabies. The Roman physician and his successors did not, however, confine its signification within its present limits, but included under it other pustular and pruriginous affections, and so caused an inaccurate latitude in its acceptation, which prevailed to a comparatively recent period. The advance of cutaneous pathology at length isolated the disease, but the verbal confusion was revived by Cullen and others, who, when scabies had been definitely fixed, chose for the designation of the itch the term anciently used in so indefinite a sense by the Greeks, *psora*, which (with a prolonged termination) Willan, with a greater regard to its old signification, appropriated to the scaly disease. No imputation of inexactness in this instance attaches to the old medical writers, for words must ever be varying and inconstant in their signification until the state of science permits the diseases which they represent to be investigated upon enlightened principles, and discriminated by a true nosology; but authors are to blame, who, after this period arrives, embarrass the received nomenclature by arbitrarily multiplying names, or changing them from their general acceptation.

Scabies is one of the cutaneous diseases the distinct identity of which is best confirmed by peculiar characters, yet in the description of which

such a variety exists as to render it extremely difficult to give a comprehensive account of its history and symptoms. An artificial arrangement would be very desirable for this purpose, but in seeking for such we find how difficult it is to fix arbitrary bounds within which natural phenomena may be circumscribed. "This troublesome disease," says Bateman, "from its affinity with three orders of eruptive appearances, pustules, vesicles, and papulæ, almost bids defiance to any attempt to reduce it to an artificial classification." (Synopsis, 7th edition, 1829, p. 278.) A ready illustration of this statement is found in the fact that while Willan has placed it in his order "pustulæ," Biett and Rayer, who have adopted his system, classify it among the vesicles; and again, Dr. Paget, the author of a late ingenious essay on the classification of cutaneous diseases, (Edin. Med. and Surg. Journal, vol. xxxiv. p. 270,) coincides with others who consider it as appertaining to the papulæ. It does not belong to our object to maintain the credit of the artificial arrangement, but we may remark that this discrepancy, which shows its defectiveness in this particular as a system, by no means detracts from its practical advantages; on the contrary, the purposes of study and description demand more urgently the aid of arbitrary methods of arrangement when the natural appearances are diversified.

It is admitted by the majority of observers, that by far the greatest part of the eruption of scabies is composed of vesicles, so that we unhesitatingly agree with the French authors above cited in regarding its type as essentially vesicular. The transparent apex of the elevation is often so minute or so fugitive as to give the idea of a papula, if not observed attentively and at the seasonable period of its course. With respect to the true papulæ, which are often interspersed amongst the vesicles, it is to be observed that in all eruptions of the skin (whether their real type be vesicle or pustule) there is a period at which the elevation is merely a papula, and it frequently happens that in a vesicular or pustular eruption some pimples proceed no farther in their development than the state of papulæ. Nothing is more common than to see among the pustules of porrigo several which have no purulent apex, having never advanced beyond the papular stage; but on this account their genuine character is not the less established, being properly regarded as *undeveloped* pustules. The papulæ which complicate the vesicles of scabies bear a larger proportion to the true type than in the example of porrigo, but they appear to possess a similar relation to it, being as it were *abortive* vesicles. The occurrence of pustules in scabies forms, indeed, a more decided variety, as one species of it seems to be truly pustular in its nature. Yet it is not to be overlooked that some of these apparent pustules are also primitively vesicles, in which an inflammation of more than ordinary acuteness has produced a purulent secretion instead of transparent serum. According, then, to the opinion here stated, we embrace the vesicular as the true type of the eruption, and regard the deviations of papulæ, and in part those of pustules, as caused by casual variations in the intensity of the inflammatory action. On the one hand, papulæ occur where the inflammation stops short of maturing vesicles; and on the other, pustules are met with when, proceeding to an immoderate degree, it fills the vesicles with pus in place of serum.

The contagious nature of this eruptive disease is the most essential character of its history. Its vesicles are minute and slightly acuminated, with a pearly semi-transparency at their summit. They may arise at any part of the body, and spread until it cover every part except the face, which appears to possess a singular immunity from their invasion. The hands and arms are always principally affected, and are often so when no other part of the body partakes of the eruption, which is sufficiently accounted for by the fact that infectious contact usually occurs in this situation. The vesicles are mostly distinct, but have a disposition to accumulate at the flexures of the joints; being almost invariably found confluent on the soft fold of skin between the fingers and at the joint of the phalanges and wrist, and often at the larger articulations, if the eruption be more extensively spread. The intense itching which is the characteristic feature of this troublesome disease accompanies the first appearance of the eruption, and, indeed, seems generally to precede it, as the inflammatory elevation which generates the vesicle is much promoted by the scratching, which the pruritus irresistibly induces. It increases from the commencement until each vesicle attains a certain degree of maturation, when it decreases. The annoyance which it produces is in proportion to the extent of the eruption; if the vesicles be few in number, are developed slowly, and confined to a circumscribed locality, it may cause little attention; but when they are numerous and extensive, and come out with rapidity, the pruritus rises to an intolerable height, and produces inexpressible irritation. The patient then seeks to assuage it by scratching, from which, howsoever he may be cautioned against it, he feels it impossible to refrain. Temporary relief may be obtained from this by changing the itching sensation into the pain of laceration, but he only lays up in store a future visitation of greater intensity. The action of the nails increases the inflammation, which causes new crops of vesicles to spring up, and aggravates the pruritus in the old. More or less of the same consequences flow from any other circumstances which give rise to even a transitory excitement of the cutaneous circulation, as the warmth of bed, the digestion of a stimulating meal, or the use of spirituous potations.

Several days elapse between the time of infectious contact and the manifestation of the pruritus, which period is called in this as in other eruptive diseases the incubation. Its length is much modified by the age of the individual, as connected with the susceptibility of the cutaneous surface to impressions. In childhood, when the skin is soft and active in its functions, the incubation has generally three or four days' duration; in adults it averages ten to fifteen, and in old age, when the skin is rigid and has lost its vascularity, this period is still more prolonged. In the bilious temperament, in which the skin's function is less energetic than in the lymphatic and sanguine, it is also comparatively protracted. The relations of climate and seasons, moreover, have a sensible

effect on it, cold and heat respectively retarding and accelerating the first appearance of the disease. The existence of an inflammatory affection of any internal organ is another condition which appears to diminish the susceptibility of the skin to its infection, and to add to the period of incubation. The circumstances connected with this latent period are worthy of attention, not only on account of their intrinsic interest as pathological facts, but because they afford an important practical deduction, which is as follows: the duration of this period has a relation to the actual course of the disease, and the facility with which it may be removed; when the eruption appears promptly after infection has been contracted, it may be inferred that the disease can be speedily conquered by the appropriate remedial applications; but if, on the contrary, the skin has exhibited a tardy inactivity in producing the eruption, when fully developed, the latter will be proportionately inveterate and less amenable to therapeutic means.

When scabies has fully appeared, although it may be modified as to its intensity by circumstances, it always assumes a progressive course, until arrested by treatment; it has no tendency like the exanthematous eruptions to a spontaneous cure. From its original seat it spreads until the whole surface is affected, but collects especially where the skin is disposed in loose folds, subject to friction, as the axilla, the internal parts of the thighs, and fold of the buttock, as well as the flexures of the articulations. The situation where it may first show itself appears to be entirely dependent on the liability of different parts to contact with infected persons. This is demonstrable from the consideration of it in different individuals, whose condition in life exposes one part of the body more than the rest: for example, in tailors, sempstresses, and shoemakers, it commences on the hands; in infants in the nurses' arms, the nates are frequently found to be the part first affected; and if, on the contrary, the nurse receive it from the child, it breaks out on the hands, and sometimes (which is more in point) on the breast. An exception to this rule would seem to exist in the case of dyers, smiths, and sawyers, whose hands and wrists are rarely primitively affected, and often escape, while it infests other parts: this is to be ascribed to the rough hardened state which the hands of these tradesmen contract from labour, and doubtless in the first two their immunity must be in some part owing to the chemical agents with which their employments bring their hands in contact. Sulphuric acid and other powerful astringents form a main ingredient in the dyers' liquors, and the iron and embers of the forge constantly impregnate the smiths' hands with sulphureous vapours, which are at once its best prophylactic and cure. Redi asserts that he knew an instance in which the face became the first part affected, from the contact of the collar of an infected mantle; but its appearance on the face at all is so contrary to experience deduced from innumerable observations, that this has been denied to be a genuine case of scabies by later writers.

Willan and Bateman divided scabies into four species, derived purely from the variety of form which the disease assumes. They have not been followed in this by the recent authors who have borrowed their arrangement. As the framer of a system, Willan was disposed to attach too much nosological importance to his divisions, and his followers conceiving that they imply theoretic error, have in many instances relinquished them. It does not appear, however, that by so doing they have attained either to more simplicity of arrangement or fidelity of description, but rather the contrary. In our opinion, the specific distinctions which Willan employed are as valuable as the grander divisions of his system, and to those who are jealous about natural arrangement they are less objectionable, as being the mere expressions of facts, which may be received without reference to any theory of classification. Artificial subdivisions of cutaneous diseases founded on real differences in external characters, if they have no other advantages, greatly facilitate their study, and without the aid derived from this source their description becomes necessarily either vague or defective. In scabies, these practical means of discrimination are particularly requisite, as its diagnosis, which is of great importance, is chiefly to be arrived at (where contagion cannot be proved) by an accurate knowledge of its external characters.

We now proceed further with its description, and in addition to the general remarks with which we commenced it, we recommend attention to the following divisions, which are the same as those proposed by Willan. Far from being the mere offspring of theory, they were suggested to him by their common use amongst the lower order, whose familiarity with it forces them to be intimately acquainted with the various forms in which it appears. Of these they distinguish four, designated the *rank*, *watery*, *pocky*, and *scorbutic* itch, which Willan adapted to his nomenclature under the following titles, viz.:—

Scabies papuliformis.
——— lymphatica.
——— purulenta.
——— cachectica.

Scabies Papuliformis, or Rank Itch.—In this form of scabies the eruption is generally extensive, and accompanied with slight inflammation in the vesicles, and intense itching. It is found chiefly to infest the fingers and wrists, but also spreads extensively upon the trunk, particularly the front part of the chest and abdomen. The elevations resemble papulæ, and thus seem to evince an affinity between this form and prurigo and some varieties of lichen; but where they are fully developed and unbroken by scratching, a close inspection may always detect the transparent apex which indicates its vesicular character. The itching is so troublesome that frequent scratching is resorted to, and the abrasion of the vesicles and even of the skin which ensues, changes the primitive appearance of the eruption; "long red lines are here and there left, and the blood and humour concrete upon the vesicles into little brown or blackish scabs." When it occurs in a sanguine habit, or if it be inordinately exasperated by scratching or other circumstances, some scattered pustules sometimes make their appearance, filled with thick yellow purulent matter.

Scabies Lymphatica, or Watery Itch.—The difference between this and the former is in-

considerable. The separate vesicles are larger and do not partake of the papular character, being full of serum to the base, which besides exhibits no inflammatory redness. The pruritus is extremely troublesome, and when the vesicles are ruptured, moist excoriations are apt to form, upon which after a certain time dark scabs concrete. The most ordinary appearance which this variety presents is a compound of the three stages just referred to, viz. the entire vesicle, the excoriation succeeding its laceration, and the scab which covers this ulcerated part when it begins to heal. It seldom extends like the former variety to the trunk, but is chiefly found collected at the lower parts of the extremities, on the fingers, wrists, back of the hands, and on the feet and toes.

Scabies Purulenta, or Pocky Itch.—This possesses more the characters of a distinct species than any of the other forms, and evinces the necessity of marking these varieties. As Bateman well remarks, "it is often mistaken by those who confine their notion of scabies to the ichorous vesicles of the varieties already noticed." Heberden had divided the disease into two species, comprehending in the first two former varieties under the name of "pustulæ exiguæ, aquâ plenæ." (Comment. de Morb. Histor. et Curat. Frankf. ad Mœn. 1804. P. 102.) The other he describes as "majusculæ cum fundamento rubro, et pure impleantur, fere tanquam variolæ." This resemblance of the round pustules which constitute this species to small-pox, caused the vulgar to denominate it pocky itch. They arise distinct, upon an inflamed base, above which they are considerably elevated: after a few days they maturate and break, having attained frequently to a diameter of two or three lines. The pruritus which they occasion is mixed with a painful tension of the part, different from that which occurs in the vesicular forms. After their breaking they leave a cracked ulceration behind, the heat and stiffness of which cause considerable pain. The pustules may spread like the vesicular form over the body, but seldom extend far from their original seat, which is usually the hands or feet. In these situations they are largest, and two or three of them sometimes coalesce between the knuckles, especially between the index finger and thumb. The scabby concretions which at length form upon the ulcerations adhere for a considerable time during the healing process. The pustular scabies occurs usually in children before the age of ten years.

Scabies Cachectica, or Scorbutic Itch.—This is not distinguished from the forementioned varieties by difference in external character; for it appears under the forms of the other varieties, at one time indiscriminately mixed, at another exhibiting them separately in different parts of the body. It mostly occurs in persons of debilitated constitution, brought on by indigence and intemperance, and is the most intractable form of scabies. It is not unfrequently combined in such individuals with other cutaneous maladies, as lichen, prurigo, ecthyma, and impetigo; and Bateman asserts that when the latter disease is superadded, it, as well as the scabies, possess a contagious character. He also remarks that the most severe degree of it which his experience made him acquainted with, exhibited itself in persons who came from India, and he had often observed it in children brought from that country. It is there denominated "courap," a term which is equivalent to itch, and is the same which Bontius (De Medicinâ Indorum, lib. iii. cap. 17) describes under the name of herpes, seu impetigo Indica, and Sauvages under that of scabies Indica.

It was, perhaps, superfluous to make a separate species of this, inasmuch as it possesses no particular form which distinguishes it from the others; yet, as it is so disposed in Willan's divisions, it might be invidious in such a matter to use an arbitrary power in altering an established arrangement, which we have taken advantage of for greater facility of description.

In whatsoever form scabies manifests itself, it is to be regarded entirely as a local affection, being never like other vesicular eruptions connected with disorder of the internal organs. It gives rise to no disturbance of the circulation, except in severe cases of the pustular scabies, which, from the inflammation sometimes attending it, causes slight febrile action in children. Some authors recount a list of the most formidable diseases as liable to be produced by its retrocession and the metastatic transport of the cutaneous irritation to the vital organs. These notions, however, are now disregarded, being justly considered as the imaginary fabrications of an exploded theory, which pretended that a specific virus residing in the serum of the blood was the cause of scabies. We conceive that the observations of others which assert that important diseases of the internal organs have been cured by its eruption are to be equally unheeded. Unprejudiced experience demonstrates that it exerts little or no pathological sympathy upon the internal organs, and therefore such cases as those narrated by Beer* and others can be only regarded as coincidences.

The disease chiefly shows itself amongst children; yet on this account it is not to be inferred that it shows a preference for youth more than age. This is to be attributed solely to the fact, that children are more brought in contact with infection than adults, from their heedlessness of exposure and inattention to cleanliness. It depends upon the same cause that amongst the working classes males are more generally affected with it than females. Climate does not appear to have much effect in modifying its prevalence,—although it is certainly more common in the northern parts of Europe than the southern, an observation which we think must be connected with the fact that individuals of sanguine and lymphatic are much more liable to it than those of bilious temperaments. Habits of uncleanliness, however, are more powerful than this predisposition arising from the temperaments, of which its great prevalence amongst the Polish Jews and Spaniards affords examples; for amongst these people, as is well known, the bilious preponderates beyond comparison over the opposite temperaments.

It prevails in so general and constant a manner in some countries that it may be said to be endemic. In Poland and Hungary the mass of the

*Geschichte eines geheilten vollkommenen, von zurückgetretener Krätze entstandenem, schwarzen Staars. (Account of an Amaurosis caused by Retrocession of Itch, which was perfectly cured.) 8vo. Vienna, 1798.

population are constantly more or less infected, and it is equally rife in Galicia and Asturias in Spain, in Lower Brittany in France, and in certain parts of the Highlands of Scotland. It is, however, no stranger amongst the indigent classes of every country, and where it is found to infest one region with peculiar pertinacity, this is not to be attributed to any special influence of the atmosphere or the soil, which alone would properly entitle it to be called endemic, but to the habits of the poor population. It has been suggested that salt diet and the neighbourhood of the sea were concerned in maintaining it in some districts, but these circumstances have no influence in producing it, although they are frequent concomitants of that which is its true promoting cause,—inattention to cleanliness of the person, and particularly of the habiliments. Change of linen is the surest protection from it in a family or in a country, and we may with certainty predict its prevalence amongst every people where custom or necessity has precluded this best preservative of the health of the skin.

This malady inspires, as might be supposed, no friendly feeling in communities, and it is curious in this respect to remark the difference between it and those contagious eruptions which put life in jeopardy, as small-pox, measles, &c. With whatsoever dread the latter may be contemplated, they do not produce disgust; but the itch, being free from danger, may be treated more disrespectfully, and is very generally regarded as contemptible. However, different nations have different opinions on this subject; it is reported of the inhabitants of the Spanish provinces before mentioned, that they retain it often from the cradle to the tomb, and that they are not only careless of its concealment, but regard it as a kind of hereditary possession; they even refuse to use means to be freed from it, alleging that they are not willing to change the customs of their ancestors. (Dict. des Sciences Méd. t. xvii. p. 183.) But in countries where civilization is more diffused, its residence is less tolerated. Here even the imputation of the itch becomes almost injurious, and sometimes engages philosophers in its refutation, of which the following is an example. "Laennec was a true Breton, fond of his country and jealous of its honour. It is amusing to observe the high tone he assumes in refuting a charge brought by a certain writer against his native country, for being infamous for an epidemic itch. He solemnly assures us, that if in very truth la gale s'observe quelquefois en Bretagne, on en doit moins accuser les localités, que le passage et le séjour des matelots." (Forbes's Translation of Laennec, Author's Life, p. xxviii.) Equally patriotic renunciations of it have been made in our own islands.

Diagnosis. — There is scarcely any disease compromising the general health in so trivial a degree in which it may be more important to the reputation of the practitioner to be able to deliver a categorical diagnosis than in scabies. He is in fact frequently consulted for no other purpose than to decide whether an individual has not brought this contagious affection into his circle; and as the physician's opinion on the one hand sets him free from this suspicion, and on the other sentences him to a temporary banishment from society or even from his employment, it is obvious how much it behoves him to be able to distinguish it without error. In forming his opinion, he should learn to be as much as possible independent of the criterion furnished by its contagious quality, for it will be generally where this point is yet undecided that his judgment will be sought for. When some evidence of exposure to infection exists in addition to the proper characters of the eruption, there is no difficulty; but if such be unattainable, it will often require all the resources which an accurate acquaintance with it and other affections which resemble it supplies to distinguish between them. The eruptions with which it is liable to be confounded are some forms of lichen, prurigo, and eczema. The papular elevations of lichen are attended with considerable itching, and are frequently abraded by scratching, so that considerable resemblance may exist between them and scabies, particularly the first variety of it above noted, (*s. papuliformis.*) If the latter be present, the apparent papulæ, examined in an unbroken state, will be found to be topped by a vesicular apex, and where they have broken spontaneously, a dark scab remains; but in lichen the papula is solid, even to the summit, and it passes away in a scurfy exfoliation. Lichen occupies the back of the hand, and the external surface of the limbs, and is seldom or never developed in the intervals of the fingers. Moreover the itching is not nearly so intense as in scabies, and is of a more remitting nature, and the papular eruption is commonly attended by some constitutional disturbance which is foreign to scabies. In the lichen *urticatus* the eruption is of a more acute nature, and has occasionally a few vesicles interspersed amongst the papulæ, which might confound an observer who relied on any single characteristic; but the diagnosis in this case is still easier than in the simple lichen—the inflamed wheel-like papulæ, causing rather a deep tingling than an intense itching, sufficiently distinguish this eruption. Finally, the suspicion of contagion will seldom attach to any form of lichen.

The itching of prurigo is of a still more vehement character than that of scabies; they were of old frequently confounded, insomuch that the former was sometimes erroneously denominated scabies *sicca*. (See Prurigo.) The diagnosis between them is not difficult if these points be held in memory. Prurigo occurs chiefly in elderly individuals; its papulæ are flat, and when abraded by the nails no serous fluid is effused, but a dark spot of blood concretes upon their surface. The situation also of the pruriginous eruption (as that of lichen) is distinguished from scabies by its preference to the surfaces of extension on the extremities, instead of those of flexion, which the latter particularly affects. Prurigo, moreover, is not contagious.

In eczema we have a vesicular eruption, which often bears a striking resemblance to scabies in the second variety, (*s. lymphatica.*) Its vesicles, however, are more flattened and confluent than those of scabies, which are acuminated and distinct. But when the disease is passed to an ulcerated and scabby state, such distinguishing characters may be wanting, and then other cir-

cumstances must be sought out. Eczema is for the most part a local affection, and when the itch has in any place assumed the ulcerations and soft scabs which resemble it, the eruption has proceeded to a considerable extent, and will doubtless show its proper form in the parts which it has most recently invaded. The irritation of eczema is a stinging or tingling sensation very different from the pruritus of the itch, and its origin may be often traced to the action of irritating causes upon the skin, as sugar, lime, and other acrid substances, or to exposure to the solar rays or great heats.

Very lately a female presented herself to the writer with an eruption at the root of the right middle finger, which from its situation and appearance was difficult to distinguish from scabies. She ascribed its origin to milking cows, whose teats were in a diseased state. The pruritus was not that of scabies, and after a careful examination it was concluded to be a vesicular form of impetigo. Bateman calls attention to the possibility of confounding the pustular form of scabies with impetigo, and even with ecthyma; and although this seems remote, it is yet only a prudent caution to keep in mind every form of cutaneous disease which bears any affinity to it.

A circumstance in the history of scabies of the greatest moment, is the simultaneous presence of the diseases which we have just contrasted with it for the sake of diagnosis. This is indeed rare in ordinary cases of itch, but the fact of its occasional occurrence forcibly impresses the necessity of cautious examination, and adds much practical importance to the diagnosis, because those complications require a line of treatment quite distinct from that of scabies. They are met with in the cases in which much inflammation has attended the scabid eruption, and (which serves to illustrate what we have said as to their different treatment) they are very frequently produced by improper applications for its cure, such as powerfully irritant lotions or frictions. The actual complication which may be present will be much influenced by the constitution and age of the subject; in young and vigorous habits, the excess of irritation will mostly take the form of eczema or of impetigo, while in those of an opposite condition pustules of ecthyma may appear, or the inflammation may seize on the cellular tissue, and an eruption of boils be the consequence. Cazenave and Schedel remark that the same subject may present at once "vesicles of itch, pustules of impetigo, pustules of ecthyma, and boils," (Abrégé Pratique des Mal. de la Peau, Paris, 1828, p. 120,) a case which would exercise the diagnostic tact of the physician to discover the primary contagious disease amongst so many complications.

Causes.—The universally diffused cause of scabies is contagion, and it appears to be the disease which of all is most readily communicated by contact. When it once gains admission into a family, the greatest caution often fails in preventing it from infecting every individual. A question exists undecided among pathologists as to whether it ever originates from any other source than contagion. It was observed by Sir John Pringle, that in military hospitals the patients often became the subject of itch after the crisis of fevers, (Bateman's Synopsis, p. 288, note); but there remains little doubt in our mind that this excellent physician in these instances mistook some of the papular eruptions, as lichen or prurigo, for scabies, for those are not uncommonly observed to occur when the skin recovers its tone in the convalescence from fever. We would make the same remark with respect to a kind of it which Heberden describes as primarily contracted by contagion, but which being cured by the customary remedies, "tamen non cessat redire semel vel bis quotamnis." (Op. cit. p. 102.) This is rather the description of the lichen simplex, occurring periodically in a person who has been once affected with scabies; for this faithful observer adds, that after its first attack it is no longer communicable by contagion, even to those who lie in the same bed, and that it as often terminated spontaneously as it was removed by any remedy. Bateman thought that it might originate without contagion in crowded, close, and uncleanly houses, and wherever the means of cleanliness were not obtainable. (Synopsis, p. 289.) These are, however, just the circumstances which facilitate the propagation of contagion. On the whole, there are no facts which contravene the opinion of those who assert that the latter is its sole origin, and it appears to us that it agrees best with every analogy.

We have reserved to this head the notice of a very remarkable circumstance connected with the etiology of scabies, the existence of the insect called by Linnæus and by preceding naturalists "*acarus scabiei*." First in the writings of Avenzoar, the Arabian physician, and subsequently in those of Ingrasias, Gabusinus, and Joubert, notices of a minute insect occurring in a certain disease of the skin attracted the attention of the English entomologist Thomas Moufet, who examined and described them with considerable accuracy. They are, according to him, minute animalcules similar to the acari of decayed cheese or old wax, which burrow under the cuticle, and excite intense itching, with an eruption of vesicles. His observations were repeated by various naturalists in different parts of Europe, and Hyacinth Cestoni, at the end of the seventeenth century, investigated the characters of this insect with much exactness, and was the first proposer of the theory which regards it as the proximate cause of the itch.*

This doctrine gave rise to a controversy which has continued ever since, and seems at the present day to be as far from being settled as ever. In the order of time, two questions are involved in this subject. By the first the acarus, or (as Latreille denominated it generically) *sarcoptes* scabiei, was universally received; but issue was joined on the opinion first mooted as a conjecture by Cestoni, that scabies is nothing else than the bite of these small insects, which produces the itching and an extravasation of serum collecting into vesicles; moreover that the contagion is effected by the transfer of those insects from one individual to another. Experiments were made, and opinions were contested negatively and affirmatively, by

* This was communicated by Cestoni's coadjutor, G. Bonomi, in a letter to an eminent physician, Francisco Redi, in whose works it was first published, in 1686. (Dict. des Sc. Méd.)

many eminent medical men in different countries. Redi, Wichmann, Osiander, Pringle, and many others, considered the contact of the insect as the only exciting cause of the itch; while as great a number insisted that the acarus was produced by the disease. Again, a middle opinion was embraced by the majority, to which Morgagni attached himself. They held that in most cases the insect was the product of the disease, but admitted that in some instances the latter owed its origin to the insect. M. Galès, apothecary to the Hôpital St. Louis in 1812, undertook a series of investigations, which he conducted with the greatest variety and perseverance, and which finally seemed to leave nothing undecided as to the whole subject. He observed with the microscope upwards of three hundred of the insects taken from the scabious vesicles.* He confined the insect upon his hand with a watch-glass, and observed it penetrating the cuticle, upon which, after a few hours, three vesicles appeared, the intense itching of which left no doubt of their identity with scabies. He inoculated in the same manner three children with the insect, who became covered with the itch. These experiments were testified to by many of the first naturalists in Paris; and as they appeared to have the force of demonstration, after their publication the opinion that the itch was produced by the insect was ratified by the assent of almost all. They doubtless proved the presence of the acarus, and moreover that its penetration of the skin is an occasional cause of scabies; but with all, this may be a very secondary matter in the production of the disease. In fact, it seems to us somewhat singular that these observations were permitted to prove more than that the insect taken from a scabious vesicle, *being charged with the virus, the fluid of the vesicle*, by penetration of the cuticle, inserted this virus, and produced the disease, like the inoculation of cow-pox.

At a later period, however, the opinion supposed to be thus incontestably fixed by M. Galès' experiments was not only called in question, but, singular to relate, the existence of the acarus was again doubted. M. Suriray of Havre, and afterwards MM. Lugol and Mouronval, revived the discussion of the subject, and, as the result of their researches, denied that any insect could be found. This extraordinary revulsion of opinion was confirmed by M. Biett, who, even with the use of microscopes of high power, was unable, in a great number of trials, to discover it in a single instance. Cazenaze and Schedel state that many others have made an equally unsuccessful search for the insect; and rejecting for themselves the idea of its existence, they announce a kind of challenge to M. Galès to transport himself again to the Hôpital St. Louis, and demonstrate it anew.

It would follow from these negative researches, that while at one period the disease is attended by the acarus, at other times it exists without it. In these countries it is a notorious fact that the insect is frequently found. Moufet originally stated that the common people were in the habit of extracting it from the vesicles with the point of a pin; but that more usually it may be found in a small channel which it frets from the vesicle in the adjoining cuticle. We have conversed with those who have frequently seen them, and whose description of their being found not in the vesicle but in the red streak adjoining it, exactly coincides with Moufet. Bateman and Mr. Plumbe bear the same testimony; and the latter adopts an hypothesis proposed by Galès and Fournier, (Dict. des Sc. Méd. art. *Gale*, tom. xvii. p. 109,) by which it is conjecturally affirmed, that when the elevation becomes large and full of lymph, it being no longer possible for the insect to exist in it, in obedience to a preservative instinct it makes its way laterally, and is then found beside and not within the maturated vesicle. He supposes, also, that it is sufficient to account for the ill-success of those who have not found it, to presume that they happened to select for their researches vesicles which had been evacuated by the acari. This does not occur to us as by any means satisfactory; but the opinion of Sauvages, adopted by Bateman, seems more plausible, that the insect is generated only in some instances of scabies, of which cases Sauvages proposes to make a particular species under the title of "scabies *vermicularis*." This is not irrational; yet we deem it more consonant with the varying history of the researches to suppose that there is a variation in the *disease itself* in this respect at *different epochs*. This view is more consistent with analogy, as we know how often the type of diseases changes at different epochs in the same locality, without therefore losing their identity. Of this fever is a familiar example, which it is unnecessary to do more than mention in respect to its change of type; but an occasional phenomenon which it presents (as was remarked by M. Ranque of Orleans) may be adduced, and reflected on in connection with the generation of the acarus scabiei. We allude to what is occasionally observed when a favourable crisis takes place at the last extremity of typhus; the head is sometimes swarmed by a sudden production of lice, so unaccountably numerous as only to permit the supposition that they are secreted by the skin.

According to the view here propounded, and in agreement with the analogy just mentioned, the animalcule of scabies is regarded as a secretory product of the disease, which at certain periods is endemic; but ignorance is professed as to the circumstances which give rise to it at one time more than another; and at the same time we agree with Bateman, that the contagious property of scabies exists in the fluid, and not in the insect, which, however, may be the occasional means of transport of the latter. We would finally remark, with regard to the whole controversy, that it includes a lesson at least to medical theorists: here many ingenious men oppose each other in a matter of fact and observation; with what sobriety, then, should dogmatic opinions be entertained, when it is often so difficult even to lay their foundation in certain facts!

[Most recent writers on the subject are disposed to consider the acarus as the cause of itch (E.

* His descriptions of the insect agree with those of Linnæus and Latreille, but are much more extended and exact. It has six legs, with a few filaments besides projecting from the body, and is not unlike the minute pulix sometimes accompanying prurigo. It lies in the centre of the vesicle, round the margin of which it deposits its ova.

Wilson, *Practical Treatise on Diseases of the Skin*, Amer. edit. p. 235, and W. Horn, art. *Scabies* in *Encyclopäd. Wörterb. der Medicin. Wissenschaft.* xxx. 138. Berlin, 1843.) Mr. Wilson classes scabies as the only example of inflammation of the skin induced by parasitic animalcules inhabiting the epidermis; yet it is not easy to understand how it is readily communicated by contact, under the idea that it must be conveyed by the insects, as it is by no means a matter of facility to extract them from the furrows where they are domiciliated.

It was not until the year 1834, and after several distinguished individuals had tried in vain, (Dr. Biett, art. *Gale*, in *Dict. de Méd.* 2de édit. xiii. 547, Paris, 1836,) that the manner of finding the acarus was clearly demonstrated. A medical student from Corsica, M. Renucci, had frequently seen the women of his country extract the insect, and had often done so himself; and he showed, that it must not be sought for in the vesicle, but in the furrow which sets out from it, and which is made by the insect beneath the epidermis.]

Treatment.—The cure of scabies appears to have been considered a matter of no slight medical interest. Treatises have been written upon it, and a vast variety of means discussed with so much earnestness, that we are led to the conclusion, (which we believe coincides with general tradition,) that it was formerly a scourge to the community of greater extent and virulence than at the present day. It is now regarded as of trivial importance. Never in itself dangerous, it gives much annoyance to the individual by its unappeasable itching; but the fear and restraint which it puts upon him of infecting others often causes as much discomfort to him as its action upon himself. Neglect of the appropriate means may indeed protract it to an indefinite length; but by their use its treatment is conducted with so much certainty that we have scarcely any other care in the choice of remedies than to select that which experience has approved of as effecting a riddance of the disease in the most secure and speediest manner. A multitude of such has been vaunted, but modern practice has contracted the most useful within a small circle; and it is unnecessary to enumerate here any of minor efficacy, as we are in possession of some whose virtues are almost infallible.

Sulphur is considered in the light of a specific remedy in the cure of itch. It is the basis of the applications which by universal consent are considered its most effectual antagonists. In the ordinary forms of the disease the common people have long used it as an ointment, mixed with equal parts of hog's lard or butter, with which they smear the parts on which the eruption exists once or twice a day. They administer it internally at the same time, in doses of from ten grains to half a drachm given in milk at bed-time. By this treatment they scarcely ever fail to cure it expeditiously. The internal use of sulphur is adapted for it in children, and is occasionally combined with magnesia; in adults, however, it is unnecessary to have recourse to any but the external use of the sulphur ointment. The assiduous use of it for a fortnight is sufficient to cure the common forms of it, if they be attacked with it speedily after its first appearance, as the duration of the treatment will be longer if long neglect has permitted it to gain a certain inveteracy.

A great improvement was made in the application of the sulphur ointment by the combination of an alkali with it. This adds to the specific effect of the sulphur the advantage of a detergent action, which loosens and dissolves crusts or scabs, and permits the skin to be well penetrated by the ointment. M. Helmerich, a French army surgeon, became famous for a method of using sulphur which cured the itch more promptly, and also permitted the greasy stain of the ointment to be removed from the linen by washing, obviating an objection to the use of unguents which was very generally felt. He kept it a mystery, but it was analyzed by M. Burdin, and found to consist of the following ointment:

Sublimed sulphur, two parts,
Sub-carbonate of potass, one part,
Axunge, eight parts, intimately mixed.*

This deserves a preference over all other methods of applying the sulphur externally. It has the most constant and prompt success, and is seldom attended by the cutaneous affections which sometimes result from the use of other stronger but more irritating sulphureous applications. It is the ointment which Biett has exclusively employed at the Hôpital St. Louis for several years. He orders half an ounce of it to be rubbed, morning and evening, over all the parts occupied by the vesicles. The action of this ointment is favourably promoted by the use of a tepid bath every second day during its application, which will rarely have to be continued beyond ten or twelve days. Another sulphureous friction which, in the Paris hospitals, rivals the reputation of the above-mentioned ointment, is made with the sulphuret of lime. A scruple or half a drachm of this powder is to be triturated with a small proportion of olive oil, so as to render it sufficiently fluid for using as a friction, and this quantity is to be rubbed upon the affected parts twice a day. This is a very effectual cure, but it is not so applicable as the former when the itch has already spread to any considerable extent.

[In more obstinate cases, the Unguentum Sulphuris compositum of the Pharmacopœia of the United States, which contains—in addition to the sulphur—ammoniated mercury, benzoic acid, oil of lemons, sulphuric acid, and nitrate of potassa, may be substituted. The writer is more in the habit of prescribing the Unguentum Sulphuris compositum of the London Pharmacopœia, which contains—sulphur, ℥iii.; veratr. pulv. ʒi.; potas. nitrat. ʒij.; saponis mollis, ℥iij.; adipis, ℥ix.; ol. bergamot, ɱ xv.]

The use of ointments over an extensive surface of the skin may be considered unadvisable in some cases, as interfering with the cutaneous transpiration. When these objections exist, substitutes of no less efficacy are found in the proper use of lotions. None of these is preferable with regard to activity to the solutions of sulphuret of potash, or of lime. These have been long known and ex-

* For the sake of depriving this ointment of the smell and appearance of sulphur, it would be agreeable to add to each ounce of the axunge a few drops of oil of lavender or bergamotte, and ten grains of the hydrargyri sulphuretum rubrum (vermilion).

tensively used in scabies, and a saturated solution of the latter is an excellent remedy in the mange of sheep or dogs. The following formula of a lotion was prescribed by M. Dupuytren, and highly extolled in France for the promptitude with which it effects the removal of the disease:

R.—Sulphureti potassæ ℥v.

Aquæ puræ lb. iss.

Acidi sulphurici ℥ss, dissolve ut fiat lotio.

Whatsoever part of the eruption has invaded is to be moistened by a gentle friction with this lotion twice a day. It has the advantage of not injuring the linen of the patient, nor does it compel him to renounce his employment during its use. However, it produces a smarting of the skin, which will sometimes require it to be used in much weaker proportions, and renders it not so appropriate in some irritable habits.

If the individual entertain insuperable objections to the use of sulphur from disgust to its odour, many other external remedies of approved efficacy are at hand. The ointment of white hellebore, in the proportion of a drachm of the powder to an ounce of lard, is both a safe and expeditious application. Solutions of the chloride of lime or of soda have been extolled as highly beneficial by some practitioners; they are used as a lotion in the proportion of an ounce to a pint of water. The aqua chlorinii applied in the same manner is also mentioned with applause. Heberden strongly recommended a lotion composed of a solution of the muriate of mercury, made with one drachm, or two, (according to the inveteracy of the disease,) to a pint of water. This is acknowledged to be a remedy of great power in curing scabies, but it is objected to by some as liable to produce the constitutional effects of mercury. We have, however, been assured that these fears are vain, by an esteemed practitioner, who has had a very favourable experience of this lotion, and has used it on his own person with success; and in our own more limited sphere of observation, we never saw any such effects from it.

[These ointments are less offensive than the ointments of sulphur, but they are certainly less sure. The same may be said of those of creasote and of chlorinated lime.]

Sulphureous baths are an excellent auxiliary means in many cases of scabies. In cases of very irritable skin they are frequently the only form in which general applications of this remedy can be made to the surface; in young children, therefore, they are a very valuable resource. The artificial are found to answer the purpose equally well with the water of sulphureous springs, and their employment possesses the advantage of being proportioned according to circumstances. They may be prepared by simply adding to an ordinary sized warm bath six ounces of the sulphuret of potash in powder, and agitating it until it be dissolved, and the water be reduced to a lukewarm temperature.

Sulphureous vapour baths are another means which possess great power in this as well as in some other diseases of the skin. This is evident from the testimony of all who have used them, from M. Gales, who was the first to construct an apparatus for their convenient administration, to Mr. Wallace, who has also ably illustrated their use. Dr. Bardsley informs us, that he has "always seen the most obstinate and neglected cases of it yield very speedily to a few fumigations." (Hosp. Facts and Observations, p. 198.) It is happily to such inveterate cases that they are mainly applicable; for even if they did possess the superior advantages over ordinary methods of treatment which are claimed for them, they are too stimulating to be employed in many cases except where the disease has become chronic through neglect, and has induced an unhealthy torpid condition of the skin. They are particularly contra-indicated where there exists any tendency to congestion in the gastric or pulmonary mucous membranes, and in females with complaints depending on morbid conditions of the uterine functions.

In the conduct of the treatment the practitioner has but little to be solicitous about; but, having used his discrimination in the adoption of the most appropriate remedy, he perseveres until the cure is complete. He should inculcate great attention to cleanliness and change of linen, especially during the convalescence. A vigilant inspection must be made for the purpose of detecting any of the complications previously noticed as apt to coexist with certain forms of the disease, or to spring up under improper treatment. If any of those be present, it will be necessary to modify his plan accordingly, and often to suspend the use of the stimulating remedies, with which he had commenced to combat the scabies. The state of the alimentary canal now demands particular attention; cooling laxatives and alteratives will be proper; and for topical applications recourse should be had to emollient fomentations, and the other soothing means specially adapted to the individual complication, for which we refer to Ecthyma, Eczema, Impetigo, Lichen, &c.

James Houghton.

SCARLATINA.—*Syn.* Morbilli Confluentes, *Morton:* Rubeola Rossalia, *Hoffmann:* Febris Scarlatina, *Sydenham:* Febris Rubra, *Heberden:* Scarlatina, *Sauvages*, *Vogel*, and *Cullen:* Purpura, *Shultz*, *Junck:* Enanthesis Rosalia, *Good:* Fièvre Rouge, Scarlatine, *Fr.:* Der Scharlachaufschlag, *Germ.:* Scarlet Fever. Scarlatina designates a contagious febrile disease, the distinguishing characters of which are, a scarlet efflorescence of the skin and of the mucous membrane of the mouth and pharynx, appearing on the second day (though often later) of a febrile disorder, and terminating about the fifth; accompanied, in the majority of instances, with inflammation of the throat, either of a phlegmonous or gangrenous character; and occasionally with tumefaction of the cervical absorbents and subcutaneous cellular membrane. Other organs become also sometimes involved in the progress of the disease, giving rise to lesions of greater or less severity. The type of the accompanying fever is various, and modifies remarkably the whole aspect of the malady. In some cases, the constitutional disturbance is so trivial as scarcely to attract notice; in others, the febrile symptoms are those of strong inflammatory excitement; while in individual instances, or during the prevalence of an entire epidemic, the fever

is of a low typhoid form, the local inflammation with which it is associated, partaking very much of the same character.

The origin of scarlatina is involved in great obscurity. It was evidently unknown to the ancients; no allusion to it can be discovered in the writings of Hippocrates, or in the early Greek and Roman writers; and, notwithstanding the opinion of some modern authors of the French school, that it was described about the middle of the sixteenth century, it is generally admitted that Prosper Martianus, an Italian physician, who gave a description of the disease as it prevailed in Rome about the middle of the seventeenth century, if not the first, is among the earliest writers on scarlatina. It made its appearance in London in 1689, and was described by Sydenham and afterwards by Morton, though it is evident by comparing the description given by these two writers, that they had observed different epidemics; the one described by Sydenham being a very mild disease compared with that of which Morton has given an account. From the various names, however, given to scarlatina on its first appearance, it is evident, that about the period to which we refer, the notions entertained with regard to it were vague and unsatisfactory; indeed, it was scarcely distinguished from measles, roseola, or purpura. For example, it was named by Morton *morbilli confluentes*; by Hoffmann, *rubeola rossalia*; by Heberden, *febris rubra*; and even till within a little more than half a century, both these diseases (measles and scarlatina) appear to have been considered by medical writers as the same, or at least as so closely allied, as only varieties of a common species. Morton, indeed, maintained their identity, and considered their relative connection to be nearly the same as that existing between the distinct and confluent small-pox. (De Morbillis et Scarlatina, Exercit. iii.) The description of the epidemic given by Huxham under the name malignant ulcerated sore-throat, which prevailed in the year 1734, resembles in almost every particular one form of scarlatina — that form in which the eruption is accompanied with affection of the throat. The treatise on this subject is a valuable record of the characters of this epidemic, the description being evidently taken from what he had observed in his intercourse with the sick. Dr. Fothergill also has given the history of a "sore throat attended with ulcers," which appeared in London in 1747–8, which there can be little doubt was an epidemic scarlatina; and from the remarks he has made, it is evident, that he had observed various forms of the disease, from the mildest to the more malignant. Dr. Withering published an essay on scarlet fever in 1778, a second edition of which appeared in 1793; to this author is due the merit of having first accurately described scarlatina as a distinct disease; since that period, various treatises have appeared both in this and other countries.

Causes.—Nothing satisfactory is known as to the exciting causes of scarlatina. It appears to be induced, like the other eruptive fevers, by exposure to the influence of a specific poison. Attempts have been made to induce the disease by inoculation, by inserting the thin scales, which are thrown off at the period of desquamation, under the skin of individuals who have never had scarlet fever, but hitherto without success. How far inoculation with the blood might be followed by different results is a question which can only be determined by experiment.

That scarlatina may be propagated by contagion is, we presume, admitted even by those who profess themselves sceptical on the question of contagion in general. Instances of the disease spreading in a manner which can only be explained by admitting its contagious origin are so numerous, that practitioners of the most limited observation must have had repeated opportunities of determining the question. We have known, in several instances, convalescents from scarlet fever, on their removal to a considerable distance from the situation in which they had passed through the disease, infect individuals with whom they came in immediate contact, though several weeks had elapsed from the period of desquamation. The period of invasion after exposure to sources of contagion is exceedingly various. Some individuals are seized within a few hours; others do not exhibit any of the peculiar symptoms for several days; and in some more rare cases, five or six weeks have intervened between the period of exposure and the accession of the disease. The poison also appears to affect individuals very differently. Of a number of persons exposed to the same source of infection, some may escape altogether; others have a mild form of the disease; or it may happen, perhaps, that in several, the disease proves severe. Even in the same family the various forms which scarlatina presents may occasionally be observed. One or more may have both the efflorescence and the sore throat; in others there may be fever with the characteristic rash but without any affection of the throat; another case may present the characters of the malignant disease; while, again, those who have been in constant attendance on the sick become indisposed with smart inflammation of the throat and a considerable degree of fever, which lasts for some days, and then subsides with the local affection. In these latter cases, (though there have been no efflorescence), desquamation of the cuticle occasionally occurs. Dr. Rush, in an account of an epidemic scarlatina which prevailed at Philadelphia, remarks that such was the prevalence of the contagion which produced the scarlatina anginosa, that many hundred people complained of sore throat without any other symptoms of indisposition. The slightest occasional exciting cause, particularly cold, seldom failed of producing the disease. (Medical Enquiries and Observations.) The same thing has been repeatedly observed in this country.

Although sporadic cases of scarlet fever are met at all seasons, it is more prevalent at the end of summer, and in the autumn, than at other periods of the year. Epidemic visitations have been most frequently observed after a warm summer, especially when the heat has been accompanied with continued rains; and when the succeeding winter has been open and mild, the disease has continued till it has been checked by frost. It generally disappears in the spring months, though it has been observed to continue uninterruptedly for one or more years.

It is necessary to advert in this place to the difference in the characters of epidemic scarlatina, though the causes of such remarkable variation are unknown. For a whole season, the disease may assume a mild aspect, so that a fatal case is rarely met with; in such instances, the danger is generally produced by some local inflammation which has supervened in the progress of the disease, or during the period of convalescence. On the other hand it should be remembered, that during a comparatively mild epidemic, one or more cases may assume a malignant character, and resist the best directed curative efforts. Sometimes an epidemic of a malignant form, or, as it is popularly termed, a *putrid* form of scarlet fever suddenly breaks out and proves extremely fatal. From its commencement the symptoms often denote a severe form; at other times on its first irruption the disease is mild, but suddenly, without any apparent cause, the symptoms assume an unfavourable appearance, which continues as long as the epidemic lasts. It is therefore of great practical importance to ascertain the prevailing type of the disease, as the character which it assumes must regulate the treatment to be adopted.

Dr. Willan observed, (On Cutaneous Diseases, p. 277 and 281,) that when the scarlatina spread widely, it exhibited in the different persons affected every gradation of appearances, from the slightest to the most malignant form of the disease; yet during its diffusion through some large families and schools, he had seen it uniformly retain the series of symptoms which occurred in the first patient, with nearly the same degree of fever. In the autumn of 1786, and occasionally since that period, the scarlatina maligna above described affected the inhabitants of several districts in London, comprising narrow courts, alleys, and close crowded streets, and afterwards extended to some adjoining villages in low, damp, or cold situations. It is, however, more frequently intermixed with the other varieties of scarlatina, and it sometimes unexpectedly supersedes the milder forms of the disease on the fourth, fifth, sixth, or seventh day of their course.

"It is truly singular," he adds, "that the slightest of all eruptive fevers, and the most violent, the most fatal disease known in this country, should rank together and spring from the same origin. Experience, however, decides that the simple scarlet fever, the scarlatina anginosa, the scarlatina (or angina) maligna, and the scarlet ulcerating sore-throat, without the efflorescence on the skin, are merely varieties of the one disease. That all of them proceed from the same source of contagion is evident, because under the same roof in large families some individuals have the disease in one form, some in another, about the same period."

Scarlatina occurs more frequently in the early than in the advanced periods of life, and in our own experience females are more liable to the disease than males. Dr. Withering states that the epidemic which appeared at Birmingham in the year 1778, affected children more than adults, but seldom occurred in the former under two years of age. In children, the number of boys and girls that suffered from it was nearly equal; but in the adults, the number of female patients considerably exceeded that of the male.

In order to determine its relative frequency in the sexes at different ages, we selected from the register of patients admitted into the London Fever Hospital, two hundred cases in the order of their admission. The following table gives the general results:—

Age.	Males.	Females.	Total.
From 6 to 10	7	8	15
10 " 15	8	15	23
15 " 20	17	40	57
20 " 25	14	39	53
25 " 30	8	21	29
30 " 35	6	10	16
35 " 40	1	2	3
40	1	0	1
42	0	1	1
48	0	1	1
57	0	1	1
	62	138	200

It is proper, however, to state that this table cannot be considered quite complete, the number of children under six years of age who take the disease not being ascertained, in consequence of the regulations of this hospital precluding the admission of children under six years of age. The table shows the great majority of females at every age, and also disproves the assertion of Sir Gilbert Blane (Select Dissertations, p. 213) and others, that the majority of those who are seized with scarlatina are under puberty.

Scarlatina in general affects the same individual only once during his life, and in this respect obeys the general law of exanthematous fevers. Occasional exceptions have certainly been observed by practitioners, though, from the testimony of Dr. Willan, a second attack of scarlatina in the same individual is extremely rare; he states that he had never seen such a repetition among two thousand patients whom he had visited in scarlatina. We certainly have met with several well authenticated instances of a second attack of scarlatina in the same person.

[Dr. Billing (*First Principles of Medicine*, Amer. edit. p. 191, Philad. 1842) states, that he has known it occur three times in the same individual,—frequently twice; in one instance, twice within ten months, in its exquisitely marked form, as to inflamed tonsils, appearance of tongue, eruption, and desquamation of cuticle. Recently, the writer attended a lady who, six years ago, was affected with it, for the first time, in childbed,—the child being born with the eruption: three years afterwards, her child had it for the second time, and died; and she also suffered severely from a second attack. Recently, from attending on a young gentleman who died of the disease, she had a third attack.

It is by no means uncommon for those who have had the disease, to suffer from sore-throat—*scarlatina faucium*—when they are in attendance upon one labouring under scarlatina. (See *Guersant & Blache*, art. *Scarlatine*, in *Dict. de Méd.* 2de édit. xxviii. 158, Paris, 1844.)]

It is proper to notice the discovery of the supposed efficacy of the extract of belladonna as a preventive of the infection of scarlatina. This was first suggested by Hahnemann, of Leipsic, in

1807. The belief that this narcotic possesses such a preventive power is gaining ground in some parts of the continent, and lately even in our own country. The following abstract will explain the views of Hahnemann on this subject. A favourite doctrine of this writer is, that diseases are to be combated by remedies, the effects of which are similar to the diseases for which they are given. This is the doctrine to which the term *homœopathia* has been given, and which has of late years gained many proselytes in Germany, France, and Italy. Hahnemann observed, that belladonna given in small doses produced heat and dryness in the throat, swelling of the submaxillary glands, and a cutaneous eruption, sometimes an efflorescence only, at other times a papular rash, like miliaria; he therefore inferred that this medicine, from its producing symptoms analogous to those of scarlatina, might prove a preservative against its infection. About ten years after Hahnemann had entertained this notion of the anti-scarlatinous power of belladonna, a severe and fatal epidemic appeared in several cities of Germany, and consequently the physicians were naturally desirous of adopting measures calculated to arrest its progress. From the result of the trials made by Berndt, of Custrin, who was the first who made a series of experiments, we find, that in an epidemic scarlatina which prevailed in Custrin in 1818 and 1819, he employed the belladonna as a preservative in one hundred and ninety-five children under fifteen years of age; though they were freely and constantly exposed to the contagion of scarlatina, only fourteen took the disease, and that after employing a stronger preparation of this drug, every individual escaped. A still stronger testimony in favour of its efficacy is given by Dusterberg, a physician of Warburg; he states, that every child who took the belladonna for a sufficient length of time before exposure to infection escaped; that when a child was left in an infected family to nature, (the belladonna not having been administered with the object of determining its efficacy) it was invariably attacked with scarlatina, while the others who took the remedy escaped. Behr, of Bernberg, also affirms that of forty-seven persons who took the belladonna as a preservative, only six were attacked. Professor Koreff, of Berlin, after extensive and long-continued trials, asserts that if the belladonna be taken in proper doses for eight or nine days before exposure, and be continued till the period of desquamation, there is little danger to be apprehended from free intercourse with persons affected with scarlatina. Similar testimony has been given as to the efficacy of this narcotic by Hufeland, Kunzman, of Berlin, and others.*

[On the other hand, the belladonna has failed to exhibit any prophylactic powers in the observation of many respectable practitioners, (Pereira, *Elements of Mat. Med. and Therapeutics*, Amer. edit. ii. 307, Philad. 1843, and Rilliet and Barthez, *Traité Clinique et Pratique des Maladies des Enfants*, ii. 641, Paris, 1843.) Dr. Pereira remarks, that whilst the facts brought forward in favour of the existence of the prophylactic fever are only negative, those which can be adduced against it are positive; for twenty cases of failure, he conceives, are more conclusive against it than one thousand of non-occurrence are in favour of it. The writer has repeatedly administered it; and, as elsewhere remarked, (*Practice of Medicine*, 2d edit. ii. 538, Philad. 1844,) until the winter of 1843, none took the disease. At that time, during the prevalence of scarlet fever in his own neighbourhood, the belladonna was sedulously administered to his children, five in number, — two of whom, the youngest three years old, and the oldest six, after having taken the belladonna for six weeks, were attacked,—the others escaping. The disease was severe, but it was not attended by any specially alarming symptoms.]

The quantity administered is very minute. Three grains of the extract of belladonna are to be dissolved in one ounce of distilled water; of this solution two or three drops are to be given twice a day to a child under twelve months old, and one drop more for every year above that age. In general, no sensible effect is produced by it, but in some instances, it brings out an eruption similar to scarlatina. It is also asserted by those who have tried this remedy, that even when it does not prove a preventive of the infection of scarlatina, which may be in consequence of its not having been administered for a sufficient length of time before exposure, it renders the disease more mild, and even that if it be taken for four or five days before exposure, the disease never proves fatal. As we have never employed the belladonna as an anti-scarlatinous remedy, we can offer no opinion of its merits, though we certainly profess ourselves sceptical as to the powers ascribed to this drug. The subject is, however, worthy of further experimental inquiry. It has one advantage, that of being perfectly harmless, if it do not act as a preservative.

Varieties.—Scarlatina occurs under several forms, to which it is necessary to advert. In the first, the affloresence is attended with mild febrile symptoms, but there is no inflammation of the throat (*scarlatina simplex*). In the second the fever is of a more severe character, and the efflorescence is accompanied with inflammation of the throat (*scarlatina anginosa*). In the third, the whole character of the disease is more severe than in either of the preceding varieties: the fever is of a low or typhoid type; the throat is affected with gangrenous inflammation, accompanied with tumefaction of the cellular tissue and absorbents of the neck, and in general with an acrid discharge from the nostrils and ears (*scarlatina maligna*). In other instances, the efflorescence is confined to the mouth and throat, and does not affect the skin. This form (to which no name has been given) is often observed during the prevalence of epidemic scarlatina; not unfrequently in adults, when some other form of the disease is prevailing in the family. It may be designated by the name *scarlatina faucium*.

1. *Scarlatina simplex.*—In this form of the disease there is only the efflorescence with a moderate degree of fever. The rash is preceded by slight symptoms of fever—irregular shivering,

* Vide Arch. Gén. de Méd. Juin, 1824. — Journ. Complement. Juin, 1824. — Hufeland, Journ. der practischen Heilkunde, Nov. 1815. — Rust, Magazin für die gesammte Heilkunde, xx. i. 182.

nausea, sometimes vomiting, thirst, and heat of skin. The degree of fever is by no means uniform; the symptoms are sometimes so moderate as scarcely to attract attention, though there is often smart constitutional disturbance, indicated by pungent heat of skin, flushing of the face, suffusion of the eyes, pain of head, restlessness, and occasionally delirium. The efflorescence or rash generally comes out on the second day of the eruptive fever, but in some instances it does not show itself till the third, and accordingly we find authors differing as to the precise period at which it appears. Sauvages and Cullen state that it does not come out till the fourth day after the accession of the febrile symptoms. Plenciz (Tractatus de Scarlatina, 1776,) does not limit the period, but affirms that the rash makes its appearance on the second or third day, or sometimes later. Heberden restricts it to the first or second day. It is, however, probable that in the majority of instances, the rash comes out on the second day of the fever, and that in cases in which it appears sooner or later, there is some peculiarity in the individual or in the disease to account for the variation.

The efflorescence, which is first perceptible on the face, neck, and chest, becomes gradually diffused over the body; in twenty-four hours or less from its first appearance the trunk is covered with the eruption; on the following day (the third) it extends to the upper and lower extremities, at which period the whole body is of a bright red colour, and pungently hot and dry. On the extremities, particularly the hands and fingers, the rash is diffuse and continuous, but on the trunk it is distributed in irregular patches, the colour being most deep on the loins, buttocks, flexure of the joints, and on those parts of the body which are subjected to pressure; it is generally more vivid in the evening, gradually becoming paler towards the morning.

This is the ordinary progress of the efflorescence in the skin: it is not, however, confined to the cutaneous tissue; the mucous membrane which lines the nostrils, mouth, and fauces being covered with the eruption, so that the lips, the tongue, the pharynx, the velum palati, the nostrils, and even the internal surface of the eyelids are of a bright red colour. The papillæ of the tongue become considerably elongated, the red points shooting through the white fur, and from which it derives its characteristic appearance. In cases where the tongue is clean, it has nevertheless a bright red colour, and the scarlet points may be seen shining through its polished surface.

The rash of scarlatina consists of innumerable red points or dots, which are at first of a pale red colour, but afterwards acquire a deeper hue, giving the affected portions of skin not only a uniform red appearance, but a perceptible roughness, which is most evident on the breast and extremities, in consequence of the greater determination of blood to the papillæ of the skin in those situations.

The efflorescence on its first appearance sometimes closely resembles a papular eruption, and occasionally small miliary vesicles make their appearance, though this latter phenomenon is rarely observed, except when the individual has been subjected to a heating stimulating regimen, or confined in a small, crowded and ill-ventilated apartment. These papular or vesicular spots, however, are now and then observed when the disease occurs under the most favourable circumstances. Dr. Mason Good (Study of Medicine, vol. iii. p. 13,) supposes that they arise from the great determination of blood to the cutaneous vessels producing an effusion of coagulable lymph, which is not entirely absorbed by the time the efflorescence subsides, hence there is occasionally, though not often, an appearance of vesicles, sometimes nearly empty, and sometimes nearly filled with a pellucid fluid, according as the effused fluid has been more or less carried off. The occasional appearance of these vesicles during the progress of scarlatina has been noticed by Rush, Withering, Plenciz, and other writers; Sauvages, indeed, under a mistaken view of their importance, has constituted a distinct species under the name *scarlatina variolodes*.

In ordinary cases of scarlatina, the eruption may be regarded at its height on the fourth day; it begins to decline on the fifth, disappearing in irregular patches; on the following day it is still more indistinct, and on the eighth day no trace of the rash is discernible. The various symptoms with which the eruption is accompanied gradually disappear with the efflorescence, but the tongue still remains morbidly red and clean. The desquamation of the cuticle, which begins about the end of the fifth day on the parts on which the eruption first appeared, proceeds, so that about the eighth or ninth, portions of cuticle are thrown off, the thickest and largest being those detached from the skin of the hands and feet.

2. *Scarlatina anginosa.* — In this form, the fever and efflorescence are accompanied with inflammation of the throat. The anginose inflammation sometimes precedes the fever, but most frequently appears at the same time with the febrile symptoms, though, in some cases, not until the rash or efflorescence is at its height: in the majority of instances, however, it is felt when the eruption appears, and goes through its progress of increase and decline with the cutaneous eruption.

The precursory symptoms of scarlatina anginosa indicate a more acute disorder than the scarlatina simplex. The headach is often accompanied with slight delirium; the heat of skin is more pungent, and the prostration more marked from the beginning. In the course of the second day, the patient complains of a sensation of stiffness or pain about the muscles of the neck, extending to the angles of the jaw and under the ears, with feeling of roughness in the throat, painful deglutition, and some degree of hoarseness. The viscid secretion from the mucous crypts of the tonsils and pharynx, which takes place in the more severe cases, aggravates the patient's sufferings, from the frequent and often ineffectual efforts made to expel it. On examining the fauces, the palate, uvula, and tonsils are red and swollen, and when the local inflammation is severe, coagulable lymph is effused in small irregular masses on the inflamed surfaces. These exudations are very liable, on a superficial examination, to be mistaken for ulcers, or, when the subjacent surface is tender

and disposed to bleed, the admixture of blood imparts to them a brown or almost black colour, and thus, more especially if there be fetor of the breath, they may be mistaken for gangrenous inflammation of the fauces. On attentive inspection, however, after cleansing the throat by acidulated gargles, the entire continuity of the membrane from which the crusts have been detached, at once distinguishes this form of acute symptomatic angina, from the gangrenous inflammation and subsequent ulceration observed in scarlatina maligna.

These exudations of lymph often extend to the lateral parts of the pharynx, and occasionally as far as the œsophagus, though, according to Rayer, they are never observed after death in the larynx or trachea. This coincides with our own experience, as in the dissections of scarlatina with anginose inflammation which we have made, we have not seen an instance of membranous exudation extending to the larynx.

As the anginose inflammation becomes developed, the febrile symptoms increase, the pulse rises, the respiration becomes oppressed, the skin more pungently hot and dry, (sometimes rising to 106°, 108°, or even as high as 112° of Fahrenheit,) and the thirst urgent. The mucous lining of the mouth as well as the tongue, especially at its point and edges, assumes a florid red colour, the papillæ being much elongated and protruding their inflamed points over its surface. All these symptoms are increased towards evening, at which period, the febrile restlessness is often succeeded by delirium.

The rash does not appear so early as in the simple form of the disease. It is sometimes perceptible on the second, but more generally on the third day, and comes out in irregular patches on various parts of the body, particularly about the elbows and wrists. It has been occasionally observed that when the attack is severe, the eruption is sooner thrown out, a circumstance which was noticed by Dr. Clark, who informs us that in an epidemic which broke out in Newcastle-upon-Tyne, in the year 1778, when it began with great vehemence the eruption was often observed on the first day, though commonly it did not make its appearance till the second or third, and sometimes not until the fourth. It evinces also a great tendency to recede or entirely vanish the day after it first comes out, and in these cases, it re-appears partially and at uncertain times, but without any perceptible change in the other symptoms, only that the duration of the disorder is protracted. About the fifth or sixth day of the disease, the fever and inflammation of the throat begin to abate; at the same time the rash declines, becoming faint first on those parts on which it first came out, its disappearance being generally followed by desquamation of the cuticle. This process is, however, uncertain. When the rash is slight, or recedes soon after it comes out, desquamation does not take place; in the more severe cases, the cuticle begins to separate after the eruption and febrile symptoms decline, and continues to desquamate to the end of the second or third week, or sometimes later, during which large portions are thrown off; sometimes the cuticle of the whole hand and fingers is completely detached, resembling precisely a glove in shape.

Though this is the usual progress of scarlatina anginosa, the disease frequently assumes a still more severe character. Thus we observe, in some instances, acrid discharge from the nostrils or ears, often accompanied with deafness; enlargement of the parotid or cervical glands, appearing sometimes at the commencement of the disease, at other times about the fifth or sixth day, but occasionally not till the decline of the eruption, and followed in some cases by abscess of the surrounding cellular tissue: and towards the decline of the disease, ulceration at the corners of the mouth, or of the tongue. Though these local affections are painful, and keep up or even increase for a time the constitutional excitement, they are seldom attended with danger; and in general, after continuing a short time after the prominent symptoms of the disease have disappeared, they subside under judicious treatment.

In scarlatina, as in all febrile disorders, the condition of the several internal organs demands attention. We have often remarked, in investigating the complications of scarlatina, the great disposition to inflammation of serous membranes; therefore, when an organ becomes inflamed during its progress, its investing membrane is much more generally the seat of inflammation, than the substance or parenchyma.

In some cases, the general symptoms are accompanied with evidence of gastro-enteritis. The tongue is morbidly red and clean, and the patient is harassed with sickness, vomiting, and diarrhœa. These symptoms are not uncommon when scarlatina prevails in the autumn, at which season bowel-affections generally prevail, and constitute a leading feature of an epidemic.

As we have already, in the article Fever, detailed the various complications which arise, and the symptoms by which they may be detected, it is unnecessary in the present article to enter into more minute details, especially as the exanthemata bear so close a resemblance to the other forms of fever. We deem it, therefore, sufficient earnestly to impress the necessity for minute inquiry into the condition of the several organs in scarlatina, and more particularly for watching the convalescence. Cases, apparently mild, are often rendered alarming from an attack of inflammation in some organ: the suddenness of the seizure and the rapidity with which it often proceeds, prove the necessity for vigilance, however mild the symptoms of the disease may be at its commencement. Dr. Armstrong has well observed, "that scarlatina anginosa is sometimes attended with moderate, and at other times with severe symptoms; and it is of great consequence to bear this in mind, more especially as the severe may follow the moderate symptoms at any period of its progress. In those cases where the symptoms are moderate, the inflammation is chiefly limited to the throat and mucous membrane of the nose, and the excitement of the arterial system subsides without inducing actual inflammation of the viscera; yet where the symptoms are comparatively severe, the inflammation is not limited to the throat and nasal lining, but attacks some of the viscera commonly under a sub-acute character." (Practical Illustrations of the Scarlet Fever, &c. by John Armstrong, M. D.)

3. *Scarlatina Maligna.*—This variety has been described by some writers by the name of *angina gangrænosa* or *cynanche maligna*. Thus Cullen, in his nosology, places it as a variety of cynanche, and likewise makes it one of the species of scarlatina, from which circumstance much unnecessary confusion has arisen. He was, however, candid enough to remark, that the scarlet eruption appears on the skin under the same form in both diseases, adding, that he had five or six times seen the angina maligna united with the common scarlatina; and that in different epidemic constitutions, sometimes one disease predominated, and sometimes the other.

In fact, two names have been given to one disease, which has almost invariably the same characters, and requires nearly the same treatment, making due allowance for the variation observed in epidemics, and the ever-varying circumstances under which it occurs. Indeed, we are inclined, from our own experience, to affirm that the scarlatina simplex, scarlatina anginosa, and the scarlatina or angina maligna, and the sore-throat without efflorescence on the skin, are merely varieties of one and the same disease.

Though several Spanish and Italian physicians had described the angina maligna, which raged with great violence and mortality in Spain and Italy in the beginning of the last century, Dr. Fothergill was the first writer in this country who described this malignant form of scarlatina as it prevailed in London in the years 1747–8. (An Account of the Sore-throat, attended with Ulcers, by John Fothergill, M. D. 4th edit. London, 1754.) From the description he has given, it is evident, that he witnessed during this epidemic the various forms of the disease, and consequently the malignant variety. This is apparent from the following passage: "Thus much, however, seems to be true in fact, that, in some cases, the disease appears to be of so mild a nature, and so benign, as to require but little assistance from art. Persons even recover from it under the disadvantages of unskilful and injurious management, whilst in others the progress of the symptoms is so rapid, and the tendency to corruption so strong, that nothing seems able to oppose it. Just as it happens in the small-pox: the benign and the distinct sort bears ill treatment without injury; in the malignant flux kind, the utmost art and experience are too often insufficient to conduct the distemper to a happy issue. Whether this diversity in the sore-throat we are speaking of is owing to difference of constitution or of seasons, to the different quality or quantity of the contagion, or the manner of receiving it, or whether there are in reality distinct species, may perhaps hereafter be more certainly determined."

A few years afterwards Dr. Huxham gave a faithful account of a similar epidemic as it appeared in London from the end of the year 1751 to May, 1753, and was very mortal. It is evident, however, that in this epidemic, as well as in others which have been subsequently described, the malignant form was only occasionally observed.

In this form of the disease, the symptoms assume very early a malignant or typhoid character; to the affection of the throat and skin are superadded great cerebral disorder, and often inflammation of the pulmonary and gastric mucous membranes. On the first appearance of the disease, the symptoms may differ little from those of the other forms of scarlatina. The pulse is at first soft and frequent, but soon becomes small, rapid, and often irregular: the patient is restless, and at times delirious, the delirium being sometimes so violent as to require restraint, though more generally it is of the low muttering kind. The rash comes out later and is very uncertain in its duration, often suddenly disappearing a few hours after it is first perceptible; and, five or six days afterwards, coming out again for a period of perhaps two or three days. It may thus suddenly recede and re-appear several times. The colour of the rash is at first faint, except in a few irregular patches, which assume a deep rose hue, but the whole efflorescence is speedily changed to a dark livid red, and in the worst forms is interspersed with petechiæ. The temperature of the skin is generally cool on the trunk of the body, and cold on the extremities; the eyes are suffused and often covered with a film of mucus; the countenance is pale and dejected, while the cheeks are of a dusky red colour; the tongue is covered with dry brown, or almost black fur; in other cases, it is smooth, red, and glossy, and often so tender and fissured that it easily bleeds; the odour from the skin and breath is extremely fetid.

The throat is not much swollen, but appears of a dark red hue, and covered with small ash-coloured sloughs surrounded by a livid base; the gangrene often extends with alarming rapidity, destroying the uvula and arch of the palate. A viscid secretion with which the fauces are covered aggravates materially the sufferings of the patient by increasing the difficulty of swallowing, as well as by the obstruction which it offers to the breathing, so that when symptomatic bronchitis occurs during the progress of the disease, there is great danger of fatal asphyxia. The inflammation generally spreads from the throat to the cervical glands, giving rise to enlargement and sometimes abscess; and when the inflammatory action extends to the nostrils, as it almost invariably does, there is an acrimonious discharge, at first thin but afterwards thick and yellow, which produces excoriation of the nostrils, lips, and angles of the mouth, which are generally in these instances covered with black crusts.

In the more severe cases of malignant scarlatina, the symptoms are more alarming from the first appearance of the disease: the pulse is small, rapid, and indistinct: there is more marked cerebral disturbance,—stupor, coma, or violent delirium; the ulcerations of the throat are more extensive, and covered with dark sloughs, and the colour of the rash becomes livid. We frequently also observe pulmonary disease in the form of latent bronchitis, which is often combined with inflammation of the gastro-intestinal mucous membrane, giving rise to diarrhœa and its pathognomonic signs. Some writers mention that hemorrhage from different surfaces,—from the mouth and throat, lungs, intestines, or bladder, takes place, under which the patient in general rapidly sinks, unless the constitutional powers have been unusually vigorous.

In a severe epidemic described by Dr. Withering, after detailing the ordinary progress of the disease, he gives the following outline of a fatal form which it frequently assumes:—"In children, the delirium commenced within a few hours after the first seizure. The flesh was intensely hot; the scarlet colour appeared on the first or second day, and they died very early on the third. In others who escaped this rapid termination, when the scarlet colour turned to brown, and their recovery might have been expected, the pulse still remained feeble and quick, the skin became dry and harsh, the mouth parched, the lips chapped and black, the tongue hard, dry, and dark brown; the eyes heavy and sunk; they expressed an aversion to all food, and extreme uneasiness upon the least motion or disturbance. Thus they laid for several days, nothing seeming to afford them any relief. At length a clear amber-coloured matter discharged in great quantities from the nostrils, or the ears, or both, and continued so to discharge for many days. Sometimes this discharge had more the appearance of pus mixed with mucus. Under these circumstances, when the patients did recover, it was very slowly: but they generally lingered for a month or six weeks from the first attack, and died at length of extreme debility. In adults, the rapidity of the fever, the delirium, &c. was such that they died upon the fourth or fifth day, especially if purging supervened. Some survived to the eighth, or to the eleventh day: in all these the throat was but little affected; the eyes had an uncommon red appearance, not that streaky redness which is evidently occasioned by the vessels of the cornea being injected with red blood, but an equal shining redness, resembling that which we remark in the eye of a ferret. But notwithstanding this morbid appearance in the eye, the strongest light was not offensive. This redness might often be discovered, by lifting up the upper eyelid some hours before it showed itself in the part of the eye that is usually visible: and it was of some consequence to attend to this circumstance, as it greatly influenced the event of the case. These patients were extremely restless, clamorous, and desirous to drink; but after swallowing one or two mouthfuls, upon taking another they seemed to forget to swallow, and let it run out at the corners of the mouth; whilst others spurted it out with considerable force, and were very angry if urged to drink again. In these cases, the scarlet colour appeared very soon after the attack, but in an unsettled irregular manner, large blotches of red intermixing with others of white, and these often changing places. Besides the full scarlet colour described as above, there were frequently small circular spots of a livid colour, about the breast, knees, and elbows. The pulse from the very beginning was so quick, so feeble, and so irregular, that it was hardly possible to count it for half a minute at a time. It is needless to add, that the greater part of those who laboured under these dreadful symptoms died. A few recovered, and others fell into a state of debility bordering upon idiotism, from which they were rescued by time and generous living. In one patient, a man, the jaw was so perfectly locked upon the third day, that it was impossible to get any thing down his throat, and he died early upon the fifth day." (Account of the Scarlet Fever and Sore-Throat, p. 18.)

In a few instances, we have seen the large joints suddenly become extremely painful, to which swelling with evidence of fluctuation succeeded, and the patient was destroyed in a very short time.

In many instances this malignant form of scarlatina proves fatal on the third or fourth day, though the patient often lingers till the second or third week: it is not uncommon for the patient to die suddenly on the second, third, or fourth day, without the practitioner being able to assign any satisfactory reason, or discover any lesion on the most careful examination of the body. Sometimes, on the other hand, recovery takes place under the most unfavourable circumstances, but the convalescence is exceedingly tedious, and often retarded by the recurrence of some local inflammation, which had arisen during the progress of the disease.

It should not be overlooked that, when the early symptoms have been comparatively mild, the disease may suddenly assume the malignant character. Indeed this form (scarlatina maligna) is more frequently intermixed with the other varieties of scarlatina, and it sometimes unexpectedly supersedes the milder forms of the disease, on the fourth, fifth, sixth, or seventh day of their course. (Willan.)

4. *Scarlatina faucium.*—It has been frequently observed, that when scarlatina prevails epidemically, cases occur in which there is no appearance of rash on the skin, the efflorescence being confined to the throat and mouth. In some cases, the characteristic red appearance in the throat is unattended with swelling; in others, the efflorescence in the throat is accompanied with swelling of the tonsils, and consequent painful deglutition. Dr. Willan states, that this complaint seems peculiar to adults, and is evidently a species of scarlatina, because it affects some individuals of large families, while the rest are labouring under other forms, and because it is capable of communicating by infection all the varieties of that disease. It is sometimes succeeded by an enlargement of the parotid glands, but not by dropsical swellings. Persons who have previously gone through the scarlatina anginosa, experience, while conversant with the sick, very uneasy sensations in the throat: in some there is a swelling and inflammation, or ulceration of the tonsils, producing considerable pain and irritation, but without the specific fever and efflorescence. (On Cutaneous Diseases, p. 274.) Similar instances have been related by Dr. Johnstone, in the description of the epidemic scarlatina which prevailed at Worcester in 1778. Some individuals, at the first seizure, were more or less severely attacked with the scarlet eruption, with swelling, redness, and ulcers in the throat; yet others in the same family, infected from them, and by them, often had the ulcerated sore throat, without any efflorescence or eruption on the skin. Again, the first seized sometimes had the simple ulcerated sore-throat only, and yet the others infected by them had the more severe attack of the disease, of fever, and scarlet eruption, as well as sore-throat.

(Memoirs of the Medical Society of London, vol. iii.)

In a paper by Dr. Lettsom, entitled Cursory Remarks on the Appearance of the Angina Scarlatina in the spring of 1793, several cases are given of this form of scarlatina. In one case the disease assumed the characters of scarlatina maligna, but without efflorescence. The sister of this patient, a day or two after, became also the subject of the disease; but in this case, the affection of the throat and fever of the malignant kind were accompanied by general florid efflorescence. In another family, one of the children had ulceration of the throat, but no eruption: a second, about a year older, caught the disease, but had both the affection of the throat and the efflorescence. In another family, some had the sore-throat without any eruption, others had the eruption with a very moderate degree of sore-throat; and this was observed not only among the children, but also among the servants. (Memoirs of the Medical Society of London, vol. iv.)

These statements accord exactly with our own experience of epidemic scarlatina. We had very lately an opportunity of observing in one family the simultaneous appearance of the various forms of the disease. In one of the children, who was the first subject of it, the symptoms early assumed a most malignant aspect; the velum and uvula were destroyed by gangrenous inflammation, and death took place about the fifteenth day. Some days after the disease had appeared in this child, one of the servants became ill, and passed through a mild form of scarlatina anginosa without any untoward symptom. No sooner had this servant recovered than the father of the child began to be indisposed, and in a day or two, considerable fever, with efflorescence of the mouth and throat, and inflammation of the tonsils, came on. The fever and anginose inflammation lasted for several days, and terminated in desquamation of the cuticle.

It appears, then, that the various forms of scarlatina may be produced by exposure to the same exciting causes, and that the differences observed depend on some individual peculiarity or idiosyncrasy, which cannot, *à priori*, be ascertained.

[The blood in scarlatina has been examined by M. Andral, and found to be constituted as in measles,—preserving, in other words, pretty nearly its mean proportion of fibrin—3 in 1000, with an augmentation of the proportion of globules, 127 in 1000. In four patients, he found the ratio of fibrin to be 3, 3½ and 4; in two others, that of the globules 136 and 146. (*Cours de la Faculté*, 1841, cited by Guersant & Blache, *op. cit.*)]

Sequelæ.—Scarlatina is occasionally followed by troublesome local affections—ophthalmia—enlargement and frequently suppuration of cervical glands—abscess in the pharynx—laryngitis—chronic bronchitis—inflammation of the ear, ending in purulent discharge from the meatus externus, or suppuration and consequently destruction of the internal ear.

In some instances, dropsical effusion comes on during the convalescence from scarlatina, and always proves an alarming affection.

Anasarca is the form in which the dropsy more generally appears, and though the fluid may be confined to the subcutaneous cellular tissue, it sometimes accumulates in the different cavities; when this is the case, the patient may be considered in great danger. It is singular, that the dropsy has been remarked to succeed as often to mild as to the more severe forms of the disease; but it has never been observed to supervene in cases of malignant scarlatina: it would, therefore, appear to be connected with the acute or subacute forms of scarlatina only. It is almost entirely confined to children, rarely occurring after puberty; Dr. Wells, however, had occasion to treat one case which occurred at the age of seventeen. It seems peculiar to some epidemics. We have seen it occur in several children of the same family, who had passed through scarlatina at the same time. Some writers seem to view this secondary affection as of trivial importance; others regard it as more serious than the primary disease. Plenciz, indeed, affirms that more persons die of it than of scarlatina. This, however, is not the result of the cases which we have witnessed, though in this country it occasionally proves fatal. It generally comes on ten or twelve days after the period of desquamation, and often without any evident cause: sometimes it does not come on for two or three weeks after the disappearance of the rash; and in one case which came under our care, the dropsical symptoms did not appear till five weeks after the desquamation. Previous to its appearance, the patient, after perhaps satisfactorily proceeding in his convalescence to a certain point, finds he does not advance, but rather retrogrades: he complains of unaccountable languor and lassitude, loses his appetite and strength, his sleep is disturbed, his pulse becomes quick, the bowels costive, and the urine scanty: sometimes there is considerable gastric disorder, indicated by sickness, vomiting, and purging. The swelling is first observed in the face and upper parts of the body, to which it is sometimes confined, though more generally it extends over the whole body, and occasionally effusion takes place in the brain, cavity of the chest, or belly. In fatal cases, fluid has been effused in these three cavities in a very short time. In an epidemic scarlatina, described by Dr. Hamilton, which occurred among the boys in Heriot's Hospital, in three cases the disease proceeded with a rapidity which afforded little opportunity for deliberation or action. The stomach gave way; all food, cordials, and medicines were rejected by vomiting. The watery effusion rapidly filled the cellular membrane, and inundated every cavity. Within less than six-and-thirty hours from the occurrence of the ailment, the boys died, labouring under symptoms denoting ascites, hydrothorax, and hydrocephalus.

In this form of dropsy, the urine generally coagulates by exposure to heat or the addition of nitric or muriatic acid, alcohol, or a solution of the chloride of mercury. Sometimes it deposits a dark-red or brown sediment, which seems to arise from the admixture of the red globules of the blood.

[Not unfrequently, in these cases, the kidneys exhibit signs of glandular disease; so that a question has even arisen, whether the anasarca may not be owing to the renal disease. (Guersant et

Blache, *Op. cit.* See, also, Rilliet and Barthez, *Traité Clinique et Pratique des Maladies des Enfants*, ii. 613, Paris, 1843.)]

As dropsical effusion is to be regarded only as a secondary affection, it is of importance to ascertain its source. We have always regarded the dropsy succeeding to scarlatina as of an acute or subacute kind, arising from increased action in the sanguiferous system; the consequence of this increased action is the effusion of serous fluid into the external tissues of the body, or when there is a still greater degree of vascular excitement, into one or other of the cavities. That this is the cause of the effusion, if not invariably, at least in the majority of instances, and certainly in all those which have come under our observation, was evident from the character of the pulse as to frequency and power, the coagulable urine, the rapidity with which the fluid accumulated if not arrested by prompt treatment, and from the efficacy of bloodletting, purging, and other antiphlogistic measures, which were generally necessary to remove the dropsical effusion.

Burserius, (Instit. Med. Pract. vol. ii.) in the account he has given of an epidemic scarlatina which prevailed at Florence in the year 1717, mentions that on opening the bodies of several persons who had died of this disease, the lungs, pleura, intercostal muscles, diaphragm, kidneys, and intestines, were more or less inflamed: that peripneumony having been considered as the primary disease, and the dropsical swelling only a consequence, blood was taken from the arm in the succeeding cases, once or oftener, as the occasion required; and that no one afterwards died of the dropsy who was thus treated.

[Effusions, of fatal tendency, occasionally take place into the larger joints. Gangrene of the extremities likewise occurs at times. In an account of scarlatina that prevailed in the London Foundling Hospital, Dr. Watson gives one case that died of mortification of the rectum; and six others that died sphacelated in various parts of the body. In the girls, some had the pudendal region mortified; two had ulcers of the mouth and cheek, which sphacelated externally; whilst one had the gums and jawbone so corroded, that most of the teeth fell out before she died. The lips and mouth of many that recovered were ulcerated, and continued so for a long time.]

Morbid Anatomy.—In scarlatina the appearances on dissection are by no means uniform; indeed, we have frequently been surprised, in examining rapidly fatal cases, to find no morbid appearances that could explain the cause of death: in such instances, it is more than probable, that the diseased condition of the blood and fluids has had an important share in the fatal issue. The skin runs rapidly into putrefaction: it is generally of a dark red colour, the redness being of a deeper colour in different parts, and frequently interspersed with livid spots. When there have been violent delirium and other symptoms of cerebral excitement, the arachnoid membrane is vascular or even opaque, with effusion of a serous or sometimes milky fluid underneath. In such cases, the substance of the brain is also unusually vascular. The mucous membrane of the mouth, cavity of the nose, pharynx, and sometimes even of the trachea and bronchi, is often red from sanguineous injection; and when there has been considerable acute anginose inflammation, there is swelling of the tonsils with exudation of lymph. In the malignant scarlatina, there is little or no swelling, but the membrane of the pharynx is sometimes of a dark livid colour, and occasionally in a sloughing state. In some cases, there is a small quantity of puriform fluid in the sacculi of the larynx, and in two or three instances we have seen ulceration of the cartilages. These appearances in the throat are, however, by no means uniform or frequently observed, and the state of the throat after death very often presents no appreciable morbid appearance, even when there has been considerable anginose affection during the disease. In the chest, redness and thickening of the bronchial membrane, the smaller bronchial tubes and air-cells being filled with a viscid secretion, and a gorged state, with extreme softening and tendency to rapid decomposition of the pulmonary tissue, are the principal morbid appearances. In the abdomen, there are seldom any appearances that can be called morbid; in some cases, the mucous membrane of the stomach or of some portions of the alimentary canal has been slightly injected, though more frequently this membrane throughout the whole tract of the intestines retains its natural colour. When purulent deposits take place in the joints—a complication or sequela which we have occasionally observed—there are not always marks of inflammation of the synovial membrane. In the last case of this kind, however, which we examined, in which pus was deposited in the left wrist and in both ankle joints, there was deposition of pus exterior to the wrist joint, among the carpal bones. The synovial membrane of the wrist and ankles was evidently redder than natural, but there was no abrasion. We are therefore inclined to think, that these purulent formations in the joints may occur without antecedent inflammation; and even in the case alluded to we doubt the co-existence of inflammation: it is more probable that the pus which was deposited was not the consequence of the inflammatory action, but that the purulent fluid was deposited from the blood in the same way as it is sometimes deposited in other parts of the body.

Diagnosis.—It is seldom difficult to distinguish scarlatina from other acute eruptive diseases. There is some resemblance, in the cutaneous efflorescence, to *measles* and *roseola*.

It may be distinguished from measles, 1st, by the period at which the eruption appears; 2d, by the accompanying symptoms; 3d, by the character of the eruption; and 4th, by symptoms which are frequently observed after the disappearance of the rash. In scarlatina the efflorescence generally appears about the second day of the fever, attended (with the exceptions stated) by affection of the throat, and the characteristic appearance of the tongue: in rubeola the rash does not come out till the fourth day, its appearance being preceded by sneezing, coryza, inflamed and watery eyes, cough, and other catarrhal symptoms, which continue during its progress. The eruption in scarlatina consists of innumerable minute dots or points, diffused in patches with uneven edges, of various

sizes and forms, and gives to those portions of the skin on which it appears a diffused bright red colour. In measles, the efflorescence comes out in irregular semilunar or crescent-shaped patches, distinctly elevated, the spots being of a deeper red in the centre than in the circumference, and leaving intervening spaces in which the skin retains its natural pale colour. The desquamation of the cuticle is besides more general and more considerable in scarlatina than in measles. The sequelæ of measles are principally affections of the organs of respiration, croup, bronchitis, or pneumonia, which are more liable to come on towards the decline of the eruption. In scarlatina, there is more frequent affection of the glandular system, and liability to inflammation of the joints and serous membranes, and to anasarcous and dropsical effusion into the cavities.

Roseola is always a much milder disease than even the simple form of scarlatina: the efflorescence is more continuous, of a deeper rose colour, and does not terminate by desquamation. Besides, in roseola, the anginose inflammation and appearance of the tongue peculiar to scarlatina are awanting. The whole duration of roseola too is short, seldom exceeding five or six days, and it cannot be propagated by contagion. It is also often symptomatic of other disorders.

Prognosis and Mortality.—It has been generally observed, that scarlatina proves more severe to adults than to children, and that when it attacks pregnant or puerperal women it is often fatal. It has been also noticed, that it is generally mild in spring and summer, but severe during the winter months.

Simple scarlatina is in general a very mild disease and seldom proves dangerous unless some local inflammation supervene during its progress; but thus a form of scarlatina, mild in the beginning, may be rendered suddenly and unexpectedly dangerous.

Scarlatina anginosa is always a more severe disease than the scarlatina simplex, since to the more acute form of fever there is superadded inflammation of the throat. The anginose inflammation, however, seldom of itself renders the disease dangerous, especially if proper measures be adopted at the beginning. There is in general a manifest disposition in the affection of the throat to terminate in resolution, and it is often surprising how readily it yields to general or local depletion. A moderate degree of swelling, with bright red efflorescence in the throat, is a more favourable indication than when there is little or no swelling, and the redness assumes a dark or livid appearance. It was stated in the description of this variety of scarlatina, that the inflammation sometimes extended from the throat to the larynx: when this takes place, the danger is imminent; since if œdematous swelling of the glottis ensue, death almost inevitably ensues. Danger may also arise from inflammation in some of the cavities—cerebral, pulmonary, or abdominal disease being thus superadded to the anginose and cutaneous inflammations.

A favourable or unfavourable prognosis may be often, in some measure, inferred from the cutaneous efflorescence. In the scarlatina anginosa, the rash appears late in the disease, and though in most instances, it is diffused generally over the surface, it is often only partial, coming out in small irregular patches on different parts of the body. In these latter cases, it is more apt to disappear suddenly, which is a less favourable circumstance than when the rash is general and remains out for several days. The colour of the eruption seems also connected with the general character of the disease. A bright red or scarlet efflorescence is more favourable than the dark red, crimson, or brownish colour which it sometimes assumes. A very pale rash, more especially if it be partial and evanescent, is also unfavourable; and when the eruption, whatever be its colour or the extent of its diffusion, disappears suddenly, and afterwards reappears, or if it do not again come out, more especially if it have receded at the beginning of the disease, the danger is considerable. The more perfectly the desquamation takes place, the case is to be regarded as the more favourable, as secondary disorders are less likely to arise.

From the description which has been given of the scarlatina maligna, the danger in almost every case must be apparent, though it does not appear to arise from the visceral complications which occasionally supervene, as in fatal cases there is seldom discovered in the internal organs satisfactory evidence of the cause of death. In estimating the amount of danger and probable issue of the case, however, it should be kept in view, that though this form of scarlatina proves fatal in a much larger proportion of cases than any of the other varieties, there is every intermediate shade or gradation between the less severe and most malignant cases. In this more severe form of scarlatina some particular symptoms or appearances however modify the prognosis. Children are observed to struggle better against it than adults, though in some epidemics no age seems to be exempt from its ravages. The existence or non-existence of local inflammation in any organ must also be taken into account, in estimating the degree of danger, and it should be kept in mind how little such topical inflammations are under the control of the treatment, which it is necessary to modify according to the general powers of the patient; if active measures be resorted to in cases of malignancy with the hope of subduing the low forms of visceral inflammation, the powers of the patient would be endangered if not irrecoverably sunk.

With regard to the prognosis of malignant scarlatina to be deduced from particular symptoms, a favourable result may be predicted from the following circumstances—mild fever and moderate affection of the throat—early and copious eruption succeeded about the third or fourth day by gentle moderate perspiration, and general desquamation of the cuticle—the throat assuming a florid red colour, and if there have been sloughing, the ulceration looking clean and healthy—diminution in the frequency, with firmness and equality of the pulse—the breathing becoming soft and free, while the eye resumes its brilliancy, and the countenance its natural expression. On the other hand, the prognosis may be deemed unfavourable, when the following symptoms occur—a partial eruption disappearing suddenly—or assuming a dusky or livid colour, more especially if accompanied with

petechiæ — smallness and great rapidity of the pulse—frequent sighing with sensation of great faintness — hot dry skin—hurried breathing not depending on disease of the lungs — acrid discharge from the nose and ears—ulceration of the lips and angles of the mouth—paleness or shrinking of the features—sunken eyes—partial cold sweats—coldness of the extremities—low muttering delirium—coma—hiccup—subsultus tendinum —involuntary stools—gangrenous inflammation of those parts subjected to pressure, as the sacrum and hips—swelling and purulent deposits in the larger joints. Huxham observed in some individuals previous to the fatal issue, the face bloated and shining, and the neck swollen and of a cadaverous appearance, the whole body even became in some degree œdematous, so that the impression of the finger remained.

[The form of scarlatina, which has been termed the *hemorrhagic*, is almost always fatal. It is indicated by the ordinary signs of purpura,—dark spots appearing here and there, followed by exudation of blood from the mucous membranes—of the mouth and nose especially, which is occasionally so profuse as to cause death. In these cases, if a puncture be made, it becomes the seat of hemorrhage. In a case of the kind referred to by Dr. Morton, (Mackintosh's *Principles of Pathology*, 2d Amer. edit. i. 224, Philad. 1837,) an abscess in the neck suddenly filled with blood, and this, making its way through a leech-bite, flowed out as if from a divided artery, and destroyed the patient in a few hours.]

The *mortality* of scarlatina varies much in different epidemics, although nothing has been satisfactorily established as to the causes which influence the fatality of the disease. The difference observed in epidemics is not confined to scarlatina, but occurs in every variety of fever, whether of the continued, periodic, or eruptive form. In some epidemics scarlatina is a very mild disease throughout; and when it does prove fatal, the cause may often be traced to the supervention of some accidental inflammation; or it may happen, that in particular instances, the symptoms may assume a malignant character, though the general aspect of the epidemic be very mild. It is unnecessary to pass under review the histories which have been recorded of epidemic scarlatina which have at various times appeared; they are alluded to, principally with the object of directing attention to the influence which certain, though unknown circumstances exert over the character and symptoms of this disease. It is often sufficient for the practical inquirer to be a diligent and faithful observer of nature, without attempting to discover the hidden causes, and invent explanations of her secret operations. The extreme mildness of some epidemics has induced many to assert, that the mortality of scarlatina has been overrated, and even Sydenham from his observance of the disease (its milder forms only having evidently been presented to his notice), came to the conclusion that it scarcely required medical aid, and when it did prove fatal, this result was to be traced to the *nimia medici diligentia*. Had the attention of this illustrious physician been directed to the epidemic described by Morton, a very short time after this opinion was delivered to the world, his candour would have compelled him to acknowledge, that the views he entertained and promulgated of the nature of scarlatina had been formed on too limited experience of the disease. The rapidity with which patients are hurried off is often striking. In an epidemic scarlatina which prevailed in Paris in 1743, we are told that every individual who was attacked perished—many indeed within nine hours from its first invasion. That which raged at Bromley, near Bow, in Middlesex, in the year 1746, it is stated by Dr. Fothergill, seemed to yield to no remedies or applications; several of the inhabitants were greatly alarmed by it, some losing the greater part of their children after a few days' indisposition. These are by no means solitary examples of the great fatality of scarlatina, as similar epidemic visitations have been recorded by Huxham, (Dissertation on the Malignant Ulcerous Sore Throat,) Cotton, (On a particular kind of Scarlet Fever, prevalent at St. Alban's in the year 1748,) De Haen, (Philos. Trans. 1749,) Johnstone, (Remarks on the Angina, and Scarlet Fever of 1788, in the Memoirs of the Medical Society, vol. iii.,) Rush, (Medical Observations and Enquiries,) Lettsom, (Memoirs of the Medical Society, vol. iv.,) Sims, (Ibid. vol. v.,) Willan, (Miscellaneous Works, edited by Ashby Smith, M.D.,) Bateman, (Reports on the Diseases of London,) Blane, (Med. Chir. Trans. vol. iv.,) Macgregor, (Ibid. vol. v.,) Tweedie, (Clinical Illustrations of Fever,) Carbutt, (North of England Med. and Surg. Journ., vol. i.,) Sandwith,* and others.

Dr. Willan has given the result of his experience of an epidemic scarlatina, from cases which occurred in his own practice in the year 1786. Of 251 cases, there were 152 of scarlatina anginosa, 42 of sore throat without eruption on the skin, and 39 of scarlatina maligna. Dr. Clark, in the description he has given of an epidemic scarlatina which prevailed at Newcastle in 1778, observed, that of 131 patients, 75 had the eruption with sore throat; in 33 the disease occurred with every distinguishing symptom of scarlatina maligna; and that in 23 cases it was succeeded by dropsy. He adds, when it is considered that great numbers had the distemper in such a mild manner as to require no medical assistance, and that application was only made for the advice of a physician when the patients were severely attacked, perhaps the malignant cases ought not to be estimated higher than as one to twenty in all who took the disease.

No deductions however can be drawn from these averages, as they have reference only to solitary epidemics, and it is well known that in one or several epidemics a large proportion of the cases assume the characters of a malignant disease, while, as was formerly stated, a few malignant cases only may occur out of a large number of individuals affected.

We find from the register of cases kept at the London Fever Hospital, that the mortality of scarlatina shows great variation. In the years 1822 and 1823, the disease appears to have been extremely mild, as none of the patients died during these years. In 1824, the mortality was one in

* Edin. Med. and Surg. Journ., No. cxvii., (a most excellent practical paper.)

twenty-one; in 1825, one in thirteen; in 1826, one in twenty-nine; in 1827, one in forty-one; in 1828, one in ten; in 1829, one in six; in 1830, one in six; in 1831, the disease was not prevalent, and none of the cases proved fatal; in 1838, the mortality was one in forty; and during the last year, the average has been about one in twenty-two. Of 644 cases treated at this hospital, the gross mortality was thirty-eight; of these there were thirteen males and twenty-five females. The following table exhibits the comparative ages of the fatal cases:—

	Males.	Females.
7 years of age	0	1
10 ditto	1	1
11 ditto	0	2
12 ditto	0	1
13 ditto	1	1

40 ditto	0	1
	13	25

[In England and Wales, the number of deaths amongst children from scarlatina was in 1838, 5802; in 1839, 10,325; less than the mortality from measles. (W. Farr, *Third Report of the Registrar-General*, Lond. 1841.) If, however, the year 1840 be reckoned, the preponderance is on the side of scarlatina:—the deaths during that year being 19,816; whilst those from measles were 9326.

In all the Atlantic cities of the United States, so far as statistical examinations have been made, scarlatina appears to be a more fatal malady than measles. In an inaugural "Essay on the Comparative Mortality of Measles and Scarlet Fever," presented to the faculty of Jefferson College in Feb. 1844, Dr. George King Smith makes the number of deaths from measles in Philadelphia, from 1807 to 1841 inclusive, 1376; from scarlatina during the same period, 2226. In New York, from 1819 to 1834 inclusive, the deaths from measles were 1337; from scarlatina, 1500. In Boston, from 1811 to 1840 inclusive, from measles 700; from scarlatina, 970.]

Treatment.—From the description which has been given of the various forms of scarlatina, it is obvious that the measures to be adopted for its treatment must have reference to each individual case, as well as to the various circumstances with which it may be associated.

It is also indispensably necessary that the treatment should have reference to the prevailing type or character of the fever, an indication which it is of the utmost importance to bear in mind in the management of this disease. We have already endeavoured to impress this circumstance strongly in a former part of this article, so that it is sufficient merely to advert to it again.

1. In the *scarlatina simplex*, the symptoms are generally so mild, that it is only necessary to confine the patient to bed, to keep the apartment cool, to prescribe occasional aperients, cooling drinks, and abstinence from animal food, so long as there is any febrile indisposition. Should the skin feel hot at intervals, it is advisable to sponge the surface with cold water, by which the morbid heat is rapidly dissipated, and the feelings of the patient are rendered more comfortable. It is seldom necessary in this form of scarlatina to abstract blood, unless it be deemed expedient in cases where the fever runs high. In those cases, it may be prudent to take away a moderate quantity of blood, with the view of subduing the vascular excitement, and preventing the local inflammations which frequently arise in scarlatina. Whether bloodletting be deemed expedient or not, an emetic is often attended with good effects; after which the bowels should be freely opened by brisk aperients, and the various saline remedies, in combination with antimony, administered as circumstances require. It is necessary to watch every case of scarlatina, however mild at the beginning, as the character of the disease is often materially altered by the sudden accession of inflammation in some internal organ, by which a mild disease may in the space of a few hours be converted into one of severity and danger.

2. We have pointed out the more active nature of the symptoms in *scarlatina anginosa*. In adults of a plethoric tendency, more especially if the patient be young, bloodletting is sometimes necessary; and even in children, a moderate bleeding from the arm, when there is much excitement at the beginning, is often useful in moderating the fever, and diminishing the tendency to visceral inflammation. General bloodletting has been strongly recommended by several continental physicians in this form of scarlatina, more especially when there is much cerebral disturbance. Morton employed it with success in the epidemic he has described; and in the scarlatina which prevailed at Edinburgh in 1733, we find it stated, that few died who were timely and plentifully blooded, which weakened the fever, relieved the throat, and was the only medicine that removed the vomiting and diarrhœa. (Edinburgh Medical Essays, vol. iii. p. 27.) Huxham advocates this practice at the commencement of the fever, when the blood was often sizy, but recommends one moderate bleeding only, as patients did not bear a large bleeding, and scarcely any a second.

On the other hand, in some epidemics, evacuations of blood are less efficacious, or wholly inadmissible, either from the form of fever being of a less acute character, or from the tendency of the general powers to decline, when active depletion has been adopted. The successful treatment of the disease by bloodletting and other antiphlogistic measures at one season, does not warrant the practitioner in employing the same plan in another epidemic; the type of the fever, the pulse, and the general aspect of the symptoms must be his guide. In the epidemic described by Dr. Withering, such was the state of the pulse, that bloodletting was inadmissible, unless in the autumn, when the

colour of the rash was not intense, or did not appear at all, the swelling of the throat great, and the pulse firm. Dr. Willan also states, that during the years 1785, 1786, 1787, and since, when the scarlatina anginosa was epidemic in the metropolis, he never saw a case in which bloodletting appeared to be indicated. Whenever it had been employed, great depression and faintness were the immediate consequences, the pulse becoming more weak and frequent, and often irregular. Of two adults who had been bled largely, one died before the period of desquamation, the other lingered in a very precarious state upwards of twenty days, but at length recovered.

It is therefore almost impossible to lay down general rules for the treatment of a disease which varies so much in its character at different times. At one season, or in one epidemic, bleeding may be required — at another, the lancet is to be employed with the greatest caution, and not unless some urgent circumstance arises to require its use. We have seldom had occasion to bleed from the arm, unless in particular instances of unusual febrile excitement, or when some important organ was threatened with inflammation. We generally prefer the free topical abstraction of blood by cupping behind the neck, which is the most effectual mode of relieving the inflammation of the throat, or by the application of leeches under the jaw, or behind the ears. We have seen great benefit also from the free scarification of the tonsils when skilfully performed, though many patients object to this mode of topical bleeding, which is also often not easily performed in timid persons.

We have seldom observed any decided benefit from the use of gargles, indeed the inconvenience felt by the patient in their employment often precludes their adoption. The inhalation of the vapour arising from warm water gives much more decided relief.

The exhibition of emetics in the commencement of scarlatina anginosa as well as of the other forms, has been strenuously recommended by some physicians. Dr. Withering prescribed them not only in the beginning, but even in the later stages of the disease. Their employment, however, should be restricted to the period of invasion, as it has been observed that they are much more beneficial at this stage than when the symptoms are more advanced. The shock which is given to the system by the action of vomiting in the early stage of eruptive fevers is often followed by most decided improvement in the general symptoms and feelings of the patient. Dr. Rush exhibited an emetic, combined with calomel, in every case he was called to, which, besides inducing vomiting, seldom failed to produce two or three stools; in several cases he was obliged, by the continuance of the nausea, to repeat the emetic, and always with obvious and manifest advantage.

The abatement in the symptoms which is generally observed after the bowels have been freely evacuated, has induced physicians to purge freely in the early stages of scarlatina anginosa, and certainly no class of remedies is more entitled to confidence than purgatives, when administered with discernment. Many writers have expressed their doubts of the safety of this practice, from the fear of inducing debility and repelling the efflorescence. Dr. Hamilton, however, has adduced powerful arguments in support of it, and has illustrated his views by an appeal to the result of cases treated in public and private practice. No variety of the disease, as appearing in different epidemics, or in the course of the same epidemic, has hitherto prevented this distinguished physician from following out this practice to the necessary extent. The pungent heat of surface, violent headach, turgescence of features, and full and quick pulse, the earliest symptoms in some epidemics of scarlatina, and which may have suggested and warranted the practice of bloodletting, are often quickly subdued by one or two brisk purgatives. Dr. Hamilton states, that full purging is not required in the subsequent periods of the disease, in which the sole object is to remedy the impaired action of the intestines; to secure the complete and regular expulsion of their contents; and thus to prevent the accumulation of fæces, which never fails to aggravate the symptoms and to prove the source of further suffering to the patient. He has added some very useful hints as to the same activity not being required in the exhibition of purgative medicines in every case of scarlatina, acknowledging, that he had not ascertained to what this different state of the bowels in scarlatina is to be ascribed, and observing that on whatever cause the difference depends, it is necessary to adapt our practice in the use of purgatives to the nature of the prevailing epidemic.

In the early stages, when there is nothing to contra-indicate the use of purgatives, a brisk aperient may be exhibited daily. We generally prescribe a combination of calomel and rhubarb at bed-time, and on the following morning a moderate dose of castor-oil, or infusion of senna with manna and sulphate of magnesia. When the cuticle begins to desquamate, and the febrile symptoms decline, active cathartics are improper; at this stage of the disease, it is necessary only to ensure the regular evacuation of the bowels, for which purpose the mildest aperients are best adapted.

Though we have advocated the employment of purgatives in the more severe cases of scarlatina, they are to be prescribed with the greatest caution, if not altogether withheld, when the mucous membrane of the intestines betrays signs of irritation or of inflammation. In such cases, the bowels are generally purged, and the dejections of an unhealthy appearance. Under such circumstances the gastric irritation must be allayed by leeches applied to the abdomen, counter-irritation, and bland nourishment. Aperients, even of the mildest class, must be withheld, until the intestinal derangement is allayed; and should it become necessary to administer an aperient occasionally, the least irritating should be selected; none is preferable to castor-oil suspended in mucilage, with the addition of a few drops of laudanum.

The free application of cold is decidedly beneficial in the acute stage of scarlatina, and more especially in the anginose form. The bed-chamber should always be properly ventilated by frequently renewing the air, and allowing a current of cool fresh air to pass round the patient. If the skin be hot, the body should be occasionally sponged with cold water, by which the morbid heat is rapidly abstracted, and the patient refresh-

ed. The sponging should be repeated when the skin feels pungently hot. The testimony of Dr. Bateman, as to the efficacy of this practice, is very strong: — "We are possessed," he says, "of no physical agent, as far as my experience has taught me, (not excepting even the use of blood-letting in acute inflammation,) by which the functions of the animal economy are controlled with so much certainty, safety, and promptitude, as by the application of cold water to the skin, under the augmented heat of scarlatina, and of some other fevers. This expedient combines in itself all the medicinal properties which are indicated in this state of disease, and which we should scarcely *à priori* expect it to possess: for it is not only the most effectual febrifuge, (the "febrifugum magnum," as a reverend author long ago called it,) but is, in fact, the only sudorific and anodyne which will not disappoint the expectation of the practitioner under these circumstances. I have had the satisfaction in numerous instances of witnessing the immediate improvement of the symptoms, and the rapid change in the countenance of the patient produced by washing the skin. Invariably, in the course of a few minutes, the pulse has been diminished in frequency, the thirst has abated, the tongue has become moist, a general free perspiration has broken forth, the skin has become soft and cool, and the eyes have brightened; and these indications of relief have been speedily followed by a calm and refreshing sleep. In all these respects, the condition of the patient presented a complete contrast to that which preceded the cold washing: and his languor was exchanged for a considerable share of vigour. The morbid heat, it is true, when thus removed, is liable to return, and with it the distressing symptoms, but a repetition of the remedy is followed by the same beneficial effects as at first." (Practical Synopsis of Cutaneous Diseases.)

[The use of ice internally is the best and most grateful refrigerant. Chlorinated soda, chlorinated lime, or the aqua chlorini, is sometimes added to the water.]

Little confidence should be reposed in any of the ordinary saline remedies. We prefer the mineral acids, more especially the saturated solution of chlorine, prepared according to the directions given in the Dublin Pharmacopœia, which contains about twice its volume of chlorine. Of this remedy a fluidrachm and a half, mixed with eight ounces of water, and two drachms of syrup of lemons, may be taken in divided portions during the day, For children, ten or twelve drops every six or eight hours is a sufficient dose.

The solution of chlorine is readily decomposed by exposure to light and air, and in this state it is very apt to disorder the stomach and bowels, producing sickness, griping pain of the bowels, or diarrhœa. It is therefore necessary, that the remedy should have been recently prepared before it is exhibited. If recently prepared chlorine cannot be readily procured, (though it is obtained by a very simple chemical process,) the diluted sulphuric acid may be substituted.

In the advanced stages of scarlatina anginosa, when the general fever has declined, and the efflorescence has disappeared, it is often necessary to give, with due caution, a little support. Mild nourishment is often sufficient, but should the pulse be soft and rather weak, with a cool skin, small doses of quinine in acidulated infusion of roses are generally very beneficial. It is seldom necessary to administer wine, except under circumstances of unusual debility after a protracted illness. The moderate use of it in such cases tends much to assist the convalescence.

When visceral inflammation arises in the progress of scarlatina anginosa, no time should be lost in endeavouring to arrest it. In such cases, the judgment of the practitioner must direct him as to the extent to which it is necessary to carry the antiphlogistic treatment. We have already entered so fully into the management of the various local lesions which arise in the progress of fever, (and the indications to be observed in scarlatina are precisely similar,) that we deem it unnecessary to repeat what has been already advanced, (see Fever,) though the necessity of watching narrowly the state of the several organs, and of adopting suitable measures on the first evidence of local inflammation, cannot be too forcibly impressed on those who may not have had much experience in the treatment of this disease.

3. In *scarlatina maligna*, the acute stage, in which only antiphlogistic measures can with safety be employed, soon passes off, and is succeeded by a low depressed state of the general powers, which renders any form of depletion not only doubtful but hazardous. If the practitioner be called on to treat this form of scarlatina at its very commencement, and before it is fully formed, an antimonial emetic is generally very beneficial, more particularly when the bowels are afterwards evacuated either by the antimony, or by an active aperient. If, however, those means be insufficient to subdue the excitement, moreover if the pulse be rapid and firm, the skin hot, and there be much pain in the head, or delirium, a moderate quantity of blood should be taken from the arm, and another aperient given. This treatment, if adopted at the onset of the symptoms, will generally not only moderate the fever, but shorten the duration and violence of the disease. In many cases, however, such is the violence of the symptoms, more especially if they have been neglected in the beginning, that the acute stage is speedily followed by symptoms of a low typhoid character, which requires a cordial tonic plan of treatment. It then becomes necessary to support the sinking powers by animal broths, quinine, and a moderate allowance of wine.

The volatile alkali has been strongly recommended in cases of malignant scarlatina; it was considered by Dr. Peart to be endowed with a specific power over the malignant scarlet fever and sore throat. He directed two drachms of the carbonate of ammonia to be dissolved in five ounces of water, of which the dose was two spoonsful every two, three, or four hours, according to the urgency of the symptoms. This remedy was administered in every form and stage of the disease, and were we to judge from the result of the cases in which this remedy was given, it would appear never to have failed even in the worst. We certainly have tried this remedy repeatedly, but our experience of it does not warrant such an inference; nor do

we deem it preferable to other diffusible stimulants. Capsicum is a remedy which appears to have been employed with much success by Dr. Stephens, in an epidemic scarlatina which prevailed at St. Christopher's in 1787, and of which an account was published in the second volume of the Medical Communications, and also in Duncan's Medical Commentaries for the year 1787. This remedy was used in the form of infusion prepared according to the following formula: two tablespoonfuls of small red pepper, or three of the common Cayenne pepper, and two teaspoonfuls of fine salt are to be beat into a paste, to which half a pint of boiling water is to be added. When cold, the liquor is to be strained off, to which half a pint of very sharp vinegar is to be added. Of this mixture, the dose for an adult is one tablespoonful every four hours, the quantity being diminished in proportion for children. This remedy has been commended by several writers who have employed it successfully; but having never employed it, we cannot offer an opinion of it.

When topical inflammations arise in scarlatina maligna, general bleeding is seldom admissible, unless they supervene in the beginning of the disease: the application of leeches, in numbers proportioned to the age and powers of the patient, is better adapted to the low forms of local inflammation which arise in this malignant disease.

With regard to the local treatment in scarlatina maligna, we may observe, that in the very beginning of the disease, the inflammation in the throat is best managed by the application of leeches under the jaw or behind the ears; but this treatment must be confined to the very onset of the anginose affection, since the inflammation in most cases very speedily passes into gangrene. The vapour arising from warm water may be frequently inhaled. Some physicians recommend the occasional exhibition of an emetic with the view of dislodging the viscid secretion with which the fauces are clogged, and unless the powers be so feeble as to render the shock of an emetic hazardous, benefit is often derived from their employment.

Acidulated bitter effusions, as of cinchona, cusparia, serpentaria, contrayerva, or an infusion of capsicum, prepared as recommended by Dr. Stephens, may be used as a gargle.

A weak solution of the nitrate of silver, or of sulphate of copper, applied by means of a proper syringe, after the throat has been well cleansed by warm water, often improves the aspect of the ulceration.

Dr. A. T. Thomson recommends the chlorosodiac solution of Labarraque in the proportion of f.ʒxii of the solution to f.ʒvss of water and ʒiv of honey, as an excellent gargle. The same solution in the proportion of ʒvi to ʒv of water, without the addition of honey, if frequently thrown into the nostrils by means of an elastic bottle mounted with a tube, soon removes the coryza. (Bateman's Practical Synopsis of Cutaneous Diseases, edited by Anthony Todd Thomson, M. D.)

Fumigations by the nitrous acid gas, (separated from pulverized nitre by the strong sulphuric acid,) or the nitro-muriatic acid gas, (chlorine,) (separated from a mixture of equal parts of pulverized nitre and of sea-salt, by the strong sulphuric acid,) have been strongly recommended by Willan.

It is almost superfluous to state, that proper ventilation is most essentially necessary in this, as in the other forms of scarlatina. The admission of fresh air around the patient generally invigorates his powers, and often proves a most excellent tonic. Warm sponging, a tepid bath, or if there be much cerebral disturbance, fomentations to the extremities may be employed in addition to the other means.

The treatment of the dropsical effusion which we have described as an occasional occurrence towards the termination of scarlatina, is to be regulated by the condition of the system, and more especially of the several internal organs. The effusion in general speedily disappears under judicious treatment; in all the cases which have fallen under our notice, the dropsy has been evidently dependent on general or local excitement, which it was necessary to subdue by bloodletting and purging, after the adoption of which measures the effusion quickly vanished. In some instances, when the state of the pulse did not require the abstraction of blood, a few doses of brisk purgatives have carried off the fluid: in others, the activity of the circulation, the heat of skin, scanty urine, and oppressed breathing, at once suggested the necessity of bloodletting, from which the most decided relief was immediately obtained, after purgatives and diuretics had completely failed. The efficacy of the antiphlogistic treatment of dropsy succeeding to scarlatina has been corroborated by many practical writers in other countries as well as our own; and though some still hesitate to adopt the practice, we are satisfied that in cases accompanied with phlogistic symptoms, it is the only safe and rational mode of treatment. Besides, when we consider the condition in which the internal organs have been occasionally found in fatal cases of scarlatina complicated with dropsy, the propriety of vigorous antiphlogistic treatment is apparent. We admit that in some instances, in which the symptoms are of a less acute character, bloodletting may be dispensed with: we allude more particularly to those in which, though the general powers be feeble, there is congestion or chronic insidious inflammation in some organ. Under such circumstances, topical bleeding, mild purgatives, and diuretics, with a bland diet, will be found more appropriate measures. As to the employment of tonics, on the supposition that the dropsical effusion depends on loss of power or tone in the exhalants, we confess we are sceptical as to this being the pathological state of the vessels in any case of dropsy succeeding to scarlatina, and therefore we are disposed to place little or no confidence in this class of remedies. When the effusion has been removed by suitable measures, pure air, mild nourishment, and attention to the bowels will be found the best mode of invigorating the general powers.

A. Tweedie.

SCIRRHUS.—The term σκίῤῥος, from σκίρος, marble, was given by the Greek physicians to certain tumours characterized chiefly by a great degree of hardness; but the application of the term

scirrhus has for a considerable length of time been limited to tumours or portions of organs or tissues which present not only this character, but which terminate in the disease called cancer. Hence the state of induration to which the appellation of scirrhus is given is regarded as the first stage of cancer. We shall overlook for the present the propriety of this distinction, and instead of confining ourselves to the consideration of scirrhus, shall in the present article give a general view of those morbid conditions which have been denominated scirrhus, cancer, fungus hæmatodes, and the several kinds of sarcoma, under the generic term of *Carcinoma*. The reasons for our grouping together under the term carcinoma so many diseases which have generally been described as differing widely from that which is commonly known by this designation, will be fully exposed as we proceed. In the meantime, however, the following may be regarded as the more remarkable phenomena which these diseases, considered in a general and anatomical point of view, present in common with one another, and which we conceive, while they express in a concise and conspicuous manner those characters by which they are distinguished, justify our having brought them together under the same general denomination:—1. They are essentially composed of a solid or fluid substance, different from any of the solids or fluids which enter into the healthy composition of the body. 2. They often present in the early periods of their formation certain characters common to all of them, however much they may differ from each other in the subsequent periods. 3. They all terminate in the gradual destruction or transformation of the tissues which they affect. 4. They have all a tendency to affect, successively or simultaneously, several organs in the same individual. 5. They all possess, although in various degrees, the same reproductive character.

Specific Divisions of Carcinoma.—When we examine the several morbid conditions which we have included under the genus *carcinoma*, we find that they present differences, some of which are of considerable importance, others less so; and therefore it becomes necessary to separate them into distinct groups, and to arrange them into species and varieties. The differences to which we allude are referable to two states of the carcinomatous substance to which the diseases in question owe their origin. The first is that in which this substance has little or no tendency to become organized: its form and arrangement appear to be determined chiefly by external circumstances, and its formation and subsequent increase are entirely dependent on the nutritive function of the organ in which it is contained. In the second state this substance exhibits, on the contrary, a greater or less tendency to become organized: although it may at first assume a determinate form and arrangement, in consequence of the influence of external circumstances, it possesses in itself properties by means of which its subsequent arrangement and development are effected, independent of the nutritive function of the organ in which it is formed, except in so far as the materials of its growth may be derived from this source.

On account, therefore, of these two opposite states of this particular substance, carcinoma may be divided into two species, the first of which we have called *scirrhoma*, the second *cephaloma*. Although neither of these terms expresses the essential characters of the respective states to which they are applied, we have not been able to find or devise others better calculated to accomplish this object; it is therefore necessary to bear in mind that they indicate only one of the characters of these states, viz. a certain degree of consistence, and which, it may be observed, is far from being constant in either, because of various circumstances, which we shall afterwards endeavour to explain.

In these two species, scirrhoma and cephaloma, the carcinomatous substance presents itself under various forms, which may be regarded as constituting so many varieties of each species.

Varieties of Scirrhoma.—The varieties of scirrhoma are determined chiefly by the relative quantity of the carcinomatous substance, the manner in which it is distributed, and the difference of colour and consistence which it presents. Thus it may be collected in numerous points in the form of a hard, grey, semi-transparent substance, intersected by a dull white or pale straw-coloured fibrous or condensed cellular tissue, and, as such, is commonly denominated *scirrhus*. When it assumes a regular lobulated arrangement, so as to present an appearance similar to a section of the pancreas, it forms what was called by Mr. Abernethy the *pancreatic sarcoma*. (Surgical Observations, London, 1804 and 1816.) Again, it may be disseminated uniformly throughout the texture of an organ, which it converts into a solid substance, resembling a slice of raw or boiled pork, and is then called by the French *tissu lardacé*. Lastly, when it presents the appearance of firm jelly, and is collected into masses of greater or less bulk in a multitude of cells, it is the *matière colloïd* of Laennec, the *cancer gélatiniforme* or *aréolaire* of M. Cruveilhier. (Anatomie Pathologique, Dixième Livraison.)

Varieties of Cephaloma.—The principal varieties of cephaloma are derived from the appearances which the carcinomatous substance presents either in different organs or at different stages of its development. When it presents the appearance of firm coagulable lymph, or fibrine deprived of the red colouring-matter of the blood, possessing a uniform, fibriform, or lobuliform arrangement, with a certain degree of transparency and vascularity, Mr. Abernethy gave to it the name of *common vascular* or *organized sarcoma*. In this state the carcinomatous substance is generally collected into a mass of greater or less bulk, in which few or no traces of the proper tissue of the organ in which it is contained are observable. If, on the contrary, it be uniformly disseminated throughout the texture of an organ, so as to transform it into a substance resembling a section of the mammary gland, or the udder of the cow when boiled, the appellation of *mammary sarcoma* was given to it by Mr. Abernethy. When it presents an appearance similar in colour and consistence to the substance of the brain, it was called *medullary sarcoma* by the same distinguished surgeon; *matière cérébriforme* or *encéphaloïde* by Laennec, (Dict. des Sciences Méd. art. Encéphaloïdes), and *spongoid inflammation* by Mr. Burns. (Lec-

tures on Inflammation.) The *milk-like* tumour of Dr. Monro, (Morbid Anat. of the Human Gullet, Edinb. 1811,) the *soft cancer* of various authors, and the *pulpy* testicle of Dr. Baillie, (Morbid Anatomy, London, 1795,) are names which have been given to the same state.

Of all the varieties of cephaloma, the last is that in which a vascular organization is most conspicuous, and as the coats of the vessels with which it is supplied are remarkably delicate, the circulation of the blood through them is readily interrupted; hemorrhage from congestive rupture takes place, and the effused blood is mixed in greater or less quantity with the brain-like matter. From this accidental circumstance, together with the protrusion of this substance through the ulcerated integuments for example, in the form of a bleeding fungus, it has been described by Mr. Hey (Pract. Observat. on Surgery, London, 1803) and also by Mr. Wardrop, (Observat. on Fungus Hæmatodes, Edin. 1809,) under the appellation of *fungus hæmatodes*. Sir Astley Cooper calls it *fungoid disease*.

Such are, we conceive, the principal varieties of scirrhoma and cephaloma, and the general characters by means of which they may be recognised. But although we have said that the essential difference between the two species of carcinoma consists in the former having little or no tendency, the latter a greater or less tendency, to become organized, it is by no means always easy, nay, it is sometimes impossible, to draw a distinct line of separation between them; for the carcinomatous deposit when first formed, and, indeed, frequently for a considerable length of time after its formation, does not furnish us with any signs which show that it will or will not become organized. We cannot determine what those properties are by means of which it is afterwards to assume a definite arrangement, or to possess within itself the powers of contributing to its subsequent development. These facts may be illustrated by the two following circumstances: 1. the carcinomatous deposit may exist as we have described it in the form of scirrhus, pancreatic sarcoma, or the lardaceous tissue, without its presenting any trace of organization; the textures which it invades being gradually destroyed by its presence, and both ultimately converted into a soft, granular, pulpy, or liquid mass, of the colour and consistence of cream or milk. 2. The same deposit may exist under the same forms as those we have just named, but it undergoes changes of an entirely opposite kind; that is to say, it assumes the characters of the mammary or medullary sarcoma, becoming more or less soft and vascular, and frequently terminating in hemorrhage by the rupture of its vessels, or in that state called fungus hæmatodes. Numerous examples might be given of scirrhus, medullary sarcoma, and fungus hæmatodes, as they are commonly called, originating in the same morbid state, and passing successively from the one into the other in the order in which we have named them. Indeed, we often met with all the varieties which we have enumerated of both species, not only in different organs of the same individual, but even in a single organ.

If such are the successive changes observed to take place in carcinoma, the distinction of the disease into species and varieties may be considered by some to be of little importance. Such, however, cannot be the case, for we know that the curability of a disease often depends on the time at which a remedy is employed, or varies with the state or period of the disease; and therefore it is obvious that whatever means may be adopted for the cure of carcinoma, we can form no precise opinion as to their relative efficacy, unless the particular condition or variety of the disease be kept in view. And it is far from being an unimportant fact that several of the varieties of both species of carcinoma differ materially from one another as regards the comparative rapidity of their development, as well as their reproductive tendency. Thus in both these respects the pancreatic differs from the lardaceous, the lardaceous from the mammary, and the mammary from the medullary sarcoma; the first often remaining stationary for a long space of time, months or years; the last frequently acquiring its maximum of bulk in a few weeks, and when removed being sometimes reproduced with a degree of rapidity which is never observed in any of the other varieties. It may be said that the more the varieties of both species of carcinoma partake of the characters of those accidental formations which resemble the healthy tissues of the body, as the cellular, cellulo-fibrous, and fibrous, they are, *cæteris paribus*, the less rapid in their development, and have less tendency to be reproduced.

Before proceeding to the description of the physical, anatomical, chemical, and physiological characters of carcinoma, we shall endeavour to establish on the evidence with which our anatomico-pathological investigations have furnished us, the seat, origin, and mode of formation of this disease; for unless we possess clear and accurate notions on these important points, we should meet with numerous difficulties besides those which are inseparably connected with our subject, under the several points of view in which it is necessary to consider it.

Seat, origin, and mode of formation of Carcinoma.—Various opinions have been entertained regarding the seat, origin, and mode of formation of carcinoma, some of which have attracted notice merely from their novelty, others from their possessing much higher claims to our consideration, and to these we shall more particularly allude.

There are several organs subject to carcinoma which, from the peculiarity of their structure or other circumstances, afford us the means of ascertaining the precise seat of this disease, its origin, and mode of formation. But to derive all the advantages which these circumstances are capable of affording, it is necessary to catch, as it were, the disease at its earliest period, that is to say, when the peculiar substance of which it consists has just been deposited, and has not effaced the texture or structure of the part in which it is contained. Investigated in this its first stage, we ascertain with greater or less facility that this substance becomes manifest to our senses either as a product of nutrition or of secretion. In the former case it is deposited in the same manner as the nutritive element of the blood enters into the molecular structure, and assumes the form and

arrangement of the tissue or organ into which it is thus introduced. In the latter it makes its appearance on a free surface, after the manner of natural secretions, as on serous surfaces in general.

Such are two of the modes in which the formation of carcinoma takes place, and also two of the principal differences in regard to the seat of the disease. Proceeding, however, still farther in our researches, we arrive at the important discovery that the carcinomatous matter exists in the blood under circumstances which can leave no doubt as to this fluid being the primary seat of its formation. As, in our opinion, too much importance cannot be attached to these three positions, viz., the formation of carcinoma in the molecular structure of organs, on free surfaces, and in the blood, we shall endeavour to demonstrate the truth of them by a statement of the evidence derived from our own researches on the subject.

1. The liver and stomach, organs in which carcinoma is of frequent occurrence, afford us the most striking examples of the formation of carcinoma in the molecular structure of organs. If we make a section of a liver containing what are commonly denominated carcinomatous tumours, that is to say, round or irregular masses of a substance resembling one or more of the varieties of scirrhoma or cephaloma, we shall often be able to detect the first stage of these tumours, and discover the manner in which they are formed. Thus, the first thing which we have frequently been able to perceive in those portions of the liver in which the carcinomatous matter was just making its appearance was a slight change of colour, observable only in a very limited and well-defined space, and which could be distinctly seen to exist in those minute divisions of the organ denominated *acini*. This change of colour may take place in a single acinus, or in several of these bodies successively or simultaneously. The red or yellow colour which they naturally present gradually disappears, and is succeeded by a pale milk-white or straw-colour, accompanied by an increase of the consistence. But the most important circumstance is, that while these changes of colour and consistence are taking place, the *form* and *bulk* of the acini remain *unaltered*. Now it need hardly be remarked that the form and bulk of the acini could not remain unaltered unless the foreign substance, to which their change of colour and consistence must be ascribed, were introduced into them in the *same order* as the normal element of nutrition, unless it were deposited in the *molecular structure* of the acini in a manner precisely similar to that in which their *nutritive function* is carried on. Otherwise, along with the change of colour and consistence which they present, we should have a simultaneous increase of *bulk*. The more we examine the acini in this state, the more shall we be persuaded that they are thus *transformed* by the molecular deposition of that peculiar substance which constitutes the essential anatomical character of the disease in question.

By tracing the transformation of the acini from a lesser to a greater degree, we can perceive them forming groups, for example, of three, four, ten, or twenty, the reunion of which constitutes tumours varying from the size of a hemp-seed to that of a cherry, in all of which the structure of the liver as characterized by the form, bulk, and arrangement of the acini, is more or less conspicuously marked, but becoming gradually less so with the increasing bulk of the tumours, until it entirely disappears, being transformed into a uniform lardaceous mass, or into some one or other of the tissues or substances which belong to either of the species of carcinoma.

We have said that a similar mode of formation of carcinoma is observed in the stomach. It is, however, chiefly in the muscular coat of this organ that it is most conspicuously seen, on account of the difference between the natural colour of the muscular fibres of this coat and that of the cellular tissue which enters into its composition. The change of colour which accompanies the presence of the carcinomatous deposit is, therefore, hardly perceptible except in the muscular fibres. These, however, become pale and acquire an increase of consistence; but their bulk does not appear to be increased at first, and they retain their form and distribution. Such, also, is the state of the intermuscular cellular tissue at the same period, except as to colour, which is not sensibly changed on account of its being naturally pale. By-and-bye both acquire a greater or less increase of bulk, become remarkably distinct, and present that fibriform arrangement, hardness, and transparency which are regarded as so characteristic of scirrhus. At a more advanced period of the disease we no longer trace this nutritive process of transformation, the muscular and cellular tissues being converted into a homogeneous mass, which is afterwards softened down, or assumes the mammary, medullary, or hæmatoid forms of carcinoma.

2. The fact of carcinoma forming on the free surface of serous membranes is strongly corroborative of the accuracy of the preceding remarks; for although in the former case we refer the presence of the carcinomatous deposit to a modification of nutrition, and in the present to a modification of secretion, the difference is merely nominal. The distinction, however, between nutrition and secretion is valuable as regards the formation of carcinoma; for considered as a modification of the latter, we possess ourselves of the advantage of studying the disease where it presents itself under, perhaps, the most simple of its forms, viz., on extensive serous surfaces, such as that of the pleura or peritoneum. Here the carcinomatous substance is found to be effused on the free surface of these membranes, without our being able to perceive that they have undergone any previous change whatever. Multitudes of tumours are sometimes found on these two surfaces, varying in bulk, consistence, and colour. Some of them are as large as a plum or an orange; others of the size of cherries, peas, hemp, or millet-seed, and composed of a substance resembling pork, the mammary gland, brain, or a mixture of the latter, fibrine, and blood. We may, in fact, have almost all the varieties of carcinoma formed in these membranes, and, as we have said, without their having undergone any previous change. Under such circumstances we must refer the presence of these tumours to the separation of the carcinomatous matter from the

blood, which, being effused in the form of a secretion, afterwards undergoes changes peculiar to itself.

3. The presence of carcinomatous formations in the blood is a circumstance of great importance, and unless it be clearly demonstrated that their presence is the consequence of a modification of the blood itself, in whatever manner produced, we should find it impossible to explain many of the phenomena which the disease presents, and more especially those which accompany its formation in molecular structure and on the free surface of the membranes.

The following facts may be adduced as furnishing strong evidence that the formation of the carcinomatous substance takes place in the blood, whether it be found in this fluid alone or in other parts of the body at the same time: 1. the presence of this substance in the vessels which ramify in carcinomatous tumours or in their immediate vicinity; 2. in the vessels of a portion or of the whole of an organ, to the former of which the carcinomatous substance is exclusively confined, and can be traced from the trunks into the branches and capillaries; 3. in vessels having no direct communication with an organ affected with the same disease, as, for example, when it is confined to a small extent of the vena portæ; and, lastly, in blood which has been effused into the cellular tissue and on the surface of organs.

The appearances which the carcinomatous matter presents in the blood are very various: sometimes they are perfectly similar to those which mark its presence in the substance or on the surface of organs. When contained in large veins, such as the vena portæ and its branches, the emulgent vein, &c. it may present the lardaceous, mammary, medullary, or hæmatoid characters, all in the same venous trunks. These varieties of the disease may be found mixed together in minute quantities, or isolated into masses so conspicuous that we can readily distinguish them from one another. Sometimes they lie merely in contact with the internal parietes of the vein; at other times they are united with these by means of a thin layer of colourless fibrine; or minute blood-vessels pass from the one into the other, and are often very numerous and remarkably conspicuous in the cerebriform matter.

The divisions of the vascular system in which the carcinomatous substance has been observed, are the venous and capillary, — a circumstance which may be ascribed to the contractile power of the arteries preventing, under ordinary circumstances, the blood from accumulating, and consequently this substance from forming within them, and not to any peculiarity of function exercised by the former. The presence of the carcinomatous matter in the veins might be, and indeed is, in general, supposed to be owing to its having been absorbed by these vessels; but without entering into minute anatomical details which disprove such to be the case, we shall again repeat the fact that there are cases of carcinoma in which the venous blood alone is found to be the seat of the disease. There is no accumulation of the carcinomatous matter either in the vicinity of the veins in which the blood is thus affected, or in any other part of the body; and in those cases in which this complication exists, as well might we refer the presence of this matter in the veins to the exercise of the function of venous absorption, as that of cellular, fibrous, osseous, and cretaceous formations in the same vessels to a similar process, which we know not to be the case.

From this view of the origin of carcinoma in the blood, its formation in the intimate structure and in the free surface of organs, after the manner of nutrition and secretion, follows as a natural consequence. The material element of the disease is separated from the blood and deposited under a variety of circumstances which modify in a greater or less degree the form, bulk, colour, and consistence which it afterwards presents, in the several periods of its development. We cannot therefore limit the seat of the disease to any one tissue, or ascribe its origin to any modification of structure or special organization, as has been done by several pathologists.

Perhaps the most ingenious attempt that has been made to explain the local origin of carcinoma is that of Dr. Hodgkin, published in the fifteenth volume of the Medico-Chirurgical Transactions. Dr. Hodgkin has endeavoured to show that the presence of a serous membrane, having a cystiform arrangement, is necessary for the production of carcinoma and some other diseases of a malignant character. The existence of the former precedes, he believes, the formation of the latter, and consequently is at once the seat and origin of the disease. That such is the manner in which carcinomatous formations are sometimes formed, we can have no doubt, inasmuch as we have had occasion to see them as they have been described by Dr. Hodgkin. But we have here no new law in operation, nor even an exception established to that the principles of which we have several times alluded to. Cysts are a very simple modification of a serous membrane; they partake of the structure and functions of the latter, and, consequently, are subject to similar diseases. If, therefore, such cysts should exist in an individual having the cancerous diathesis, they may, in the same manner as a natural serous membrane, become the seat of any variety of carcinoma. But although carcinomatous tumours, such as those described by Dr. Hodgkin, are found in cysts, attached, single, or in groups, and covered by a reflected serous membrane, these tumours may, and frequently do, not originate in the cysts. They form in the cellular tissue external to the cysts, and during their development project inwards, carrying before them as their common envelope the internal and serous lining of the latter. Such, in fact, is seen to be the origin of these tumours in most of the cysts represented by Dr. Hodgkin in the work referred to. They are situated external to the cyst, are supplied with vessels which do not belong to the cyst, and are placed in the same circumstances as tumours formed in the cellular tissue where no cyst is present.

As an objection to the general application of the cystic origin of tumours, it may be observed that there are numerous organs in which the presence of cysts is not to be detected at any period of the development of carcinoma; and therefore, when they do occur in other organs, they must be looked upon as a mere coincidence, or as a conse-

quence of the disease, and not as a cause or necessary condition of it.

After what we have just said on the cystic origin of carcinoma, it will not be expected that we shall do more than notice the theory which maintained that the formation of this disease depended on the previous existence of an accidental organization, which received the name of *hydatid*: how far such was the appellation it should have received, must now be a matter of indifference.

Mr. Abernethy referred all adventitious formations to the coagulable part of the blood as their origin, and fixed their seat in the cellular tissue, in the parenchyma, and on the surface of organs. This plastic substance was supposed by him to be effused in one or other of these situations, to become organized, and to derive the materials of its subsequent growth from the vascular system of the surrounding parts.

According to Andral, the cellular tissue is in general the seat of carcinomatous formations; but, that as they depend on a modification of secretion, they may form wherever this function is accomplished; the speciality of each being determined by a previous modification of the economy in general, or of the functions of nutrition, innervation, or hematosis in particular.

The only other opinion to which we shall allude regarding the seat and origin of these formations, considered in an anatomico-pathological point of view, is that of Cruveilhier. This pathologist regards all organic transformations and degenerations (as he calls them) as exclusively the result of the deposition of morbid products in the *cellular element* of organs. He believes that the *tissus propres* of organs are incapable of undergoing any organic lesion except hypertrophy and atrophy. Both these statements we have shown to be discordant with facts. The source whence these products are derived is, according to the same author, the venous capillary system, to which we formerly alluded, and we assigned a reason for their being found in these vessels, and especially in the venous trunks and their larger branches.

[Although cancer in its various forms may be a mere local degeneration, it can scarcely be doubted, at the present day, that such degeneration is connected with a special condition of the system, or is a cachexia. Accordingly, this has been made to enter into the definition of the disease by pathologists. One of the most recent, Dr. W. H. Walshe, (*Op. cit.*) properly defines cancer to be,—"a disease anatomically characterized by the presence of scirrhus, encephaloid or colloid, originating in a general vitiation of the economy, and possessing the properties of assimilation, of reproduction, and of destroying life by a peculiar cachexia."

J. Müller, from his anatomical researches, is disposed to consider, that no division of pathological structures into *homologous* and *heterologous* can be established; and he maintains, that the elementary structures of all morbid growths, hitherto examined, resemble, in every respect, the structures presented in the several stages of development of the elements of the healthy tissues of the body; and as the element in the healthy tissues is a nucleated cell, so also cells growing upon nuclei, and developing new cells within themselves, or elongated into caudate or spindle-shaped bodies, or in a still higher stage of development forming fibres, are conceived to form the main structure of all morbid growths. Blood-vessels are later formations, as they are known to be in the materials that constitute the embryo. It appears clear, however, that even if we admit the nucleated cell to be the same in the healthy and the heterologous tissue, there must be an impulse seated in the one which is not present in the other, and which leads to a different development; and hence we may, with much propriety, regard cancer as a heterodite or heterologous formation. (For the microscopical characters of cancer, see J. Müller, *Op. cit.* and Walshe, art. *Cancer*, in Cyclop. of Surgery, or Amer. edit. by Dr. J. M. Warren, p. 12, Boston, 1824.)]

Physical characters of Carcinoma.—The physical characters of this disease comprehend the form, bulk, colour, and consistence which it presents in the different tissues and organs of the body, and in the several periods of its development.

Form.—Carcinoma presents considerable variety of form. In its first stage, and when the material of which it is composed is deposited after the manner of nutrition, carcinoma assumes the particular form or structure of the organ which it affects, as that of the liver and stomach, the acini of the former, and the muscular, cellular, and mucous tissues of the latter, determining in these organs respectively the primary form of the disease. In the brain, lymphatic glands, testes, we cannot, however, perceive any particular arrangement of the carcinomatous matter at this early stage, either on account of the colour, homogeneous aspect, or minute structure of these organs, preventing us from detecting its presence, and the manner in which it is deposited.

At a more advanced stage of the disease, the forms which the carcinomatous matter derives from the structure of the parts in which it is deposited disappear, and those which it afterwards presents are determined chiefly by external circumstances. The most important of these forms are the *tuberiform*, *stratiform*, and *ramiform*.

1. *Tuberiform* carcinomatous matter is by far the most frequent, and presents considerable variety. When this matter is deposited in organs possessing a uniform density, and in parts submitted on all sides to an equal degree of pressure, it assumes a globular form. Although at first globular, it becomes pyriform on natural and accidental serous surfaces, either on account of the mode of its attachment, or of less resistance being opposed to its growth in one direction than in another. It assumes a fungiform shape when placed in circumstances which facilitate its lateral, and retard its peripheric development, as when it passes from a dense into a soft tissue, or escapes from beneath the skin to the surface of the body. It often presents a lobulated appearance when accumulated in separate portions of the cellular tissue into rounded masses, grouped together and included within a common capsule; and in the submucous tissue in particular it frequently exhibits the external arrangement of the cauliflower or mulberry. That appearance of carcinoma which resembles the structure of the pancreas depends generally on

the agglomeration of very small globular or pyriform tumours, separated from one another by cellular or cellulo-fibrous tissue, but enclosed in a common capsule.

2. *Stratiform* carcinomatous matter is chiefly met with in the subserous cellular tissue. Although it may be deposited in layers of various extent, which present no definite arrangement, it more frequently assumes the form of thin circular patches, varying from the breadth of a pin's head to an inch or more in diameter, and presenting an appearance similar to what might be imagined to follow the infusion of a small quantity of milk into a number of isolated points of the subserous cellular tissue. Patches of this kind, which are composed of a substance having the colour and consistence of cream or milk, are most frequently met with beneath the pia mater and pleura pulmonalis, and are remarkably conspicuous in the latter situation, on account of their white pearly aspect contrasting so strongly with the surrounding dark colour of the lungs. These patches may occur in the situations we have named without the substance of the brain or lungs presenting any trace of carcinoma; but we have never met them unless when the disease existed in some other organ, as the breast, eye, liver, stomach, kidney, or uterus. In some cases, lymphatics filled with fluid carcinomatous matter are observed to communicate with the patches; in other cases no such vessels are observed.

3. We formerly alluded to the *ramiform* arrangement, when treating of the seat and mode of formation of carcinoma in the molecular structure of organs and in the blood. This arrangement, as well as the seat of the carcinomatous matter in the veins on which it depends, may readily be detected in the liver, where this matter is collected in the form of tumours of various sizes. When such tumours are divided and submitted to pressure, we can often perceive the carcinomatous matter issuing from a number of small circular orifices in the state of a creamy fluid; and if these orifices are attentively examined by a careful dissection of the tumour from its cut surface towards its circumference, we find that they are the cut extremities of veins filled with this matter to a greater or less extent beyond the tumour. But there is no organ in which the ramiform arrangement of the carcinomatous matter is so conspicuously seen as the kidney. The whole of the venous system of this organ, including the emulgent vein to its termination in the vena cava, is sometimes found completely distended with this matter, either in a fluid state, of the consistence of brain, or as firm as the pancreas. When the kidney thus affected is divided, it appears as if it were formed of a multitude of encysted tumours of various sizes, on account of the carcinomatous matter being contained within, and bounded by the walls of the cut extremities of the veins. This form of carcinoma of the kidney is easily ascertained by dissection, or by the introduction of a probe from the emulgent vein into its branches.

A similar arrangement is also remarkably conspicuous in carcinoma of the stomach. Not only are the minute veins, which ramify beneath the mucous membrane in the vicinity of the disease, filled with the carcinomatous matter, but also the larger branches seen on the external surface of the stomach, and the coronary veins in which they terminate. The abdominal division of the vena portæ furnishes us with a remarkable example of the ramiform arrangement of carcinoma, isolated from any organ affected with the disease.

There is another variety of form of the carcinomatous matter which may be noticed in this place, as it may be regarded as a modification of the preceding. It is that which is observed when this matter is contained in the lymphatics and lacteals, and which is derived from the particular form of these vessels. The lacteals, more frequently perhaps than the lymphatics, contain this matter, and are sometimes seen in great numbers quite filled with it on the surface of the stomach and intestines, and between the folds of the mesentery, in carcinoma of these organs.

Such are the principal forms of carcinoma, whether we consider the disease in a general or special point of view. They are certainly not equally prevalent, nor precisely the same in both species, viz. in scirrhoma and cephaloma, nor in the several varieties of each; but they are found to occur in all of them; and as the modifications which they present in this respect are very unimportant, it is not necessary to allude to them more particularly.

Bulk.—The quantity of the carcinomatous matter deposited in the molecular structure or on the free surface of organs is extremely various, but it is perhaps never so great in the former as in the latter. In the liver it may vary from the size of a pin's head to that of an orange. In softer or more yielding organs, as the lungs, testes, and even the mamma, it may equal in bulk the head of an infant or of an adult; and in the intermuscular and subcutaneous cellular tissue its bulk is sometimes still more considerable. We now speak of individual tumours, and not of those masses formed by the aggregation of tumours, during their progressive development, as occurs in the liver, lungs, &c. nor of those produced in a similar manner in the abdominal cavity, posterior to the peritoneum, in carcinoma of the mesenteric glands.

The influence of pressure in favouring or retarding the development of carcinomatous tumours, and consequently in modifying their bulk, is most conspicuously seen when they are situated near the external surface of the body. So long as their progress outwards is obstructed by an unyielding fibrous membrane, they often remain for a considerable time nearly stationary; but so soon as this obstacle is removed, they acquire a rapid increase of bulk. This rapid increase of bulk on the removal of all pressure is still more remarkable when these tumours project through the ulcerated integuments in the frightful form of bleeding fungi. But the best illustration of the influence of pressure on the development of these tumours is met with in carcinoma of the eye. A tumour which may have required several months before it reached the external surface of this organ, will, after it has been removed, together with the whole contents of the orbit, reappear, and in the course of one or two weeks acquire a much greater bulk than before the operation.

Independently, however, of this physical circumstance, which modifies so conspicuously the bulk of these tumours, there is another of an opposite nature, which requires to be particularly noticed on account of its constituting the distinctive character of the second species of carcinoma. We allude to the physiological properties of the cephaloomatous tumours, by means of which they possess within themselves the power of increasing their development to an almost unlimited extent. It is to the vascular organization, which we shall afterwards describe, of the tumours of this species, that the rapidity of their growth and the great bulk which they attain are to be attributed, and which renders them less subject to the influence of pressure than those of the species scirrhoma. However, unless we were aware of the modifying influence of pressure, we should often be unable to explain why tumours possessing the same characters are subject to differences both as regards the rapidity of their development and the bulk which they acquire.

Colour. — The colour of carcinoma differs greatly from that of any of the other adventitious formations. It is, therefore, a character of considerable importance, inasmuch as it frequently enables us to distinguish this disease from others of the same class; and we have already seen that it is chiefly by the same means that we are led to a knowledge of the seat and forms of carcinoma in the early stages of its formation. It is most frequently white, with a shade of grey or blue; sometimes it inclines to yellow, brown, or red, in consequence of the colour of the organs affected with the disease, of the presence of blood, bile, pus, or other fluids in various proportions, or of some other accidental circumstance. But the principal modifications of colour of carcinoma are seen in the several varieties of both species of the disease, these varieties, as we have already stated, resembling more or less in colour that of the organ or tissue whence have been derived their respective appellations; as that of cartilage, of the pancreas, of fresh boiled pork, of coagulated albumen or fibrine, of the mammary gland, of the substance of the brain, or a mixture of the latter and blood.

Consistence.—To none of the physical characters of carcinoma has so much importance been attached as to that of consistence, but more especially to an increased degree of this property when considered in relation either to the disease itself or the tissues of the affected organ. Hence the term *scirrhus*, which implies a state of induration, in consequence of its being frequently not only one of the first, but likewise one of the most marked changes which we are capable of perceiving in the affected organ, has been employed to characterize the early or occult stage of carcinoma. The opposite condition of carcinoma, that in which this disease presents a degree of consistence less than that of the organ which it affects, has been considered as a change succeeding to the state of induration or scirrhus, and the result of a process of softening; consequently, as indicating a more advanced period of the disease. But the degree of consistence of the carcinomatous formations is not an invariable character of a particular stage of their development; for these formations may, when first perceivable, be as hard as cartilage, soft as brain, or fluid as cream; or they may become soft or fluid after having remained for a greater or less length of time in a state of hardness. This variety in the consistence of the carcinomatous formations depends on the following circumstances: —1st. the nature of the organ in which the carcinomatous deposit is contained; 2d. the elementary composition of the deposit; 3d. the subsequent changes occurring either in the deposit itself, or in the tissues with which it is in contact.

1st. The structure, situation, connection, and greater or less density of organs and tissues, greatly modify the consistence of the carcinomatous deposit, either in consequence of a difference between the quantity of this substance relative to that of the tissues in which it is contained, or of a difference in the degree of resistance opposed by the latter to its accumulation or development. Thus it is more consistent in the liver than in the lungs or brain; in the skin than in the cellular tissue or a mucous membrane; in a tumour situated beneath a dense covering than on a free surface.

2d. Modifications in the composition of the carcinomatous deposit exercise a considerable influence over the degree of consistence which it presents, for we often meet with it possessing various degrees of consistence, when examined at the same stage of its development, and in the same or in different organs. Examples of this kind, although common in almost every organ of the body, are best seen where the deposit is collected into isolated masses containing little or none of the natural tissues, and where consequently its consistence must depend on the nature of the elements of which it is composed. It is found in this state in cellular tissue and in serous membranes, and more especially on accidental surfaces, such as those of sores formed by the destruction of the protruded portion of tumours, or after the removal of an external organ affected with carcinoma. In these situations this substance may, at the same stage of its formation, present the opposite extremes of consistence, being in one case as hard as cartilage and more or less transparent, and in another as soft as brain, or quite fluid and opaque. But these opposite extremes of consistence are most strikingly manifested in those fungiform tumours which arise from the bottom of the orbit after the extirpation of the eye, or from the cicatrix of the integuments after the removal of the breast in consequence of carcinoma. In these two instances it is obvious that the stage of development of the tumours is the same in both; and that the difference of consistence which they present is no evidence of their being different in their nature, is equally obvious, inasmuch as the hardest of them often assume, after a certain length of time, the consistence of the softest, a part or the whole of the dense transparent substances of which they are composed being gradually transformed into a soft, brain-like, pulpy mass. This process of transformation is also most conspicuous in those tumours which constitute the *vascular* or *organized* sarcoma of Mr. Abernethy. They are at first more or less transparent, presenting the appearance of a solid mass of albumen, coagulable lymph, or fibrine, but become gradually opaque, soft, and pulpy, resembling fœtal brain, and are then not to be distinguished from those carcino-

matous tumours which, from their commencement possess the cerebriform character. These examples will suffice to show that the carcinomatous deposit, besides being modified in its consistence by the tissues in which it is contained, is equally so in consequence of a difference in its composition; that its consistence may or may not be the same when first formed; that it may be either hard or soft at this period; and, consequently, that the latter state is not necessarily preceded by the former, as was maintained by Laennec and the greater number of pathologists who have published on this subject since his time.

3d. The last modification of consistence of the carcinomatous formations is that to which the attention of pathologists has almost exclusively been directed. It depends on a series of changes taking place either in the carcinomatous matter itself, the tissues with which it is in contact, or in both at the same time. But in order that these changes may be more fully understood, we shall first describe the chemical and anatomical characters of carcinoma.

Chemical characters of Carcinoma. — In order to ascertain the chemical composition of the several varieties of scirrhoma and cephaloma, it would be necessary to procure a sufficient quantity of the carcinomatous matter isolated from the tissues with which it is so frequently more or less intimately united or combined. The difficulty, and in many cases the impossibility of obtaining it in several of these varieties in a separate state, has prevented the pathologist from determining accurately its chemical composition. Indeed, the results of the analyses that have been published may be regarded as indicating the chemical composition of particular organs and tissues affected with carcinoma, rather than of the carcinomatous matter itself. The most recent analysis of carcinoma in the scirrhomatous and cephalomatous states, is that published by Lobstein in his "Traité d'Anatomie Pathologique." Seventy-two grains of scirrhous breast were found to contain—

Albumen	2 grains
Gelatine	20
Fibrine	20
Fluid fatty matter	10
Water	20
	72

Seventy grains of the uterus in a state of scirrhus contained—

Gelatine	15 grains
Fibrine	10
Fatty matter	10
Water	35
	70

According to the same author, it would appear that the chemical composition of cephaloma is not the same at different periods of its development. Thus in the first stage of the disease, or that of *crudity*, it was found to contain a greater proportion of gelatine than of albumen; and in the second stage or that of softening, that is to say, when the carcinomatous matter is of the consistence of soft brain, the albumen is in much greater quantity than the gelatine.

[Other observers enumerate, also, gelatin among the constituents of encephaloid and scirrhous; in an analysis, however, by M. Foy, not a particle of that principle was detected in either. (Walshe, *Op. cit.*)]

For the reasons already stated, it must be obvious that no great importance can be attached to these results of the chemical analysis of the carcinomatous matter; and, independent of the difference of composition which it must present from its admixture, in various proportions, with the same or different tissues, it is highly probable that it is likewise modified, in this respect, by the physiological influence of the organ in which it is formed, and the constitution of the individual in whom it exists.

Anatomical characters of Carcinoma. — We have already pointed out the most important circumstances illustrative of the anatomical characters of carcinoma, when treating of the specific divisions of the disease, its varieties of form, bulk, and consistence; its seat and mode of formation. We shall, therefore, now examine more especially the structure or anatomical arrangement of the carcinomatous matter itself.

We formerly stated that the carcinomatous matter may exist in two states; that in the first state it has little or no tendency to become organized, its form and arrangement being determined chiefly by external circumstances; and that in the second it exhibits a greater or less tendency to become organized, possessing in itself properties by means of which its form, arrangement, and development are effected. The carcinomatous matter may, as we have seen, exist in three situations, viz. in the molecular structure of organs on free surfaces, and in the blood. It is, perhaps, only in the two latter situations that we can submit it to minute anatomical investigation. When, therefore, we examine anatomically a mass of carcinomatous matter contained in a large vein, or situated on the surface of a serous membrane, in loose cellular tissue, on the surface of a sore or cicatrix after the removal of an organ affected with carcinoma, we find it composed of the following elements in various proportions, viz. carcinomatous matter; cellular, fibrous, and serous tissues; and blood-vessels.

The *carcinomatous matter*, whatever may be its consistence, almost always forms by far the greater bulk of the disease. If, however, its consistence be considerable, it generally presents a uniform, granular, or radiated, and, when soft, a lobulated arrangement. These three varieties are sometimes met with in the same tumour, and indicate the progressive development of the disease, the radiated arrangement being seen at the basis, the uniform and the lobulated towards the circumference.

The *cellular tissue* is often small in quantity, and sometimes so fine and loose, as not to be perceptible till after the carcinomatous matter has been separated from it by pressure and maceration. It encloses that matter, separates it into granules, bundles, or lobules, intersects these in various directions, and serves to conduct the vessels which administer to the nutrition and growth of the disease.

The *fibrous tissue* is not often met with as an

anatomical element of carcinoma in the situations in which we are now considering this disease. The *serous tissue*, on the contrary, is frequently present, and may form either a capsule to the carcinomatous substance, which is then said to be *encysted*, or give rise to the formation of cysts of various sizes, containing gelatinous, albuminous, or other fluids.

When the carcinomatous matter is deposited in the molecular structure instead of on the surface of organs, as we have just been considering it, the quantity of the cellular and fibrous tissues which intersect it in various directions is sometimes very considerable. In carcinoma of dense organs, such as the breast, uterus, ovaries, liver, walls of the stomach, &c. these tissues are often very abundant. Indeed, in the early stage of carcinoma of these organs, a firm, pale, compact, cellulo-fibrous-looking tissue is not unfrequently the only anatomical element discoverable, and which on this account, and from the increase of bulk with which it is accompanied, has been described by Andral as *hypertrophy* of the cellular tissue, an appellation which does not appear to us to be warranted by analogy or by the changes which this tissue subsequently undergoes. For hypertrophiated cellular tissue, such as we find in *elephantiasis Arabum* or *Barbadoes leg*, has no tendency to terminate in carcinoma; nor does hypertrophy of the heart from disease, or of the muscles of voluntary motion from frequent exercise, ever present any other change than that implied by this term, except a certain increase of consistence, generally in proportion to the increase of bulk which has taken place. Besides, admitting that a certain degree of hypertrophy may precede the presence of carcinoma, the facts which we have already brought forward in illustration of the mode of formation of the disease, its seat and origin, clearly show that no such change is necessary, inasmuch as all the varieties of carcinoma may form in situations in which the cellular tissue is either extremely small in quantity or does not at all exist. What, therefore, appears to be hypertrophiated cellular tissue must be regarded a tissue *sui generis*, produced by the uniform distribution and molecular deposition of the carcinomatous matter, either in the cellular tissue of an organ, or in an accidental tissue of a similar kind, formed at the same time, and deposited along with the carcinomatous matter. Such is, in fact, the manner in which the cellular and fibrous tissues which enter into the composition of the carcinomatous matter are generally formed. These tissues are most conspicuous in the early stage of the disease, becoming gradually less apparent as it advances, and ultimately disappearing in consequence of their undergoing the carcinomatous transformation, or other changes which we shall afterwards describe.

The *blood-vessels* which enter into the composition of the carcinomatous matter vary greatly in number, and sometimes also in bulk. They are rarely perceptible in any of the varieties of scirrhoma; are generally few in number in the first and second varieties of cephaloma, or in the organized and mammary sarcoma of Abernethy; but in the last variety or medullary sarcoma, they are often so numerous as to form the greater portion of the brain-like tumour in which they ramify. When these vessels are examined in cephaloma, they are found to vary in diameter from the breadth of a hair to a line, and present that peculiarity of distribution, always more or less conspicuous in newly-formed blood-vessels; that is to say, the ramifications of which they are composed communicate with a common trunk at its opposite extremities in the same manner as the hepatic and abdominal divisions of the vena portæ do with this vessel. They are frequently varicose, their walls are remarkably delicate, and they have altogether much more a venous than arterial character. They appear to be formed apart from the vascular system of the surrounding tissues, as they can be seen forming from small specks of blood situated at the centre or at the circumference of the carcinomatous mass, in the form of striæ, or slender streaks of blood, and gradually assuming a cylindrical arrangement and ramiform distribution, and thereby constituting what may be called the *proper circulation* of cephaloma. The communication which exists between these vessels and those of the organ in which the carcinomatous substance is contained, is frequently very imperfect,—a circumstance which, together with the delicacy of their structure, renders them extremely liable to congestion and rupture. The most minute divisions of these vessels terminate by penicillated extremities in the carcinomatous matter, where they communicate with veins and arteries belonging to the affected organ. The latter vessels, which may be said to form the *collateral circulation* of cephaloma, are seldom so numerous as the former, but there are cases in which they appear to constitute the greater part of the vascular structure of the disease. They proceed in a radiating direction, from the pedunculated attachment of a tumour for example, or arise along its circumference in the cellular tissue which separates it from the neighbouring parts. It is by means of these vessels that the materials required for the nutrition and growth of such tumours are supplied; and, as we shall afterwards see, the partial or even complete destruction of these and other tumours similarly situated, is occasioned by causes which interrupt this their collateral circulation.

The blood-vessels which are seen in scirrhoma appear to be no other than branches of those which belong to the neighbouring tissues, and which have become inclosed within the substance of which its several varieties are composed.

Physiological characters of Carcinoma.—The anatomical characters just described are the most unequivocal circumstances by means of which we are enabled to perceive the existence and estimate the degree of those properties termed vital or physiological which manifest themselves during the developement of carcinoma. But it is more especially the formation of cellular tissue and blood-vessels in the carcinomatous matter which shows it to be in possession of these properties. We have already seen that the functions of circulation and nutrition are actively carried on in the carcinomatous matter. Of these functions, that of circulation is far the most important, inasmuch as many of the more remarkable phenomena which present themselves during the progress of carcinomatous formations depend on changes

which take place either in the proper or collateral circulation which we have described. Thus, the quantity of blood contained in a carcinomatous tumour, and consequently various shades of colour of the substance of which it is composed, will depend much on the degree of facility with which the circulation is performed in either or both systems of vessels. An imperfect communication between these vessels, owing to the manner in which they are connected, or the presence of a mechanical obstacle in the situation of the collateral veins preventing the return of the venous blood, frequently gives rise to congestion of the whole or a portion of a carcinomatous tumour, the colour of which becomes more or less red, purple, brown, or black. The congestion thus produced may be such as to give rise to rupture of the vessels, and internal or external hemorrhage. In the former case the carcinomatous substance, when situated externally in the form of a tumour, is seen to acquire a rapid increase of bulk, proportioned to the extent of the effusion, and, when examined afterwards, is found to be infiltrated with blood, or broken down and mixed with clots of this fluid, and irregular masses or layers of fibrine, thereby producing, when the tumour possesses the cerebriform character, appearances very similar to those observed in cerebral apoplexy from sanguineous effusion. If the obstacle interrupt entirely the circulation in the tumour, nutrition ceases, and death ensues in all those parts of it from which the obstructed vessels proceeded. The termination of carcinoma in mortification from obliteration of veins is far from being a rare occurrence. It sometimes occurs in whole tumours, but is most frequently observed in portions of them, or in some of the small tumours of which larger ones are frequently composed, that are attached by narrow pedunculated extremities. The unequal development of one of these small tumours may give rise to compression of a neighbouring one; or the tissue to which they are attached may, from its unyielding nature, act as a ligature on their pedunculated extremities, and intercept the return of the venous blood through them. The same thing sometimes happens to tumours that have perforated fasciæ or even the skin. The protruding portion, now relieved from the pressure to which it was before subjected, increases rapidly in bulk; but the dimensions of the opening remaining the same, very soon exercise a degree of constriction which arrests the circulation through the vessels of the neck of the tumour, and it dies and sloughs.

Changes of a similar kind result likewise from the presence of the carcinomatous matter acting as a stimulus, and exciting various degrees of congestion. In consequence of the congestion thus produced, and the modification of nutrition which necessarily follows, softening takes place, not only of the carcinomatous substance, but likewise of the tissues which enter into its composition. Softening of this kind is sometimes effected with great rapidity, and tumours which before felt firm or even hard, acquire a soft, pulpy feel, and, when laid open, are found to contain a fluid of the consistence of cream intermixed with shreds of cellular tissue, detached blood-vessels, blood, and sometimes pus. This process of softening is frequently seen taking place in carcinomatous tumours that have perforated the skin, and when considered in connection with the state of the circulation which has given rise to it, enables us to explain the peculiar appearance of those frightful solutions of continuity by which it is followed, such as their projecting everted edges, and rugged central excavation. It is well known that it is the most projecting part of a tumour situated beneath the skin in which a solution of continuity commences, and the reason of this is, that it is here the circulation is first arrested from the greater degree of compression to which the blood-vessels are subjected, together with the increased influx of blood caused by a greater degree of excitement. The most elevated portion of the skin becomes atrophiated during the first stage of compression and irritation, that is, when the circulation of the blood through it is only impeded; but so soon as this all-important function has ceased, which is announced by a change of colour from bright to dark-red, purple or black, and a diminution of sensibility and temperature, it begins to soften, soon sloughs, and exposes the subjacent portion of the tumour whose circulation had been similarly modified, softened, and deprived of its vitality, to a greater or less depth. The edges of the solution of continuity of the skin when first formed are sharp and irregular; they are not *everted;* they are, on the contrary, sometimes *inverted;* and their thickness is in proportion to the depth of the slough. The peculiarity of form assigned to them is produced by the subsequent development of the carcinomatous substance situated beneath them, which, being entirely freed from pressure all round their internal margin, necessarily projects forward, as it grows, towards the centre of the tumour hollowed out by the softening and sloughing process, and, consequently, carries them gradually upwards and backwards. They acquire at the same time a great accession of bulk, and form a rounded undulating border, beneath which the skin is found doubled upon itself, encircling the carcinomatous excavation.

All these changes, viz. congestion, hemorrhage, softening and sloughing, which we have described, take place in both species of carcinoma. In scirrhoma, however, they originate in the vascular system of the tissues included within the carcinomatous substance, but are not on that account less frequent and destructive than those which arise in the proper and collateral circulation in cephaloma. In general the softening is less complete, the hemorrhage not so considerable, and the sloughing more extensive in the former than in the latter.

Softening may take place in any portion of a carcinomatous tumour, although it has been maintained that the central portion is the primary seat of this change. Instead of being softer, the centre of the tumour is often much harder than any other portion of it. In such cases it consists of a nucleus of firm, grey, semi-transparent substance and obliterated blood-vessels, forming a central depression, around which the rest of the tumour presents a radiating structure. The depression is not observed unless when the tumour is divided, or is situated on the surface of an organ, as the liver, where tumours of this kind are generally

met with. In the former case the depression arises in consequence of the softer substance, after the division of the tumour, raising itself by its elasticity above the unyielding nucleus; in the latter it is produced by the peritoneum adhering to the surface of the tumour when small, and preventing its development in that direction. If the tumour does not come in contact with the peritoneum until it has acquired a considerable size, it presents no such depression, or only a very small one. Hence the reason why, in carcinoma of the liver, we meet with some tumours having a smooth globular surface, and others with a central depression of greater or less extent.

Nerves have never been detected in any of the varieties of carcinoma as a *new formation*. They are sometimes included within agglomerated tumours, or even in a single tumour that has happened to form in a situation through which they pass. It is on this account that some pathologists have supposed the carcinomatous matter to be supplied with nerves: and M. Maunoir of Geneva (Loc. cit.) hazarded the opinion that cephaloma, no doubt from its frequently resembling the substance of the brain, is in reality this substance effused by the nerves when under the influence of some peculiar morbid state; an opinion to the accuracy of which the facts related in the preceding pages do not leave even the semblance of probability.

The last circumstance connected with the pathological anatomy of carcinoma to which we shall allude, is the development of the subcutaneous venous system sometimes so conspicuous when the disease affects the breast in the form of a tumour, or any other external part where the skin is capable of considerable extension. The dilated and varicose state of these veins is simply the consequence of the mechanical obstacle occasioned by the tumour to the venous circulation in its vicinity, and not the result of any special influence exercised by the disease. It is produced by tumours of every description, similarly situated, —fatty tumours and even cysts, and cannot therefore be considered as furnishing any evidence of the existence of carcinoma in particular.

The great difficulty generally experienced by physicians in distinguishing carcinoma under the various forms which it presents in the different stages of its development, and in different organs of the body, will, we trust, furnish a sufficient excuse for our having given such a lengthened description of what strictly relates to the anatomy of the disease. If we have not succeeded in conveying a clear impression of this part of our subject, much assistance may be derived by consulting the coloured plates of the second and third fasciculi of the author's work on the Elementary Forms of Disease.

[In a recent work, already referred to, Dr. Walshe has thus classified the genus cancer or carcinoma:

GENUS CANCER OR CARCINOMA.

Species.	*Varieties.*	*Synonyms of the Species.*
Encephaloid	Common vascular sarcoma. } Abernethy. Mammary sarcoma? } Solanoid. Recamier. Zang. Nephroid. *Idem.* Napiform. *Idem.* Carcinoma fasciculatum vel hyalinum. Mueller. Fungus hæmatodes. Hey. Hematode cancer. Auct. Gall.	Spongy or ossivorous tumour. Ruysch. Palletta. Struma fungosa (testis). Callisen. Spongoid inflammation. Burns. Milt-like tumour. Munro. Medullary sarcoma. Abernethy. Cerebriform disease or cancer. Laennec. Pulpy testicle. Baillie. Carcinus spongiosus. Good. Carcinoma spongiosum. Young. Fungoid disease. A. Cooper. Hodgkin. Medullary fungus. Maunoir. Chelius. Acute fungous tumour. C. Bell. Medullary cancer. Travers. Cephaloma. Hooper. Carswell. Carcinoma medullare. Mueller. Soft cancer. Auct. Var.
Scirrhus	Pancreatic sarcoma? Abernethy. Napiform. } Recamier. Chondroid. } Lardaceous tissue. Auct. Gall. Carcinoma reticulare. Mueller.	Carcinomatous sarcoma. Abernethy. Carcinoma scirrhosum. Young. Scirrhus cancer. Travers. Scirrhoma. Carswell. Carcinoma simplex fibrosum. Mueller. Stone cancer. Auct. Var.
Colloid	Pultaceous cancer. } Cruveilhier. Pearly alveolar ditto. }	Areolar gelatiniform cancer. Cruveilhier. Carcinoma alveolare. Mueller. Gum cancer. Hodgkin.

These three species of carcinoma are thus described in a tabular manner by Dr. Walshe:

Encephaloid.	*Scirrhus.*	*Colloid.*
Resembles lobulated cerebral matter.	Resembles rind of bacon traversed by cellulo-fibrous septa.	Has the appearance of particles of jelly inlaid in a regular alveolar bed.
Is commonly opaque from its earliest formation.	Has a a semitransparent glossiness.	The contained matter is strikingly transparent.
Is of dead white colour.	Has a clear whitish or bluish yellow tint.	Greenish yellow is its predominant hue.
Contains a multitude of minute vessels.	Is comparatively ill-supplied with vessels.	(Its vessels have not been sufficiently examined as yet.)
Is less hard and dense than scirrhus.	Is exceedingly firm and dense.	The jelly-like *matter* is exceedingly soft; a colloid *mass* is, however, firm and resisting.
Is frequently found in the veins issuing from the diseased mass.	Has not been distinctly detected in this situation.	The pultaceous variety has been detected in the veins.
The predominant microscopical elements are globular, not always distinctly cellular, and caudate corpuscula.	The main microscopical constituents are juxtaposed nuclear cells; caudate corpuscula do not exist in it.	Is composed of cells in a state of *emboitement*.

Encephaloid.	*Scirrhus.*	*Colloid.*
Occasionally attains an enormous bulk.	Rarely acquires larger dimensions than an orange.	Observes a mean in this respect.
Has been observed in almost every tissue of the body.	Its seat, as ascertained by observation, is somewhat more limited.	Has so far been seen in a limited number of parts only.
Very commonly coexists in several parts or organs of the same subject.	Is not unusually solitary.	Has rarely been met with in more than one organ.
Is remarkable for its occasional vast rapidity of growth.	Ordinarily grows slowly.	Grows with a medium degree of rapidity.
Is frequently the seat of interstitial hemorrhage and deposition of black or bistre-coloured matter.	Is comparatively rarely the seat of these changes.	
When softened into a pulp, appears as a dead white or pink opaque matter of creamy consistence.	Resembles, when softened, a yellowish brown semitransparent gelatinous matter.	Undergoes no visible change of kind.
Subcutaneous tumours are slow to contract adhesion with the skin.	Scirrhus thus situate usually becomes adherent.	
Ulcerated encephaloid is frequently the seat of hemorrhage, followed by rapid fungous development.	Scirrhous ulcers much less frequently give rise to hemorrhage, and fungous growths (provided they retain the scirrhous character) are now more slowly and less abundantly developed.	
The progress of the disease after ulceration is commonly very rapid.	There is not such a remarkable change in the rate of progress of the disease after ulceration has set in.	
Is the most common form under which secondary cancer exhibits itself.		
Is the species of cancer most frequently observed in young subjects.	Is much less common before puberty.	Has so far been observed in adults only.]

Local and other relations of Carcinoma.—There are *no organs*, and *few tissues*, which may not become affected with carcinoma. Among the former, the stomach, liver, uterus, breast, and testes, are *much more frequently* the seat of the disease than any of the other organs of the body. It is also worthy of remark that it is met with more frequently in certain portions of organs and systems than in others. Thus, when it affects the uterus, it is almost always the os tincæ in which it commences; in the stomach it is much more frequently the pyloric than the cardiac orifice; it much more often affects the stomach than the œsophagus or intestines; the large than the small intestines. In the latter, it is rarely met with, and perhaps only in the duodenum and commencement of the jejunum; and in the former it is exclusively confined to the rectum, sigmoid flexure of the colon and ileo-cæcal valve, unless when propagated from a neighbouring organ by contiguity of tissue.

If we pass in review the several tissues subject to carcinoma, we find that the cellular is infinitely more so than any of the other tissues in which the disease occurs, although we have proved that it is far from being so frequently the seat of the disease as was, and still is, generally believed. The mucous and cutaneous tissues are the next in the order of frequency, and lastly the osseous, venous, and arterial. We have never observed the disease in cartilage, tendon, or ligament; but we have shown, when treating of the mode of its formation in the stomach, that, contrary to the general opinion, the muscular tissue of this organ is frequently the seat of it.

The number of organs that may become affected with carcinoma in the same individual varies considerably. In some cases there may be only one organ or tissue affected with the disease, as the stomach, intestines, œsophagus, liver, lungs, kidney, uterus, testis, breast, brain, eye, tongue, chin, cellular tissue, lymphatic glands, bone, capillaries, and veins. In other cases it may be found in a great many organs and tissues in various stages of its progress. It is seldom that double organs, such as both eyes, the mammæ, testes, or kidneys, are affected at the same time. We have never met with carcinoma of the pancreas, muscular, venous, and arterial tissues, serous, mucous, and fibrous membranes, without the disease being present in a neighbouring organ or tissue, and from which it was communicated to the former.

The greater liability of some organs and tissues than others to become affected with carcinoma is a circumstance of considerable practical importance. So, likewise, is its occurrence as a primary and secondary affection. In this latter respect the disease may be *secondary* only as regards the *order of its appearance*, the same morbid condition of the economy which gave rise to it in one organ giving rise to it in the others, which become successively affected; or it may be secondary in one organ in consequence of the *intimate physiological connection* existing between it and another previously affected; and, lastly, it may be secondary from *mere contiguity* of tissue.

In the first case the secondary appearance of the disease is recognised partly by the extent which it occupies, and partly by the physical and anatomical characters which it presents in the different organs in which it is present. By the same means, and more especially in consequence of two or more organs being found to be much more frequently than others affected with the disease, we infer that its propagation in the former is influenced by the intimate physiological connection which is known to exist between them, as is exemplified in carcinoma of the uterus and mammæ, and of the liver and stomach succeeding to each other. The secondary production of carcinoma from contiguity of tissue, whether of a similar or dissimilar kind, is frequently observed; such as the gradual extension of the disease from the walls of the stomach to those of the intestines, and from the latter to the parietes of the abdomen; from the stomach to the liver; from the uterus to the bladder or rectum, and *vice versâ*. But in all these cases the contiguous tissues and organs become united or continuous before the disease passes from the one to the other, which is then

propagated by the gradual molecular deposition of the carcinomatous matter, in the same manner as we see it accomplished in the skin during the ulcerative stage of the disease.

An opinion very different from that we have now given respecting the secondary production of carcinoma has long been entertained, chiefly by surgeons. Finding, as they frequently must have done, cancer in an internal organ which had given no signs of its presence until after it had existed for a greater or less length of time in some external part, they considered the production of the disease in the former situation to be subsequent to that in the latter, and to arise in consequence of the absorption of a specific virus from the supposed primary disease, and its transmission into the system. This opinion was strengthened by the fact that symptoms of cancer of an internal organ frequently make their appearance soon after the breast, testicle, or other external part has been removed by a surgical operation, and was considered as fully confirmed by another fact, viz. that the lymphatic glands situated in the vicinity of a cancerous tumour or ulcer are seen to become affected during the progress of the primary disease. We shall only remark with regard to this view of the secondary production of carcinoma, that the facts adduced are far from justifying the application which has been made of them; for they furnish no proof that the occurrence of the disease internally, at any period subsequent to its existence externally, may not depend on the same morbid condition of the economy producing its effects successively or simultaneously, in a greater or less number of organs, inasmuch as we know that carcinomatous tumours may exist for a considerable period, even in the most important of the internal organs, without giving rise to any appreciable modification of function calculated to lead to their detection. Hence, under whatever circumstances the signs of carcinoma may present themselves for the first time in an internal organ, we cannot determine either the length of time it may have existed, or the relative order of its succession. Besides, the extension, as it is called, of carcinoma from the breast or testis, for example, to the neighbouring lymphatic glands, affords no proof that it takes place through the medium of absorption; for we have found these glands in the axilla, and in the lumbar region, extensively diseased in carcinoma of the breast and testis, without any of the carcinomatous matter of which all these were composed being visible in the lymphatic vessels passing from the one to the other. The more natural explanation of the occurrence of the disease in these glands in such cases is, that, being subjected to the irritation which accompanies the latter stage of the disease, (the period at which the lymphatic glands are generally observed to become affected,) they become the seat of congestion, and, as we have already endeavoured to show, the material element of carcinoma being contained in the blood, it is separated from this fluid and deposited in their substance.

We are, however, well aware that there are cases in which this matter is absorbed and accumulates in the lymphatic glands; but from the circumstance just stated, and from the fact already noticed that these glands may be the only organs in the body in which, after the most careful examination, the disease is found to exist, we are surely not entitled to say that they are always secondarily affected, whatever signification we may attach to this term. We have seen several instances of cephalomatous tumours formed exclusively in the mesenteric glands and abdominal lymphatic glands; and in one case the latter glands of the principal regions of the body, on both sides of the neck and under the jaws, in the axillæ and groins, in the chest and abdomen, were extensively affected with the disease, and forming tumours varying from the size of a cherry to that of an egg. The spleen was the only other organ which presented any trace of the disease.

Carcinoma is a disease which is far from being equally frequent at the *different periods of life*. It is observed to make its appearance most frequently in the male from between thirty to forty or fifty years of age, and in the female after the cessation of the menstrual discharge, than at any other period of life. It is also on account of the more complicated nature of the organs of reproduction in females that they are more subject to the disease, generally considered, than males; for the uterus and mammæ are the organs which, in the former, are most frequently the seat of the disease. In the latter it rarely makes its appearance in the breast, and not so frequently in the testes as in the uterus. The stomach and liver are, according to our own observations, the most frequent seat of the disease in males, although these organs are, perhaps, equally so in females. The tongue, and especially the lips, are often affected in the former, and rarely in the latter. It is also worthy of remark that from childhood up to the age of puberty, and even to twenty or twenty-five years of age, we seldom meet carcinoma unless in particular organs or regions of the body. Thus it is chiefly the lymphatic and mesenteric glands, the great joints, as the elbow and knee joints, the brain, and cellular tissue, where it is considerable in quantity; whereas the stomach, intestines, uterus, and mammæ are almost exempt from the disease till a later period of life. And it is interesting to observe that the exceptions to its non-occurrence in these latter organs within the period alluded to are met with in such of them only the exercise of whose functions are susceptible of being prematurely and preternaturally excited, particularly the testes and ovaries.

These remarks on the relative frequency of carcinoma under the circumstances of age and sex apply to the disease generally, and not to both species and their varieties; for while scirrhoma is rarely met with within the period which we have specified, cephaloma is of frequent occurrence, and seldom proceeds to such an extent or with such rapidity in advanced as in early life; a circumstance which may probably depend on the greater activity of nutrition and the more plastic quality of the blood in the latter than in the former condition of life; and thus also a corresponding character may be given to the morbid products which manifest themselves in each.

The frequency of carcinoma is said to be considerably influenced by *temperament*. Thus out of forty-four cases of the disease in which the origi-

nal temperament was sufficiently characterized, Breschet and Ferrus found the lymphatic to prevail twenty times, the sanguineous twelve, the bilious eight, and the nervous two; and in almost all the patients submitted to their observations, the lymphatic temperament had acquired a marked predominance during the progress of the disease. (Dict. de Méd. t. iv. art. *Cancer*.)

The observation of carcinoma in individuals of different *habits* and *modes* of life submitted to the influence of various external agents arising out of locality, profession, or climate; in the married and unmarried; in women who have or who have not had children; in the poor and wealthy; in the temperate and debauched, &c. &c. has not led to very satisfactory results regarding the relative frequency of the disease. It is, however, said that it is as rare in peasants and country-people in general, as it is common among the inhabitants of large cities; and that it is more frequent in the lower and higher than in the middle classes of society.

Causes and nature of Carcinoma.—The observations which we have made on the relative frequency of carcinoma as to age, sex, temperament, and condition of life, contain the greatest part of what we have to say on the *predisposing* causes of the disease. Among these have long been enumerated the frequent and direct operation of irritating substances; external injuries, especially blows; the abuse of stimulating potions; immoderate indulgence in venery; the depressing influence of moral afflictions; bad food, conjoined with the debilitating effects of cold and otherwise unhealthy habitations; the injurious influence of one or more of these predisposing causes on particular organs being determined or modified by the individual or accidental circumstances of the case. The frequent occurrence, however, of carcinoma in individuals in whom none of these predisposing causes seem to have co-operated in the production of the disease, as well as its non-occurrence in many who have been subjected to the influence of these causes, has led many pathologists to consider it as having an hereditary origin. They believe that the *germ* of the malady, or *cancerous virus*, is transmitted from the parent to his offspring, and cite, in favour of their opinion, the occurrence of the disease in several members of the same family. This opinion, however, has few advocates, particularly since Alibert, (Description des Maladies de la Peau, p. 118,) Biett, and Dupuytren (Dict. des Sciences Médicales, t. iii. p. 677,) have shown that the carcinomatous matter may be introduced in the form of inoculation into the digestive organs, the serous cavities or veins, without giving rise to the disease; experiments, it may be remarked *en passant*, to which no more importance can be attached than to the fact that the disease may occur in several individuals of the same family. A more generally received opinion, and one much more in accordance with the results of accurate observation, is, that the manifestation of the disease is at all times, and under all circumstances, dependent on the previous existence of a peculiar state of the constitution, either congenital or acquired, termed *diathesis*. The evidence on which this opinion rests we have in great part already exposed when treating of the seat, local origin, and mode of formation of carcinoma. We have shown that the material element of the disease — without which it can have no existence—is contained in the blood, is separated from this fluid after the manner of nutrition or secretion, either in the molecular structure, or on the free surface, of organs; and that, while the formation of the disease is thus going on, there may be no appreciable physical or physiological modification of the part in which it is observed. It is thus that we meet with carcinomatous tumours in the brain, which, from their bulk and other characters, must have existed long before the functional disturbance of the organ gave signs of their presence; and we have an equally striking example of the silent development of these tumours in the eye, until, acting simply as a foreign body, they obstruct the rays of light, and render vision more or less imperfect. In persons, too, apparently in the enjoyment of the most perfect health, we often see the disease making its appearance in the form of a small pimple, proceeding more or less rapidly in its course, extending in breadth and in depth, and terminating ultimately in death, in spite of all the means which art has devised. In others, a similar pimple arises under similar, or even unfavourable, circumstances, proceeds like the former to ulceration; and although it may have been neglected, irritated, and excited from time to time, and maltreated in every possible way, disappears, and leaves the patient in perfect health. There is, indeed, no form of inflammation which may not exist for any definite length of time, and in every organ of the body, without being followed by carcinoma. Of the truth of this position every candid inquirer must be fully aware, although it is still attempted to support the unphilosophical theory which maintains that this disease is always preceded by chronic inflammation. It would, however, be a great practical error were we to overlook the influence of this pathological state on a constitution predisposed to carcinoma; for this disease does make its appearance in organs which we have every reason to believe would not have become affected with it, had they not been previously modified by the former. We must, therefore, conclude that, if carcinoma makes its appearance in individuals, however they may have been placed in regard to the operation of what are called predisposing and exciting causes, there must be present in such individuals a peculiar condition or disposition of body, previous to the manifestation of the disease. In what this disposition consists, we are entirely ignorant. Its very existence is made known to us only by means of the peculiar characters of the products to which it gives rise. We have certainly seen that the great function of nutrition is that which is more especially affected, and that, as the material element of carcinoma is contained in the blood, it is highly probable that a modification of this fluid constitutes the primary if not the essential condition of the formation of the disease. But, unacquainted as we are with the nature of nutrition as a physiological function, we can offer no explanation of the nature of the change effected in the blood, nor, consequently, of the nature of carcinoma. It is, however, an interest-

ing fact,—the result of our anatomical researches in particular,—that, as carcinomatous formations derive the materials of which they are composed from the blood, instead of their being local *transformations* or *degenerations* of pre-existing tissues, they do not, in this point of view, form an exception to the law, viz. that the natural and healthy solids, as well as the fluids of secretion, derive also their respective materials from the same source; and, therefore, we are led to hope that a more intimate knowledge of the manner in which these two functions are performed will enable us, at some future period, to determine the nature of a disease which hitherto has only been rendered more obscure by the attempts which have been made to explain it.

[For some excellent observations on the etiology of Cancer, see the work of Walshe, already cited.]

Symptoms of Carcinoma. — Considered in a general point of view, the symptoms of carcinoma refer to changes taking place during the progress of the disease, as they occur in the carcinomatous substance itself, in the organs in which it is contained, and in remote organs or the constitution generally. The symptoms are therefore local or general. The former are referable to changes in the bulk, consistence, form, colour, temperature, sensibility, circulation, nutrition, and special functions of the organ affected; the latter to changes in the functions of circulation, nutrition, and innervation in general. Both series of phenomena are greatly modified by the seat, stage, or period of the disease. They present also marked differences in the two species of carcinoma, those observed in the first species being often absent in the second; or, being present in the former from the commencement, either do not occur in the latter at all, or only towards its termination. We shall pass in review the *local* and *general* phenomena which accompany the presence of carcinoma in those organs the disease of which belong more especially to the province of medicine.

Local symptoms. — Few of the changes to which we have referred the *local* symptoms of carcinoma are discoverable in internal organs, and all of them may be absent in the early stage of the disease. Changes in the *colour*, *temperature*, *circulation*, and *nutrition* of the affected organ, cannot be detected by direct observation; and those of *bulk*, *consistence*, and *form*, can be determined only in certain organs, and at a more or less advanced period of the disease, such as the stomach and intestines, liver, spleen, kidneys, ovaries and uterus, lungs, and mesenteric glands; in all of which organs these changes may be recognised either by the touch, percussion, or auscultation. But it is more particularly the change of bulk which is detected by these means, and which, as a local symptom of the presence of carcinoma, is that to which the greatest importance is to be attached. The increase of bulk which accompanies the presence of carcinomina is not perceptible till the disease has made some progress. It is most considerable in solid organs, such as the liver, kidney, ovary, &c., and is seldom very marked in hollow organs, such as the stomach or intestines. Considerable increase of bulk may, however, have taken place in the walls of the stomach and intestines, without our being able to detect its presence, which happens when the carcinomatous matter accumulates in the direction of the internal surface of these organs. In such cases an increase of bulk of a different kind is produced, viz. dilatation, in consequence of the obstacle presented by the carcinomatous matter to the passage of the food or fæces. When dilatation of the stomach is thus produced, the obstacle is situated at the pylorus; when of the small intestines, it is, in the great majority of cases, situated at the termination of the duodenum or commencement of the jejunum, and caput cæcum coli; and at the sigmoid flexure of the colon and rectum, when the dilatation occupies the large intestines. The increase of bulk which the stomach and intestines acquire in consequence of an obstacle of this kind is sometimes very great. In some cases of scirrhus pylorus, the stomach has been found to occupy the greater part of the abdominal cavity, stretching down to the symphysis of the pubis, and from one lumbar region to the other; and the large intestines sometimes measure from four to six inches in diameter, when similarly affected. We have seen the small intestines equal in size to the ordinary dimensions of the stomach. It is important to know that the extent of the dilatation is not to be taken as the measure of the extent of the disease. The greater the dilatation the greater we may infer is the obstacle by which it is occasioned; but this obstacle may consist in a slight scirrhous enlargement, which prevents the passage of the food or fæces as effectually as when it is occasioned by one or more tumours of considerable size, or great thickening occupying several inches in length of the whole circumference of the walls of the stomach and intestines.

There are two circumstances connected with the dilatation of these organs from carcinoma which merit particular notice. The first is the *disappearance* of the dilatation at a particular period of the disease. This may happen a considerable time after the dilatation was first perceived, and is the consequence of the destruction of the carcinomatous substance from softening, ulceration, or sloughing. The obstacle being thus removed, a free passage is opened to the accumulated contents of the stomach and intestines, and the dilated walls of these organs are allowed to contract, and in some instances regain their natural dimensions. The second circumstance is the *re-occurrence* of the dilatation, which we have observed to take place only in the intestines. It does not occur, unless the mucous and muscular coats have been destroyed by ulceration, after the destruction of the carcinomatous substance, and not until cicatrization has commenced. The cicatrix being formed of cellulo-fibrous tissue, contracts and produces stricture of the intestine. The passage of the fæces is again obstructed, and the intestine acquires an increase of bulk much greater than before the destruction and removal of the carcinomatous substance. We shall again allude to these changes in bulk when speaking of the modifications of function, and the diagnosis of carcinoma in the digestive organs.

The increase of bulk which accompanies carcinoma of the liver is often very considerable. Cases have been met with in which the left lobe

of the liver extended into the left hypochondrium, and the right down to the iliac fossa on the same side. It is always produced in this organ by the accumulation of the carcinomatous matter in the form of tumours, which may often be felt projecting above its surface. It is chiefly from this latter circumstance that we are enabled to detect carcinoma of the liver. It is, however, necessary that the tumours should occupy the convex surface of the liver, and that this organ should project beyond the false ribs.

In one instance only have we found the spleen, when affected with carcinoma, much increased in size; it was nearly six times larger than natural. We have also found the kidney enlarged to the same extent in a young person, but it is seldom more than twice its natural size in this disease. Carcinoma of the uterus is not accompanied by any perceptible increase of bulk, unless examined *per vaginam*, when, in the early stage of the disease, the os uteri is found enlarged and projecting into the vagina. The ovaries acquire the size of the fist or even of the head of a child, but never become so large as when they are the seat of dropsy, or contain fibrous tumours. We have never seen the bulk of the lungs so increased by the presence of the carcinomatous deposit as to give rise to dilatation of the walls of the chest. We have already noticed the great increase of bulk which accompanies carcinoma of the mesenteric and lymphatic glands.

The only modification of the *sensibility* which, as a local symptom, accompanies carcinoma, is that of pain. There is, however, no symptom of carcinoma more deceptive than pain. The importance attached to it, more particularly when it possesses a *lancinating* character, must have originated in the study of the disease in external parts of the body, as the face, breast, or the skin and subjacent tissues in general; for there are several organs in which the pain is either very slight or seldom acquires the lancinating character ascribed to it: such is the case in carcinoma of the liver, spleen, kidneys, ovaries, stomach and intestines, (with the exception of the rectum,) the mesenteric glands, and even the brain. It is also to be remembered that pains, described by patients as lascinating, may occur without any trace of carcinoma being found in the organs to which they are referred.

Of all the varieties of carcinoma, it is that of scirrhus which is most frequently accompanied with pain; and it is also in this variety that the pain is most severe, acute, and lancinating. In medullary sarcoma this symptom is less frequent and severe than in any of the other varieties. But it is not according to the several varieties of carcinoma that we are to form an estimate either of the frequency or severity of the pain. For this symptom may, in both these respects, be said to vary with the degree of induration of the carcinomatous substance; of the distension or compression, and of irritation to which this substance gives rise in the neighbouring tissues. Under the influence of the two former of these conditions, pain would seem to result from compression of the nerves which happen to be included within the dense carcinomatous substance, or that are distributed in its immediate vicinity. Pain from irritation may also be produced under similar circumstances, but it is much more frequently when softening and sloughing of the carcinomatous substance, and ulceration of the neighbouring tissues, have taken place, that pain from this cause makes its appearance, and acquires a degree of severity which gives rise to the most intolerable suffering. It is in this stage of the disease that pain occurs in internal organs, in consequence of the extension of the irritation to the nerves of sensation.

The pain may be intermittent, remittent, and continued, whatever may be the organ affected with carcinoma. The intermittent character is most frequently observed during the early stage of the disease; and the remittent and continued during the progress of softening, sloughing, and ulceration. Numerous circumstances concur to produce these varieties in the duration of the pain in carcinoma; but in the great majority of cases they appear to depend on varying and opposite states of the sensibility and circulation of the affected organs. For we know that the direct application of those means which increase the sensibility and circulation excite, in an organ affected with carcinoma, pain when absent, and increase it when present; whilst those remedies which are known to diminish the sensibility and the action of the vascular system, effect also a diminution or an entire cessation of the pain in this disease.

The symptoms which depend on the *modifications of the functions of organs* affected with carcinoma, are far from being so conspicuous as the fatal character of the disease would lead us to suppose. We allude to the *special* modifications of function observed in carcinoma of internal organs. Before taking a general view of these modifications of function, we may remark that there is not one of them which may not be found to accompany other diseases than carcinoma. They nevertheless require to be studied with great care, because of the effects to which they give rise being sometimes more intolerable than the disease itself, and requiring a separate mode of treatment.

The modifications which are observed to occur in the special functions of organs, present great variety not only in different organs, but also in the same organ, according to the stage, extent, and situation of the disease. Thus the function of digestion is not so frequently disturbed in the early as in a more advanced stage of the disease, nor is the disturbance so great in the former as in the latter case. This difference in the effects of carcinoma on the function of digestion may be explained on the following principles, viz. that the carcinomatous substance, when first deposited, acts merely mechanically, and therefore does not interfere with the function of digestion, unless it occupies a great extent of the walls of the stomach, or prevents the egress of the digested food; whereas during its subsequent development, this substance undergoes those changes which we have already described, viz. softening, sloughing, and ulceration. The absence of irritation in the former case, and its presence in the latter, furnish an obvious reason why digestion is seldom disturbed in the one case, and more frequently and

to a greater degree in the other. The influence of carcinoma as to extent and situation, over the function of digestion, is very great. A carcinomatous tumour of from three to four inches in diameter, and projecting from one to two inches above the mucous membrane of the stomach, if situated at the small or large curvature, may be accompanied by but a very slight derangement of the function of digestion; whereas a tumour not larger than a filbert, situated at the pyloric orifice, may disturb this function to an extreme degree. It is, indeed, very often in consequence of the mechanical operation of carcinoma preventing the egress of the food or chyme, that we are first led to detect disorder of the function of digestion, and to suspect the nature of the disease on which it depends. In such cases more or less of the digested food is retained; the succeeding meal is partially or imperfectly digested; the stomach becomes distended, and being irritated by the continual contact of its contents, rendered more stimulating by decomposition or fermentation, contracts forcibly, and they are rejected by vomiting. Vomiting is an invariable consequence of carcinoma of the pylorus, accompanied with a diminution of bulk of the orifice of this part sufficient to interrupt or impede the exit of the chyme or indigested food. Perhaps the most frequent cause of vomiting is the mechanical obstacle occasioned by the carcinomatous substance in the pyloric portion of the stomach. This modification of the function of the stomach as a mechanical effect, we have never observed in carcinoma of any other portion of this organ. Vomiting, however, frequently occurs, whatever may be the situation of the disease, in consequence of the irritation which accompanies the softening process, and the ulceration by which it is followed. Vomiting from irritation may, in general, be distinguished from that occasioned by a mechanical obstacle situated at the pylorus. The former takes place however small the quantity of fluid taken into the stomach; the latter, only when the quantity is considerable. Vomiting from irritation is sudden, and accompanied by a disagreeable or painful effort; that from a mechanical obstacle gradual, and instead of being accompanied by pain, frequently affords relief from this state or a considerable degree of uneasiness. It is in this case a kind of passive act, the consequence of the great dilatation of the stomach, and sometimes of the inferior portion of the œsophagus also. The presence of dilatation of the stomach, which is easily detected by percussion, will enable us to distinguish vomiting from a mechanical obstacle from that occasioned by irritation.

The periodical character of vomiting is, in the great majority of cases of carcinoma of the stomach, to be attributed to the presence of a mechanical obstacle at the pylorus. The vomiting occurs at certain intervals, which vary with the extent of the obstacle, the quantity and kind of food taken, and other necessary and accidental circumstances, as the susceptibility of the patient and the state of those organs which exercise a sympathetic influence on the function of digestion. In some cases of this kind, the vomiting, after having continued for several weeks or months, disappears for a considerable time before it recommences, and in other cases ceases entirely. We have met with examples in both cases, referable to opposite physical conditions of the pyloric orifice. In both cases the vomiting depended on the pyloric orifice being obstructed by thickening of its walls, or the presence of projecting or pendulous tumours; and the partial or permanent cessation of this symptom, to the patency of this orifice being restored, in consequence of the destruction of the carcinomatous substance. The return of the vomiting in the former case was owing to the return of the disease in such a form as to obstruct anew the exit of the contents of the stomach; and in the latter, the entire cessation of this symptom was to be attributed to the progressive extension of the ulcerative and sloughing processes, and, consequently, the complete removal of the obstructing cause.

The *quantity* and *quality* of the matters vomited are variable. Both will be modified by the quantity and quality of the food and drink; the former by the capacity of the stomach, and the absence or presence of irritation; the latter by the nature of the ingesta, the state of digestion, and the stage and variety of the disease. It is only at the early stage of carcinoma, or at least before softening and ulceration have taken place, that the vomiting consists of a watery or mucous secretion. At a more advanced stage, the rejected food is less altered by the digestive process than before, and is often accompanied by a quantity of gas of a disagreeable odour. In the great majority of cases, and always towards the termination of the disease, the contents of the stomach rejected by vomiting contain a substance resembling the lees of wine, a mixture of chocolate, or soot and water. This substance may appear in the form of little particles, patches, or streaks, among the other matters vomited, or it may be in such quantities as to give to the whole contents of the stomach a deep brown or black colour. Its appearance always indicates the effusion of blood into the cavity of the stomach from hemorrhage, either in consequence of the softening of the carcinomatous substance, or the sloughing of this substance and of the contiguous parts. It is on this account regarded as a fatal symptom, and as indicating the speedy termination of the disease. (The cause of the black colour of the effused blood we have already explained in the articles Mortification and Perforation.) It is also at this period that the odour of the breath and the rejected matter is most offensive; and that the appetite, if not previously much affected, is entirely lost, perverted, or replaced by a morbid craving for peculiar kinds of food. There is only one other circumstance connected with vomiting to which we shall allude, viz. the rejection of the food taken the previous day or even at a later period, whilst the last meal is retained. This kind of choice, as it would seem, of the stomach between fresh and digested food, is not frequently observed. We do not recollect to have observed it except in cases of carcinoma of the pyloric portion of the stomach.

The modifications of the special functions of the intestines produced by carcinoma are in many respects very similar to those which we have described as occurring in the stomach. We have already noticed the mechanical influence of the disease in

preventing the passage of the food and fæces, the accumulation of the latter, and the subsequent dilatation of the intestine. In no other respect does carcinoma interfere with functions of the intestines, except when it gives rise to great irritation or inflammation of the mucous membrane and subjacent tissues, or when it terminates in sloughing and ulceration. Diarrhœa is the consequence of the former, and hemorrhage a frequent attendant on the latter of these morbid conditions. The rejection of fæcal matter by vomiting is not often observed in carcinoma of the intestines. The stools sometimes present the same melanotic character as the matters rejected by vomiting in the last stage of carcinoma of the stomach. They also indicate the last stage of the disease in the intestines, coincide with the appearance of the hemorrhage, and depend on the subsequent discoloration of the effused blood.

Carcinoma of the liver may occur without any appreciable derangement of the special function of the organ being observed. We are disposed to believe that a suspension of the secretion of the bile very seldom occurs in the disease. In the great majority of the cases of jaundice which we have seen to accompany carcinoma of the liver, we have found the ductus communis choledochus, the hepatic duct or its principal branches, much compressed or obliterated by the carcinomatous substance in the form of large tumours. The same mechanical operation of these tumours on the trunk of the vena portæ or its larger divisions in the liver, prevents the return of the blood of the chylopoietic viscera to this organ ; hence that form of ascites which always accompanies this state of the portal vessels.

There is often no apparent alteration in the quantity or quality of the bile, even in the most extensive forms of carcinoma of the liver. This fact is determined not only by the colour of the fæces during life, but by the examination of the organ after death; the substance of the liver presenting no unusual colour, and the gall-bladder being filled with bile of the natural consistence and colour.

There is no apparent modification of the secretion of the urine in carcinoma of one of the kidneys, although the disease may be so extensive as to leave no trace of the natural structure of the organ. We have never found both kidneys affected. On the contrary, the sound one is generally larger than natural, and appears to supply by its increase of bulk or energy the place of the other, as the quantity of urine voided in a given time is not sensibly diminished.

The much more frequent occurrence of carcinoma after than before the cessation of the menstrual discharge, prevents us from estimating accurately the influence which this disease exercises on the special function of the uterus and ovaries. Impregnation, however, has been known to take place in carcinoma of the os uteri, and of one of the ovaries. For farther information on carcinoma of the female organs of generation, see Uterus, Diseases of.

Only a few remarks are necessary on the modifications of function which accompany carcinoma of the spleen, pancreas, mesenteric and lymphatic glands, epiploon, and serous membranes in general. With regard to the spleen, we have only to remark that its cellular organization may be completely effaced by the presence of the carcinomatous matter, and consequently it is rendered incapable of receiving more blood than is necessary for the nutrition of its solid parts, and the growth of the disease. Carcinoma of the duodenal extremity of the pancreas, in consequence of the compression of the duct which passes in this direction, gives rise to an accumulation of the secretion of this organ, and great dilatation of the duct throughout its whole extent. It is in consequence of the increase of bulk of the pancreas which accompanies such cases, that we are sometimes led to suspect retention of the secretion of this organ. Diminished or suspended absorption are the occasional consequences of carcinoma of the mesenteric and lymphatic glands. Emaciation, when attributable to no other cause, may be regarded as indicating the modifications of function alluded to, of the former glands, and œdema of some external part, of the latter, both of which are rare occurrences, particularly œdema. An accumulation of the secretion of serous membranes, and a greater or less degree of obstruction to the motions of the contained organs, are the functional derangements which accompany carcinoma of these membranes and of the epiploon. The latter, when affected with carcinoma, is generally drawn up in the form of a thick irregular mass, and fixed to the stomach along its great curvature; or it is sometimes split into several portions attached above to the stomach, and below to the uterus, ovaries, or walls of the abdomen, forming so many thick bridles, which not only interrupt the motions of the intestines, but sometimes pull the stomach downwards, giving rise to an uneasy dragging sensation in the latter organ, and a sense of tightness or constriction in the former.

The function of respiration may be interrupted to such a degree by the mechanical presence of the carcinomatous matter, as to terminate in fatal asphyxia. We remember one case in particular of this kind. It occurred in a young man about twenty-five years of age, who, six weeks previous to his admission into hospital, performed the active duties of a soldier. He complained only of difficulty of breathing; he had a slight cough, followed occasionally by the expectoration of a small quantity of mucus. The difficulty of the respiration rapidly increased, and terminated in asphyxia, without the occurrence of fever or emaciation. Both lungs were nearly filled with large masses of the medullary sarcoma. The remaining pulmonary tissue was compressed, but not otherwise altered. This case affords a striking example of the mechanical effects of carcinoma, and the rapid and extensive development of the medullary variety of the disease. Carcinoma of the heart has been seldom met with to any great extent, and so far as we know, no particular modification of function has been observed to accompany its presence. We have already minutely detailed the changes effected by this disease in the capillary and venous circulation.

The functional lesions which accompany carcinoma of the brain, cerebellum, and spinal cord, vary considerably with the seat of the disease re-

lative to these organs individually, as well as to particular portions of them. But in neither of these respects does it give rise to any symptom which can be regarded as pathognomonic of its presence. As a foreign body, it gives rise sometimes to a degree of compression sufficient to produce partial or complete paralysis; loss of memory, or difficulty of speech; and derangement of the intellectual faculties. But these latter changes depend principally on the irritation and softening of the substance of the brain in contact with the carcinomatous mass. Even paralysis is more frequently produced by these subsequent changes than by compression. We have met with two cases of medullary sarcoma of the cerebellum, characterized by a remarkable development of the function ascribed to this organ by Gall. Both patients, young men, were between 18 and 19 years of age. The left lobe of the cerebellum in one of them contained a carcinomatous tumour, of the variety mentioned above, as large as a hen's egg; in the other the tumour was less, and projected from the centre of the cerebellum into the fourth ventricle. We could not ascertain how long they had practised the act of pollution, but both were emaciated and weak when admitted into hospital. One of these patients was left to himself, and died about two months after his admission, in a state of extreme debility. The other lived nearly three weeks. When warned of the fatal consequences which must soon follow the practice which had already reduced him to a state of great misery, he declared that although he was conscious of the nature of his situation, it was not in his power to resist the influence under which he felt himself compelled to act. His hands were secured, but without the desired effect. As a last resource, the whole of the prepuce was removed, yet in this mutilated state he attempted to gratify the fatal propensity. He died a few days afterward, having had several severe convulsive attacks.

Paralysis of the superior and inferior extremities, of the muscles of respiration, of the bladder and rectum, have been observed in carcinoma of the spinal cord. It is hardly necessary to observe that the seat and extent of the paralysis depend on the portion of the spinal cord occupied by the disease.

General Symptoms.—The general symptoms of carcinoma do not make their appearance before the last stage of the disease. Their severity depends much on the nature of the organ, and the extent to which it is affected; but it is principally the irritation produced by the presence of the carcinomatous substance during the period of softening, sloughing, and ulceration, that determines the gravity of these symptoms. It is in this, the last stage of the disease, that the circulation and innervation become deranged, and that fever and a diminution of the nutritive function are first observed. It is likewise at this period, but more frequently a few days or weeks before death, that the skin assumes a pale earthy, or dull ochry tint; that debility and emaciation make rapid progress; and all the functions of the economy become implicated in the deteriorating influence of the disease. It is this group of the general symptoms which constitute what is called the *cancerous cachexia*. The febrile symptoms, as well as the diminution of nutrition, in general are greatest when the seat of carcinoma is the uterus or stomach; and least in those organs, as the brain and lungs, in the former of which softening, and in the latter compression, may terminate in death, before either of these symptoms has become conspicuous. General dropsy does not often occur, and is never great. Ascites frequently accompanies carcinoma of the liver, for the reasons which we have already stated. Dropsy of the inferior extremities occurs more frequently in carcinoma of the ovaries and uterus than of any other organ. It is the consequence of compression of the iliac veins, but it may also be occasioned by the extension of the inflammation which accompanies the ulcerative stage of the disease to these vessels. Compression of the vena cava by tumours in the liver, or by the enlarged mesenteric glands, may also give rise to the same state of the inferior extremities.

Diagnosis.—It is not until carcinoma has made considerable progress, that we are sometimes able to recognise its presence in internal organs, by means of a careful consideration of the local and general symptoms which we have enumerated. We have had frequent occasion to remark how little importance is in general to be attached to any one of these symptoms taken individually. But when the local signs, viz. the changes in the bulk, form, and situation of organs, occasioned by the disease; its relative frequency in different organs and in particular portions of the same organ, are taken in connection with the special and general modification of function which may be present in individual cases, the greatest possible assistance is afforded us in establishing the diagnosis. The degree of facility with which this important object may be accomplished, will depend on the number of the signs and symptoms present, and the possibility of detecting them by the means of investigation in our possession. Thus it is more easy to detect carcinoma of the stomach than of the lungs, of the latter than of the brain; because of our being able to ascertain the presence of the greater number of the local signs of the disease in the first case, only a few of them in the second, and none at all in the third. And when the sense of sight can be applied with that of touch and hearing, the diagnosis seldom presents much difficulty, as in the case of carcinoma of the os uteri and rectum.

It is necessary to observe that too much reliance is not to be placed on the presence of those general symptoms which constitute the cancerous cachexia; for there are morbid conditions of the stomach and duodenum, associated with derangement of the biliary secretion, which give rise to a state of debility and emaciation, accompanied with discoloration of the skin, which so closely resembles the cancerous cachexia, that the one is not to be distinguished from the other. The difficulty of establishing the diagnosis in such cases is likewise increased by the circumstance that the same chronic character prevails in both. There is, therefore, no possibility of distinguishing between carcinoma of the stomach and such morbid conditions of the same organ, unless the local phenomena of the former be very conspicuous.

It is hardly necessary to remark that the presence of carcinoma in an external part of the body is to be regarded as a diagnostic sign of great importance, in all cases of a doubtful character in which functional derangement of an internal organ has existed for some time. In such a case we should regard the frequent occurrence of vomiting after meals as indicating the existence of carcinoma of the pylorus, even should no tumour be felt in this situation, or dilatation of the stomach. If the presence of a tumour were detected in any part of the abdominal cavity, we should not hesitate to say that it was of the same nature as the external affection; and the occurrence of paralysis, under the same circumstances, would justify us in attributing it to carcinoma of the brain or spinal cord.

We shall not, in this general article, attempt to determine how far it may be possible to distinguish carcinoma from other diseases to which internal organs, considered individually, are subject. Besides, in the description which we have given of the signs and symptoms of carcinoma, we have already endeavoured to point out those which more especially characterize the presence of this disease in individual organs.

Prognosis.—In no disease is a fatal termination so universally admitted as in carcinoma. The possibility of the cure of carcinoma of internal organs has never been supported by substantial evidence; and the examples are few indeed in which we are disposed to believe that the disease has been removed from an external part by surgical or other means, without its recurrence in the same or some other part of the body at some other future period.

Treatment.—A host of remedies have been proposed for the cure of carcinoma; the greater number of them have been tried in almost every form of the disease, but they have nearly all failed to justify the high praises formerly bestowed on their curative virtues. Some of them, however, have been found to retard, if not to arrest the progress of the disease; and, what is of great importance, to alleviate the sufferings and prolong the life of the patient. We shall notice those remedies only, the successful administration of which has been rendered evident in carcinoma of external organs, as under such circumstances the nature of the disease is less likely to have been mistaken. We shall speak first of those remedies which effect a salutary change in the nutritive function of the affected organ, and thereby retard or arrest the progress of the disease; secondly, of those best calculated to prevent, remove, or mitigate the local and general effects to which it gives rise.

1. The remedies which retard or arrest the progress of carcinoma consist of those which exercise a direct or indirect influence on the nutritive function of the affected organ. Among the former, or those which operate directly, the local abstraction of blood by means of leeches, and compression, hold the first rank. The first of these means should be employed for a considerable length of time, at intervals of one, two, or three days, and the quantity of blood taken should be regulated chiefly by the strength of the patient. The diminution of bulk of the original tumour which follows this mode of treatment, is sometimes very considerable. In the great majority of cases the tumour is not entirely removed. It may be reduced from the size of a hen's egg to that of a nut, and in this state remain stationary for years without giving rise to pain or any inconvenience whatever. The alternate use of local bleeding and compression effect more rapidly the reduction of bulk just noticed than when either is employed separately; but the former should, as a general rule, be always employed so as to produce a certain degree of indolency in the tumour, before the latter is had recourse to.

The beneficial effect of pressure, first employed by Mr. Young, (Cases of Cancer, &c. London, 1816,) has been satisfactorily determined by M. Recamier, one of the physicians of the Hôtel Dieu of Paris. The following are general results obtained by this physician:—

1st. Of one hundred patients treated by M. Recamier for carcinomatous affections, sixteen appeared to be incurable, and underwent only a palliative treatment. Thirty were completely cured by compression alone; and twenty-one, submitted to the same means, derived considerable benefit from it. Fifteen got rid of the affection radically, by means of ablation alone, or chiefly by ablation combined with pressure; and six by means of compression and cauterization. In the twelve remaining patients, the disease resisted all the means employed.

2d. Tumours similar, or at least analogous to those which degenerate into incurable cancer, are cured by methodical compression, and some other internal and external remedies.

3d. When a tendency towards resolution of a swelling of the mammary gland, which has not yet degenerated, has been produced for a considerable length of time by means of compression, the resolution of the swelling continues even after the compression is no longer employed: but if the swelling has degenerated, and, after having obtained a great diminution of its bulk, compression be laid aside, the swelling may resume its former bulk, and its degeneration proceed with greater rapidity than before.

4th. Compression may assist in preventing the return of cancer after ablation.

5th. The resolution of chronic inflammation is greatly favoured by compression alone, or combined with local bleeding, &c.

6th. Various tumefactions of the neck of the uterus are resolved by compressing this part by means of a pessary in the form of a hollow cone terminating in an open olive-shaped extremity.

7th. It is reasonable to hope, that if compression were employed at an early period, that is to say, before the degeneration of those tumours susceptible of this mode of treatment, the resolution of a greater number of them would be obtained, and the necessity of the ablation of cancer of the breast, so frequently followed by a return of the disease, when not encysted, be greatly diminished. (Recherches sur le Traitement de Cancer, par M. Recamier, t. i. p. 474.)

Although compression and local bleeding cannot be employed in the treatment of carcinoma of internal organs, properly so called, we have thought it proper to notice the results which M. Recamier states he has obtained by their external applica-

tion, as encouraging to the physician, and as affording a strong presumption that the cure of this disease, even in internal organs, is not altogether beyond the resources of his art.

It is also in consequence of a modification of nutrition in general, and consequently of that of the affected organ, that the beneficial effects of some general remedies, in carcinoma of external organs, are chiefly to be attributed. Some of these remedies appear to modify nutrition by effecting some unknown change in the composition of the blood, as aconitum, conium, and arsenic; others, by acting on the capillary circulation and absorption, as mercury, in alterative doses, and various preparations of iodine.

The beneficial effects of tonics, as preparations of iron, the fixed and volatile alkalies, mineral waters, such as those of Plombières, Barèges, and Vichy, and all other remedies which increase the vital energies, invigorate digestion, and promote absorption and secretion, may also be referred to a favourable change induced in the nutritive function of the affected organ, by the introduction of these remedies into the circulating system.

The salutary operation of these local and general remedies is much increased by a judicious combination of both, regulated according to the circumstances of individual cases. But while employing any of these remedies, it is of the utmost importance to regulate the diet and regimen of the patient in such a manner that neither of them may interfere with the operation of the remedy employed. M. Recamier, in the work already referred to, has shown that the curative virtues of conium, for example, depend greatly on the quantity of food consumed by the patient; that is to say, the operation of this remedy was more or less powerful when only a small quantity of food was allowed, and hardly perceptible when the quantity was considerable. While using the conium, he therefore restricts the patient to a severe diet; and in this way he says he has succeeded in curing several cases of carcinoma of the uterus, liver, spleen, mammæ, testes, and of the extremities. The following are the principles of the treatment:—

1st. The patient takes a dose of the extract of conium, evening and morning, two hours before the first and two hours before the last meal. The amount of the first dose is half a grain, which is gradually increased to six grains each time. This dose is continued for a fortnight in order that the organs may become habituated to its operation, and is afterwards increased to twelve grains each time, beyond which it is not necessary to carry the remedy because of its influence being sufficient. The twelve-grain dose is continued for from two to three or four weeks.

2d. After each dose of the conium, as well as at meals, the patient uses a decoction of sarsaparilla, (composed of two ounces of the root to two pounds of water,) instead of water.

3d. Only the third of the ordinary quantity of food is allowed, which ought to be very simple, and divided into three small meals.

4th. If the conium disagree in one form, it should be given in another, or the aconitum may be used instead, but in lesser quantity than the conium. Towards the end of the treatment the dose of the conium is gradually diminished, and the diet gradually increased.

M. Recamier ascribes the success he has obtained in the use of the conium not only to the strict observance of these dietetic rules, but also to the method he has employed in the preparation of the extract. The plant is submitted to the action of the vapour of vinegar or alcohol, before the juice is expressed from it; the juice is afterwards exposed to the heat of a sand-bath, and evaporated to the consistence of an extract. The extract thus obtained has not the nauseous odour of that usually employed, while it possesses all the deobstruent virtues, and sits better on the stomach than the latter.

[The only class of remedies, that can be expected to afford any essential benefit, are those that are capable of inducing a new condition in the system, by modifying the function of nutrition; such as the various preparations of iodine, combined with a thorough change of every thing surrounding the individual. The cachexia is the real morbid condition, and the cancerous affections in particular organs are but so many evidences of it, as tubercles in the lungs are mere expressions or indications of another form of cachexia, equally possessing the whole system. Hence it is, that cancerous tumours on the external parts of the body are so apt to recur after they have been removed by the surgeon. Still it must be admitted, that in cases of scirrhous tumours, when they have been removed early, there has very frequently been no return of the disease. In such cases the cachexia has been less strongly marked, and time, apparently, has not been permitted for the local mischief to increase the morbid disposition. It would seem, too, that the particular species of cancer influences the probability of recovery. There are few examples of permanent recovery after the removal of encephaloid tumours.

Recent statistical inquiries by M. Leroy d'Etiolles, offer no great encouragement to the surgeon to attempt to remove by the knife the local evidences of systemic mischief. Of 2781 cases occurring in the practice of 174 surgeons, 1227 happened in persons above 60 years of age. The cases of cancer of the uterus were about 30 per cent., those of the heart 24 per cent. Cancer of the mouth was in women only as 1 to 1½ per cent.; whilst in men, probably—he suggests—from the use of the tobacco-pipe, it was as much as 20 per cent. Of 1172 patients not operated on, 18 lived more than thirty years after the first appearance of the disease; whilst of 801 operated on by excision or caustic, the existence of only 4 was prolonged for a similar time. 14 patients operated on, and 34 not operated on, lived from twenty to thirty years; and 88 in the first category, and 228 in the second, lived from six to twenty years after the first appearance of the disease. The ordinary duration of life after this period, amongst persons not operated on, is said to be five years for men, and five and a half for women; whilst among those operated on, it is no more than five years and two months for men, and six years for women. Hence it would seem, that setting aside the immediate danger from the operation, the removal of cancerous disease by the knife had but little influence in prolonging life. Further observa-

tions are necessary, however, before these influences can be regarded as generally applicable. (See on the whole subject of cancer the excellent Essay by Dr. Walshe, especially the Amer. edit. by Dr. J. M. Warren.)]

II. The remedies best calculated to prevent, remove, or mitigate the local and general effects of carcinoma of internal organs, vary with the nature of these effects and the seat of the disease. The state of irritation and fever, and pain, at whatever period of the disease they may occur, may be greatly moderated by the use of the conium, aconitum, opium, hyoscyamus, the acetate or muriate of morphia; whilst at the same time the use of all kinds of stimuli is to be avoided, particularly if the digestive organs be the seat of the disease; and the patient himself kept as much as possible in a state of quiet of body and mind. If the os uteri be the seat of the disease, additional benefit may be derived from the use of leeches applied to this part, and also sedative injections. It is only in this latter situation that sloughing and ulceration can be detected, and local remedies applied to remove some of the disagreeable effects of the one, or retard the progress of the other. The chlorurets of lime and soda are, perhaps, the best remedies we can employ in this case, as they not only destroy the disgusting odour which accompanies this stage of the disease, but remove the putrid and irritating fluids which are then discharged. The retention of the contents of hollow organs, from compression or obstruction, is an occurrence which ought to be guarded against by regulating the quantity and quality of the food, for negligence in this respect may be followed by fatal consequences, if the obstacle be situated in the intestines.

It is not in our power to prevent the occurrence of ascites from compression of the vena portæ, nor of œdema of the inferior extremities from compression of the cava in carcinoma of the mesenteric glands, or of the iliac veins when the ovaries or uterus are affected with this disease. But the quantity of the effused fluid may be prevented from becoming so great as to affect the respiration, or give rise to painful distension of the integuments, by the use of those remedies usually employed in dropsy from obstruction to the return of the venous blood. (See Dropsy.)

When carcinoma has arrived at that period when the cancerous cachexia announces the extension and fatal termination of the disease, the efforts of the physician must be directed solely to the mitigation of the sufferings of the patient. It would indeed be a valuable discovery — a remedy capable of removing pain without producing any injurious effects on the economy; for if this symptom were removed, there are many cases in which carcinoma would run a much longer course, and give rise to comparatively little functional derangement.

We have not in the course of this article alluded to the perforation of hollow organs from carcinoma. With regard to this termination of carcinoma, we shall only remark that it most frequently takes place in the uterus and stomach, the rectum and urinary bladder, the transverse arch of the colon and jejunum, and the peritoneum. The perforation of the rectum, bladder, and peritoneum, is the consequence of the extension of the disease from the uterus; that of the transverse arch of the colon, the consequence of its extension from the stomach. (See Perforation, Peritonitis, Stomach and Uterus, Diseases of.)

Robert Carswell.

SCORBUTUS. — This is the general appellation of nosologists for the disease long known in our own country by the name of *scurvy*. The latter term, however, in professional as well as in popular use, has had an extended and very vague signification, embracing various morbid conditions of the skin which differ often essentially from each other, and are unallied to the subject of the present article. Illustrations of this remark might be adduced from various sources. As an instance, in the English translation of the Pentateuch the word scurvy is twice used synonymously with scabies in the Latin. (Lev. xxi. 20, xxii. 22.) This and similar applications of it we think may be traced to its early use in an adjective sense; the substantive scurf having its literal prototype in the Saxon language, and referring, as is well known, to exfoliations of small particles of the cuticle; an occurrence not uncommon in the disease now called scurvy, but which has no title to a characteristic symptom.

The word *scorbutus*, as Good observes, is neither Greek nor Latin, nor belongs to any language whatever, but is an intolerable barbarism, deduced probably from the Sclavonic word 'scorb,' the identical disease of which we have to treat having been frequently endemic in Russia and other northern countries: it has gratuitously received a sort of Latin termination. It has also been referred to 'schorbert' in the Danish language, and 'scorbeck,' *i. e.* sore mouth or 'scheurbuych' in the Dutch. Most authors, says Lind, have traced it to 'schorbock,' a griping or teazing of the belly, by no means a usual symptom, but so stated by a mistake in the etymology of the word. Scorbutus has also been called gingibrachium and gingipedum, from its affecting the gums, arms, and legs. It is probable also that the word 'stomacace,' (from στοματος and κακος, disease of the mouth) and 'sceletyrbe' (from σκελος, the leg, and τυρβη, disorder) have by the ancient writers been employed to designate this affection. It may be well also to mention here that 'scorbutus' has two derivatives, which have had the same extensive and corresponding misapplication as the original, viz. the terms scorbutic and antiscorbutic, the former referring to a peculiar virus supposed to be the common root of a large class of diseases, the latter to the substances employed for their removal, constituting a very formidable and extraordinary catalogue.

To prevent misconception, it seems necessary for us to premise that the following discussion relates to a peculiar disease, distinct, so far as we know, from the papular, pustular, squamous, and other diseases of the skin which have been unfortunately confounded with it; a confusion which has given rise to evils of the greatest magnitude, as exemplified not only in the errors of the careless and illiterate, but in their endless dissemination with all the force of authority from the written doctrines of the respected and erudite. It may not be without its use to mention, that from the

confusion of terms above adverted to, the best medicine for the prevention and cure of scorbutus was for a very long period overlooked and neglected, to the immense sacrifice of human life; and from the same cause it is stated that on the recommendation of Böerhaave, mercury was employed by the medical officers of the imperial army of Hungary in 1720, in the treatment of four hundred soldiers suffering from real scorbutus; every one of whom having been subjected to a course of this medicine died in consequence. (Elements of Medical Logic, by Sir Gilbert Blane, M. D. p. 217.)

Scorbutus, or true scurvy, is a disease which pervades the whole of the human frame, and is characterized by general debility, fœtor of the breath, sponginess and turgidity of the gums, livid subcutaneous spots, particularly at the roots of the hairs, ecchymoses, spontaneous hemorrhages, and frequently contraction of the limbs. Cullen has placed it in the class *Cachexiæ* and order *Impetigines*, and has thus defined it: "In regione frigida post victum putrescentem, salitum, ex animalibus confectum, deficiente simul materia vegetabili; asthenia, stomacace, in cute maculæ diversi coloris, plerumque livescentes, præsertim ad pilorum radices." Mason Good has arranged it in his class *Hæmatica* and order *Dysthetica*, as one of three species under the generic name *Porphyra;* including under it every variety of petechial eruption not depending on fever. The first species, viz. "P. simplex—petechial scurvy," he has defined "spots numerous but small and flea-bite shaped, chiefly in the breast, arms, and legs, paleness of visage." The second "P. hæmorrhagica—land scurvy," in which the spots are circular, of different sizes, often in stripes or patches irregularly scattered over the thighs, arms, and trunk; occasional hemorrhage from the mouth, nostrils, or viscera; great debility and depression of spirits. In the third species, viz.: "P. nautica —sea scurvy," the spots are of different hues intermixed with some which are livid, principally at the roots of the hairs, teeth loose, gums spongy, and bleeding, breath fetid, debility universal and extreme. The first and second species having been particularly discussed in the article Purpura, in conformity with the usage of modern writers, require no further comment in this place, than that they have been so distinguished from the circumstance of their having frequently occurred in young persons living in the interior of the country, and previously enjoying good health with all the necessaries and comforts of life, but who, nevertheless, having failed to derive benefit from the diet and regimen usually found adequate to the cure of sea-scurvy, have not unfrequently been recovered by opposite means; circumstances which appear to indicate some essential differences in the pathological conditions under which they occur. This opinion has been further strengthened by the blood drawn from the veins being also dissimilar; under the former circumstances being livid and very loosely coagulable, and under the latter having the usual appearances characteristic of an inflammatory disease. It is to be remarked, however, that the scurvy as it is developed at sea is a form of disease in its characters precisely similar to that which was commonly termed land-scurvy long prior to the distinction of Mason Good above adverted to; the only difference being that of the situation of its occurrence and the class of persons (mariners) who have been most frequently its victims. In our own country, though now happily a rare disease, it was formerly, even in the inland parts, of great frequency; and in other northern states, particularly on the shores of the Baltic, where the products of vegetation, at least in their fresh state, have formed a very insignificant portion in the diet of its inhabitants, it is now even occasionally endemic. Its former frequent occurrence in besieged towns and garrisons, under the combined circumstances of defect in the quantity and quality of food, fatigue, anxiety, disappointment, and exposure to the united influence of a cold and damp atmosphere, further prove that any particular influence from the sea is not essential to its generation. A memorable instance in point presents itself in the account of the siege of Thorn; where we find that between five and six thousand of the garrison, besides a great number of the inhabitants of the town, were cut off by the disease, when the Swedes, who were the besiegers, were altogether exempted from it; and it is further remarkable that no sooner were fresh vegetables admitted to their use than the mortality subsided, and the disease disappeared. (Lind on Scurvy, Part III. ch. ii. p. 395.)

Considerable discrepancy of opinion has prevailed as to the origin of scorbutus; whether it be of recent date, or referred to in the earliest productions of medical literature. It has been contended, chiefly by the continental writers, though some of high estimation in our own country have coincided in the opinion, that the ancient physicians were acquainted with it, although it has not been accurately described by them. On the other hand, there are authors of great celebrity, amongst whom are to be found Friend, Lind, and Trotter, who have maintained that the Greeks, Romans, and Arabians never could have witnessed it; considering it indigenous to the colder regions of the globe, and chiefly incidental to the privations consequent to long voyages, which from their ignorance of the compass and the science of navigation generally, they never undertook. Sieges, however, and seasons of dearth have been common to every period and country, the former of much longer duration in ancient than in recent times; and though experience has determined that the climates, or at least the vegetable productions of tropical latitudes, and their consequent use in the diet of the inhabitants, would in general insure its prevention, we have abundant proof that its existence is not incompatible with high temperatures. The ancient physicians, too, it is contended, have left us details more closely corresponding to the symptoms of scorbutus in our present acceptation of the word than any other disease with which we are acquainted. Thus Hippocrates, in his description of disorders of the spleen, has noted the occurrence of the following assemblage of symptoms. "The abdomen is distended, and subsequently the spleen is enlarged, becomes hard, and the seat of acute pain; the complexion is changed and has a dusky (μελας) pallid appearance, like the colour of a pomegra-

nate; a disagreeable odour is exhaled from the ears and gums; the latter recede from the teeth, and ulcers break out on the tibiæ like nocturnal pustules or blotches, (οκοια περ επινυκτιδες;) the limbs are attenuated and the bowels costive." Again, in his second book of Prognostics, he observes that in those who have tumid spleens, the gums are diseased and the mouth emits a fetid odour, but those whose spleens are enlarged without any consequent hemorrhages are attacked with ill-conditioned ulcers in the legs and black scars. His description of the convolvulus sanguineus (Ειλεος αιματιτης) more nearly represents the scurvy than that of the σπλην μεγας. "A bad odour is emitted from the mouth, the gums recede from the teeth, and blood is effused from the nostrils: but sometimes ulcers break out on the legs, and while some are healing others break out afresh, the skin about them is of a dark colour, thin and tender, and the patient is not disposed to walk or use any exertion." In the original the affirmative is asserted, that the patient is disposed to exertion, a circumstance so inconsistent with ulcerations of the legs, hemorrhages, and other symptoms, that commentators agree that the negative particle (ου) must have been omitted: this derives further confirmation from some additional remarks of the same writer, referring to a former description of another kind of convolvulus for the remaining symptoms, in which it is said that the patient's legs are wearied, and if he walk they tremble, and if he should ascend an acclivity that he breathes with difficulty, the elbows being raised as if they were suspended, &c.; the causes of which, he states, are heating food taken by persons using little or no exercise, and who, thus weakened, were suddenly forced to take long and fatiguing journeys in very cold weather; the ειλεος, it must be remembered, being a term not confined by the ancients to express affections of the smaller intestines, but applied to denote also pains in the other parts of the abdomen. (Enquiry on Scurvy by Francis Milman, M. D. Lond. 1782, p. 179.) Celsus has given a similar character of the ulcerations attending scurvy to that of Hippocrates: "Ulcera autem omnino non sanescunt, aut certe cicatricem vix recipient;" and in another part seems to have translated the observations of Hippocrates: "At quibus magni lienes sunt, his, gingivæ malæ sunt, et os olet, aut sanguis aliqua parte prorumpit; quorum si nihil evenit, necesse est in cruribus mala ulcera et ex his nigræ cicatrices fiant:" (Lib. ii. c. vii.), and in another passage, on tumefactions of the spleen, he has almost confirmed the conjecture above mentioned, expressly observing, "in intenta ambulatione cursuque dolor et quædem difficultas est;" and he thus proceeds: "hoc vitium quies auget, itaque exertione et labore opus est, habitâ tamen ratione, ne febrem ista, si nimium processerint, excitent." (Liv. iv. c. ix.) Aretæus, (lib. i. c. 14,) Paul of Ægina, (lib. iii. c. 49,) and Avicenna, (lib. iii. c. 2,) as well as other Greek and Arabian physicians, have described the same chain of symptoms.

It seems highly probable also that the true scurvy has been referred to both by Strabo and Pliny; by the former of whom we are told that the Roman army, sent into Arabia under Ælius Gallas in the reign of Augustus, underwent great hardships and fatigue from difficult marches, sometimes in a marshy unhealthy country, and at others from long and troublesome navigations, which Syllæus purposely protracted. "Proinde," says he, "ad Album Pagum pervenit, jam exercitu oris et crurum vitiis (qui morbi sunt ei regioni peculiares) tacto stomacacen et sceletyrben dicunt; quorum illa circa os, et circa crura resolutio quædam est ex aquis et herbis proveniens." (Strabonis Geograph. lib. xvi.) Pliny has left an observation which seems to bear on the same point. He states that the Roman army under the command of Cæsar Germanicus, having encamped in Germany beyond the Rhine, near the sea-coast, met with a fountain of sweet water, by the drinking of which in the space of two years the teeth drop out, and the joints of the knees became paralytic (compages genubus solverentur). The physicians, he adds, called the disease stomacace and scelotyrbe, and discovered a remedy for it, viz. herba Brittanica, "a salutary medicine not only in disorders of the mouth and nerves, but for the quinsy, bite of serpents," &c. (Plinii Histor. Naturalis, lib. xxv. c. iii.)

It has been denied, however, that the scelotyrbe was an indication of scurvy, because Galen has spoken of it as a kind of paralysis,* by which the patient is disabled from walking straight; but such an effect does not seem at all inconsistent with the detail of the symptoms. It has been argued, also, that the stomacace may have stood for aphthous and similar disorders of the mouth; and that other concomitant symptoms equally constant and remarkable, particularly the petechiæ and ecchymoses, could not have failed to elicit the notice of the early writers, if the disease they described had been scurvy. On the other hand, from the comparative rarity of the occurrence of scurvy in the southern climates, it is not to be presumed that the attention of the ancient physicians should have been very particularly directed to it. There is, besides, a peculiarity in the combination of the symptoms, a difficulty in referring them to any other known disease, and an apparent identity of circumstances under which they had been induced. It is likewise an established fact that in many instances the presence of scurvy has been acknowledged, and it has been expressly noticed, without the appearances which have been supposed to constitute the deficiency in the description of the ancient writers. Thus Sennertus observes, "In aliquibus nullæ erumpunt maculæ; aliis tota crura violaceo pinguntur ut tibialia ejus coloris superinducta jurares." To cite another authority, Nitzeh, who had very extensive experience of the disease as physician in the imperial Russian armies, and published an elaborate account of it in the year 1747, has noticed the occasional appearance of the other symptoms of scorbutus without the petechiæ which usually accompany it. (See Lind on Scurvy, p. 423.)

From a consideration of all the circumstances of the question at issue, it appears a reasonable conclusion that the conjecture of the antiquity of the disease is well founded, and that the slight diversity of the effects, if any, by which it has

* Mason Good imagines that Galen referred to chorea, under the name scelotyrbe. — Study of Med. vol. iii. p. 432. First Edition.

been manifested at different periods, is to be accounted for by the infinity of varying circumstances which exert their modifying influences on disease, rather than by any essential differences in the actual morbid condition under which it has been induced. It will be sufficient to mention the diversity of periods, of seasons, of climates, of localities, of occupations, of diet, besides numberless others of a moral nature. It is further corroborative of the antiquity of scorbutus, though we mention it in continuation of its history, rather than with the view of dwelling on incidents from which no deductions of practical value are to be drawn, that with the revival of literature after the siege of Constantinople, we find an undoubted record of its occurrence. It is characterized in the most particular manner by the Sieur Joinville, from the appearances it presented in the Christian army under St. Louis IX. in Egypt, about the year 1260. They had only one sort of fish, viz. the bombette, and their religion would not suffer them to eat meat during Lent; circumstances which, together with bad air and great scarcity of water, were supposed to have induced the disease. (Histoire de Louis IX. par le Sieur Joinville.—Milman on Scurvy. Lond. 1782. p. 184.) In the year 1486, it is stated by Fabricius in his account of the antiquities of his own country, (Misnia,) to have been a new and unheard-of disease, spreading as supposed by contagion, and proving extremely dangerous. (Op. supra cit. p. 186.) In 1497 it was the acknowledged occasion of dreadful havoc in the crew of Vasco de Gama in his passage of discovery by the Cape of Good Hope, (Hackluyt's Collection of Voyages, vol. iii. p. 225); and its destructive ravages have since been awfully pourtrayed in the narratives of the early English navigators, particularly in those of Cartier, Sir Francis Drake, Davis, Cavendish, and Dampier. Sir Richard Hawkins mentions that within his naval experience, he had known of 10,000 men having perished by the scurvy;* and from the same cause Commodore Anson, in the course of his voyage round the world, lost more than four-fifths of his men.

Until the year 1796, scorbutus may be said to have been the universal scourge of our maritime connections; and it is supposed to have destroyed more sailors than the various accidents incidental to a sea life, united with the terrific consequences of naval warfare. Happily, however, since the above-mentioned period it has been of very rare occurrence in our ships of war and naval hospitals; so rarely, that on the high authority of Sir Gilbert Blane, the year adverted to may be regarded as the era of its extermination. The accomplishment of this he attributes in an unqualified manner to the curative as well as preventive use of citric acid; no instance of the disease having occurred in his extensive experience which resisted its influence. To such testimony, perhaps, it behoves us to yield our implicit assent; but, satisfied as we are with the immense mass of evidence adduced in favour of the wonderful efficacy of the remedy referred to, we cannot but take into the account the co-operative influence of the great improvements in naval economy, successfully commenced with a view to the prevention of scorbutus by the justly esteemed navigator Captain Cook, and brought to comparative perfection under the happy auspices of the enlightened and venerable director of the medical department of the navy, Sir Gilbert Blane himself. The records of medicine abundantly prove the prevalence, and even the great fatality of scorbutus on our own shores at a former period, although its appearance at the present day is most rare, as is well known to every practitioner of medicine. This salutary change is fully accounted for by the drainage of the country; by the introduction of fresh vegetables as a considerable proportion of the habitual diet of the people; and those improvements in our national economy by which the use of fresh meats has been rendered available at all seasons of the year, and substituted for the dried and salted provisions formerly a principal article of subsistence throughout the winter. The want of fresh vegetables at former periods is plainly evinced by the historical fact, that as late as the commencement of the sixteenth century, the art of gardening was so little understood in our country, that Katharine of Aragon, queen of Henry VIII., to procure a salad, was obliged to despatch a messenger to the Netherlands for it; and it was near the close of Henry's reign before the necessary vegetables for the purpose, as well as cabbages, turnips, carrots, and some other edible roots, were produced; the small quantity of this kind of food previously used having been imported from Holland and Flanders. (Hume's History of England, ch. xxxiii.)

But to return to the general history of scorbutus. Krantz, the historian of Saxony, is supposed to be the first writer whose works are extant who calls it scurvy; and the next, Euritius Cordus, in his Botonologicon, published in 1534, wherein the chelidonium minus, called by the Saxons schorbock root, is extolled as a remedy. It is mentioned, also, in the same manner in the Medicina Herbaria of J. Agricola, published in the year 1539. But in an intermediate period, in 1535, we find that the most decisive and deplorable effects of it were evinced in the crew of James Cartier in his second voyage to Newfoundland, when we are informed of the providential discovery of a remedy (in previous use amongst the people of Stadacona,) viz. the decoction of the bark and leaves of the ameda or hanneda, afterwards gratefully designated by them "the tree of life."† In 1555, the History of Northern Nations, by Olaus Magnus, contained, amongst the diseases peculiar to them, a long description of scorbutus. Soon afterwards we find three cotemporary physicians of eminence treating expressly of it, viz. Rousseus, Wiems, and Ecthius. The works of the two former, in the opinion of the learned Astruc, were not published until the year 1580, and the epitome of Ecthius, which, according to Forrestus, was the transcript of a letter

* The Observations of Sir Richard Hawkins, knt. in his Voyage to the South Sea, A. D. 1593. — Purchas's Pilgrim, part iv. p. 1374.

† "I am inclined to believe, from the description given by Cartier of the ameda tree, that it was the large swampy American spruce. Some have supposed it to be the sassafras, others the white-thorn; but in his third voyage he mentions the white-thorn, and makes the ameda to be three feet in circumference." — Lind. on Scurvy, p. 178.

dated 1541, not until 1583. In 1604 appeared a work on the subject by Engelanus, which for many years was regarded as the standard of public opinion. This was succeeded in 1624 by that of Sennertus, and in 1627 by the description of Vander Nege, drawn from personal observation of its extensive prevalence at the siege of Breda. In 1667 Willis published a systematic treatise on the disease, which, like that of Engelanus, continued for some time to be the prevailing authority. In 1708, however, it gave place to the observations of Boerhaave, and to him succeeds a long list of writers; but, as of those who preceded him, we shall mention such only as have been held in estimation, attaching the dates to their several publications. (Lind's Treatise on Scurvy. Lond. 1757.) Mead, in 1749; Russell and Huxham, in 1750; Addington, in 1753; Bisset, in 1755; Lind, in 1757; Macbride, in 1767; Hulme, in 1768; Milman, in 1782; Trotter, in 1797; and Blane, first in his work on the Diseases of Seamen, published in 1785, and subsequently in a paper on the health of the navy, inserted in the sixth volume of the Medico-Chirurgical Transactions of London, in 1815, and transcribed in a pamphlet of the same title printed for private circulation in 1830. Besides the above mentioned, there are doubtless others which merit attention; and much valuable information on the subject is to be found in the periodical miscellanies, chiefly of a remote date.

Symptoms.—The symptoms which constitute scorbutus having rarely if ever appeared except when there has been an obvious exposure of the subject of them to the concurring influence of several of those termed its predisposing causes, other indications of the approach of the disease will be confirmed, or the suspicion of it diminished, in proportion as such a connection of circumstances can or cannot be ascertained. Of the predisposing causes the most uniformly present has been the combination of cold with humidity of atmosphere, either general or partial; whilst at the same time the diet has consisted of food defective in its nutritious qualities, and particularly of provisions rendered dry and hard by the process of salting as usually adopted to preserve them for sea use, together with a total privation, or the use of a comparatively insignificant quantity of succulent vegetables in their fresh state. Under this privation, as it has frequently occurred at sea, a craving desire for them, particularly for such as are of an acid taste, and also for pure water, when the supply of that article has been scanty, has been so often observed to precede the disease, that practical authorities have considered such desires as premonitory symptoms. Their operation has been feelingly portrayed in the narrative of Lord Anson's voyage, on the occasion of the approach of his ships to the island of Juan Fernandez: the scenery of which having been depicted, the writer observes, "Such a scene, so beautifully diversified, must have been delightful to an indifferent spectator; but in the distressed condition of the Centurion's men, who were in a manner languishing for the land and its vegetable productions, a situation of mind which always attends the scurvy, it is not to be conceived with what transport and eagerness they viewed the shore, and how impatiently they longed for the greens, the fresh water, and the other refreshments then in sight." And it is further observed, "that those only who have endured a long series of thirst, and can readily recall the desire and agitation which the ideas alone of springs and brooks have at that time raised in them, can judge of the emotion with which they eyed a large cascade of the most transparent water, which poured itself from a rock near one hundred feet high into the sea at a small distance from the ship." "Those who had been long confined to their hammocks now exerted all the strength they had left in crawling up to the deck to feast their eyes with the reviving prospect. Thus they coasted along the shore, contemplating the enchanting landscape, which improved as they advanced; but the night closed upon them before they had discovered a proper bay. At four the next morning the third lieutenant was despatched with the cutter to discover the bay they sought for, and at noon he returned with the boat laden with seals and grass; for the boat's crew did not stay to search for better vegetables, as they well knew that even *grass* would prove a dainty, and indeed it was soon eagerly devoured." (Anson's Voyage round the World, 1740–4, ch. iii.)

Another indication of the scorbutic diathesis, unnoticed by preceding writers, says Sir Gilbert Blane, is a soft indolent tumour, which arises under the skin on a part which has received a slight blow or contusion, so slight as not to break the skin. It most commonly appears about the elbow or forearm, and generally disappears without inconvenience, its contents being absorbed. (Observations on Diseases of Seamen, 1785, p. 465.) Scratches and wounds which under other circumstances would scarcely elicit attention, are apt to proceed to troublesome ulcerations, and betray their real character with the further development of the disease.

Amongst the more obvious symptoms, the earliest is usually a change of colour in the face, which, as well as the rest of the skin, becomes pale, and has a bloated appearance. When narrowly examined, it is seen that the lips and caruncles of the eye, where the blood-vessels lie most exposed, are of a greenish hue. The countenance denotes the state of the mind, which is depressed. The patient complains of lassitude, and is averse to all kinds of bodily exercise; the inability to use it is soon manifested by stiffness and feebleness of the knees, and excessive fatigue and breathlessness or panting are the consequences. The gums soon become itchy, swelled, and are apt to bleed upon the gentlest friction. On inspection they present a livid red appearance, are soft and spongy, and become extremely putrid and fungous. The odour of the breath is, as may be supposed, excessively offensive, and hemorrhages are apt to occur from the gums, as also from other parts of the body.

The skin at this time feels dry, and continues so through the whole course of the disease. If the patient be feverish, it is extremely rough, sometimes resembling that which is vulgarly called goose-skin. But most frequently it is smooth and shining, with suffusions of reddish, bluish, or rather black and livid spots. These are of different

sizes, occupying spaces from the smallest possible to that of a handbreadth or more, increasing generally with the progress of the disease. They are to be seen chiefly on the legs and thighs, often on the arms and trunk, but more rarely on the head and face. The legs are apt to be œdematous, the swelling at first being confined to the ankles, and conspicuous only in the evening, but gradually extending to the whole limb, and becoming less and less transient.

Such are the most constant and essential symptoms of the disease in its first stage; but a diversity is sometimes observed in the order of their appearance. Thus, when there has been great debility from previous illness, the gums for the most part are first affected; whereas, when the individual has been deprived of exercise in consequence of a fractured bone or other injury, the parts so affected become first scorbutic. As for example, if a patient is suffering from a strain of the ankle, the first indication of scorbutus will be pain, swelling, and œdema of the leg, with the purple subcutaneous spots and ecchymoses which more especially characterize the disease. It is remarkable, also, that if there have been previous disease, particularly rheumatism, chronic pains from bruises, and other effects of local injuries, these are apt to be renewed, and the disease on which scorbutus may have supervened to appear in a more aggravated form. (See Lind on Scurvy, chap. ii.) A striking instance in confirmation of the preceding remark is mentioned in the account of Lord Anson's voyage. The individual spoken of had been wounded, about fifty years before, at the battle of the Boyne, but had speedily recovered, and had continued well for a great number of years preceding an accession of scorbutus; but upon this, and during its progress, the same wounds broke out afresh, and appeared as if they never had been healed; nay, what is still more astonishing, the callus of a broken bone, which had been completely formed for a long time, was found to be destroyed, and the fractured part as if no consolidation had ever taken place.

The subjects of scorbutus frequently suffer from shifting pains: some complain of them, according to a common expression, throughout their bones, being particularly severe in their limbs and lumbar region, and in the joints and legs when they are swelled. But the most frequent seat of pain is the thorax; a sense of constriction in it with stitches on coughing being usual symptoms. "I believe indeed," says Lind, "it will universally be affected unless the bowels are very open. The pain shifts from one part of it to another, often to opposite sides, and is at first perceived upon coughing only; but in a more advanced stage it commonly fixes in a particular part — most frequently in the side, where it becomes extremely severe and pungent, so as to affect the breathing — a dangerous symptom." As scorbutic pains often change their position, so they are always exasperated by motion of the body, especially the pain of the back, which on such occasions proves very troublesome.

The next thing observable is, that if any epidemic should prevail at the same time with scorbutus, the subjects of the latter are in consequence predisposed to be attacked by it, even if there should appear to be no correspondence between the two diseases. Such a concurrence, however, Lind considers much more fortunate than when the new disease may be, as he terms it, of a putrid nature, as small-pox, measles, dysenteric fever, &c.; "it is then," he adds, "that co-operating with the scorbutic acrimony, they produce most fatal and malignant symptoms." The head is seldom or never affected with pain, unless when fever is present, which may be considered altogether an adventitious circumstance. When fevers supervene on scorbutus, they usually prove fatal; but that species which at a former period was most destructive, more so even than the plague, was the petechial or gaol fever, of which we read in works of the last century, contracted in large, crowded, and sickly ships or prisons. According to the habit and constitution of the patient, there will be some diversity in the performance of the alvine function. In some patients it is natural, in others there is extreme constipation; but generally the bowels are in a relaxed state, and the dejections are extremely fetid. The appearance of the urine is very variable at different times, even in the same patient, except that it is generally high-coloured, and soon becomes rank and fetid. It is said, also, to turn blue vegetable infusions to a green colour. The pulse varies according to the habit of the patient and stage of the disease, being in general slower and more feeble than in health. After a time the patient is commonly deprived of the use of his inferior extremities, the flexor tendons of the ham being contracted and the joints swelled; livid spots and ecchymoses are to be observed, particularly on the legs, and frequently hard and very painful swellings in different parts. "In some," says Lind, "I have seen, without any swelling, the calf of the leg quite indurated." There is great proneness to syncope upon exertion, and not unfrequently upon occasions of this kind, or any sudden exposure to a fresh atmosphere, scorbutic patients have instantly died. The tendency to profuse hemorrhages increases with the progress of the disease, and these are apt to take place from the nose, gums, lungs, intestines, &c., as well as from any ulcers which may be present.

Besides the morbid appearances of the gums already mentioned, they are liable to be affected with deep ulcerations, the teeth most commonly are loosened and often fall out; but caries of the jaw rarely ensues, nor is this affection of any of the bones a usual consequence, but has probably been considered so from the occasional complication of scorbutus with syphilis; as ptyalism has also from its synchronous occurrence when mercury has been exhibited for the cure of the latter disease.

When scorbutus approaches its fatal termination, the painful and livid swellings above referred to often break, and assume the fungous appearance characteristic of scorbutic ulcers. The hemorrhages become more profuse and general; the increasing dyspnœa is accompanied in some cases with pain under the sternum, but most frequently in one of the sides. In others, however, without any complaint of pain, the respiration becomes suddenly quick and laborious, and death unexpectedly puts a period to the disease. The mind throughout is depressed and anxious, but at last

there is generally a total indifference and apparent torpor of every faculty. The appetite for food is rarely impaired, and death has even seized the sufferer in the act of eating. Nyctalopia is an occasional occurrence in the progress of scorbutus, though rarely noticed in the descriptions of it. Dr. Hulme recorded its appearance in his inaugural dissertation printed in 1765; and Sir Gilbert Blane states that it had been reported to him by Mr. Telford. It was also a common occurrence amongst the scorbutic patients in the garrison of Gibraltar, during the siege of that place. (See NYCTALOPIA.)

To the complications of scorbutus with other diseases is to be attributed the Protean character which has frequently been ascribed to it, and which, from a comparison of descriptions, it would seem to have manifested. The conjoined diseases have been most frequently such as are incidental to the same predisposing causes, namely, fevers, continued, intermittent, and remittent; rheumatism, diarrhœa, and dysentery. It has often also been complicated with syphilis, and occasionally with catarrh and ophthalmia. Besides these, numerous other diseases are mentioned by writers as having preceded its occurrence; but scorbutus always exerts the predominating influence, and sometimes even has simulated the worst form of idiopathic disease, as phthisis pulmonalis,* the symptoms of which have subsided on the treatment appropriate to the removal of the former.

Scorbutic ulcers are to be recognised by the following characteristics: instead of pus they excrete a thin, fetid, sanious fluid, mixed with blood; their edges generally are of a livid colour, and as it were puffed up; a coagulum is soon formed on their surface, which can with great difficulty be wiped away or separated from its subjacent parts. These are soft, spongy, and putrid. When, however, the removal of this coagulum has been effected, the same appearance presents itself again after the lapse only of a few hours, and soon constitutes a soft bloody fungus of considerable size, formerly familiar to sailors, and commonly called by them *bullock's liver*, which in its boiled state the former resembles both in colour and consistence. "It often rises," says Lind, "in a night's time to a monstrous size, and although destroyed by cauteries actual or potential, or cut smooth with a bistoury, in which case a plentiful hemorrhage generally ensues, at the next dressing it is as large as ever."

Pathological Anatomy.—Although scorbutus, as we have already stated, was until the latter end of the last century a very fatal disease, and has been the subject of numerous dissertations, few accounts have recorded the *post-mortem* examinations of individuals who have died of it. On this part of the subject the essay of M. Poupart, from observations made at the hospital of St. Louis, in Paris, (Mémoires de l'Académie des Sciences, 1699, p. 237; also Lind on Scurvy, p. 255,) is the most minute and explicit we possess. Added to the external appearances of the body as described in the living subject of the disease, extravasations of dark-coloured blood have been found very generally under the integuments in the muscles, so as to render them hard and rigid, and in some of the glandular parts of the body, particularly the spleen. The brain was always in its natural state. Serous fluid was frequently found in the thorax, stated to have been of various colours, and so corrosive as to excoriate the hands which have been wetted with it. In some who had suffered from dyspnœa, and had died suddenly, the cavity of the chest and also the lungs were void of *serum;* but there were adhesions of the pericardium to the latter, and of the lungs to the pleura costalis and diaphragm. In some who died suddenly without any obvious cause, the auricles of the heart, it is stated, were as large as a man's fist, and full of coagulated blood. The glands of the mesentery were generally obstructed and swelled. Some of these were found partly corrupted and imposthumated. In the liver of some few, the extravasations were hardened. The spleen was three times bigger than natural, and fell to pieces as if composed of coagulated blood. Sometimes the kidneys and lungs were studded with imposthumes. The ligaments of the joints were corroded and loose, and instead of the synovial fluid there was only a greenish liquor, to the causticify of which the corrosion of the ligaments was attributed. The epiphyses were found entirely separated from the shafts of the bones, the cause in the living subject of a crepitating noise on motion, which was sometimes distinctly audible. In some, the cartilaginous portions of the ribs were separated from the bone, and the bony part, at the point of separation from the cartilage, was carious to the breadth of four fingers. In some subjects, on squeezing the sternal extremities of the ribs, the spongy portion was separated in a corrupted state, leaving only the external and internal bony plates. In some were found abscesses of the glands of the groin and axilla. Dr. Mead tells us, that upon opening the abdomen of a scorbutic patient, he was struck with amazement at the monstrous size of the spleen, which weighed five pounds and a quarter, whereas the liver weighed but four pounds and a quarter; but its bulk seemed to be its only defect; for it retained its natural shape and colour, and had not the least scirrhosity or other hardness. Its interior parts were as usual of a dark livid hue, with lax fibres and deep-coloured blood. (Medical Works of Richard Mead, M. D. Dublin, 1767, p. 421.)

In the beginning of the disease, according to the observations made by the surgeons of Lord Anson's expedition, (Mr. Ettrick and Mr. Allen,) the blood as it flowed out of the orifice of the wound might be seen to run in different shades of light and dark streaks. As the disease advanced, it ran thin and seemingly very black, and after standing some time turned thick and of a dark muddy colour; the surface in many places of a greenish hue, without any regular separation of its parts. In the third degree of the disease it came out as black as ink, and though kept stirring in the vessel many hours, its fibrous parts had only the appearance of a quantity of wool or hair floating in a muddy substance; and when it issued from the body, as in hemorrhages, the appearances of this fluid were the same as to colour

* Medico-Chir. Review, for June, 1824. On scurvy in his Majesty's ship Leander, on a voyage from Trincomalee to the Cape of Good Hope.

and consistence, whether it was discharged from the mouth, nose, stomach, intestines, or any other part. In dissected bodies, the blood in the veins was so entirely broken, that by cutting any considerable branch, the part to which it belonged could be emptied of its black and yellow liquor. The extravasated blood was also precisely of the same kind.

Diagnosis.—The symptoms already detailed as characteristic of scorbutus, considered in connection with the circumstances under which they are stated to occur, or in other words its immediate causes, are sufficient data to render it distinguishable from every other disease; but in the present state of our knowledge a consideration of the latter is necessary to prevent it from being confounded with certain forms of purpura, viz. purpura simplex and purpura hemorrhagica; both of which until a recent period were regarded as manifestations of the disease under discussion. Good, as already stated, has classed the three together as species of the same genus, under the name Porphyra, Scurvy,—an arrangement which was sanctioned by the opinion of Willan, who viewed them as allied. A comparison of the symptoms alone would seem to warrant the conclusion that they are constituted by diversities of degree only of the same morbid condition. But that this uniformity does not exist, particularly as regards purpura hemorrhagica and scorbutus, has been inferred from the successful issue of the treatment of the former by the pursuance of the antiphlogistic system, especially by the exhibition of purgatives, and in some instances even by bloodletting, when the occasional causes of the latter have not been found to exist, and the remedial measures appropriate to its removal had been resorted to in vain. In many instances a plethoric state of the system and a febrile disposition have pointed out the divergence from the line of symptoms which characterize scorbutus, and the peculiarity has been further marked by the nature of the diet and the previous condition of the patient. But it must be acknowledged that it is often impossible to recognise the distinction between purpura and scorbutus, or appreciate any difference in their occasional causes, except that amongst those of the latter the influence of a cold and humid atmosphere appears almost, if not always, essential to its production. When the state of the pulse and the condition of the patient have suggested the advantage of bloodletting in purpura hemorrhagica, the appearance of that fluid on being allowed to stand has been that of blood drawn in inflammatory diseases, presenting on its surface a thick and tenacious coat of coagulated lymph. The cruor has also been firm and cohesive, and difficult of diffusion when shaken in the serum, and altogether different, (as will be seen by comparison with the description already given,) from blood drawn in scorbutus.

Prognosis.—Although scorbutus has "slain its tens of thousands" on land as well as at sea, and from its former fatality was not inaptly classed amongst pestilential diseases, the means of treating it have been so well ascertained and established, that for the most part, having citric acid at command, and still more certainly an abundant supply of fresh and succulent vegetables, with the power of protecting the patient from a continuance of the operation of its occasional causes, its cure may be much more certainly anticipated than that of any other disease in which the visible effects are as general and as threatening to the extinction of life. When deprived of the means above specified, as formerly often happened at sea, and as is even now frequently the case as regards fresh vegetables, citric acid may in general be depended on as a very efficient antidote; but without it the probabilities of arresting the progress of the disease will be infinitely diminished, and the recovery of severe cases rendered hopeless.

The first favourable symptom in the advanced stages of the disease, when fresh fruits and vegetables have been obtained, is a change from a constipated to a lax state of the bowels; the skin becomes moist and soft; some increase of bodily power follows; a tranquil pulse together with an improvement in the appearance of any ulcers which may be present; and a change in the aspect of the petechiæ and ecchymoses, their livid colour gradually assuming a yellow hue from the centre to the circumference, the skin at the same time resuming its natural colour, is then observed.

The most unfavourable symptoms are dyspnœa, stitches in the side, frequent faintings, a weak and quick pulse, involuntary evacuations, and excessive hemorrhages. An unexpected and fatal termination of scorbutus has occasionally, we have said, taken place upon any unusual exertion, or on sudden exposure to a fresh atmosphere. When complicated with other diseases, as dysentery or diarrhœa, the unfavourable aspect of scorbutus is rendered still more so, in proportion to their severity and the difficulties there may be to encounter in checking their progress. Diseases, also, of an incurable nature, the tendencies to which have been previously established, may be developed by the presence of scorbutus, such as phthisis, and other organic lesions productive of hydrothorax, ascites, &c. But at the same time, in forming a prognosis, it must be borne in mind that phthisis itself and other organic lesions have been simulated by this disease, and that their symptoms have subsided when the peculiar affection which constitutes scorbutus has been subjected to its appropriate treatment; and that the most unfavourable sequelæ will sometimes disappear when solely consequent upon the disease under discussion.

Causes.—The predisposing causes, or those which induce an aptitude in the body to be attacked by scorbutus when exposed to its usual excitants, are numerous, and vary in their nature, but concur to occasion debility whatever they may have been. Thus we find that preceding diseases, whether acute or chronic, have been very common precursors, and that persons recovering from fevers, or who have been previously weakened by frequent relapses, have been often subjects of it. Indolence and inactivity appear also to have contributed to produce the susceptibility. The persons in a ship's crew termed *skulkers* or sluggards have been usually the first attacked; and it has been observed that those whose condition on board-ship exempts them from much exercise, have also been early amongst the number affected. We are told that in one of Lord Anson's ships,

the Centurion, out of fifty cases of scorbutus four only survived, and of the whole number of marines attached to the squadron (seventy), all but eleven died of it. It has been observed also in the Dutch service, that if there were seven on board that had the scurvy, four of these were marines, though the number of the latter was, of course, proportionately much less than that of the sailors. Corpulent persons have appeared to be peculiarly prone to it, and on shore it has been observed to affect individuals of sedentary occupations more frequently than those engaged in the active duties of life; and where it has been endemic, very frequently to attack the sedentary mechanics whilst the rural population have entirely escaped. On the other hand, however, excessive fatigue, over-exertion, and want of necessary rest, induce the same predisposing condition. Thus, it has not unfrequently occurred after long and harassing marches, and at sea succeeded occasions of much laborious duty; numerous instances of which might be adduced, if space were allowed us for the detail.

But of all the predisposing causes, none has been observed to have more frequently, if not invariably, exerted its influence, than cold combined with moisture either from the atmosphere generally, or from the equivalent influence of a humid apartment or damp clothes. When scorbutus made such havoc in Lord Anson's squadron on doubling Cape Horn, the weather had been very tempestuous, the wind cold and cutting, accompanied with snow and sleet. At the siege of Azof, when the Russian army suffered from it severely, the same circumstances existed. In the account of his voyage round the world, La Perouse states that he was very fortunate in preserving his crew from scorbutus, an effect which he attributed entirely to maintaining a dry state of the atmosphere between the decks. Captain Cook's success in this respect seems to have depended considerably on similar precautions. In Captain Parry's first voyage for the discovery of a North-West passage, the influence of humidity in this particular was very conspicuous. "Mr. Scallon," he states, "had been complaining for some days of pains in his legs,—first considered by the surgeon as rheumatic, but which he was soon convinced by the appearance of the gums depended on scorbutus. This occurrence, so uncommon amongst the officers of a ship, led to a particular inquiry as to its cause, and it was discovered that Mr. Scallon's bedding was in so damp a state in consequence of the deposit of moisture in his bed-place, as to render it no longer questionable." In Captain King's expedition in 1826, the crews of the two ships which he commanded, viz. the Adventure and the Beagle, continued healthy until May 1828, when scorbutus began to show itself whilst in the straits of Magellan, notwithstanding they were plentifully supplied with lemon-juice, sugar, preserved meats, pickles, cranberries, fish, wild fowl and wild celery. There was, however, excessive moisture of the atmosphere, and great mental depression prevailed in the crews from want of occupation, which in this instance would seem to have been excitants of the disease.

Mental depression, indeed, appears on most occasions to have had a powerful influence in predisposing persons to scorbutus. During its endemic prevalence, the timid, the discontented, and the inactive, have been frequently the first attacked. From this cause probably it is that newly impressed seamen have been particularly liable to it, and that it has often shown itself among the inhabitants of besieged towns. Hypochondriacs and persons of a melancholic temperament have been so commonly its subjects, that the hypochondriacal disorder, the atrabilious habit, and scorbutus, have by many of the old writers been considered as different degrees of the same disease. (Enquiry into the source of Scurvy, by Francis Milman, M. D. 1782.) Amongst a variety of other debilitating circumstances conducive to scorbutus, exposure to the impure air of crowded apartments and the free use of ardent spirits have been so commonly its precursors, that they require to be especially particularized. It has also been observed that individuals of uncleanly habits, both with regard to their persons and clothing, have been more liable than others to the disease.

Various opinions have been entertained as to the immediate or exciting causes of scorbutus, and, as frequently has occurred in reference to epidemic or endemic diseases, its propagation has been attributed to contagion. Sennertus, Boerhaave, and Hoffmann, are of the number of those who have advocated this opinion; and in Sir Gilbert Blane's work, published in 1785, we find that it was not discountenanced by him. It has been so completely subverted, however, by subsequent experience that it would be needless to discuss the question. Its hereditary transmission has also been asserted, but of this there is no satisfactory proof or even plausible argument.

At all times it has been an accredited opinion that its origin has been referable, with the concurrence of the predisposing circumstances already mentioned, to an insufficiency of nutriment, or to some noxious qualities of the ingesta, and these for the most part included in the following particulars—in certain impurities in the water or other liquids used for drink; in a preponderating proportion of farinaceous substances ill-fermented, or which have not undergone that process, or otherwise in a faulty state; in the use of animal food in a state of putrefaction, decomposition, or hardened and changed in its nature by the process of salting, as for sea use; simultaneously with privation or an insufficient supply of fresh vegetables, or a scanty allowance of such dietetic drinks as contain their elementary principles.

The connection of scorbutus with the use of such diet has to a certain degree been rendered obvious, by the successful issue of changes in the dietary of our own navy, determined on in consequence of the numerous facts corroborative of the supposed influence of the former system on the generation of this particular disease. The necessary concurrence of so many circumstances apparently essential to its production renders it impossible to estimate their individual operation, and this knowledge can be obtained only (if the opportunity should ever occur) by a more full and exact inquiry into the coexistent condition of the blood and other fluids of the body than

has ever yet been made. From its former prevalence principally amongst sea-faring people, an idea has been entertained that the large quantity of salt used in their food was exclusively an excitant of scorbutus; but Dr. Lind has shown that the daily use of considerable quantities of sea-water has in no degree aggravated it, and that an entire abstinence from salt or salted meat has had no mitigating effect on its symptoms. (Page 52.) It is certain also that scorbutus has prevailed where the operation of this article could not even have been suspected; as, for instance, on the occasion of Lord Anson's ships leaving the coast of Mexico, when they were plentifully supplied with fresh meat. The soldiers in the Russian armies, who suffered from scorbutus at the siege of Azof, had no salt provisions. During a scarcity of corn it raged amongst the poor inhabitants of the colder districts of Italy near the Alps, who subsisted chiefly on the decoction of roots, and often passed whole days without any food at all. In the Transactions of the College of Physicians, Dr. Milman has related two cases of the disease appearing in a very severe form in individuals who had lived for three months on tea, without milk or sugar, or any other article of diet except bread. (Milman on Scurvy, ch. ii.) From its occurrence also in prisons, and so lately as the year 1819 in the Milbank Penitentiary, under a dietary of fresh animal and vegetable food combined, it may be inferred that the prejudicial effect of salted meat depends either on its being deprived of its nutritious qualities, or upon its being otherwise rendered indigestible. It is also somewhat corroborative of this view, that the direct effect of the addition of salt to blood out of the body is a change of its colour from black to red, the reverse of which is the consequence of scorbutus in the blood of the living body. With regard to diet, however, the most constant peculiarity which has apparently caused the occurrence of scorbutus, has been a deficiency in the proportion or an entire privation of *fresh* vegetables, or rather, it should be said, of those which are of a succulent nature,—as an instance in point, may be mentioned the occurrence of scorbutus in Porchester Castle and at Norman Cross, about the beginning of the late revolutionary war, before those arrangements were put into practice which afterwards so effectually secured the health of the prisoners. Under similar circumstances it appeared in a prison-ship near Porchester Castle. (See a paper on the health of the Navy, by Sir Gilbert Blane, in the London Med. Chir. Trans. vol. vi. p. 502. 1815.) In these situations, however, it is to be remembered that there was a co-operation of several circumstances conducive to the disease, viz. deteriorated air, a dull uniformity of life, depression of spirits, want of exercise, &c. &c. It is scarcely necessary to observe that the saline effluvia in sea-air has been alleged as the cause of scorbutus. It is obvious that a circumstance so constantly prevailing at sea and on its shores could never have had so partial a consequence, and that the disease has almost entirely disappeared, though the cause alleged remains the same. It has been moreover remarked that there are few artificers so healthy as those who prepare salt from sea-water, and are thus continually exposed to the impregnated vapour which rises in the processes of drying and purifying this article. (*Lind*, ch. i. p. 53. Stevens on the Blood, p. 311. Lond. 1832.)

The hypotheses which have been promulgated in explanation of the physical condition on which scorbutus, or, in technical language, its proximate cause, depends, have accorded with the revolving doctrines of general pathology, but have been chiefly founded on those principles which refer disease to morbid changes in the fluids, or else to a corresponding condition of the properties of the living solids. For the most part, and up to the present day, scorbutus has been attributed to the former, even by those who have ably advocated the opposite opinions with regard to disease in general. Much further investigation, however, into the elementary components both of the solids and fluids of the body in their healthy and morbid state, and into the influences of external agents upon them, than has hitherto been made, is requisite to clear up the difficulties of this intricate question. The peculiar opinions on the subject which from time to time have elicited attention, require to be noticed in this place; but it must be premised that the principles of treating the disease founded upon them have been very inadequate to the end in view, which has been achieved most completely by observation alone, or, in other words, by that enlightened empiricism, which suggests the right application of established facts in the art of therapeutics, although much knowledge may be wanting to elucidate the nature of the changes produced in the body by which the object is effected.

The early writers on scorbutus have applied the general doctrines of the humoral pathology to the explanation of its various phenomena; more especially ascribing them to a putrid state of the blood, occasioned, as it was supposed, by defect in the function of the spleen, this organ at the period having been considered essential to the process of sanguification. Willis, (Tract. sec. de Scorbuto,) consistently with his pathological speculations in general, referred scorbutus to a state of *dyscrasy* of the blood, which he fancifully described as of two kinds, under the terms of the sulphureo-saline and the salino-sulphureous; the former to represent a supposed superabundance of sulphur, for the correction of which he taught that the depleting system was requisite, and above all things the avoidance of the hot and acrid antiscorbutics; whilst, on the contrary, in the *salino-sulphureous*, when the salts of the blood were supposed to predominate, he considered the warmer medicines were proper, and such as contained a volatile salt, together with preparations of steel and other tonics. The dyscrasy of the blood, he further presumed, was the occasion of a corresponding state of the nerves, or, according to his system, of the *liquor nervosus;* which thus secondarily, he imagined, conduced to the manifestation of some of the symptoms. The opinions of Boerhaave (Opera, cap. De Scorbuto) on this subject appear to have been equally hypothetical: he contended that scorbutus was occasioned by that part of the blood which constitutes the crassamentum being inordinately thick and viscid, and the serous portion too thin, salt, and acrid. The acrimony of this fluid

he imagined was either acid or alkaline, according to the nature of the food by the use of which the disease appeared to be induced: if, as at sea, it had consisted of salted meats, or of such as yielded little nutriment, as a consequence that there would be an acid, or, to use his own phrase, a muriatic acrimony; but if the food had been in a putrid state, that the acrimonious principle would be alkaline.

Although Hoffman exposed the fallacy of the humoral pathology in general, his views of the nature of scorbutus coincided for the most part with those of Boerhaave; and Cullen, who first and most successfully controverted the same system of pathology, admitted its influence in giving rise to this disease. Presuming from the appearance of the blood, from that of the secretions and excretions, and from the fetor of the breath, that a morbid condition of the blood does give rise to it, he contends that a putrefaction or a nearer approach to it than is consistent with health, is a necessary consequence of living entirely upon animal food, without a frequent supply of vegetable aliment, and thereby of producing and evolving a larger proportion of saline matter. In confirmation of this, he observes that every interruption of perspiration, that is, the retention of the saline matter, contributes to the production of scurvy, whether produced by the direct application of cold, or by any other circumstance which might weaken the force of the circulation, such as the neglect or want of exercise, fatigue, and despondency of mind. It will be sufficiently obvious, he adds, that if the preternaturally saline state of the blood in scorbutus be admitted, the throwing into the body along with the aliment an unusual quantity of salt may have a great share in producing the disease. Even (he proceeds) supposing such salt to suffer no change in the animal body, the effect of it may be considerable; and this will be rendered still more probable, if it may be presumed that all neutral salts consisting of a fixed alkali are changed in the animal body into an ammoniacal salt, which he apprehends to be that especially prevailing in scurvy. (First Lines of the Practice of Physic, by William Cullen, M. D.) Sir John Pringle supported a similar doctrine, that scurvy was the result of "a gradually accumulating putrefaction" in the blood, from the putrescency of salted food, which he deemed the chief cause of the disease. (Obs. on Diseases of the Army, Appendix, p. xci.)

The theory of fixed air, which was considered the principle of cement or bond of union on which the firmness, soundness, and cohesion of bodies depends, was advanced by Macbride in support of the opinions which referred scorbutus to a putrescent tendency in the blood; the loss of that principle appearing to him to account for the altered state of this fluid, and the method of cure depending on its restoration, which he proposed to effect by conveying it to the body by the free use of the infusion of malt and essence of wort. Dr. Trotter differed from his predecessors in his application of the pneumatic doctrines of pathology to this disease, the remote causes of which, in his view, tended to deprive the blood of oxygen; and to the restoration of this principle through the medium of the acid fruits he attributed their antiscorbutic efficacy. "We are of opinion," he remarks, "that the citric acid is decomposed by the organs of digestion and assimilation, after which the oxygenous principle is blended with the circulating mass." This supposition Dr. Trotter considers as further confirmed by the blackness of the blood discharged, and by the speedy change to a florid hue which the fungous ulcerations assume within a few hours after the acids have been administered. (On Scurvy, p. 141.) Dr. Beddoes adopted the same hypothesis, but extended it to the abstraction of oxygen from the whole system, in explanation of the phenomena of the disease.

Lind disputed the idea of putridity of the blood in scorbutus, and referred the primary changes to a relaxation of the tone of the animal fibres, a weakening of the powers of digestion, together with a stoppage of perspiration, the tendency of which, he admits, was to produce *spontaneous putrefaction*, the process of nutrition being suspended. (Lind on Scurvy, p. 234.) This view of the subject was followed up and most ably advocated by Dr. Milman, in an essay remarkable also for the elegance of its composition, published in 1782. "Whether," says he, "I consider the nature of the causes producing scorbutus, or the actual state of the blood in the disease, or the secretions which occur in its progress, they all concur to make me believe that it does not consist in a putridity of the blood. Nor does there appear to be any quality which can be discerned or defined in the blood of scorbutic persons by which the nature of their disease can be characterized." The theory which Dr. Milman has substituted, it would exceed our limits to enter into in detail, but it consists of the following propositions:—that scorbutus is not a disease of the fluids, but of the solids; that its seat is in the muscular fibre; that its proximate cause consists of a gradual diminution of the vital power; and that the subsequent diminished cohesion between the particles of the muscular fibres, and the tendency of these to putrefaction, are links of the chain. In reference to the action of salt provisions, he considers, with Lind, that they tend to excite scorbutus not by their saline, but by their indigestible nature, and through defect of nutriment occasion an enfeebling of the vital principle productive of languor in all the functions of the body, and ulteriorly of a general disposition to putridity. (Milman on Scurvy, chap. vi.) This view of the proximate cause of scorbutus is supported by the argument that all its predisposing causes are of a debilitating nature, and by the extraordinary influence of mental impressions in favouring its occurrence as well as its prevention and cure, such impressions being considered inadequate to the occasion of a sudden change in the chemical condition of the fluids. The agency of such impressions, however, through the medium of the nervous system, is supported by numerous illustrations in the phenomena of health and disease. On the other hand, it must be acknowledged that those means which appear to contribute in general to the strength and activity of the solids, such as fresh animal food, soups, wine, bark, and a variety of other tonics and stimulants, have been found to exert very inferior powers over the disease in com-

parison with the vegetable acids; which, nevertheless, are well known to produce an attenuating effect on the body, and this not unfrequently whilst they are accomplishing its cure.

Broussais contends that in scorbutus, whatever may be its cause, there is first an irritation of the internal membrane of the digestive canal; 2dly, an imperfect assimilation of the elements, especially of fibrin and gelatin, either in the tissues formed out of them, or in the blood which directs them to different parts of the body; 3dly, that in consequence of defect of nutrition a diminished cohesion of fibre ensues, which accounts, in his view, for the imperfect contractility and fragility of the muscular fibre, for the rupture of vessels and the escape of their fluids, and finally, for the easy disorganization of the issues on the occurrence of scorbutus. (Treatise on Physiology applied to Pathology, Transl. Philadelphia, 1832.)

We shall conclude this part of the subject by noticing some observations of Andral, which appear to us to be most consistent with all the facts on which an opinion of the nature of scorbutus can be established. In the threefold respect of the vital phenomena, intimate structure, and chemical composition, no line of demarcation can be drawn with strictness and precision between the blood and the solids. Physiologically speaking, it is impossible to conceive that one of these two parts of the same whole could be modified without the other being so likewise. On the one hand, inasmuch as the blood nourishes the solids, and as without its presence they cannot support life, the state of the solids cannot but be influenced by the state of the blood. The chemist might as well say that the nature of a body does not depend on the nature of the elements that compose it. On the other hand, the solids, considered with respect to their relations to the blood, form but two classes, the one contributing *to make* the blood, such as those concerned in the processes of absorption, digestion, arterial circulation, and respiration; the other contributing to *unmake* it, those, namely, concerned in the processes of venous circulation, secretion, and nutrition. No one solid, therefore, can undergo the slightest modification without producing some derangement in the nature or quantity of the materials destined to form the blood or to be separated from it. Physiology, then, leads us to the conclusion that every alteration of the blood must be succeeded by a modification of the solids. Viewed in this light, there is no longer any meaning in the disputes between the solidists and the humorists; and the system appears to constitute but one great whole, indivisible in the state of health as well as in that of disease. With regard to scorbutus in particular, he observes that the causes under which it is developed epidemically, the symptoms that characterize it, the remarkable state of the blood itself, and the nature of the lesions discovered on examining the bodies, all combine to prove that this disease depends on a primary alteration of the blood. (Andral's Pathol. Anat. translated by Townsend and West, vol. i. p. 641 and 678.)

Prevention of Scorbutus.—The prevention of scorbutus in this and in some other countries in which it formerly prevailed having been completely effected, or rather the disease having disappeared in consequence of the dietetic consumption by all classes of persons of fresh vegetable food at every season of the year, of drinks which contain their elementary principles, of water in a pure state, of milk, of fresh animal food, and the disuse, as an article of daily subsistence, of dried and salted meats, together with the general drainage of the country, the greater security, dryness, and warmth in the dwellings, the improvements in clothing, and greater attention to cleanliness, it would be superfluous to enter into a formal detail of measures for its prevention on land; more especially as the process of civilization advances us so much the farther from the sources of this and other epidemic diseases. But, although improvements comparatively as great have been effected in our naval economy, and have been sufficient to lead to the general extermination of scorbutus, yet under particular circumstances the greatest vigilance has been frustrated by the superior power of its occasional causes, and their unceasing operation at sea renders unremitting attention to certain prophylactic measures necessary to ensure security against its occurrence. These consist of the removal, if possible, or, at least, of the counteraction of the predisposing and occasional causes of the disease; and in the daily use of a certain quantity of lemon-juice, the preventive efficacy of which is well established although its operation has not been satisfactorily explained. The application of such preventive measures has for the most part been happily illustrated in the narrative of the memorable voyage of Captain Cook. To his sagacity we are indebted for the first impulse to those regulations by which scorbutus is so successfully prevented in our navy. It will be remembered that the crew of his predecessor Lord Anson, in a similar voyage of discovery, had experienced the most dreadful havoc from this disease, and the prevention of it seemed to present as great difficulty to himself as any circumstance of his projected voyage. The maintenance of the general health of his men he discerned was the main point of security, and to command this he was especially careful that they should not be subjected to excessive or unnecessary fatigue, and as much as possible that they should be protected from the noxious influence of a cold and damp atmosphere. In the first place he instituted three instead of two watches,* by which eight hours of uninterrupted rest were allowed to his men for four of duty; their strength was consequently more recruited, and they were also less exposed to the weather than if they had been at watch and watch, and if necessary they had dry clothes to change. The hammocks and bedding every fine and dry day were not only ordered upon deck, but each bundle was unlashed and so spread out that every part was exposed to the air. Besides the ordinary modes of whitewashing and scraping the decks, stoves were kin-

* Dr. Trotter disputes the advantage of this arrangement. "We," he observes, "who see things on the spot, and are daily accustomed to reason on the discipline of ships, are clearly decided in favour of two watches; our most accomplished and intelligent officers have also from experience put it beyond dispute."—Medical and Chemical Essays by Thomas Trotter, M.D., p. 25. We believe, however, that *three watches* are now the more general custom in our navy, at least in large ships.

dled and carried successively through them, which not only served to dry the ship, but, by heating the impure air below and rendering it specifically lighter than the common air, to make it rise and pass through the hatchways. In the torrid zone he shaded his people from the scorching sun by an awning over the deck, whilst in his course within the Antarctic circle they were provided with coats of woollen stuff, furnished with hoods to cover their heads. He attended also particularly to their diet, taking care that there should be always a plentiful supply of water both for this purpose and for the promotion of cleanliness. He prohibited the custom of using the fat which was boiled out of the salted meats in lieu of other food; having observed that symptoms of indigestion were the common consequence, and the latter not unfrequently a preliminary of scorbutus. (*Milman*, p. 33.) Captain Cook begins his list of preservative stores with malt. "Of this," he says, "was made sweet wort,* and given not only to those men who had manifest symptoms of the scurvy, but to such also as were considered most liable to it." This article, although he did not consider it adequate to the cure of scurvy, he praised as one of the best antiscorbutic medicines known in his day. Sooins or sowens,† an article of diet well known in Scotland, was also considered by him of great antiscorbutic efficacy, and was dealt out to his men in messes sweetened with sugar and flavoured with some French prize wine, which, though sour, was thought to improve the flavour. Captain Cook was provided with lemon-juice prepared for sea use, but the necessary quantity not being understood, it was neglected and erroneously underrated. But the article of most extensive use for the same purpose was sour kroute (sour cabbage), well known in German diet. Sour kroute or croute (*Saures Kraut*, German; literally sour herb or pickled cabbage,) is prepared by slicing the soundest and most solid cabbages in the way cucumbers are used in this country. In this state they are put into a barrel in layers, hand high, and over each is strewed a handful of salt and caraway seeds; in this manner it is rammed down, stratum super stratum, till the barrel is full, when a cover is put over it, and it is pressed down with a heavy weight. After standing for some time in this state, it begins to ferment, and it is not till the fermentation has entirely subsided that the head is fitted to it, and the barrel is finally shut up and prepared for use. Vinegar, as some have supposed, is not employed in its preparation. It was recommended to the use of the British navy by Dr. Lind, the great freedom of the Dutch from scorbutus having been attributed to the free use of it. The quantity allowed was two pounds weight to each man per week, besides a pound and a half to two pounds with every gallon of peas, for making soup. He was supplied also with portable soups, which, as far as possible, he made the vehicle of vegetable aliment; and by such means, and by diminishing the quantity of salted provision, to his honour be it said, he preserved his crew from scorbutus, although the period of his voyage had extended to three years and eighteen days, passed in all latitudes from 52° N. to 71° S. It is still more remarkable that of a company of 118 men he lost but one, who there is reason to suppose was labouring under phthisis previous to his departure from England.

The comparative exemption of our own navy from scorbutus during the last thirty-five years, is, we conceive, to be attributed in no small degree to the regulations enforced for the maintenance of the general health of the sailors, together with the improvements by which this object has been advanced. A frequent inspection of the men's clothing is made, to ascertain whether there is a sufficiency for the purposes of personal cleanliness and of protection from the effects of the weather, both as regards their bedding and wearing apparel. The strictest attention is given to the ventilation, cleanliness, and dryness of ships. For what are called windsails (which were found to be imperfect and inconvenient ventilators, from their use being inadmissible with hatches closed in bad weather when they are most wanted, and when the men were asleep, on account of the large volumes of cold air which they admitted) has been substituted a contrivance free from those objections, borrowed from a French frigate: this consists of square wooden trunks (for which brass tubes have since been used) running from the hold or lower deck and terminating in the open air. A contrivance which has still more recently been preferred, is a funnel placed vertically near the middle line of the ship, before the foremast, leading through the forecastle-deck where there is neither hatchway nor ladder, and under which are the sleeping-places. The removal of all offensive substances by sweeping and scraping has been much more particularly attended to than formerly; but instead of washing the decks, particularly in cold or damp weather, the preservation of dryness, so essential to comfort and health, as well as to the prevention of scorbutus, has been carefully studied, and rubbing with hot sand, scraping, and portable fires, have been generally substituted. By these precautions, also, the deteriorating agency of moisture on the ship's provisions, as well as on other articles in common use, has been prevented, and thereby a source cut off, which otherwise might have been largely conducive to the generation of this disease. This important point has been further promoted by having portable fires in iron stoves carried all over the ship. Formerly a prolific source of foul air and bad smells in ships were the putrescent matters absorbed and retained by gravel, sand, and other earthy substances used for ballast, for which are now substituted small masses or pigs

* Infusion of malt, proposed as a preventive as well as a remedy for scorbutus, was recommended by Dr. Macbride on the supposition that it would ferment after being taken into the stomach, and give out carbonic acid gas—its alleged remedial principle. Laying aside all regard to the theory on which it was suggested, experience seems to have determined that it is a nutritious beverage, and that it has been productive of considerable advantage in the objects for which it was proposed. It has been used rather as an article of diet than medicine, and has been generally directed in the quantity of from one to four pints daily.

† This food is prepared by putting some oatmeal into a wooden vessel, pouring hot water upon it, and continuing the infusion till the liquor begins to taste sourish, i. e. till a fermentation comes on, which, in a place moderately warm, may be in the space of two days. The water is then poured off from the grounds, and boiled down to the consistence of a jelly.

of iron; and iron tanks, instead of the lower tier of water-casks, are placed over the iron ballast. The tanks adverted to are cubes of four feet in dimensions, each capable of containing about two tons of water: as they are not corruptible, like wood, they impart no bad quality to it, and by their durability insure an ample supply; whereas the decay of casks in long voyages and in remote parts of the world where they cannot be replaced, has occasioned the utmost distress.

The improvement suggested by Sir Robert Seppings, Surveyor of the Navy, and explained by him in the "Philosophical Transactions" for 1814, the object of which was to add to the strength, solidity, and durability of ships, has been highly conducive to the purity of the air in them; first, by the obliteration of those cavities under the floor of the hold which used to be the receptacle of filth and vermin, and the perpetual sources of offensive and noxious exhalations; secondly, from commanding at all times the most perfect ventilation, the timbers of the frame which run up the side of the ship maintaining a constant communication with the open air, with the hold and spaces between the decks; thirdly, by virtue of this new construction, a ship being less liable to leakage, together with the new method of ballasting, all the unwholesomeness and offensiveness belonging to bilge-water is done away.

The promotion of the general health of seamen, and consequently the prevention of scorbutus, is further effected by the superior quality of all the articles of victualling; by the plentiful supply, when in port or within reach of it, of fresh meat, succulent vegetables and fruits; and when at sea, by the daily use of cocoa for breakfast, or of tea, coffee, sugar, &c. and a less proportion of ardent spirits. To these are to be added the more liberal allowance as to quantity of the diet at sea; and, under circumstances particularly conducive to the generation of the disease, an increased allowance of farinaceous articles in lieu of the necessary diminution in the rations of salted meats. The former consist for the most part of biscuit, wheat-flour, oatmeal, peas, and pearl barley, and, as substitutes for fresh vegetables, though of infinitely inferior antiscorbutic efficacy, dried raisins, currants, prunes, preserved fruits, spices, pickles of various kinds, vinegar, molasses, and as much wine for each man as is equivalent to one-half of the allowance of spirits, the latter being suspended. (See Paper by Sir Gilbert Blane on the Health of the Navy.—Med.-Chir. Tr. vol. vi.)

But to the general supply of lemon-juice, judiciously dispensed to ships of war since the year 1795, Sir Gilbert Blane ascribes the complete eradication or rather the prevention of scorbutus. Usually, after ships have been a fortnight at sea, to every individual in them a fluidounce of lemon-juice mixed with an ounce and a half of sugar is served out daily, which, with the addition of water and of wine or spirits, affords a grateful beverage, the use of which is enforced when the neglect of it is suspected, or under particular apprehension of the invasion of the disease. It is in consequence of this prophylactic, Sir Gilbert Blane infers, that there are now many surgeons in the navy of long standing who have never seen a case of the disease; and, as appears from the inspection of a great number of journals, that it has either not appeared at all, or else in so slight a degree that it was speedily checked by an increase of the quantity of the antidote. No other remedy yet known can ward off, he observes, this dreadful scourge of mariners under the use of salt provisions for an indefinite length of time; nor does it produce, he adds, any bad effects on the constitution like some specifics in other diseases. The decisive superiority of lemon-juice has led to the disuse of a variety of articles formerly in repute for the prevention of scorbutus, such as sour kroute, infusion of malt, essence of spruce, elixir of vitriol, &c. Of the sour kroute we have already spoken; and we have alluded to the use of the infusion of malt. "Although," says Dr. Trotter, "I have no idea of impeaching the veracity of those who established the credit of the malt preparation, yet I must beg leave to observe that in my own practice I have not seen it attended with any good effects. Lind speaks of it only as a very nourishing liquor, well adapted for scorbutic patients." The essence of spruce,* or rather spruce-beer, the form in which it has been commonly used, seems to possess, says Sir Gilbert Blane, similar and equal antiscorbutic virtues with fermented malt liquor, as beer or porter; and it has this advantage, that the materials for preparing it can be readily carried about and used as occasion may demand. (Observations on Diseases of Seamen, p. 302.) The use of elixir of vitriol in the cure of scorbutus was of very early date, and, on the principle that what will cure will prevent, it was recommended to the use of the navy by Dr. Huxham, who states that it had been found "greatly serviceable." The assertion, however, is not corroborated by general experience, and the converse of the proposition seems more applicable to the circumstance in question; at most, probably, it had been useful in correcting the unwholesome qualities of impure water, for which purpose it has been occasionally added to it in very minute proportion.

We have yet to mention the necessity, in a prophylactic point of view, of regular exercise. Although often called upon for extraordinary exertion, it occasionally happens with seamen that there are long intervals in which systematic attention to this branch of hygiene is especially requisite. Independently of its direct influence on the maintenance of the general health, it may be made subservient to an equally important object in the prevention of scorbutus, viz. to occupation of mind, and in sailors, its diversion from those gloomy views to which, under suspension of duties, they are peculiarly prone; a fact which, however astounding it may at first appear, reflection will assent to be consistent with his condition. To separate, as his duties require him, under perilous circumstances, from those to whom he is linked by the bonds of affection; to be peculiarly subjected to disappointment, and to unexpected delay in schemes to which the brightest hopes are attached; to have been taught by reason and experience that

* Captain Ball states that the essence of spruce a little diluted did wonders at St. Domingo, both in prevention and cure. It acted as a purgative, and was therefore carefully administered; it sat on the stomach when every thing else was rejected. — Med. Naut. by T. Trotter, vol. i. p. 349.

the perils which he has no fear to encounter are frequent and more than ordinarily liable to frustrate them; and in many instances the necessary system of moral discipline being wholly inconsistent with the physical condition, are circumstances sufficient to account for the state of mind above mentioned. The despotic system, formerly in force, of impressing seamen, doubtless had a powerful influence in predisposing them to disease. Their country, says Dr. Trotter, has taken advantage of their situation, and their service is indispensable to the safety of its commerce and territory. It is only therefore mild treatment that can reconcile an impressed sailor to his fate, and if he be so unfortunate as not to overcome it, some fatal disease, as scurvy, will be the consequence; among people of this description it first makes its appearance. An officer, therefore, cannot too minutely study the genius and the temper of those he has to command; but the good effects of it and the satisfaction he will experience, will more than repay his assiduity.

In the narrative of Captain Parry's voyage already referred to, it appears that that able officer was fully impressed with the expediency of amusement as well as of exercise for the preservation of the health of his men, and was particularly aware of the antiscorbutic efficacy of occupations being afforded to them. The mode of their pursuance must depend on the circumstances which are present, and much of the advantage must arise from the ingenuity and address with which the means are devised. The narrative of Captain Parry's expedition to the Polar seas affords a happy illustration in point, many circumstances of it having been congenial to the production of scorbutus, but which, nevertheless, by salutary precautions, was most successfully opposed. Although some of these have been already discussed, their practical application with that of others is so advantageously set forth in the following passage, that no apology, we conceive, is necessary for transcribing it. "The commander finding himself shut in for a long and dreary winter, devoted his attention, with judicious activity and a mixture of firmness and kindness, to mitigate those evils which even in lower latitudes had often rendered an arctic winter so fatal. His provisions being very ample, he allowed the sailors weekly a pound of Donkin's preserved meat and a pint of concentrated soup, instead of a pound of salt beef; beer and wine were served instead of spirits; and a certain allowance was made of sour krout, pickles, and vinegar. The sailors were also called together daily and made to swallow a quantity of lime-juice and sugar in presence of the officers; their improvidence being such as to afford otherwise no hope of their spontaneously imbibing this salutary draught. Their gums and skins were also regularly examined, in order to detect scurvy in its earliest symptoms. It was necessary to be very economical of fuel, the small quantity of moss and turf which could be collected being too wet to be of any use. By placing the apparatus for baking in a central position, and by several other arrangements, the cabin was maintained in a very comfortable temperature; but still, around its extremities and in the bedplaces, steam, vapour, and even the breath settled, first as moisture and then as ice; to dry and remove these annoyances became therefore a part of their daily employment."

Exercise, it is stated, was enforced on the men when they were prevented from leaving the vessel, by obliging them to run round the deck to the tune of an organ; this they did not at first entirely relish, but no plea against it being admitted, they converted it at last into a matter of frolic.

To keep their minds agreeably occupied, schools, masquerades, and plays, were adopted; in reference to the latter it is observed that the very expectation thus raised among the seamen, and the bustle of preparing a room, were extremely salutary, and when the *North Georgian Theatre* opened, with "Miss in her Teens," these hardy tars were convulsed with laughter, not a little excited perhaps by viewing their officers in the singular and novel position of stage performers. At all events the Arctic management was extremely popular. As the small stock of plays contained in one or two chance volumes was soon exhausted, original compositions were produced and afterwards formed into a collection. The officers had another source of amusement in the *North Georgian Gazette*, of which Captain Sabine became editor, and all were invited to contribute to this chronicle of the frozen regions. Even those who hesitated to appear as writers enlivened the circle by severe and good-humoured criticisms.

Treatment.—Recovery from scorbutus, to use an expression of Lind's, presents a remarkable instance of the quick diminution of the effect from the cessation of the cause; an observation which has been so amply confirmed by experience that it may be regarded as a most important axiom in the therapeutic consideration of the disease. There are remedies, nevertheless, which expedite and even effect its removal under disadvantageous circumstances, and this with a degree of rapidity which, considering its apparent ravages, seems most extraordinary and peculiar to itself, the more so from our knowledge of its nature being very imperfect, and the salutary operation of such remedies by no means obvious. We reject theory, therefore, from our consideration of this part of the subject, in the spirit of the following remark of one who has well appreciated its importance in practical medicine: "Cujus autem rei non est *certa notitia*, ejus opinio certum reperire remedium non potest. Verumque est, ad ipsam curandi rationem nihil plus conferre quam experientiam." (*Celsus*, lib. i.)

It has been found an essential step to the relief of a person suffering from scorbutus that he should have the advantage of a dry atmosphere, both as regards the apartment which he inhabits, and the various articles of his bedding and wearing apparel. Next to this, to gratify the cravings of his appetite, an instinctive index, apparently, to the chief corrective of his disease by a satisfying supply of esculent fruits and fresh vegetables: "be they of any sort," says Lind, and all experience has verified the remark, "they will for the most part prove effectual." At different periods, however, a specific virtue in the cure of scorbutus has been attached to particular articles of the vegetable kingdom, and those which are succulent and possessed of an aromatic quality, especially the alkalescent plants of the class tetradynamia, have been re-

garded as powerfully antiscorbutic;* but that their power in this respect does not depend on their alkalescent property is proved by the fact that the vegetables and fruits in which the acid principle abounds have been alike efficacious, and even in a still higher degree. Of the latter, those of the genus Citrus, and of the natural order Hesperidæ, viz. the Citrus medica, lemons—C. aurantium, oranges — C. acida, limes — C. decumana, shaddocks — particularly the three first, have obtained pre-eminent repute, even to the extent of being considered specifics — a denomination to which they appear to be as much entitled as medicines adapted to the cure of any disease. Their efficacy, however, having been gainsayed by a physician whose writings have attracted considerable notice,† and their claim to therapeutic estimation resting entirely on experience of their effects and deference to authority confirmatory of it, we conceive it necessary to enter into detail of evidence in support of the treatment of the disease by the remedial agents the efficacy of which has been denied.

The earliest notice we can find in reference to this point is in the third epistle of Rousseus, dated 1564, wherein it appears that some Dutch sailors who were suffering from scurvy, and the cargo of whose ship on their return from Spain consisted of lemons and oranges, accidentally discovered that their use was the means by which they recovered their health. "And if people," observes Lind, (p. 160,) "had been less assiduous in finding out new remedies, and trusted more to the efficacy of these fruits for preventing this fatal pestilence to seamen, the lives of many thousand sailors, and others, especially during the last war, might in all probability have been preserved. But some have been misled to recommend many other things, as of equal, if not superior, antiscorbutic qualities to these; and have reduced them to a level with other acids, and many falsely supposed antiscorbutic medicines; from whence the many unhappy disappointments hitherto met with in preventing this disease at sea seem to have arisen."

In 1593, Sir Richard Hawkins experienced the antiscorbutic efficacy of lemon-juice in his crew, who were attacked by it in its virulent form within three or four degrees of the equinoctial line. In a work of considerable merit, entitled the Surgeon's Mate, or Military and Domestic Medicine, by John Woodall, master in surgery, dated London, 1636, we find an excellent disquisition on scurvy, and the following apposite remarks: "further experience teacheth, which I have oft found true, that where a disease most raigneth, even there God hath appointed the best remedies for the same grief, if it be his will they should be discovered and used; and note, for substance, the lemmons, limes, tamarinds, oranges, and other choice of good helps in the Indies, which you shall find there, do farre exceed any that can be carried thither from England, and yet there is a good quantitie of juyce of lemmons sent in each ship out of England by the great care of the merchants, and intended only for the reliefe of every poore man in his neede, which is an admirable comfort to poore men in that disease. Also I finde we have many good things that heale the scurvy well at land, but the sea chirurgeon shall do little good at sea with them, neither will they indure. The use of the juyce of lemmons is a precious medicine, and well tried; being sound and good let it have the chiefe place for it will deserve it, the use whereof is: It is to be taken each morning, two or three spoonfuls, and fast after it two houres, and if you add one spoonful of *aqua vitæ* thereto to a cold stomack it is the better. Also if you take a little thereof at night it is good to mixe therewith some sugar, or to take of the syrup

* Formulæ for the preparation of medicines for the cure of scurvy were formerly inserted in the Pharmacopœias of London, Edinburgh, and Dublin, under the titles of Succi Scorbutici and Succi ad Scorbuticos; these were compounded of the juices of garden scurvy grass (cochlearia officinalis); brooklime (veronica beccabunga); water-cresses (nasturtium officinale); and Seville oranges. Besides these, of the infinite number of anti-scorbutics which have been in great popular estimation, and commonly recommended by medical writers until within the last half century, the chief are the horse-radish (cochlearia armoracia); garden purslane (portulaca oleracea); black and white mustard (sinapis alba et nigra); the biting stone crop (sedum acre); celandine (chelidonium minas); marsh trefoil (trifolium palustre); common and Roman wormwood (absinthium latifolium et tenuifolium); fumitory (fumaria purpurea); hemp agrimony (eupatorium cannabinum); the garden radish (raphanus sativus); the garden lettuce (lactuca sativa); the garden endive (cichonium endivia): common juniper (juniperus communis); dandelion (leontodon taraxacum); the common onion (allium cepa); garlic (allium sativum); the leek (allium porum); squill (scilla maratima); the potato, sliced and raw in vinegar (solanum tuberosum); the fir (pinus abies); sorrel (rumex acetosa); &c. Bishop Berkeley wrote a treatise, in 1744, to insist on the curative efficacy of tar water in scorbutus; and Alston, (1750) another on the superiority of lime-water for the same purpose.

† Dr. Stevens; see his Observations on the Healthy and Diseased properties of the Blood. 8vo, London, 1832. Dr. Stevens's denunciation of the treatment of scorbutus by the administration of vegetable acids, seems to rest on the general effect observed of their admixture with the blood out of the body—viz. that of changing its colour from red to black, and by consequence, on the supposition that in this as well as in some other diseases in which the latter quality has particularly characterized the appearance of that fluid, such means would be found not only to keep up but to aggravate the disease. This morbid appearance Dr. Stevens attributes to its privation of its saline constituents, and hence in scurvy, and in other diseases in which it is in a black and vitiated condition, he asserts that "the natural saline waters, or the active non-purgative alkaline salts, act like a charm" (p. 309)—it being the property of these substances (contrary to that of the vegetable acids) on their addition to black blood out of the body to change its hue to red. On this principle Dr. Stevens explains the good effect attributed to the nitrate of potash in the treatment of scorbutus, and on the same ground would administer the muriate of soda, to the excessive use of which its production (as observed in the text) has been commonly attributed. Dr. Stevens, however, in another place (p. 451), has stated that during a residence of twenty years in the West Indies *only one case of scurvy* had come under his notice, and that case, he asserts, was decidedly brought on by the excessive use of citric acid which an American gentleman had been recommended to use as a preventive against yellow fever; consistently with his theory too, that on its being laid aside and the carbonate of soda substituted, the patient was completely cured in three weeks. "To those," he observes, "who are disposed to see the contrast betwixt the effects of the neutral salts and the citric acid in the treatment of scurvy, I would recommend the perusal of Mr. Cameron's paper on this disease, which they will find in the Medico-Chirurgical Review, for 1829"—more conveniently, perhaps, for that purpose inserted in our text, and which, if considered with that degree of candour which the cause of therapeutic science demands, would only serve to prove what little credit is due to the following remark of his own, (p. 264.) "With respect to scurvy it would not be difficult to prove, from the writings of Trotter and others, that this disease, which at one period was so distressing in the British navy, was frequent and fatal almost exactly in proportion to the quantity of citric acid which was used as a preservative, and unfortunately also as a *cure* for the disease."

thereof is not amisse. Further note, it is good to be put into each purge you give in that disease. Some chirurgeons also give of this juice daily to the men in health as a preservative, which course is good if they have store, otherwise it were best to keep it for need." In want of these he adds, "use the juice of limes, oranges, citrons, or the pulp of tamarinds, and in want of all these use oyle of vitrioll, as many drops, as may make a cup of beere, water, or rather wine if it may be had, onely a very little as it were sower." In another place he writes, "And generally note that bitter and sower medicines prevail most to the cure of this griefe, amongst which you have that are approved goode thereto, those that follow as chiefe, juyce of lemmons, of limes, of citrons, and oranges." In the account of his voyage to the East Indies, published in 1683, Dellou, a French physician, recommends for the prevention of scurvy, that each person on board should provide himself with the juice of citrons, lemons, and dried fruits, especially prunes. The same remedies we find recommended in the treatise of Martin Lister, published in 1694.

It is remarkable, however, that epidemic scurvies were allowed to rage in various parts of the world, and in none more than in the British navy, for more than a century and a half after Woodall had pointed out the usefulness of lemon-juice, without its being generally employed. So complete was this neglect, that in 1740, when Lord Anson proceeded on his circumnavigation, no provision of any kind appears to have been made against the disease, and we find Mr. Walter, the chaplain of the expedition, and discriminating historian of it, declaring that "in some instances the prevention and cure of the malady could not be effected by any management or remedies which could be made use of at sea:" (p. 113.) But it is mentioned that on *nearing* the island of Tinian, lat. 15°. 8′. north, and in 114°. 50′. west longitude from Acapulco, it was part of a very grateful account of it they obtained from a Spanish prisoner, that it afforded plenty of lemons, limes, sweet and sour oranges, cocoanuts, and bread-fruit. We are informed also that on making shore their sick amounted to 128, and notwithstanding the extreme debility of the greatest part, twenty-one of them dying on the day of their arrival and the following day, yet during the whole two months in which they staid there, they did not lose above ten more, and that the remainder reaped such benefit from the fruits of the island, and "*in particular those of the acid kind*, that within a week most of them were so recovered as to be able to move about without assistance."

The calamities of this unfortunate expedition, and the sufferings they underwent, created a general interest, not only with medical men, but with the public at large, on the cause and nature of the disease, and the most likely means of controlling its ravages.

The stamp of correct observation founded on most extensive experience, which Dr. Lind's treatise on the subject, published in 1753, has been always acknowledged to bear, renders his testimony of the highest worth. "The result of all my experiments was," says he, "that oranges and lemons were the most effectual remedies for this distemper at sea. I am apt to think oranges preferable to lemons, though, perhaps, both given together will be found most serviceable." In another case, "I cannot omit upon this occasion observing what caution is at all times necessary in our reasoning on the effects of medicine, even in the way of analogy, which would seem the least liable to error. For some might naturally conclude that these fruits are but so many acids, for which tamarinds, vinegar, *sp. salis.*, *elixir. vitriol.* and others of the same tribe would prove excellent succedaneums. But upon bringing this to the test of experience, we find the contrary. Few ships have ever been in want of vinegar, and for many years before the end of the late war all were supplied sufficiently with el. vitriol. Notwithstanding which the Channel fleet often put on shore a thousand men miserably overrun with this disease, and many hundreds besides died in their cruises. Upon those occasions tar-water, salt-water, vinegar, and el. vitriol. especially, with many other things, have been abundantly tried to no purpose; whereas there is not an instance of a ship's crew being ever afflicted with this disease where the before-mentioned fruits were properly, duly, and in sufficient quantity administered."

Again, says this observer, "in seemingly desperate cases the most quick and sensible relief was obtained from lemon-juice, by which I have relieved many hundred patients labouring under almost intolerable pain and affliction from this disease, when no other remedy seemed to avail." Finding the acid to operate violently upon the stomach and bowels of those who were much weakened, he recommended the addition of wine and sugar, as constituting the best antiscorbutic, and was in the practice of ordering about four ounces and a half of lemon or lime-juice, and two ounces of sugar, to be put into a pint of Malaga wine, which he thought sufficient for any weak patient to take in twenty-four hours. Dr. Trotter, however, states as the result of his experience that any such preparation was unnecessary, and that the happiest effects were produced by allowing the patients to suck the juices immediately from the fruits themselves.

In another place Dr. Lind says, "summer fruits of all sorts are here in a manner specific, viz., oranges, lemons, citrons, apples, &c.;" he moreover devised a method of preserving the juice of the two first-mentioned, so as to render them available at all times and in all climates, whether in the midst of the ocean or under the arctic circle.

The testimonies of Sir Gilbert Blane and Dr. Trotter in favour of the antiscorbutic efficacy of these fruits are equally strong, and when we consider the extensive opportunities of observing this disease which fell to the lot of these three eminent physicians, their qualifications for forming correct opinions, and the immense mass of evidence adduced by them in support of the remedies in question, the conclusion is irresistible that their adaptation to the removal of this disease is established on as firm a basis as that of any article of the materia medica to any disease whatever. The late venerable and talented director of the medical department of the navy, has in the year 1830 confirmed the opinion he gave to the world of these remedies in 1785, by the triumphant fact that the

scurvy has been prevented, subdued, and totally rooted out of the navy by the general use of lemon-juice, supplied for the first time at the public expense in the year 1795, and which operated so speedily that in less than two years afterwards it became extinct and has remained so. (Brief Statement of the Improvement of the Health of the Navy, by Sir Gilbert Blane, M. D., London, 1830.) Of all the articles either for medicine or diet he had observed for the cure of scurvy, lemons and oranges are of much the greatest efficacy. They are real specifics, if anything deserves that name; but upon what principle their superior efficacy depends, and in what manner they produce their effect, he acknowledges that he was wholly at a loss to determine, the only sensible effect being a small increase of some of the secretions. In another place he says that he has never seen the scurvy resist the juice of these fruits, and in the perusal of several hundreds of surgeons' journals that he had met with only two cases which seemed to resist it. "It is sui generis—nil simile nec secundum." "It may be affirmed with truth that it performs not only what no other remedy will perform in this disease, but what no known remedy will effect in any known disease whatever." (Medico-Chirurgical Transactions, vol. vi., p. 500. London.)

Dr. Trotter, in his account of the health of the fleet in 1795, remarks, "from the middle of March to the 12th of June, upon comparing notes from the reports of surgeons, it appeared that not less than three thousand cases of scorbutus (the subjects of which were unfit for duty) had been cured on board ship by the fruit or preserved juice, and that twice that number with slighter symptoms were relieved by the fruit, the juice, and salads." (Medicina Nautica, vol. i. p. 134.) Mr. Moffat, surgeon to H.M.S. Triumph, 1796, in which scurvy had prevailed to a considerable extent, reported to Dr. Trotter, "that the scorbutic cases as usual yielded to the lemon-juice in every instance. So general," he adds, "was the tendency to it, that almost every case of contusion or ulceration was attacked with the disease, nor could their cure be accomplished without a few doses of the acid." (Ibid. p. 157.) In p. 151, vol. i. of the Medicina Nautica we find the following entry:—"Jan. 2, 1796. This day the squadron under Rear-admiral Harvey arrived at Spithead, after an absence of eighteen weeks from England, bringing three thousand soldiers from Isle Dieu. This squadron had been repeatedly supplied with refreshments from Plymouth and Cork. The scurvy appeared nevertheless *in all the ships*, but was quickly cured by lemon-juice." In the report of Mr. Kenning, surgeon, of the Invincible, dated June 8, 1795, (Med. Nautica, vol. i. p. 411,) in which ship there had been in all one hundred and sixteen cases of scorbutus, it is stated that of twenty-eight attacked in the month of April, the worst were supplied with three lemons and one orange daily, the others with two lemons, and that *in every instance* after the third day, and sometimes sooner, they began to recover, and were shortly well. In May fifty-six fresh cases were treated with the same remedies with equal success. In the latter end of the month the fruit was all expended, but there still remained a few gallons of lemon-juice, which lasted until the 2d of June. Patients continued to apply, and two of those that had been recovering before the lemons were expended, got worse in the short interval from the 2d to the 5th day, the day on which a fresh supply of lemons was received. Their complaints were soon checked by the *fresh fruit*, but not so fast by the juice, though it was given in some cases to a pint per day." In Lord Bridport's squadron, which (in 1795) had suffered severely from scorbutus, there was not a case in which lemon-juice was given where it did not produce a cure in the space of a few days. (Ibid. vol. i. p. 417.)

Dr. Baird, surgeon of the Hector, a ship in which scorbutus prevailed to a considerable extent, gives the following account: "I began with giving the lemon-juice in the quantity of an ounce and a half daily, and encouraged by the material change I perceived in about four days, I increased it to three or four ounces per day, always taking care to join a sufficient quantity of sugar to prevent it from irritating the bowels; in twelve or fourteen days the worst of them were able to return to duty, every symptom being then removed, except some slight degree of stiffness in the hams, which gradually wore off." "When I consider," he adds, "the alarming progress which the scurvy was making among the Hector's ship's company previous to the administration of lemon-juice as a preventive, the sudden check given to it afterwards and its powerful effect in very bad cases, I think I shall not be accused of presumption when I pronounce it, if properly administered, a most *infallible remedy*, both in the cure and prevention of the disease." (Ibid. vol. i. p. 426.)

Mr. Walker, surgeon of the Hannibal in 1795, writes, "during our late cruise, numbers were afflicted with the disease (scurvy); the citric acid to the quantity of three ounces per day cured many, and always stopped its progress. It was given with wine in the following manner:

℞ Vin. rub. ℥ii.
Succi lim. ℥i.
Sacchari, ʒii. *m.* fiat haustus ter die sumendus." (Ibid. vol. i. p. 407.)

Dr. Trotter himself remarks that the superior efficacy of the acid fruits in the cure of scurvy is so well ascertained, that it might seem superfluous to add any fresh remark to what is so fully admitted. These articles are certainly more beneficial as they approach to the nature of the citric acid, which is that abounding in the lime, lemon, &c. Our summer fruit in this country, such as the apple and gooseberry, lose their acidity as they come to maturity, so that in their immature state they contain most of that principle valued in the cure of scurvy. "In all cases of scurvy," he adds, "which I have attended, I have remarked the longings and desires of the patient for acids, which also have been mentioned by some of the earliest writers on the disease, and more or less by others since that time. It is one of the strongest instincts in nature we are acquainted with.—Having repeatedly observed the scorbutic slaves throw away the ripe guavas, while they devoured the green ones with much earnestness, I resolved to try if there were any difference to be remarked in their effects. For this purpose I selected nine

blacks, affected in nearly a similar degree with scurvy. To three of these I gave limes, to three green guavas, and to three ripe guavas. They were kept under the half-deck, and served by myself twice or thrice a day. They lived in this manner for a week, which was about the time we left the coast of Africa, and it is to be remarked that the three negroes restricted to the ripe guavas continued in much the same situation, while the others were almost well."

Whenever the fresh fruit, i. e. oranges and lemons, can be procured, they should be preferred to their juice prepared by evaporation for sea use according to the methods devised by Dr. Lind, and to the crystallized citric acid obtained according to Scheele's formula by combining the fresh vegetable acid with lime, and then precipitating by means of sulphuric acid. (See Pharm. Lond.) The former by keeping is somewhat liable to spoil, though as stated by Mr. Moffat, a naval surgeon of experience, he found it fully adequate to the purpose of the fresh juices at the end of fifteen months. The crystallized acid, reduced to the strength of lemon-juice by solution in from sixteen to eighteen parts of water, is, however, an excellent substitute for the fresh juice. This solution should not be prepared long before it is required for use, being apt to undergo decomposition, but in its recent state it has proved equally efficacious, according to the testimony of Dr. Trotter and others, with the fruits themselves. (Med. and Physical Journal, vol. iv. p. 154.) Although all the esculent fruits and fresh vegetables have been found effective in the cure of scorbutus, and particularly, as we observed before, those in which an acid principle prevails, it seems impossible to estimate their relative powers in this respect. The vegetable acids which have had trial, viz. the acetic and tartaric, appear to have exerted little if any power over the disease, nor have we any proof that the sulphuric, the nitric, and the muriatic acid, though frequently tried, have been at all beneficial.

Mr. Patterson, a surgeon in the navy, published a treatise in 1794, in which he infers that a solution of nitrate of potassa in vinegar is preferable to lemon or lime-juice as an antidote to scorbutus; its good effects he ascribes entirely to the oxygen contained in the former. At first he used a solution of two ounces of nitre in one quart of the ship's vinegar, and gave half an ounce of the solution, to some twice, to others thrice in the day, and as frequently bathed the local affections with it. From the good effect it produced, which was unattended either by nausea, colic, or diarrhœa, he was induced to increase the dose of the above-mentioned solution to an ounce, and to repeat it as before. At length, instead of two, he dissolved four ounces of nitre in a quart of vinegar, and used it in the same quantities and manner as before. He adds, "some patients cannot bear the solution without the addition of water, whilst others without the least inconvenience bear it undiluted. The discharge by stool, or the presence of gripes and nausea, guide me with respect to increasing or diminishing the dose; but, at the same time, it is not a slight degree of nausea, colic, or diarrhœa that renders an alteration in the quantity of the medicine necessary. To a great number of scorbutic patients eight ounces of this strong solution, containing one ounce of nitre, have, in the course of the day, as long as such a quantity was necessary, been administered to each with the greatest success. Also, a circumstance no less curious than pleasing, large and frequently repeated doses of this medicine have been given in cases of scorbutic dysentery, and instead of increasing I have always found it remove the disease. Sometimes, notwithstanding the free use of the nitric vinegar, I have known constipation take place to a considerable degree, in which case I have found intermediate doses of the potassæ supertartras necessary and highly advantageous. This very constipated state generally occurred where the disease was far advanced; but in a few particular cases in delicate habits, and where the disease was not far advanced, I perceived even small doses of the nitric vinegar ruffle the stomach and intestines; to prevent or remove which, I have found two, three, or four grains of camphor with each dose of the medicine very effectual."

The beneficial effect of the nitrate of potash in scorbutus has been more recently testified by Mr. Charles Cameron, surgeon in the Royal Navy, in a letter, dated December 10, 1829, to the Commissioners for Victualling. The Fergusson, he states, sailed from Ireland on the 16th of December the preceding year, with two hundred and sixteen male prisoners, amongst whom scorbutus, in several instances combined with dysentery, prevailed to a considerable extent. Before reaching Rio Janeiro, their state was such that he had reason to fear he should lose several, and others were fast approaching the same lamentable condition. Having on several occasions experienced the excellent effects of a "solution of nitre," as recommended by Patterson, he was induced to employ it. "From the moment I commenced the use of it," he observes, "many, although almost hopeless cases, began to improve rapidly, and before we accomplished one-third of our voyage, I found the health of the sick improve so fast under the new treatment, that I did not think it necessary to go into any port, and on our arrival at Sydney the general health of the prisoners was much better than when they embarked in Ireland. I am willing," he adds, "to ascribe much of this favourable change to the effect of climate, but I feel assured that a solution of nitre in vinegar or lemon-juice is the best remedy ever proposed in the treatment of scurvy."

Two of the patients who recovered exhibited symptoms of the last stages of phthisis, and expectorated large quantities of purulent matter. With regard to the patients in general, he says, the most distressing symptoms which they complained of in the early stages of the disease were, a sense of oppression and sinking at the pit of the stomach, which a few doses of medicine invariably relieved or totally removed. Mr. Cameron's preparation consisted of eight ounces of nitre dissolved in so much vinegar as made the solution amount to sixty-four ounces. Sometimes equal parts of vinegar and lime-juice were used, a little sugar was generally added to render it more palatable, and about four drops of ol. menth. piperitæ, diffused in a small portion of alcohol, was added to the whole, which rendered it more grate-

ful to the stomach. An ounce of this solution was a dose, and from three to eight doses, according to the stage of the disease and the severity of the symptoms, were given at equal intervals during the day, from six o'clock in the morning till eight at night. Mr. Cameron, at the conclusion of his letter, observes that he has previously tried nitre in several bad cases of scurvy, where neither vinegar nor lemon-juice could be obtained, and, except that sometimes it did not appear to sit so easy on the stomach, with the same beneficial effects.

With the view of restoring the supposed deficiency of oxygen to the scorbutic system, it has been proposed to impart it to the body through the medium of the lungs; but the attempt which was made in cases of the disease as it appeared in the voyage of La Perouse round the world, was wholly unsuccessful.

From the salutary effect in cases of scorbutus produced by vegetable matter in general, peculiar efficacy has been ascribed to particular articles, the use of which accident or analogy from time to time has suggested; it may be that future discoveries will determine their relative title to the estimation in which they may have been held, and the precise principle on which it depends, but the superiority of lemon-juice as an expeditious and certain remedy being well established, other articles of the vegetable kingdom, and the drinks prepared from them, are to be regarded rather as useful auxiliaries, and may be selected from those in popular repute as the inclination or particular habit of the patient may dictate. It will be no inconsiderable advantage also to introduce them to use according to the dietetic form most grateful to the taste, instead of prescribing the nauseating compounds which until the last half century were supposed to possess especial virtues conducive to the removal of this disease.*

[Of late, the antiscorbutic effect of raw potatoes has been frequently deposed to.]

Beer, porter, simple infusion of malt, cider, perry, spruce-beer, various wines made from the subacid fruits, and even pure water, will present useful and agreeable beverages to scorbutic patients. The Lisbon diet drink (decoctum sarsæ compositum) and the compound decoction of guaiacum, have also been found serviceable for the recovery of patients from this disease. Of the dietetic vegetable substances, those which have been commonly preferred and considered to be most especially adapted to the removal of scorbutus, have been the various subacid fruits, and the several herbs used in salads, a form in which with their usual additions, vinegar and mustard, they have been considered especially efficacious. Dr. Trotter, in his Medicina Nautica, has adduced numerous instances of their efficacy, and the popular favour they elicited serves to corroborate the opinion entertained of them by professional writers for this particular purpose.

Another agreeable method of supplying the system with vegetable aliment, and which has been advantageously adopted in scorbutus, has been the combination of it with fresh animal matter through the medium of broths and soups, as well as in the ordinary forms in which they are commonly prepared for dinner use. Lind states that milk is useful to scorbutic patients, with whom it generally agrees, but that whey, "by reason of its more diuretic and cleansing quality, is preferable."

"Thus," says the last-mentioned writer, "we have numberless instances of people after long voyages, miraculously, as it were, recovered from deplorable scurvies without the assistance of many medicines, for which, indeed, there is no great occasion, provided the green herbage and fresh broths keep the belly lax, and pass freely by urine, sweat, or perspiration."

Since scorbutus has become a very rare disease, the materia medica has been enriched by the addition of some valuable articles, the general properties of which suggest their adaptation to the purposes of its treatment; these are the chlorides of lime and soda, and the sulphate of quinine. At sea, the chloride of lime will doubtless be advantageously applied to the preservation of water and to the correction of such as may be putrescent, to the prevention of unwholesome exhalations, and to the general purification of the air. Solutions of it as gargarisms and lotions for ulcers give promise of considerable advantage, and from the little experience already had of its internal use, encouragement is given to its further trial. Dr. Robertson informs us that he has used the chloride of soda in one instance—with the benefit he anticipated. (See Dublin Hospital Reports, vol. v. 1830.) With some other remarks with which he has been so kind as to favour us on this disease, he observes,—"I had occasion, in the year 1831, to see a case resembling scurvy in all its phenomena, (indeed, had it occurred in a seafaring person instead of a person living in a midland county, I should have pronounced it a well-marked case of that complaint,) where the liquor chloridis sodæ, given in doses of half a drachm in conjunction with the decoctum lichenis Islandici, had a strikingly beneficial effect. The patient was speedily brought by it from a state of cachexia threatening death to a very tolerable degree of health and enjoyment. Were it ever my fortune to treat scurvy extensively again," he adds, "I should trust chiefly to quinine or the chloride of soda internally, and to the chloride of lime properly diluted as a topical application; with, of course, a liberal supply of vegetable matter where it could be obtained."

The costive state of the bowels which occasionally prevails to an extreme degree must be counteracted by aperient medicines, or, if need be, by the stronger purgatives. In many instances the advantage derived from the operation on the alvine canal of a single dose has led to their frequent repetition, and the most beneficial results have ensued. Lind was favourable to the combination of medicines of this class with diuretics, or to the

* "A vegetable substance called *nopal*, the stalk of the cactus opuntia, which keeps well at sea, has been lately discovered in India to be an extremely salutary article of diet, and to resist scurvy: but the author read in the surgeon's journal of one of the East India Company's ships, that in spite of the use of this and of spruce-beer at the same time, sixteen cases of scurvy arose, in one of which it was so severe as to prove fatal."—Paper by Sir Gilbert Blane, on the Health of the Navy; Medico-Chir. Tr. vol. vi. p. 501.

use of such as embraced the twofold property. Selections have accordingly been made from the supertartrate, acetate, and sulphate of potash, the tartrate and sulphate of soda, and the sulphate of magnesia, dissolved in the infusion of senna, of tamarinds, or of prunes, with the addition of some aromatic tincture, and further combined if requisite with jalap, rhubarb, aloes, scammony, colocynth, or some of their preparations.

The complication of inflammatory disease with scorbutus in constitutions naturally robust and not much debilitated, will sometimes require venesection and the general adoption of the antiphlogistic treatment, according to the nature and degree of the supervening disease; but diarrhœa, dysentery, pneumonia, and other morbid conditions which have been coexistent with it, have not unfrequently resisted modes of treatment peculiar to them, and have disappeared together with scorbutus when the remedies appropriate to the latter disease have been had recourse to.

In reference to the concurrence of scorbutus and dysentery, Dr. Trotter observed that they frequently disappeared together, and readily yielded to a diet of fresh meat, citric acid, and esculent vegetables; without requiring any of those remedies more particularly adapted to the last-mentioned disease, as it occurred under other circumstances. (Med. Nautica, vol. i. p. 377.) The same remark has been illustrated by Sir James M'Gregor, in his reference to a case of severe ophthalmia, which appeared conjointly with slight symptoms of scorbutus where the latter disease was endemic. It resisted a variety of applications, both external and internal, for five months, when the acid of limes was thought of, which in twelve days effected a cure. (Edin. Med. and Surg. Journ. vol. i. p. 283. 1805.)

In some cases of apparent phthisis accompanying scorbutus, we find in the observations of Mr. Cameron, already cited, that the disappearance of both forms of disease was evidently effected by the remedies appropriated to the removal of scorbutus alone.

It has been commonly observed, that however promising and speedy recovery from scorbutus may be, to prevent its recurrence it is necessary for a considerable time to persevere in the counteracting regimen, and to avoid as much as possible the predisposing and occasional cause of the disease. When fresh vegetables can be procured, and the object is not to cure, but to guard against a relapse, the use of acids will be advantageously suspended. Practical authorities have expressed opposite opinions as to the general effect on the constitution of their continued use, but on the whole there is good reason to believe that, when long continued, they have produced injurious effects on the digestive organs.

Great care should be taken that scorbutic patients be not too suddenly exposed to an atmosphere differing in its temperature or other qualities (except in point of dryness) from that which they have breathed for some time previously. Any sudden exertion should also be avoided, for numerous instances might be adduced in which inattention to these particulars has been immediately followed by death, in cases in which it was not in the least to be expected. We read in the narrative of Lord Anson's voyage, that in the removal of his crew from the Centurion to the island of Juan Fernandez, twelve of them died on being exposed to the fresh air; and on the first breaking out of the disease many of the people, though confined to their hammocks, were cheerful, talked in a loud strong tone of voice, and eat and drank heartily, but on being only moved in their hammocks from one part of the ship to another immediately expired. Others, trusting to their seeming strength, resolved to get out of their hammocks, but died before they could reach the deck, and it was common to see the men drop down dead upon a violent effort of duty.

The local affections which are manifested in scorbutus are often extremely distressing, but, it must be remembered, are always secondary to the constitutional disorder, increasing in malignancy with its progress, and manifesting a contrary disposition whenever a salutary change has been effected in it: this correspondence, too, takes place with an almost incredible degree of rapidity, and such as is rarely, if ever, exemplified under any other circumstances of disease. The constitutional disorder, therefore, should be the first object of regard in the cure of every local lesion which depends on scorbutus: a contrary procedure only can account for the numerous and complicated formulæ which are to be found in the early treatises upon it, all of which, it may be inferred from accumulated experience, will be nugatory whilst their immediate cause is allowed to continue uncorrected. Local applications, however, with the contemporaneous use of constitutional remedies, are not unproductive of advantage. To relieve the spongy and rotten state of the gums and of the mucous parietes of the mouth and pharynx, astringent gargles, particularly those containing sulphate of alum, have been found very serviceable. Two drachms of this substance, or more, may be dissolved in half a pint of water or of a decoction of cinchona for the purpose. Lind recommends also the tincture of cinchona, which may be used alone, or mixed with port wine or camphor mixture. The tinctures and other preparations of myrrh, of kino, of catechu, may likewise be selected from the class of astringents for the same purpose, and will be advantageously diluted with water or with camphor mixture, to be sweetened and inspissated with honey. In the advanced stages, the mineral acids have been found more efficacious; water, barley-water, the infusion of roses, or other vegetable substances acidulated with the sulphuric or muriatic acids, and made agreeable with the addition of honey or simple syrup, will form convenient gargles. "The quantity of the acid," says Lind, "must be proportioned to the greater or less degree of putrefaction. The fungus must be often removed, or if needful be cut away; and by frequent gargarizing the mouth kept as clean as possible. Where the ulcers appear deep and spreading, they are to be checked with a touch of *vitriol*, or *sp. salis*, either by itself, or diluted according as the patient bears it." Analogical reasoning leads us to infer that a solution of chloride of lime is peculiarly adapted to the purposes of this disease, whether in the form of gargle for the mouth, or as an immediate application to ulcers in other parts. To the latter the

astringent applications already mentioned as useful in the corresponding condition of the mouth and gums have been advantageously employed. "Sulphate of alum, in the proportion of two drachms to a quart of water," says the experienced and talented writer of the Medical Topography of New Orleans, Dr. Robertson, of Northampton, (Edin. Med. and Surg. Journal, vol. xii. p. 146,) in his observations on 'the Sloughing Scorbutic Ulcer,' as it appeared extensively in that place, "was upon the whole an admirable local remedy, and seemed to possess wonderful powers in stopping the ravages of sphacelus, and giving a healing tendency to spreading ulcers. In the same cases equal parts of basilicon and oil of turpentine (melted and applied warm to the ulcer), mixtures of lime-juice, or rum and water, charcoal cataplasms, common poultices, bark decoctions, and bark in powder, were employed; but though they kept the sores cleaner, they were often of no avail to arrest the sloughing process." Several of the early writers, and Lind amongst the number, particularize the unguentum *Ægyptiacum** as adapted to the ulcerations of this disease. Mr. Murray, a naval surgeon, in a communication to Dr. Lind, observes, "I have applied a strong tincture of bark lately to scorbutic ulcers, and have found it highly beneficial. The powder of the hydrargyri nitrico-oxydi sprinkled on the fungoid ulcerations, and the ointment of this substance, after the sloughs have been removed and the ulcers cleansed by carrot and other detergent poultices, have also been of some use; but no permanent benefit is to be anticipated from any other treatment than a diet of nutritious food of which fresh vegetables constitute a considerable proportion, the efficacy of which will be materially augmented by including amongst them the acid fruits or their juices, such as lemons, limes, shaddocks, apples, pears, gooseberries, &c. whilst at the same time the patient is secured from the influence of the predisposing and occasional causes of the disease." The latter remarks apply also to the œdematous swellings of the legs and the rigidity of the hamstrings, for which local relief also is often demanded. Frictions with warm flannels, (which for this purpose were formerly medicated with the fumes of benzoin, amber, and warm aromatic gums,) have answered this end, and have been advantageously followed up by gentle compression with bandages. But in extreme cases, warm fomentations, local steam-baths, or, as Lind has recommended, sweating the limb "by burning of spirits," (the local vapour-bath of the present day,) with some of the various other contrivances in common use for the promotion of heat locally, are better calculated to afford relief.

An important part of our duty would be unperformed were we to limit ourselves to the detail of those means by which scorbutus has been successfully treated, for we know not what additional light may be reflected on the obscure parts of this subject by a knowledge of such as have been found unsuccessful. The cost of the experience, too, by which it has been gained forbids its waste, and in practical medicine it must be acknowledged that a beacon is often of not less use than a guide. In the first place, "it is to be observed," says Lind, (page 216,) "that this disease, especially when advanced, by no means bears bleeding, even although the most acute pains upon the membranes, a high degree of fever, and dangerous hemorrhages would seem to indicate it. The patient generally dies soon after the operation. Nor does it bear strong cathartics, which are often injudiciously administered in its commencement. From blisters there is danger of a gangrene. As to vomits, though I have never had any great experience of their effects, yet by the observation of others squill vomits have been found serviceable. 2dly. Persons in the advanced stages of this disease are not, without great caution and prudence, to be exposed to a sudden change of air. On such an occasion they are to be given a glass of generous wine well acidulated with lemon or orange-juice, which is likewise the best cordial in their fainting fits. The sloth and inactivity belonging to the disease are not to be mistaken for wilful idleness. This," continues Lind, "has proved fatal to many, some of whom, when obliged by their officers to climb up the shrouds have been seen to expire and fall from the top of the mast. 3dly. After a long abstinence from green vegetables and fruits, scorbutic persons should be treated like those nearly starved to death; that is, not permitted for a few days to eat voraciously, or surfeit themselves; otherwise they are apt to fall into a dysentery which often proves fatal.

"Lastly, medicines of the fossil or mineral kind, such as steel, antimony, and especially mercury,† do manifest harm. Opiates occasion an unaccountable depression of spirits, with a sense of oppression on the chest, and when absolutely necessary, as in fluxes, should be of the warmest kind," (i. e. we presume combined with aromatics and cordials.)

W. Kerr.

SCROFULA.—The term scrofula is derived from the Latin *scrofa*, a hog; and χοιρας, the corresponding word in Greek, plainly acknowledges a similar origin, (χοιρος, a pig:) but whether this etymology has arisen from the filthy condition in which scrofulous children are often found, or from the hog being subject to a similar disease, or from the appearance presented by scrofulous glands lying in clusters under the skin, or from the tumid throat and neck of such subjects, is not so easy to determine and seems of small importance to inquire. It is sufficiently evident, however, that a strong association existed in the minds of the Greeks and Romans between scrofula and the animal in question. Another term by which this malady has been designated is struma. Celsus very distinctly describes the disease as it affects the absorbent glands under this name; and adds that it occurs also in the female breast. Among

* Gray, in his Supplement to the Pharmacopœias, gives the following as the formula for this ointment:—Rough verdigris ppd. v. oz. honey xiv. oz. vinegar vii. oz.; boil to a proper consistence.

† Sir Gilbert Blane stated to the select committee of the House of Commons appointed to inquire into the state of the Penitentiary at Milbank in 1823, that if he had found, when he was in office as commissioner, a navy surgeon who by his journal had administered a particle of this medicine in the treatment of sea scurvy, he should have felt it his duty to move that such surgeon be struck off the list.—Edin. Med. and Surg. Journ. vol. xxii. p. 142.

modern nations the French have named the disease *les écronelles*,* probably a corruption of *scrophules*; the Germans *der Kropf*, from the swelling under the chin; and the English the king's evil. This last term commemorates the imaginary virtues of the royal touch, to which, from the time of Edward the Confessor till the reign of Queen Anne, multitudes of cases of scrofula were submitted, and very many of them were supposed to have been cured. A similar practice existed in France, with equal belief in its success; and miraculous powers for the cure of scrofula were likewise claimed for different Romish saints, for the heads of certain noble families, for the seventh son, and for many consecrated springs in different parts of Christendom.

It may be truly asserted that no original temperament, complexion, or frame of body, confers complete immunity from scrofula; yet a little observation will convince us that individuals possessing certain characteristics are more frequently the subjects of this malady than others. The scrofulous constitution is often indicated by a fair complexion, light silky hair, long shining eyelashes, large, watery, and often blue eyes, with dilated pupils, and a red patch on either cheek, contrasted with a dazzling whiteness of the skin, which is itself usually thin, smooth, and readily irritated by slight causes. Thus scrofulous individuals are more liable to chilblains, which appear often on their hands; and in such persons the application of a blister is generally followed by an eruption of pustules on the skin around, and the formation of successive crusts. The insertion of a seton, the wounds of leeches, and even simple venesection sometimes produce the same effect: so great, indeed, have we known the irritability of the skin in scrofulous children, that washing with scented soap has caused the immediate appearance of a papular eruption. Scrofulous persons often present the look of florid health and a full habit; but the soft parts are flabby, and easily shrink away under fatigue, privation, or disease; and when the operation of these causes is completely at an end, such individuals are restored with the same rapidity to their former plethoric condition. The scrofulous habit is, in short, characterized by a deficiency of what has been termed *stamina*, and enduring tone. Children who possess this constitution are familiarly known as feverish children; a very slight irregularity of diet or exposure to cold or moisture throwing them immediately into a state of febrile excitement. Their frames possess an undue proportion of irritability, and they are peculiarly prone to attacks of inflammation. The mucous membranes of the scrofulous, like the external integument, are also delicate, and their vessels readily give way and pour out blood: thus bleeding from the nose is a common occurrence in persons of this constitution; and in them hemorrhage is more frequent from the urinary passages and ramifications of the windpipe. The conjunctiva in scrofulous individuals is very liable to inflammation, and the mucous membrane of the intestines is readily irritated and diarrhœa induced. In such subjects the mucous secretions are very abundant and often acrid, and the membranes themselves frequently become thickened: hence arise excoriations of the nostrils and of the upper lip, which becomes in consequence chapped and swollen; and the half-open mouth is a common characteristic of scrofulous persons, owing to the partially obstructed state of the nasal passages. Most scrofulous persons are of small stature, and have slender limbs; nor is it very uncommon in such individuals to find some member or organ imperfectly developed, defective in its power, or curtailed of its proportion: yet multitudes of scrofulous persons are met with of a very different description—individuals remarkable some for their lofty stature and apparent strength, and others for the surpassing symmetry and beauty of their persons.

The moral and intellectual qualities of the above, which is the largest class of scrofulous subjects, correspond with, and in all probability are derived from those of their bodies: the temper is quick and irritable; the desires and passions are ardent; the perception is keen, the imagination is predominant over the judgment; and the mind is characterized by a want of firmness and solidity, and an inability to persevere steadily in the pursuit of any one object. To this observation, however, there are many brilliant exceptions, where the strumous constitution is seen combined with mental qualities of the highest order.

In a second class of persons who are disposed to scrofulous disease, the complexion is dark, the skin harsh, and the habit indolent; the countenance is swollen and pasty, and all the functions of the body are sluggish and imperfect: the nervous energy is feeble, the feelings are obtuse, and the moral and intellectual powers occupy a very low rank. Scrofulous cases of this character are not by any means uncommon in Britain, although far more rare than those first described; but extreme instances are frequent in some districts of Switzerland and France; and in these human nature appears reduced almost to the level of the brute creation, assuming forms which awaken feelings of humiliation and disgust. Scrofula, which is always tedious and difficult of cure, becomes still more obstinate and unmanageable when it makes its appearance in those of a dark complexion and sluggish temperament.

[The writer's experience leads him to say, that scrofulosis occurs quite as frequently in the dark complexioned. The negroes of the south are very subject to it, and in its most severe forms. (Guersant, art. *Scrofule*, in *Dict. de Méd.* 2de édit. xxviii. 207. Paris, 1844.)]

This disease exhibits itself under a great variety of symptoms, according to the part of the body which it happens to affect: hence the difficulty of framing any definition of it which is at once accurate and comprehensive.

The most certain evidence of the existence of scrofulous disorder is afforded by the production of a soft, brittle, unorganized matter, resembling curd or new cheese, which is found mixed with the purulent contents of scrofulous abscesses, or deposited in rounded masses of different degrees of firmness, and varying in bulk from the size of a millet-seed to that of a hen's egg: sometimes it is contained within the natural cavities and canals

* In some parts of Scotland the disease is called by the common people "*the cruels*;" an evident corruption of the French word.

of the body, sometimes it is enclosed in cysts, and occasionally it is diffused, as if by infiltration, through the natural texture of a part. To the rounded masses of this substance, which, as they enlarge, often acquire the irregular form of a tube ous root, the name of *tubercle* has been assigned, and the substance itself has been named *tuberculous matter*. We venture to assert that the presence of tuberculous matter is a satisfactory proof of the existence of scrofula; but we do not by any means maintain that scrofula cannot exist without the deposition of this substance. The researches of pathological anatomy have satisfactorily shown that scarcely any living texture of the human body is altogether exempted from tuberculous deposits. This morbid production has been observed on the free unbroken surfaces of mucous membranes, within mucous follicles, and forming the contents of lymphatic vessels the tunics of which were themselves sound, (*Andral*, Précis d'Anat. Patholog. tom. i. p. 419, and tom. ii. p. 446): granules of tuberculous matter, sometimes insulated, sometimes clustered together, have also been detected within the clots of blood contained in the cells of the spleen. (*Andral*, op. cit. tom. ii. p. 431. Carswell's Illustrations, &c. Fascic. 1, plate iii.) The history of tubercle certainly entitles us to consider it as a morbid secretion; but when it is thus found lying free within a healthy lymphatic vessel, or enveloped in the coagula of the splenic cells, we are led to suspect that in such cases it has probably been formed by some change in the constitution of the lymph or blood, from an alteration in the proportions of their ingredients, or the addition of some coagulative substance, or the withdrawal of something which these fluids usually contain. The cellular tissue has been hitherto considered as of all others the most common seat of tubercle; but Dr. Carswell has stated that it is far more frequently met with in contact with mucous surfaces; and he has certainly adduced very strong arguments in support of this opinion, which he has also illustrated by most beautiful engravings. (See Fascic. 1.)

For a particular history of this substance in its etiological, pathological, and chemical relations, we must refer the reader to the articles Tubercle and Tubercular Phthisis, and content ourselves, in this place, with noticing such circumstances as have more especial reference to the subject of the present article.

According to Dupuy, (De l'Affection tuberculeuse,) all the domestic animals of France, not excepting the dog, as well as those imported from warmer countries, are subject to tuberculous deposits: his researches further show that this disease in the inferior animals is much more frequently combined with the presence of vesicular worms than it is in man. He has traced the conversion of the cysts containing these animals into collections of tuberculous matter, and has thus given a degree of support to the opinions of Dr. Baron, who maintains that all tuberculous disease originates from vesicular worms or minute serous cysts. But although we admit that such adventitious cavities often become, at least in the inferior animals, the nests in which the matter of tubercle is deposited, the assertion that all tubercles arise in this manner may well be disputed when we find that such cysts or vesicular worms, or traces of them, are by no means always co-existent with tuberculous disease, and that they often attain a very great magnitude without exhibiting any symptoms even of incipient transformation.

Opinions directly opposed to each other have been held by writers of great eminence as to the immediate cause of tubercles; one party ascribing their origin in every case to inflammation, (*Broussais*, Examen des Doctrines Médicales, tom. i. *Alison*, Edin. Med. Chir. Trans. vol. i. and iii.); another as exclusively asserting that they are in no instance dependent on inflammatory action, and that when inflammation co-exists, it does so as the consequence, and not the cause, of tubercles.* After carefully reviewing the discussions on this question, we have come to the conclusion, that on some occasions tubercles have been found where no symptom of previous inflammation could be recollected, nor any trace of it discovered on inspection after death, (*Andral*, Précis d'Anat. Pathologique. *Lombard*, Essai sur les Tubercules); while in other instances the deposition of tuberculous substance seems to have been distinctly connected with the development of inflammatory action. But as inflammation often occurs without the formation of tubercles, it is obvious that this alone is not sufficient for their production, and that the addition of something else is required to that end. Inflammation, therefore, may be viewed as an occasional cause of tubercles, producing this effect only in frames of a scrofulous disposition.

Some organs are more liable to tuberculous deposits than others, and the liability differs at different periods of life: the organs which are most frequently affected with tubercles in children are not those in which they are oftenest met with in adults. In children the disease tends more to implicate several organs at once; and in them it is more common to find the lungs unaffected, although tubercles be discovered in other parts of the body. (*Lombard*, op. cit.) The existence of tubercles in the fœtus is certainly rare, but it has been proved beyond question by the dissections of Langstaffe, (Lloyd on Scrofula,) Lombard, West, Orfila, (*Velpeau*, Thesis ad aggreg. p. 10,) and Chaussier, (Procès verbal de l'Hospice de la Maternité, 1812, p. 62): they continue infrequent from birth till two years, after which they are often met with; and during the fifth year their occurrence appears to be much more common than at any period before puberty. From eighteen till forty, tubercles very frequently occur; affecting, however, chiefly the lungs, intestines, and some parts of the lymphatic system.

* *G. L. Bayle*, Recherches sur la Phthisie.—*Laennec*, Auscult. Médiate.—*Gendrin*, Hist. Anatom des Inflammat.—*Lobstein*, Anat. Patholog. tom. i. This able advocate of these opinions admits the production of what he terms miliary granulations on the surfaces of inflamed serous and mucous membranes, but denies their identity with tubercles. In this manner he endeavours to set aside the arguments drawn from such cases as those of Dr. Alison, and also the results of the experiments of Cruveilhier and others, who produced the appearance of myriads of small tubercles by injecting mercury into the bloodvessels and lungs of animals; each minute globule being found enclosed within an effusion of tuberculous-like matter. These experiments we have always considered as any thing but conclusive: for where is the evidence that the effused matter is truly tuberculous?

These results are drawn from the researches of pathological anatomy; but to speak merely from symptoms, independent of the verifications of dissection, scrofula has been observed by us in the form of enlarged axillary glands within the first fortnight after birth: it is not usual, however, for the absorbent glands to be affected till the period of the first dentition; the occurrence is still more frequent during the second. At puberty the disease often disappears spontaneously, and after this age external scrofula is very rarely observed to originate; but instances are not wanting in which persons well advanced in life have been attacked for the first time by scrofula, more especially among those who have been long confined in prisons or workhouses. To show the various ages at which the disease may develop itself, Lalouette (Traité des Scrophules, Paris, 1780) states that in a scrofulous family one daughter was affected at fourteen, another at sixteen, a third at twenty-six, and the father at sixty-six. Cases have occurred to the writer where scrofula has appeared in youth, undergone an apparent cure, and again manifested itself in advanced life, when it proved fatal.

In former times it was believed that scrofula was communicable from one individual to another; and the occurrence of the disease in many members of the same family, and its diffusion among the inhabitants of particular districts, seemed, through a loose mode of reasoning, to afford ground for this opinion. Positive experiments have been made by Kortum, (De Vitio Scrofuloso. Lemgov. 1798,) Goodlad, (On the Lymphatic System,) Hebreard, (Dissertat. sur les Tumeurs Scrofuleuses,) Le Pelletier, (Sur la Maladie Scrofuleuse, p. 16,) and others, to propagate the disease by rubbing in scrofulous matter, and by inserting it under the skin of animals, and even of the human subject; while Pinel, Alibert, and Richerand, (Nosograph. Chirurg. tom. i. p. 161,) have carefully watched the effects of allowing scrofulous and healthy children to associate together without restraint; but in no instance was there the least reason for believing the malady to be communicable by any of these modes of infection. The observation of British practitioners fully corroborates the opinion of the non-contagious nature of scrofula, although the writers of this country have not directed so much attention to the subject; because a belief in the contagion of scrofula was abandoned by our physicians long before it ceased to be current among those of the continent.

In this respect scrofula differs remarkably from that form of tuberculous disease in animals which has been named glanders: for this last is not only communicable from one animal to another, but also to man.* It would be curious to inquire whether glanders in man is itself communicable to other human beings: that it is so is by no means improbable, for it has been proved by expement to be capable of being communicated from man to the inferior animals. (*Coleman*, in Travers on Constitutional irritation.) It is proper here to state that M. Dupuy has expressed strong doubts of the contagious nature of glanders, and has asserted that he knows of no well-conducted experiment in favour of this doctrine, but some against it. He is disposed, on the contrary, to refer glanders to hereditary transmission, and to various unfavourable circumstances in the rearing of horses, similar or analogous to those which are admitted as predisposing to scrofula, such as cold, damp, and shady pastures, insufficient nourishment, and the debilitating effects of castration. (De l'Affection Tuberculeuse.)

Daily observation must convince us that a scrofulous constitution is often transmitted from parent to child; therefore the disposition to the disease may be truly said to be hereditary; nay, the dissections already referred to prove the actual development of scrofula even before birth, in the progeny of a strumous mother. Like other hereditary gifts, it may miss one generation and reappear in the succeeding; just as some individuals are observed to resemble in external appearance their grandfathers more than their fathers.

A striking example of the hereditary nature of scrofula was lately presented to the writer by a family respecting whom he was consulted. The father was a tall, thin, and sickly man, who suffered much every year from winter cough; the mother a person of full relaxed habit, with a look of florid health, and in fact not often affected with illness. Of nine children to whom she had given birth, two females and six males had died with phthisical or mesenteric symptoms, between the ages of three and fifteen months; the survivor was a boy nearly twelve years old, who enjoyed moderately good health. The last of these little victims of transmitted disease died just as he had completed his third month, after having suffered under symptoms of phthisis. On inspecting the body, the lungs were seen mottled with many yellow spots, and when cut into they exhibited myriads of tubercles, varying from the size of a small mustard-seed to that of a pea: all of them were opaque, and many converted into pus. The glands at the root of the lungs were enlarged, indurated, and some of them converted into abscesses, the walls of which were lined with firmly adherent fibrin, and their contents were a thick purulent fluid. The mesenteric glands were enlarged, hardened, and many of them contained softened tuberculous matter. The spleen contained some small granules of a white colour and cheesy consistence. There was a good deal of subcutaneous fat, but none in the omentum. A very few weeks after the death of this child, the father, who had been eager to learn whether his offspring drew their fatal disease from himself or from their mother, declined rapidly in strength, and fell a victim to phthisis.

Scrofula is supposed by most writers to be of more frequent occurrence among females than males; and Le Pelletier (Sur la Maladie Scrofuleuse,) has stated, as the result of a comparison of the cases in the Parisian hospitals, that the proportion of strumous females to males is as five to three. In all inquiries into the relative prevalence of disease in the two sexes, it must be recollected that the female population, especially of large towns, considerably exceeds the male; and

* *Elliotson*, in Lond. Med. Chir. Trans. vol. xvi. p. 171. *Travers*, On Constitut. Irritat. 2d edit. p. 398. *Schilling and Weiss*, in Rust's Magazin. fur die gesammte Heilkunde, 1821. Also *Remer*, in Hufeland's Journal, March 1822.

hence it is to be expected that a great number of scrofulous females will apply for medical relief. But on reviewing the matter carefully, and referring to an examination of hospital patients made for another purpose, we are convinced that the disease is really more frequent in the female sex. Dr. Cullen was of opinion that scrofula was oftener transmitted from the father than the mother, which he conjectured might arise from the circumstance that more scrofulous men than women enter the married state; but he has nowhere explicitly asserted that males are more liable to the disease than females. (First Lines. *Scrofula.*)

We proceed now to pass briefly in review the various parts and organs of the human body in which scrofula most commonly appears, and to point out the modifications of this disease induced by the different properties and textures of the parts affected.

The first which presents itself is the common integument; and here several forms of cutaneous disease are distinctly referable to the class of scrofulous affections. The three species of porrigo named favosa, larvalis, and furfurans, together with eczema impetiginodes and rubrum in their chronic forms, may be fairly enumerated among strumous diseases; at least if we are entitled to draw any inference from the facts that these eruptions are found in combination with the generally admitted symptoms of scrofula, and are as often benefited by anti-strumous remedies as the symptoms just mentioned are usually observed to be. Eruptions of this description, when they affect the scalp, ears, and face, are very apt to occasion swelling of the glands at the back part of the head, on the sides of the neck, and under the jaw; at first from simple irritation, or perhaps the absorption of morbid fluids; afterwards, the swelling becomes permanent, from the deposition of tuberculous matter. Other causes of an irritating or inflammatory kind, as dentition and exposure to cold, are known to produce such glandular tumours, terminating like the others, where the habit is strumous, in the deposition of the same curdy substance. Thus we have a second order of parts more deeply seated than the skin affected with scrofula, often from the causes stated above, and sometimes, it would seem, spontaneously. The absorbent glands, indeed, are the parts of the body which have long been regarded as the peculiar seats of scrofula, and their enlargement and induration are still considered as affording more unequivocal evidence in the living body of the presence of that disease than any other circumstance except the discharge of tuberculous matter. A lymphatic gland, when first affected with scrofula, is soft and fleshy, and its size is increased; the texture, as proved by inspection, then becomes firmer, and the colour paler than in health: as the disease proceeds, portions of the gland are observed to have altogether lost their flesh-colour, and acquired a degree of semi-transparency, and a texture approaching to that of cartilage; at length a deposition of soft white or yellowish curd-like substance is found to have taken place, and the true scrofulous tubercle is now manifest. (*Abercrombie*, Edinb. Medico-Chir. Trans. vol. i. p. 683.)

The size to which strumous glandular tumours attain is in some instances enormous. The lower jaw and upper part of the neck are occasionally seen hung round with such voluminous swellings as completely to deform the countenance; and we have seen, in the case of a strumous middle-aged male, both groins occupied by vast glandular tumours, the larger of which equalled in size the half of a child's head at birth. These inguinal swellings were firm, nodulated, and without pain; they had commenced only six months before as clusters of hard kernels, which by degrees enlarged and coalesced into the enormous morbid masses now described. It has been stated by a very able and accurate observer that scrofulous glands always possess a higher temperature than the healthy parts in the vicinity; but the trials which we have made, and they were often repeated, did not detect any greater heat in such swellings, unless when they were actually inflamed.

Scrofulous glands are commonly supposed to be obstructed and impervious to the fluids which are naturally transmitted through them, but it is certain that they are in many instances capable of being injected with mercury from the intrant lymphatic, (*Soëmmering*, De Vasis Absorbentibus, sect. 37, p. 90); and hence we may infer that, though partially changed, some portion of them may still give passage to their proper fluids.

Scrofulous tumours do not uniformly originate from the degeneration of lymphatic glands, but arise in many cases from the deposition of tuberculous substance in the subcutaneous cellular tissue, in different parts of the body, quite independent of any absorbent gland: their resemblance, however, to glandular swellings is such as to deceive the inexperienced; nay, they were named even by Wiseman, the first surgeon of his day, *adventitious glands*. When these scrofulous tumours are cut into, they are found to be composed of cysts varying in size and density, usually lined with a fibrinous exudation, and filled with tuberculous substance, sometimes crude, at others softened, or converted into curdy pus.

Absorbent glands affected with scrofula, and cysts of tuberculous matter in the cellular tissue, may remain for a long time without exciting any irritation; but their tendency is to become soft by the secretion of purulent fluid from the internal surface of the cavity, which is soon followed by inflammation of the integuments. Ulceration succeeds, and the morbid contents are discharged from the body, sometimes by one, at others by many small apertures: but a cure does not follow; either fistulous openings remain, discharging a thin glutinous fluid mixed from time to time with curdy particles, or an indolent ulcer succeeds, or both may result from the expulsion of tuberculous matter. The contents of scrofulous glands and tumours on the surface of the body occasionally undergo the cretaceous transformation; after remaining long indolent, suppuration at last takes place, and masses of earthy substance, sometimes of considerable bulk, are extracted from their cavities. On macerating these calculous concretions in water, we have found them to separate readily into a multitude of gritty particles like dried mortar. In some instances, strumous glands are converted into prominent spongy tumours of a

red colour, and covered by a silky cuticle, which frequently breaks, and gives issue to small superficial collections of purulent matter.

Scrofulous ulcers are characterized by their flabby and often pale granulations, and the thin unhealthy integument which usually overlaps their margins. This undermined skin is of a purplish or livid hue; showing the languor of its capillary circulation, and its proneness to be destroyed by gangrenous erosion. Such ulcers, though usually productive of little uneasiness, sometimes become exceedingly irritable and painful, requiring the employment of powerful narcotics to give relief to the patient. The thin discharge which scrofulous sores yield often concretes upon their edges into straw-coloured crusts, under which the ulcer, if small, sometimes heals. Scrofulous cicatrices possess a peculiar wrinkled and puckered appearance, with small portions of projecting skin, and even complete bridges admitting a probe to pass beneath them; features by which their real origin, long after a cure, may be readily discovered. These appearances of scrofulous scars seem to be produced by the great attenuation and irregular destruction of the integument, and the slow and interrupted mode in which such ulcers heal; and they may always be in a great measure prevented by careful and judicious surgical treatment. When scrofulous cicatrices are cut into and examined after death, the affected glands are found wasted away, no vestige of them being left excepting a few bands of condensed cellular tissue attached to the cicatrized integument. The healing of a scrofulous ulcer is often followed by the advance of other tumours to suppuration, or perhaps the formation of new ones in some adjoining or distant part of the body. Thus one train of evils succeeds another, till the constitution of the patient begins to yield to the debilitating effects of the irritation and discharge, or the disease fastens on some organ of greater importance in the economy, and life is at length destroyed by hectic fever, colliquative perspirations, and diarrhœa.

Another form in which scrofula sometimes attacks the integument is that of lupus, the usual seats of which are the lips and nose; but we have also seen it affecting the genitals. Scrofulous lupus commences by the appearance of small red button-like prominences, which usually remain indolent for some time, then become excoriated and form eroding ulcers, with pale shining spongy granulations and encrusted margins; or, perhaps, the work of destruction goes on under a thick incrustation, which drops off from time to time, to show the ravages which have been committed. The progress of the disease is sometimes hastened by the formation of sloughs, especially when the parts are cartilaginous; and in this way perforations are made into the nostrils, and sinuses scooped out within the thickness of the lips. In lupus of a well-marked scrofulous character, the face usually becomes swollen and raised into pallid flabby prominences, which deform the countenance, and give to it a very sickly and disgusting aspect. See the article Noli me Tangere.

Scrofulous individuals are subject to the formation of large chronic abscesses, which sometimes arise with great rapidity, as if from a sudden deposition of fluid rather than as the consequence of regular suppuration. The usual seat of such abscesses is in the cellular tissue connecting the large muscles, or within their sheaths, and under fasciæ; and their contents are at first a serous effusion, afterwards sero-purulent fluid, with curdy flakes; and more rarely a thin pus. In such cases, sloughing of the cellular tissue is not uncommon; spongy masses of it, like wet tow, coming away along with the discharge, or plugging up the lancet puncture. These abscesses are named by French writers *abcès froid* and *abcès par congestion*; and their origin is usually the irritation of some diseased joint or bone in their immediate vicinity. It does not appear that abscesses of this description result from the softening of tuberculous matter previously deposited, but that the curdy flakes are thrown out from the internal surface of the abscess during the formation of its more fluid contents.

The lymphatic system has been generally considered as the primary, and by some the only seat of scrofula; and in all treatises on the diseases of the absorbent vessels, this malady occupies a prominent station. In almost every case of advanced scrofulous disease of the mesenteric glands, the lacteals connected with them will be found affected, and more or less filled with tuberculous matter; but the absorbents in other situations have not been very often observed to be the seats of strumous disease. Several well-authenticated cases, however, are recorded, in which tuberculous matter was found deposited within these vessels, and that in such quantity as completely to obstruct them.*

The following instance of scrofulous affection of the lymphatic vessels occurred to the writer. A gentleman, after applying an astringent lotion to a simple excoriation of the cervix glandis, was affected with indurated swelling of the prepuce, and the appearance of hard tortuous cords within the integuments of the penis, which after a few days could be traced all the way to the pubes. A glandular swelling took place in one groin, which after a considerable interval suppurated, burst spontaneously, and at length healed. No perceptible benefit accrued from a slight mercurial and purgative plan of treatment; but amendment commenced under the use of sarsaparilla and iodine, and the disease wholly disappeared after a tour of several weeks' duration, since which the individual has continued to enjoy good health.

The inflammation of the superficial lymphatics in the horse, is believed by the best writers on veterinary medicine to constitute the disease named *farcy*, (*Percival*, Lectures on the Veterinary Art, vol. iii.), and M. Dupuy (De la Maladie Tuberculeuse) regards the small tumours termed *farcy buds* as tuberculous deposits.

The sublingual and submaxillary glands are often the seat of scrofula; the parotid more rarely, but a chronic swelling of that organ is occasionally seen in scrofulous subjects of a dark complexion. Tumefaction of the tonsils is seldom

* *Sir A. Cooper*, Medical Records and Researches, vol. i. 1st and 2d Cases.—*Paletta*, Exercitat. Patholog. p. 109, fig. 4.—*Lieutaud*, Hist. Anat. Méd. vol. ii. obs. 770, 771, 771 a.—*Otto*, Seltene Beobachtung. Theil ii. No. 33.—*Andral*, Précis d'Anat. Patholog. t. i. pp. 419–421.

absent, when the strumous constitution is strongly marked: this exists from an early period of life, and is perhaps in some instances congenital. The tonsils so affected jut out in rounded tumours from between the arches of the fauces: they are peculiarly prone to inflammation, and when it occurs, the swelling is often such as to threaten suffocation, especially when stimulant astringent gargles have been incautiously employed. The inflamed tonsils become speedily spotted with aphthous crusts, which are succeeded by superficial ulcerations, always indolent, and sometimes ending in brown excavated ulcers, which we have known to exist for weeks without any remedy being used, and then to yield rapidly to cinchona.

Scrofula occasionally attacks the tongue,* the disease alternating with strumous eruptions, especially in the face: it sometimes assumes the form of aphthous ulcerations and fissures of the margin; but its most characteristic features are small knots or nodules superficially imbedded in the substance of the organ, varying in size from a grain of small shot to that of a horse-bean. They cause no uneasiness unless when firmly pressed, and then the pain is slight and pricking. The mucous membrane covering them is red and prominent, and soon breaks in the centre, giving rise to an ulcer, which spreads and destroys by sloughy erosion, with much pain, profuse salivation, furred tongue, and fetid breath. The ulcers under proper treatment become clean, contract, and heal; but the hardness remains, fresh nodules form in other parts of the organ, and the same train of suffering is gone through after a longer or shorter interval, according to the state of the patient's health and the regularity of his mode of life, until a decided improvement be produced on the constitution by time, change of climate, or the employment of remedies.

The mucous membranes are frequently affected with scrofulous disease: allusion has just been made to the aphthous exudations and superficial sores which appear on the tongue and tonsils of strumous individuals; in other instances there are small blisters and excoriations on the inside of the lips and cheeks, and on the fauces, and that wholly independent of any syphilitic disease, or the previous exhibition of mercury. The pituitary membrane in scrofulous subjects is easily irritated, and the secretion of mucus is usually copious and often acrid: nay, in some instances the morbid condition of the part proceeds so far as to induce small ulcerations, constituting one form of ozœna. If the progress of this affection be not arrested, the fine long laminæ within the nostrils become in part denuded, and at length necrosed; and it is from the decomposition of dead osseous substance that the horribly offensive odour is produced which renders this malady so peculiarly disgusting. To those around the patient it is always so; but he himself is sometimes unconscious of the odour, in consequence of the diseased condition of the pituitary membrane, and the loss of smell resulting from it. The most frequent cause of ozœna is, without doubt, syphilis; but it occurs chiefly in those syphilitic cases where the habit is strumous, and it is met with also as the effect of scrofula alone. It has not been ascertained whether ozœna ever originates from the deposition of minute tubercles on the pituitary membrane; but that this sometimes occurs is far from improbable. In the glanders of horses, which is an analogous affection, the existence of tubercles in the lining membrane of the nostrils has been satisfactorily shown by Dupuy to form a leading feature. (De l'Affection Tuberculeuse, pp. 30 & seq.)

Scrofulous children are more liable than others to inflammatory affections of the windpipe, and to that fibrinous exudation on its mucous surface which occurs in croup; yet this cannot properly be classed among strumous diseases.

But the ultimate terminations of the respiratory mucous membrane are frequently the seat of scrofula: some eminent pathologists, indeed, are of opinion that the air-vesicles of the lungs are the usual situations in which tuberculous matter is originally deposited in cases of scrofulous phthisis. Dr. Alison informs us that he has repeatedly found tuberculous matter in the air-vesicles, these minute cavities being partly filled with air and partly with this substance, (Edin. Medico-Chir. Trans. vol. i. p. 427); and the dissections of Dr. Carswell, (Illustrations of the Elementary Forms of Disease, Fascic. 1,) which he has so happily perpetuated by his drawings, appear to us to have set this point completely at rest. M. Gendrin, however, asserts that the substance effused into the air-vesicles is nothing more than the product of common inflammation, and not at all tuberculous; but he candidly admits that Laennec expressed a contrary opinion while the subject was before them, and he is ready to acknowledge that inflammation is a powerful occasional cause of the production of tubercle. (Hist. Anatom. des Inflammations, tom. ii. pp. 310, 601.)

The digestive mucous membrane is subject through its whole extent to scrofulous disorder of function, and in its intestinal portion at least to extensive scrofulous transformations. A feeble action of the stomach is an almost uniform accompaniment of well-marked strumous disease; and the mucous lining of the alimentary canal is in such cases either torpid or unduly irritable, the food remaining lodged as a source of oppression and disturbance, or being hurried rapidly forward, and expelled before it has had time to afford adequate nourishment to the system. Tubercles are met with in the walls of the intestinal tube in children, and still more frequently in adults: Louis states that in his examination of more than 350 phthisical subjects above the age of fifteen, he found tubercles in the small intestines of one-third, and in the large intestines of one-ninth of the whole. (Recherches sur la Phthisie.)

The subsidiary organs of digestion and assimilation suffer also from scrofula; but the spleen and the pancreas are more frequently the seats of tubercles than the liver; yet the last of these organs is more or less functionally deranged in almost all strumous cases, which the chalky and various-coloured motions of such patients sufficiently demonstrate. The great irritability of the mucous tunic of the intestines in many scrofulous cases, and the tubercles which so often form within the mucous follicles and walls of the tube, naturally lead to ulceration, and hence arise many

* Mr. Russel has alluded to this affection, but without describing it. See Russel on Scrofula.

cases of disease of the mesenteric glands. At first they become merely swelled, but ultimately tuberculous deposits take place within their substance, constituting what has been named mesenteric consumption, or tabes mesenterica. For a full account of this affection, we refer the reader to the article TABES MESENTERICA.

Scrofulous disease of the mucous membrane of the female genital organs is of frequent occurrence, and forms the most obstinate description of leucorrhœa, producing languor and debility, disordering and sometimes putting a total stop to menstruation, and in very many cases preventing conception. The morbid discharge in this disease is interrupted on the appearance of menstruation, and is increased in quantity before and after that occurrence. It varies in character from an opaque white mucus to a greenish yellow or blood-streaked purulence; and the surface which furnishes it is not limited to the vagina, but apparently extends throughout the whole internal lining of the uterus. It does not appear that tubercles have been detected in the vagina, but scrofulous ulcers have been seen there, probably arising from the destruction of tubercles, while the cavity of the uterus itself and the Fallopian tubes were found filled with tuberculous matter. (*Carswell*, Op. cit. pl. ii.) Tubercles have also been found imbedded in the walls of the uterus, and still more frequently in the ovaria. (*Meckel*, Handbuch der Pathol. Anat. B. ii. Theil. ii. s. 386. *Louis*, Recherches sur la Phthisie. *Lombard*, Essai sur les Tubercles.)

In men, scrofulous disease of the mucous membrane of the urinary channels and cavities is not unfrequent; and it is an affection particularly obstinate and unmanageable. The writer has known it to continue in the urethra for five years, at the end of which time it came under his care. The urethral membrane was then so soft and spongy that the most cautious attempt to introduce an instrument occasioned a profuse hemorrhage: after a lengthened treatment, the discharge at last yielded to tonics, the cold plunge-bath, and astringent injections. Chronic, or mucous cystitis, is often of a scrofulous character, (see CYSTITIS;) and there is ground for believing that the same affection passes up along the ureters, and even extends itself within the chambers of the kidney. Tuberculous deposits have been found within the coats of the bladder, (*Louis*, Op. cit. *Lombard*, Op. cit. *Delaroche*, Bulletin de la Société de Méd. t. 13. 14,) and lining the interior of the ureters, (*Laennec*, Auscult. Méd. t. i. p. 556. *Louis*. Also *Carswell*, Op. cit. pl. ii.); very frequently also in the cavities and substance of the kidneys, and sometimes in the renal capsules. (*Baillie*, Morbid Anatomy.) The glands of Cowper, the prostate, vesiculæ seminales, and testicles, have all been found the seats of tuberculous deposits. They occur most frequently in the prostate gland and testicles, particularly in the latter; and the symptoms to which they give rise render them objects of considerable importance to the practical physician as well as to the surgeon. See PROSTATE GLAND, DISEASES OF.

The changes produced in the testicle by scrofula vary considerably, according to the degree of attending inflammation, and the rapidity with which the disease has formed. We have, most commonly, a hard solid enlargement of the organ, usually affecting first the large head of the epididymis, slow in its growth, and obstinate in resisting the operation of remedies. It may remain indolent for some time, but at length abscess forms, the scrotum inflames, adheres, and gives way, discharging a curdy substance mixed with pus. The disease now extends to other parts of the epididymis and to the body of the testicle; sinuses form under different parts of the inflamed integument; and fistulous openings take place, which give issue to a thin, ill-conditioned fluid, mixed with curdy particles. At other times a more rapid inflammation occurs, and an abscess forms, which on bursting discharges scrofulous pus; a fistulous opening succeeds, the gland wastes away, and at length nothing remains but a small, shrunk, and hardened mass. On dissecting a strumous testicle, the natural fabric of the organ is found more or less indurated by the deposition of dense organized substance; tuberculous matter is discovered in different spots, in the tubuli seminiferi epididymis, and sometimes even in the vas deferens. Small scrofulous abscesses are also occasionally found disseminated through the substance of the gland. (*Sir A. Cooper*, On the Testis. Carswell's illustrations, pl. ii.) This disease is much more common after puberty, when the actions of the testicle are awakened, and it has become exposed to numerous causes of irritation and injury; but we have known it occur at a very early age, in the case of a child which exhibited other strong marks of the strumous constitution. In almost every instance only one testicle is attacked at first, but after a time the other is usually affected; and it is not uncommon for both to continue suffering from the disease at the same time. Andral has well remarked the frequency of scrofulous affection of the testicle, and has pointed out the palpable omission of Louis, who has assigned no place either to the testicle or the bones in his enumeration of parts in which scrofulous deposits have been found.

Another organ which is subject to scrofula is the mamma; scrofulous disease of which occurs both before and after puberty, but much more frequently after that period, and often during the excitement of the first lactation. Scrofula of the mamma appears under different shapes, and in its earlier stages is not always easily distinguished from disease of a more formidable character. Sometimes a hard lump forms in the breast, and remains nearly quiescent for several years; at others the whole gland is affected with scrofulous enlargement; but in every case of the disease its tendency is to suppuration, and the purulent matter discharged is more or less mingled with curdy flakes: instances likewise occur in which large masses of tuberculous substance come away. (*Lloyd*, On Scrofula.) In the progress of such cases the integuments become inflamed, assume a livid colour, and are extensively detached from the parts beneath; new abscesses and apertures form, and the adipose and glandular tissues are traversed by many fistulous passages, while the contiguous parts are condensed and hardened. In strumous disease of the breast, there is always an enlargement of the gland instead of that contrac-

tion which occurs in one form of carcinoma: the tumour is tender when squeezed, never possesses the stony hardness which exists in the disease just named, and there is never, we believe, retraction of the nipple.

The mucous membranes of the eye and lachrymal passages are peculiarly liable to scrofulous disease; its influence on the latter is indicated by the long-continued discharge of puriform mucus, varying in its colour and consistence; while strumous inflammation of the conjunctiva constitutes a very large proportion of all the inflammatory affections to which this organ is subject. Beer asserts that in Vienna nine-tenths of all the cases of ophthalmia in children are of a scrofulous character, (*Jos. Beer*, Lehre, &c. b. i. s. 588); and Benedict of Breslau estimates the proportion in that city as high as ninety-five in the hundred. (Handbuch, &c., b. ii. s. 165.) The eruption of the minute vesicles, (phlyctenulæ) or pustules, which occurs in scrofulous inflammation of the conjunctiva, seems to approximate it to other diseases of the same class, when numerous crops of very small tubercles are seen on the investing membranes of various organs; but it does not appear that true tuberculous matter has ever been detected in any part of the eye.* Scrofula likewise attacks the margins of the palpebræ and Meibomian follicles, causing the appearance of vesicles and ulcerations named ophthalmia tarsi; and it is believed by Mr. Todd to occasion chronic enlargement of the lachrymal gland. (Dublin Hospital Reports, vol. iii.)

The organ of hearing, like that of sight, is the frequent subject of scrofula, which in many instances is productive of early deafness, and, there is reason to believe, is the cause of that imperfection of hearing which is sometimes seen to pervade several members of the same family. The lining membrane of the external auditory passage is in most instances the seat of the disease, which is usually marked by profuse watery, then mucous, and at length purulent discharges, forming what may be named strumous otorrhœa. It is in general unattended with danger, but it rarely exists without producing a greater or less imperfection of hearing. In some instances, however, the disease spreads more deeply; the membrane of the tympanum becomes inflamed and is perforated, the small bones of the ear are discharged, and irremediable deafness ensues; or perhaps caries of the petrous portion of the temporal bone takes place, and the result is fatal. (See Oralgia and Otitis.) Strumous otorrhœa has been known to alternate with other mucous discharges, such as leucorrhœa and chronic cystitis, (*Lallemande*, Recherches sur l'Encéphale, lettre quatrième); and its disappearance has been followed by enlargement of the cervical glands, swelling of the testicle, and various diseases of the eyes and skin. (*Itard*, Maladies de l'Oreille.) Like other scrofulous affections it sometimes resists all remedies, and at length disappears at puberty.

The synovial membranes of joints are undoubtedly much more liable to disease, in scrofulous subjects, than others; inflammation is more readily excited, and effusion of fluid into their cavities is more easily induced. In such persons we frequently observe several joints affected at the same time. In a case of six years' duration, lately placed under the writer's care, the left hip-joint, the right knee, and the joints of the right great toe were all suffering under disease, with displacement of the head of the femur and shaft of the tibia; there were, besides, many ulcers and sinuses around the joints, and indurated cervical glands: this patient had a strongly marked strumous countenance. The secretion of scrofulous pus into synovial cavities is not uncommon, but the existence of tubercle within the substance of the membrane itself appears to be of rare occurrence. Dr. Craigie states his belief that tubercle has been found in the synovial membrane of the hip-joint. (Elements of Patholog. Anatomy, p. 810.) There is indeed a remarkable change of structure, which takes place slowly in the synovial membranes, particularly that of the knee-joint, and which, as it occurs most frequently in the scrofulous, some may be inclined to regard as of scrofulous origin. This morbid alteration of texture, which was first accurately described and illustrated by Mr. Brodie, (Pathological Observations on the Joints,) consists of the conversion of the synovial membrane, and afterwards of the adjacent soft parts, into a pulpy substance of a light brown colour, intersected by white membranous threads, and traversed by minute red vessels. But there is another affection of the joints, in which the characters of scrofula are unequivocally exhibited; in this the disease originates in the cancellous structure of the bones, which is found to contain deposits of tuberculous matter: and the cartilages and synovial membranes are affected secondarily by the spreading of the inflammation.

In scrofulous persons the bones are more slender throughout; their cortex or outer wall is much thinner, and their interior more soft and vascular than the bones of persons of sound and vigorous constitution: in the inferior animals affected with tuberculous disease, according to Dupuy, (De l'Affection Tuberculeuse,) this peculiarity is still more strongly exhibited. Scrofulous children sometimes fracture the thigh or leg merely by falling on the carpet; and in other instances the bone does not snap across, but bends like a piece of tin; and the injury may be remedied by straightening it as we do a rod of that metal. The effects of scrofula on the bones are considerably different, according to the comparative density of their texture; but in all instances the process of disorganization appears to commence by an increase of their vascularity, or a greater or less degree of inflammation. In the dense fabric of the bones of the skull and the shafts of the long bones, scrofula is a frequent cause of necrosis; while in the spongy heads of bones, the small bones of the hand and foot, and the bodies of the vertebræ, this disease manifests itself, first by increased vascularity and softening of the cancellated structure while the firm exterior remains entire and unchanged; then a deposit takes place of a clear yellow fluid, which is succeeded by or probably converted into a soft cheesy substance or

* Strumous disease of that organ seems to exist also among animals. M. Dupuy considers the specific ophthalmia of horses as one of the consequences of the tuberculous affection.

true tuberculous matter. (*Brodie*, Patholog. Observ. on the Joints.—*Lloyd*, On Scrofula.) This alteration in the texture of the bones is slow in its progress, and its existence is not indicated by any decided symptoms until it is considerably advanced. A dull and deep-seated pain gives the first warning of the disease, the soft parts then become swelled, the motions of the neighbouring joint are restrained and painful, and abscesses now form around it, containing a scrofulous pus; the investing cartilages and synovial membrane next suffer, effusion takes place into the articular capsule, and perhaps a high degree of inflammation is induced by the escape of tuberculous matter or a portion of necrosed bone into the cavity of the joint. In the progress of the disease the destruction of the head of the bone or edge of the socket, and of the ligaments which preserve the bones in their places, enables the more powerful muscles to draw the lower one from its situation, and produce what is named secondary luxation. The writer has repeatedly observed dislocation of the tibia produced by the separation of the epiphysis from the shaft of the bone; the leg being in this manner completely displaced, although the articular surfaces of the knee-joint were in proper apposition.

Not only the bones but also their investing membrane of periosteum is subject to tubercular deposits,* giving rise to swelling, inflammation, suppuration, detachment of the periosteum from the bone, and ultimately to necrosis, or absorption of the osseous tissue, which is replaced by dry tuberculous substance without softening of the bone. To this form of tuberculous disease we would refer some of those cases which have been named osteo-steatoma. This morbid deposition, which we have seen lying in contact with the bone in large angular masses, bears a striking resemblance to suet or adipocire; but its nature is truly that of coagulated albumen, for it emits, under a strong heat, the odour of burnt cheese or horn, and produces no greasy stain when rubbed on paper.

Scrofula manifests itself by unequivocal proofs both in the bodies of the vertebræ and the fibro-cartilaginous substance which is interposed between them. The former become more vascular, are softened by the partial absorption of their earthy and saline constituents, and afterwards receive a deposit of yellow, cheesy, or true tuberculous matter. These changes naturally lead to caries and destruction of the bone, which yields to the superincumbent weight; and the spine bends at an angle more or less acute according to the number of vertebræ which are diseased. The bend is in general directly forward; but when the sides of the vertebræ have suffered most, the curve is of course lateral. (*Brodie*, Opus cit. p. 289.) In the progress of this disease the soft parts around become affected, and collections of purulent matter form, which, passing down in front of the spine and along the course of the psoæ muscles, ultimately make their appearance under Poupart's ligament at the upper part of the thigh, and sometimes on both sides, nearly at the same time. On other occasions the matter points in the loins, or near the anus; and in some rare instances it has burst into the spinal canal, with an immediately fatal result.

When chronic disease has thus been producing such extensive disorganization in the osseous substance of the spinal column and in the soft parts around, it is not to be expected that the membranes of the spinal cord, the medullary substance itself, and the nerves which branch from it, should escape injury; accordingly we find that the first symptoms of caries of the spine are, a feeling of weight and aching in the part, itching and numbness, pains shooting round to the front of the trunk; and, when the disease is farther advanced, pains and twitchings of the limbs, succeeded by palsy of all the parts below the affected vertebræ, and of the sphincters of the bladder and rectum. The nervous symptoms are not always limited to the parts below the seat of the disease: in some cases we have pains of the arms, although the disease be situated in the middle dorsal vertebræ. (*Copland*, on Diseases of the Spine.) On inspecting the contents of the spinal canal, where death has occurred during the existence of caries of the bones, effusions of serum or plastic lymph are found between the osseous surface and the dura mater, and sometimes they are found firmly adherent; plastic lymph and pus are also discovered within the arachnoid, or the membranes are found glued together. Tuberculous deposits have been observed within the substance of the spinal dura mater, and between that membrane and the arachnoid; most commonly connected with scrofulous disease of the bones, but sometimes wholly independent of it. (*Ollivier*, De la Moelle Epinière, t. ii. pp. 760–764.) The medullary substance itself has in such cases been found softened or attenuated; sometimes entirely destroyed for a short space, and the vacuity filled up with a sanious pus.

When scrofulous disorganization of the bones has been effectually checked, it is astonishing to mark the efforts made by nature to repair the loss and support the fabric by new osseous growths: we have even occasionally seen them formed in the vicinity of the disease, even although its activity was still unabated.

Scrofulous affections of the spine often commence in the intervertebral substance, which becomes soft in the centre, and is then destroyed by ulceration and absorption; the disease afterwards extending to the bodies of the vertebræ. There is no reason to doubt that ulceration of the intervertebral substance is in most cases of a scrofulous nature; yet it must be admitted that tuberculous matter has very rarely been observed in this texture; partly, perhaps, because it has not often been carefully sought for. Andral states that he once met with a mass of tubercles within the substance of the intervertebral cartilages. (Précis d'Anat. Patholog. t. i. p. 424.)

Lateral curvature of the spine has been supposed by some writers to be in almost all cases produced by strumous disease of the bodies of the vertebræ. Certain it is that scrofulous individuals are most liable to lateral curvature of the spine; but this may with more propriety be ascribed to a general debility and relaxation of the

*Otto has found tubercle within the tissue of the periosteum. See Compend. of Pathol. Anat. translated by South, vol. i. p. 240.

frame, and of the muscular and ligamentous system in particular, than to any positive softening of the osseous texture. Were the bones softened from scrofula in every case of lateral curvature, how is it possible that so many cures should be effected, or that such multitudes of females should be met with in comparatively good health, yet having permanent lateral flexure of the spine? Scrofulous disease of bones in other cases requires powerful counter-irritation to check its progress; but in this form of spinal disease, rest in the horizontal posture, friction, a regulated exercise of the muscles, and attention to the general health, are sufficient, in a great majority of instances, to accomplish a cure. Lateral curvature of the spine not unfrequently precedes angular projection from caries: hence it has been inferred that the latter is but the second stage of the former disease: of this, however, there is no proof; nor is it at all unnatural that a feeble individual, whose spine sinks readily into a serpentine bend, should afterwards become the subject of a more formidable disease, affecting the bones themselves. The vertebræ after death, in cases of serpentine curvature, are most commonly found free from disease,* which would seem to show that scrofulous softening of the bones is rarely the cause or this deformity; for it is highly improbable that so great a change in the texture and form of the vertebræ should be repaired without leaving behind it some traces of its previous existence.

The serous membranes in different parts of the body often exhibit decided marks of scrofulous disease, myriads of minute tubercles or tuberculous granulations being found adhering to their surfaces or imbedded in their tissue; and sometimes enveloped in the false membranes connecting them, which have formed during inflammation. Thus the pleura, the arachnoid, the pia mater, the peritoneum, are frequently found affected with scrofula; and a few instances are recorded where tubercles have been observed in the pericardium. (*Baillie*, Morbid Anatomy, p. 9.) When this disease attacks the membranes of the brain, its symptoms are usually the same as those of acute hydrocephalus; and its termination takes place by effusion within the skull or spinal canal, to which sometimes is superadded softening of the medullary substance. The children of scrofulous parents are well known to be more prone than others to cephalic disease; and in this manner the whole offspring of such individuals are sometimes cut off in succession during infancy. When tuberculous disease affects the peritoneum, it seems, whether originally induced by inflammation or not, to produce, after a time, that state: dropsical effusion then follows. As the disease proceeds, the fluid is absorbed, and the opposite surfaces, loaded with tuberculous matter, become glued together, obliterating the cavity of the peritoneum, and fixing the floating viscera in their places. We have seen this disease in a boy of twelve years pervading the whole trunk, gluing the contiguous viscera to each other, to the parietes of the chest and abdomen, and to the diaphragm, filling up the anterior mediastinum, and presenting numerous white cheesy tumours within the substance of the viscera themselves. The heart alone was free from disease. A separation of the lowest part of the sternum, which was much softened, had taken place, and the point of the ensiform cartilage was directed forwards and upwards; a consequence apparently of the swelling of the abdomen, and the restraint imposed by the strong adhesions on the motions of the chest in respiration. Such cases are always complicated with scrofulous disease of the mesenteric glands, and usually with ulceration of the coats of the intestines, which have thus been perforated, allowing a free communication through the adherent sides of the contiguous tubes. In some cases it has appeared that the ulceration had commenced in the peritoneal surface; (*Gregory*, Lond. Med.-Chir. Trans. vol. ii. p. 269;) while in others the mucous lining of the bowel seems to have been the first eroded. (*Howship*, Practical Observations in Surgery and Morbid Anatomy, p. 269.) The same result will follow from both processes; but certainly the ulceration from within outwards is what we consider most likely to happen from the greater proneness of mucous membranes to that state.

The frequent occurrence of scrofula within the central organs of the nervous system has been satisfactorily ascertained. Wiseman, whose knowledge on this subject greatly surpassed that of most of his contemporaries, appears to have suspected the fact; but it was reserved for modern pathologists† to show how frequently tubercles are formed within the encephalon and spinal cord. Before the age of two years they are not common; but from this period onwards till puberty they are of frequent occurrence. Their most usual seat in the brain is the upper part of the hemispheres; and in the spinal cord they occur much oftener in the cervical than in the dorsal or lumbar portions: according to the most accurate observers, they are very often enclosed in cysts. (*Andral*, Précis d'Anat. Pathol. tom. ii. p. 841.) It is singularly deserving of notice that tubercles have been repeatedly found in the nervous centres where no symptom during life had induced any suspicion of their existence; and the scalpel has as frequently been unable to disclose any deviation from healthy texture in the substance immediately surrounding them.

The thyroid gland was long believed to be peculiarly subject to scrofula; and the chronic enlargement of that organ, named bronchocele, was at one period regarded by the best writers of their day as a distinctly scrofulous disease; (*Sennertus*, Medicina Practica.—*Laurentius*, Hist. Anat. corporis humani;) nay, it is remarkable that even in recent times the introduction of iodine as a general anti-strumous remedy originated in the supposed connection of bronchocele with scrofula. But on reviewing the history of the two diseases, we shall find so many points of difference as to convince us that they are altogether distinct and

* *Shaw*, Diseases of the Spine. We have lately examined a number of preparations with a view to this point, and the result fully corroborates the assertion of Mr. Shaw.

† *Leveillé*, Becherches sur les Tubercules du Cervau, 1824. *a thesis.*—*Gendrin*, Sur les Tubercules du Cervau et de la Moelle Epinière, 8vo.—*Ollivier*, Sur la Moelle Epinière.

independent. (See article Bronchocele.) In support of this opinion it may be sufficient here to state that bronchocele is of rare occurrence in the large manufacturing towns of Britain; while scrofula prevails throughout their population, cutting off thousands in infancy, and scattering among the survivors the germs of debility and protracted disease. The thyroid body, though rarely the seat of true scrofula, is not wholly exempt from it, more than one instance of its occurrence having come under our observation. The disease commences with a moderate degree of swelling, which is followed by the formation of a small indolent abscess: this after a time bursts spontaneously, discharging a thin pus mixed with curdy flakes; the apertures remain fistulous for a considerable time, while the tumefaction of the gland subsides.

The lungs have long been known to be particularly liable to scrofulous deposits; and so rare is it to find tubercle in any other situation without also finding it in the lungs, that Louis states he never met with an instance in all his numerous dissections excepting once, in the case of a man who had died of fever. (Recherches sur la Phthisie.) Scrofulous disease of the lungs constitutes what has been named tubercular phthisis; to the article on which, the reader is referred.

[Scrofulosis is very analogous to, although not identical perhaps with, tuberculosis. They both occur in persons who have like habits and general appearance; but there is this difference, as regards at least tuberculosis of the lungs, that it is most frequently developed after puberty,—the period when the tendency to scrofulosis is usually diminished or arrested. Moreover, scrofulous disease manifestly exists where there is no reason to believe in the existence of tuberculous matter. (*Scrofula, its Nature, Causes and Treatment*, by W. Tyler Smith, M. D. p. 6. Lond. 1844.) A person having scrofula, however, in early life, would seem to be more liable to tuberculosis at an after period. Some recent observers, however, argue strenuously for the identity between scrofulosis and tuberculosis. MM. Rilliet & Barthez (*Traité Clinique et Pratique des Maladies des Enfans*, iii. 5. Paris, 1843,) affirm, that having examined the bodies of a large number of scrofulous children, at the Hôpital St. Louis, they met with no instance in which tuberculous deposits did not exist in some part or other. Many affections, commonly termed scrofulous, as ophthalmia, they consider of a secondary nature, accidentally complicating the original scrofulous or tuberculous habit, but not essentially scrofulous in their nature. They propose to banish the term scrofula from medical nomenclature, as being vague and apt to mislead, and to substitute for it the term *tuberculization*. M. Bredow, of St. Petersburg, (*Ueber die Scrofelsucht*, Berlin, 1843,) seems to entertain a similar view; but he proposes to retain the word scrofula, to designate tuberculous disorganization of the lymphatic glands; and the terms tubercle and tuberculous disease for the same affection existing in other organs. (Dr. West, *Brit. & For. Med. Rev.* April 1844, p. 565.)]

The heart has been found affected with scrofula but rarely: Dr. Otto, (Compendium of Pathological Anatomy, translated by South, p. 290,) of Breslau, a very learned and able pathologist, never once met with a case of this sort; yet several cases of its occurrence are on record from Fabricius Hildanus, (Observ. Chirurg.) and Needham, (Wiseman's Surgery, vol. i. p. 404; at the apex of the heart,) down to Andral, (*Andral & Bayle*, Revue Méd. Franç. et Etr. 1821,) Lobstein,* and Macmichael.† Tubercle of the heart never occurs except when the system is strongly imbued with strumous disease; and its existence in this situation does not appear to have been indicated by any peculiar diagnostic symptom.

The occurrence of scrofulous disease in the voluntary muscles appears to be not less uncommon than in the heart: instances, however, have been met with of tuberculous deposits in these organs, both in the human subject and the monkey.‡

The effect of scrofula in modifying the symptoms of a large proportion of the diseases to which the human frame is subject, has been long known to medical observers, and meets us daily in the course of our practice. Inflammatory affections, in a particular manner, exhibit the effects of this influence; losing the acuteness of their character, and becoming tardy and indolent, difficult of cure, and requiring for its accomplishment the use of stimulants and tonics. Frequent and striking examples of these facts are presented to us by many of the early consequences of syphilitic infection, and by the extensive tribe of ophthalmic diseases. Injuries of the soft parts, particularly where there has been much loss of blood, also often afford unequivocal evidence of the presence of a strumous habit: hence it is common for persons who are jealous of the imputation of scrofula to declare that their wounds are always readily healed. So strong sometimes is the modifying power of scrofula, that the writer has known the stump of a strumous girl's arm, which was removed on account of an extensive laceration, to discharge distinct curdy matter at the second dressing.

Scrofula appears to possess a certain degree of connection with several other diseases. Some congenital affections, such as hare-lip, spina bifida, and external hydrocephalus, are more frequently met with among scrofulous children than others; and it is worthy of remark that in many cases of congenital peculiarity or defect, the same have been observed in ancestors, or near collateral relatives of the patients.

Of all the diseases allied to scrofula, perhaps the most closely connected is rickets, (see art. Rickets;) yet the distinction between the anatomical characters of the two diseases is sufficiently well marked. In rickets the whole texture of the bone is softened, though not exactly in the same manner in both species of that disease; but in scrofula, tuberculous matter is deposited in the can-

* Anat. Patholog. At the apex of the heart, as large as the point of the thumb, and apparently formed in the substance of a false membrane.

† Lond. Med. and Phys. Journal, 1826, p. 119. The tubercles in the heart were connected with others in the lungs; yet they may have been originally distinct.

‡ *Otto*, Opus cit. p. 252, in the sterno-mastoid of a girl —in the muscles of the neck and thigh of scrofulous monkeys.—*Laennec*, Auscult. Médiate, tom. i. p. 556. In the sterno-mastoid of a phthisical man. *Lombard*, Opus cit. Intercostal Muscles.—*Reynaud*, Archive Gén. de Médecine, tom. xxv. 1831, pp. 149. 301. This writer has given a very interesting account of the tuberculous affections, particularly phthisis, occurring in monkeys at the Jardin des Plantes.

cellous structure, the outer wall remaining entire, or becoming necrosed: or tubercle invades the bone from the periosteal surface, the osseous substance being removed by absorption. Encephaloid or medullary tumours may also be enumerated among the affections connected with scrofula; they occur chiefly in individuals of a strumous habit, and the materials of which they are composed bear, in their last stage of softening, a considerable similitude to those of tubercle.* There is a fungous tumour, occurring in the lips and cheeks of young scrofulous subjects, which we have repeatedly met with; in its external characters it bears a very close resemblance to encephaloid; but it is formed with much greater rapidity, and admits of cure by a well-directed alterative and purgative treatment, and the application of leeches, astringents, and escharotics. It is the opinion of some experienced practitioners, that carcinoma occurs more frequently in persons of a strumous constitution than others; and our own observation inclines us to entertain a similar belief. The concurrence of scrofula with urinary calculus has led to the supposition that the two diseases are intimately connected; but it does not appear that they are in any way dependent on each other: the same causes, however, are likely to induce both. (See art. CALCULOUS DISEASES.)

The greater sensitiveness of most scrofulous individuals renders them more prone to diseases of the nervous class: hence an aggravated form of hysteria is more frequent in such persons; and we think with Dr. Cheyne, that epilepsy affects strumous subjects oftener than others. (See EPILEPSY.) The diseases of the mind claim an alliance with scrofula, which has not attracted the attention of writers on this subject so much as it seems to merit. An eminent physician of great knowledge and experience in the treatment of insanity has stated to us his belief that more than one-half of those who are subject to mental derangement are of a scrofulous constitution, having some manifest indication of its existence in their persons. With the view of elucidating this subject, we examined all the paupers of a lunatic establishment. Of forty-four females, exactly one-half presented indurated or enlarged glands of the neck or throat, and several had extensive scrofulous cicatrices. Of forty-six males, twenty-eight had no decided symptoms of scrofula, though several of these had the strumous aspect; sixteen presented the marks already mentioned in reference to the females; and two belonged to families known to be afflicted with scrofula in an aggravated form. All of these ninety lunatics were adults, and not one of them exhibited any active symptoms of scrofulous disease. It has been remarked to the writer by the physician already referred to, that he has often observed active scrofulous symptoms to alternate with attacks of mania. In several cases he has known the purulent expectoration of phthisis to cease during the urgent symptoms of insanity; and, on the other hand, reason has been seen to return before the pulmonary disease proved fatal—soothing the feelings of affectionate relatives, and shedding a calm over the last days of the consumptive lunatic. In accordance with what has just been stated, the severity of the symptoms of scrofula does not appear to promote the development of mental disease, but rather to impede it; for in families eminently scrofulous, we have sometimes observed the individual least afflicted with that malady to be the victim of insanity; while those who suffered most from scrofula possessed sound minds; as if the local irritation, or the drain from the body afforded some protection against mental derangement. It has often been remarked by medical writers, and the observation of every physician must confirm the accuracy of the statement, that precocity of mental development, and superior genius, are in a great majority of instances the accompaniment of the scrofulous constitution.

Causes.—In considering the causes of a disease so deeply rooted in the constitution as scrofula is universally acknowledged to be, it is necessary to direct our attention to circumstances very remote in the history of those who are its subjects. The foundation of a scrofulous habit is frequently laid during the fœtal state, by the transmission of that peculiar organization of the frame from parents who themselves possess it. Nothing, indeed, can be better established as the result of general observation than the hereditary nature of scrofula. This peculiarity of constitution may also be communicated to the fœtus by some defect of energy in one or both of the parents, arising from extreme youth, or very advanced years, or great disparity of age, or that premature decay which is induced by a life of dissipation, or the debilitated states resulting from protracted illness; or, on the part of the mother, repeated miscarriages, and by defective nourishment and other similar causes. Various occurrences, likewise, may take place during gestation—such as accidents, frights, prolonged disease, mental distress,—which interfere with the proper development and growth of the embryo, and entail upon the child that feebleness of constitution which, if not identical with scrofula, leads to its appearance on the application of causes not adequate under other circumstances to produce that disease. The writer was recently called upon to examine a boy of six years, labouring under a complication of scrofulous ailments; the history of whose case may serve to illustrate the influence of injuries received by the mother during gestation. In this instance the mother was a tall and rather slender woman, apparently enjoying good health; the boy was puny for his age, his movements were quick and restless, his articulation very imperfect, and his mind in a state approaching to idiotcy: the lips were seamed with the scars of former ulcers, the conjunctivæ relaxed and injected, the tarsi inflamed, ulcerated and almost without cilia; the countenance pale and bloated; the skin dry and scaly; many of his teeth were gone, and most of those which remained were in a state of decay; the cervical glands were indurated, but not much enlarged. The last phalanx of one thumb was double, and each extremity of the fork had a perfect nail. He had always been a very sickly child, had had repeated suppurations in the groins, and was then labouring

*The earliest distinct account of encephaloid as it affects the extremities, is to be found in Ruysch, Observat. Anatomico-Chirurgic. No. 81, where he describes it under the title of the spongy or ossivorous tumour, and states that it was known to the Germans under the name of *schwamm*, and to the Dutch under that of *been eter*.

under chronic diarrhœa, part of his food passing undigested. During the time that his mother was pregnant with him she had suffered many severe falls, the first towards the end of the third month.

Scrofula is also observed to originate in the healthy offspring of healthy parents under certain circumstances, the principal of which are habitual exposure to cold and damp, privation of free air and light, and want of healthful exercise. Instances are recorded where persons previously in good health have been affected with scrofula after being confined in the dungeons of a prison, and there scantily fed. (*Pinel*, Nosog. Philos. t. iii. pp. 380, 385.) The influence of such causes in producing tuberculous disease in the inferior animals has been made the subject of experiment by Dr. Jenner, (*Jenner*, in Beddoes on the Med. Use of factit. Airs), Dr. Baron, (Delineations, &c., pp. 25 et seq.,) and others; and the results have satisfactorily shown both the great extent of that influence, and the power which we possess of removing the factitious disease by replacing the animals in healthy situations, and supplying them abundantly with wholesome food. The operation of cold and damp, as causes of scrofula, is greatly augmented even by a slight local injury.

A moist, cold, and variable climate, like those of Great Britain and Holland, is particularly favourable to the development of scrofula; in proof of which it is sufficient to adduce the great prevalence of the malady in both of those countries. A very cold or a hot climate, on the other hand, serves rather to protect us against scrofula; the former, dry and bracing, invites to exercise and promotes digestion, and thus strengthens the system; while the latter favours the excretions, particularly that of the skin, and preserves the body from those sudden changes of temperature which in our island so often lay the foundations of scrofulous affections. But when an individual whose constitution has been formed in a warm climate is removed to a cold and variable one, the occurrence of scrofula is exceedingly frequent; convincing proofs of which are every day afforded by those natives of warm climates who reside in our island, as well as by the diseases of birds, monkeys, and other animals which have been brought to us from warmer latitudes. (See *Reynaud*, on the Diseases of Monkeys at the Jardin des Plantes. Archives Gén. de Méd. t. 25.) Indeed it is not necessary for the inhabitants of warm climates to leave their native countries to experience the effects of a cold and variable atmosphere in the production of scrofulous disease: it is sufficient for them to ascend their own mountains, when they will be exposed to the same influences, and suffer the same evil consequences as if they had removed to a more northern climate.* The information communicated by Dr. Ferguson regarding the diseases of the black troops in different situations in the West Indian islands, illustrates this point in a very interesting and satisfactory manner. (*Alison*, in Edin. Medico-Chir. Trans. vol. i. p. 398.)

* In every latitude there is a point of elevation above the plains where the thermometer never sinks below 32° Fah. Even at the equator this exists at a height of 15,207 feet. See Suppl. to Encycl. Brit. art. *Climate*; also *Humboldt*, Geography of Plants.

Among the causes which appear to give rise to scrofula in children, are the practices of rearing them by the hand and suckling them too long—two extremes, both of which often lead to the same result, the imperfect nourishment of the child. The former of these is a fruitful source of scrofula in England, the latter in Scotland, where it is usual among the labouring classes for children of sixteen and eighteen months to be still at the breast: in some instances we have known them suckled for upwards of two years. A similar injurious effect will be produced by allowing the same wet-nurse to suckle several children in succession, which we have known to be pursued as far as three, when debility and symptomatic amaurosis forced the woman to resign her charge. Imperfect nourishment of the child, and consequent tendency to scrofula, is also likely to be induced in those cases where the wet nurse menstruates regularly during lactation. It is an opinion professed by Wiseman and other writers of great ability and experience, that a scrofulous wet-nurse may occasion the disease to appear in the child to whom she gives the breast; and the idea appears consistent with reason, not on account of the existence of any scrofulous poison, capable of being imbibed by the infant, but because it is natural to suppose that the milk of a scrofulous female will not afford the same substantial nourishment as that of a woman in sound and vigorous health.

[When a close investigation is made, it will be seen, that infants of the scrofulous habit display evidences of imperfect formation—Dr. Stokes says—of arrest of development. Their development resembles, in some respects, that of the fœtus prior to the seventh month of intra-uterine existence: the abdomen is prominent; the liver large; the head large; and the extremities small. The writer has always entertained the view, that the condition of the system is such as to require an increase of the plastic powers; and a radical error appears to him to have been incurred by those who apply to all scrofulous inflammations the rigid system of regimen and therapeutics which are adapted for ordinary phlegmasiæ. These views have been strengthened by the observations of recent histologists. It has been remarked by Gerber, (*General Anatomy*, by Gulliver, London, 1842,) that "albuminous or unorganized tubercles (which with great propriety are called scrofulous tubercles,) can only be produced from exudations abounding in albumen, poor in fibrin," and such exudations, it need scarcely be said, are more likely to take place from blood itself defective in the fibrinous or essentially plastic element.]

Another case of this disease is confinement in ill-ventilated apartments; for the deficiency of pure atmospheric air cannot be long endured, especially during youth, without the most injurious consequences. While the frame is building up and the constitution acquiring that character which is to distinguish it through life, all the processes of the economy are peculiarly active, and any defect of what is to perfect the animal fluids and give energy to the nervous power, is felt with greater force, and is productive of much more injury than at an after period. Ill-aired apartments are in general imperfectly light, and the want of this vivifying influence of light favours

the formation and development of scrofula; for the human body requires a certain exposure to light for the proper performance of its function, little less perhaps than plants, although in them the loss of colour renders the effects of seclusion more strikingly manifest. The experiments of Edwards on the spawn of frogs and on tadpoles clearly demonstrate the agency of light on the formative processes of living organization. He found when the light was excluded that the eggs were never fully hatched, and that tadpoles did not undergo their transformation at all, or did so after a considerable delay; but their size increased, although they were kept in darkness. (De l'Influence des Agens Physiques sur la Vie, p. 398 et seq.) In accordance with the results of these experiments, it has been observed that monstrous births are exceedingly frequent among the miserable occupants of the dungeons under the fortifications of Lille. (London Medical Gazette, Sep. 29, 1832.) We may in part ascribe to the deficiency of light the prevalence of scrofula among the inhabitants of cellars and of narrow alleys, where the beams of the sun never gain admittance. We are even inclined to think that the custom now so general among the wealthier classes in this country of sitting in darkened rooms during the day is far from being conducive to vigorous health; and where the young are concerned, we do not hesitate to say that it must be injurious. It is a custom borrowed from the luxury and effeminacy of warmer latitudes, and one which is calculated to enervate the body and induce a tendency to strumous disease.

In a great metropolis like London, where the moving crowds of human beings and the number of carriages are such that children cannot be allowed to go abroad in the streets, they grow up feeble and often scrofulous; while in villages and even in some populous towns, where they are almost constantly at play in the open air, they prove healthy and vigorous. The mischievous effects of the want of air, and sun-light, and healthful exercise, may be seen among the rich as well as the poor, though not to the same extent. The confinement, mental fatigue, and anxiety to which female children in particular are so unremittingly subjected during their education, prove fertile sources of scrofula in boarding-schools, and even in the families of the higher classes: bodily health is too often sacrificed to the idol of accomplishment, and the intellectual powers, perhaps originally of excellent quality, are forced into a state of extreme culture and morbid precocity, destructive of all genuine soundness and vigour.

Acute diseases, especially those accompanied with cutaneous eruptions, as small-pox, measles, and scarlet-fever, are often observed to have the effect of producing the development of scrofula; and the more tedious the convalescence, the more frequently do symptoms of this disease ensue. Various other causes of debility prove the means of developing scrofula — as long watching, protracted anxiety of mind, severe study, especially in the young, habits of dissipation, excess in sexual indulgences, solitary vice, profuse discharges of all kinds, repeated syphilitic disease; the abuse of mercury, of narcotics, of warm bathing, and of powerful evacuants. Different local irritations have the effect of causing the neighbouring lymphatic glands to swell, and where a strumous tendency exists, to become the seats of tuberculous deposits, as we see exemplified in the consequences of difficult dentition, and of the inflammatory affections of the mucous membranes of the respiratory and alimentary canals. Too great indulgence in sleep has been enumerated among the causes of scrofula, and excess in this particular will certainly debilitate and thus dispose to the disease; but we are inclined to believe that the indulgence in sleep which appears to induce scrofula is, in fact, usually occasioned by that feeling of weakness and exhaustion which is among the earliest symptoms of the approaching development of the disease.

[**Nature.**—The pathology of scrofula, and the definition of the term, are differently expressed by different authors. Some define it to consist essentially of inflammation of the lymphatic ganglions, especially of those of the neck. This acceptation, however, is too incomprehensive, and expresses but imperfectly the grand characters of the disease. Although inflammation of the ganglions, and chiefly of the cervical, is very common in scrofulosis, it is often absent; and it can only be regarded as a functional expression of the morbid diathesis. The disease, as has been shown, often expresses itself elsewhere, as in coxalgia, white swelling, vertebral caries, &c. &c. Scrofulosis is a morbid condition of the whole system of nutrition; and hence, ought to be classed amongst the cachexiæ—the inflammation and enlargement of glands, like the eruption in variola, rubeola, &c. being merely attendant phenomena. The lymphatic ganglions are liable to simple inflammation from ordinary irritation. A thorn, run into the finger, may cause enlargement of the ganglions in the axilla; inflammation or irritation of the mucous membrane of the intestines may give rise to mesenteric ganglionitis, owing to the extension of the irritation to the lymphatic ganglions that are seated between the irritated part and the centre of the lymphatic system. In like manner, nutritive irritation, occurring in one of a scrofulous diathesis, may occasion inflammation of the same glands; but, being general in its influence, scrofulosis may express itself in various other forms besides ganglionitis. With some, it has been a question, whether it be not dependent upon a morbid state of the blood. This is not probable, inasmuch as the disease, or rather a tendency to it, must exist prior even to the formation of blood. An impulse to it must be present in the materials furnished by one or both parents at a fecundating copulation; which impulse may persist and be developed at an after period of the individual's existence. This tendency may not be received in sufficient force from the parents to be developed in their immediate progeny; but, like facial resemblances, may be strongly exhibited in the grandchildren. Some writers, among whom is Dr. Stokes, (*Lectures on the Theory and Practice of Physic*, 1st Amer. edit. p. 311, Philad. 1837,) place scrofulosis in the system of white vessels; in which, according to them, the lymphatics execute the function of veins. This view, however, implies a something which probably has no existence—*white* blood. The want of colour in cer-

tain of the tissues, as in the conjunctiva and serous membranes, is probably due to the thin stratum of *red* blood circulating in their vessels, which renders the colour inappreciable. A very thin stratum of any coloured liquid, viewed by transmitted light, appears to be colourless; but if the quantity of liquid be increased, the colour becomes manifest. This is what occurs in inflammation of the white tissues: the quantity of red blood in the vessels is increased sufficiently to render its colour perceptible—not that there is an enlargement of arteries, destined in health to convey white blood, so that they now admit red corpuscles, as supposed by some. There would, in fact, seem to be no white arteries, and, consequently, no white veins. Were such vessels to exist, they would be liable to constant obstruction from the red corpuscles. The function executed by the lymphatics would seem to be to break down the old tissues and convert them into lymph—a fluid essentially the same in every part of the lymphatic system—which eventually enters the circulation. They are engaged in the great process of assimilation, or in the decomposition and renovation of the tissues. Scrofulosis, then, must be regarded as a peculiar morbid condition of the whole system of nutrition.]

Treatment.—The treatment of scrofula naturally divides itself into the preventive and curative, the former of which is the more generally successful, and obviously the more important. All children are liable to become scrofulous, and those more especially whose parents or near relatives are the subjects of this disease. Hence particular attention is required to prevent the formation of the strumous constitution in children, and the development of the disease in those who may from birth be marked by this peculiarity of organization. Indeed, it will not be undeserving of our care to influence as far as we can the sound and perfect formation of the embryo, by more than ordinary attention to the health of the mother during her pregnancy, wherever there is reason to apprehend the existence of a scrofulous disposition.

When the child of a scrofulous father is born, the infant, unless the mother is free from all traces of the disease, ought to be consigned to a wet-nurse of sound and robust constitution, having an abundant supply of milk. This alone ought, for some months, to be sufficient for the nourishment of the child; but after a time, should it appear delicate, a little isinglas jelly may be allowed in addition, or liquid yolk of egg, or beef-tea, together with some preparation of wheaten meal or flour, or pure starch. Daily immersion in cold water, and gentle friction of the whole body will be found of great utility. The child ought to be warmly clothed, to be carried about in the open air as much as possible, and the apartment in which it sleeps ought to be kept at a steady moderate temperature, and perfectly well ventilated. All rooms occupied as nurseries for children ought to be spacious and lofty, never situated in a sunk floor nor in an attic, and, if possible, considerably above the level of the ground—directions which will be readily understood, when it is recollected that low rooms are ill ventilated and often damp, while those in the attic story are particularly liable to variations of temperature.

As the child grows up, a similar plan of management will be found to avert, as far as it can be accomplished, the formation of a scrofulous habit, and the development of the disease in those who exhibit that tendency. A plain and nutritious diet, containing a larger than usual proportion of animal food, warm clothing, daily exercise in the open air, the cold plunge-bath, cool and well-ventilated rooms, moderation in the pursuits of pleasure, of study, and of business; strict temperance and virtuous habits; may be said to comprise all that is most likely in our mode of living to give protection throughout life against the occurrence of scrofulous disease. To those in affluent circumstances who can be removed to a climate more genial than that of Britain, such a change, if judiciously made in early life, will confer a still greater security from scrofula. (*Dr. James Clark*, On the influence of Climate. See also art. CLIMATE, in this work.)

When a well-marked strumous tendency exists, the management of the mind urgently demands our attention; and attempts ought to be made at a very early age to correct whatever is deficient or excessive in its operations. Children who are of a dull and apathetic character ought to be roused by presenting to them objects which are likely to interest and enliven, while the ardour of others in the pursuit of knowledge should be cautiously repressed; and when the genius gives promise of unnatural precocity, means should be used to retard the unfolding of the mind, and allow the faculties to mature themselves by slow degrees. The moral feelings, in an especial manner, require a strict control for the purpose of giving them a just direction, and preserving individuals of a sensitive character from indulging in those extravagant manifestations of sensibility which, if permitted, are apt to endanger the soundness of the mind.

Before proceeding to consider the cure of scrofula, it will be necessary to direct our attention to the different conditions of those who are afflicted with this disease. It is frequently engrafted on a feeble and attenuated frame; but it exists also in combination with a plethoric habit, perhaps deceiving with a false show of strength; the first of these forms being often exemplified among the poor, the second among the rich, although not by any means uniformly so. Hence a broad line of distinction arises between the methods of treatment adapted to such different types of the disease. In the former a generous diet and stimulating remedies are required; in the latter spare living, moderate evacuants, and local depletion are necessary: both, however, demand the employment of those tonic means which tend to communicate vigour to the constitution, and which increases that power of resisting the occasional causes of disease and repairing the injuries of the frame; a power which it is the remarkable characteristic of the scrofulous constitution to be devoid of, or to possess in a very imperfect degree.

To consider in detail, the method of treating each of the extensive class of strumous affections would involve us in the repetition of what will be found under various specific heads of disease, and swell the present article far beyond its due limits. It will be sufficient, after premising a few general

remarks, to pass in review the chief of the numerous remedies which have been held in estimation for the cure of scrofula; pointing out, as we proceed, the particular circumstances under which they have appeared to produce most benefit.

The management of scrofulous patients, in respect of air, exercise, clothing, and diet, must be conducted upon the principles already laid down, but varied according to the exigencies of each individual case, still keeping steadily in view the improvement of the constitution.

On the subject of diet it is deserving of notice that, besides those varieties before alluded to, a very nourishing food may be prepared by boiling a small bag filled with suet in cow's milk. We have made trial of it on the recommendation of Dr. Paris, (On Diet, 2d edit.,) and found it to answer remarkably well in cases of scrofulous marasmus when almost every other article of diet caused irritation of the bowels, and passed through undigested. It bears a near resemblance to goat's milk, but has the advantage of being more astringent.

Some eminent writers have not hesitated to state their belief that air, exercise, and proper clothing and diet, comprise the best and only method of controlling and removing scrofula. To such an opinion we cannot subscribe, although we fully acknowledge the vast importance of attending to these particulars, and the natural progress of cases of external scrofula towards a cure, after the age of puberty. An amusing instance of the effect of air and exercise alone in the cure of a scrofulous sore in the leg is afforded by the case of a young nobleman, who, after suffering under a variety of regular treatment, had a hole cut in his stocking, and was sent to range the fields, when a crust soon formed, and the ulcer healed. It is worthy of remark that this individual became afterwards insane.

1. *Evacuants.* — Although it be true, in a general sense, that scrofula is a disease of debility rather than of strength, and that profuse discharges, whether natural or artificial, prove among the most powerful of its exciting causes; yet in the early stage of many scrofulous diseases, and sometimes during their progress, a cautious employment of evacuants is found to be productive of the best effects; but it is only by a careful study of the existing symptoms of inflammation in each individual case that we are enabled to make use of depletory means with confidence and success. In strumous persons the occurrence of inflammatory symptoms is to be watched with unceasing care, and above all those of the respiratory mucous membrane, as well as of the serous membranes of the head and abdomen: a well-timed venesection in such cases may be the means of cutting short symptoms which would speedily induce the eruption of a crop of tubercles; on the fatal consequences of which, whether slow or rapid in their progress, it is unnecessary to enlarge. Leeches are often preferred from the timidity of patients and their friends, and sometimes perhaps from the indolence of medical attendants; but their effects are frequently irritating and exhausting, and, even in children, far inferior to those of the lancet. Cupping is also preferable to leeching, the ease and rapidity with which blood can be taken by this method placing it nearly on a level with venesection. The detraction of blood from the vicinity of parts suffering from scrofula, or in danger of becoming the seats of scrofulous affections, is in very many cases necessary; and in these both leeches and cupping may be employed, but under the guidance of a wise discretion, for which no general rules can be given. To promote the efficacy of sanguineous depletion, and supply its place when circumstances render it unsuitable, the tartrate of antimony may be exhibited in small doses, as a nauseant and diaphoretic; and it will sometimes be necessary to have recourse to this remedy during the progress of the tonic plan of treatment when it appears, as often happens, to be producing too much excitement. The tartrate of antimony or ipecacuan is also used, with excellent effects, in emetic doses, for the purpose of preparing the stomach for the reception of tonic medicines in many scrofulous cases.

Long-continued nausea, whether produced by sea-sickness or by the persevering use of tartar-emetic, has a powerful effect in dispersing indolent tumours, and has been successfully employed for that purpose. Two cases of this nature, and one of presumed tuberculous phthisis, cured by the use of nauseants, have been communicated by Dr. Jenner; and he has expressed a hope that by such remedies we shall be enabled to affect the absorption of tubercles. (Baron's Inquiry, pp. 158, et seq.) All that we know of the action of the absorbents leads us to believe that they are capable of removing tubercles; and that such an operation, to a certain extent, does really take place, is proved by the changes which that substance undergoes in its progress to the cretaceous transformation. If tuberculous masses of long standing are thus changed, what reason have we to doubt that the soft curdy matter of which they are at first composed is often absorbed and carried back into the circulation, to be converted into some less noxious constituent, or altogether expelled from the system?

The action of strong purgatives is sometimes, though rarely, required in scrofulous diseases; but the neutral salts combined with the administration of mercurials are very useful, as we shall presently point out. Moderate aperients, and those which tend at the same time to improve the powers of digestion, are required in the treatment of almost all scrofulous cases. Rhubarb and soda, and rhubarb and magnesia are well adapted to such cases; and as a mild evacuant, when the bowels are loaded, castor oil is very serviceable.

2. *Mercurials.*—Of all the remedies employed in the treatment of scrofula, perhaps none have enjoyed a greater reputation than mercurials; but it is only from their purgative and alterative effects that they prove beneficial, and not when they produce that powerful influence on the frame which so rarely fails to ensue from their free exhibition. In the forms of calomel and blue-pill, mercury enables us to relieve the bowels from those morbid accumulations which are so apt to collect in strumous cases, and to restore to the liver its healthy action, which is rarely preserved, at least for any length of time, during the existence of scrofula. The success of a mild alterative plan of treatment,

aided by the use of saline purgatives with senna, has been admirably illustrated by Mr. Abernethy (On the Constitutional Origin of local Diseases); and more exclusively in reference to the disease now before us by Mr. Lloyd. (On Scrofula.) Other mercurial preparations are also employed with benefit in different forms of scrofula: thus the hydrargyrum cum cretâ will be found very serviceable when the secretion of bile is faulty or deficient, whether combined with a torpid or relaxed state of the bowels, as in the early stages of mesenteric disease. The internal use of corrosive sublimate is also valuable, particularly in scrofulous ulcerations and leucorrhœal discharge; provided it be administered cautiously and in minute doses such as the eighth of a grain three times daily. It seems to act rather by stimulating the mucous membrane of the alimentary passages, and promoting perspiration, than by any influence it exerts over the secretion of the liver. Mercury has likewise been employed in the form of ointment, rubbed on the skin for the relief of scrofula, and, according to the report of Mr. Brandish (On the Use of Caustic Alkali in Scrofula, &c.), with the most beneficial effects. It was his practice to use it in small quantities, continued nightly for months, but never during the cold season; it is proper to add that he avoided the full operation of the mineral, and combined its employment with the internal exhibition of liquor potassæ, with a generous diet, and the occasional use of vegetable tonics. Of this practice in cautious and experienced hands, we are inclined to think favourably, although it must be admitted that medical opinion in the present day is adverse to the employment of mercurial frictions in scrofulous cases generally. But the local application of camphorated mercurial ointment to diseased joints and indurated testicles is now acknowledged to be in very many instances highly efficacious. (*Scott*, Observations on the Treatment of Chronic Inflammation, &c.)

As a sequel to the subject of mercurials, it will not be out of place to mention another remedy, less hazardous in its operation, but not of less approved efficacy in scrofula,—namely, *sarsaparilla*. We find it recommended by Wiseman (Vol. i. pp. 410 et seq), and after a period of neglect it has been again restored to merited favour. It is a mild tonic, and well adapted to those cases where the skin is in a harsh and unkindly state: it proves a restorative to the stomach, and is found very useful in the chronic diarrhœa of strumous children. The decoction is the usual form in which this drug is exhibited, but the bulk of this preparation often renders it objectionable, particularly for children; and in most cases, both of children and adults, a much more concentrated preparation, such as the solid or fluid extract, will be found to possess many advantages. Powdered sarsaparilla, conjoined with soda, is an excellent form, though much less palatable than the extracts: it has been given with marked benefit in scrofulous disease of the tongue.

A feeble digestion, and prevailing acid condition of the stomach and alimentary tube, are the frequent concomitants of scrofulous disease; hence the employment of the *alkalies* and alkaline earths, but particularly the former, has been attended with very beneficial effects in its treatment. All the alkalies have been used with advantage in scrofula; but the liquor potassæ is that which in our hands has proved the most decidedly useful. The dose must be large, as Mr. Brandish has shown—from half a drachm to a drachm and a half three times daily, for an adult; given in malt tea, mild ale, or infusion of hops. (*Brandish*, Op. cit.) Carbonate of soda is generally more agreeable to patients, and may be given freely with good effect, especially when combined with sarsaparilla, cinchona, or bitters. The volatile alkali (carbonate of ammonia) has also been administered in scrofulous cases (*Charles Armstrong*, on Scrofula), and with excellent results. But its stimulant and diaphoretic properties render it suitable only for cases in which there exist torpor, languid circulation, impaired appetite, and a dry husky state of the skin, such as we often meet with among the poor, and in that form of the disease so well characterized by Alibert (Nosologie Naturelle), under the designation of *scrofule nomie*.

A considerable number of the remedies which have enjoyed reputation in the treatment of scrofula, have belonged to that class which increase the secretion of urine. The alkalies which we have just considered are of this description; and besides these, we may enumerate the muriate of lime, the muriate of barytes, and nearly all the mineral waters to which scrofulous patients are in the habit of resorting. These saline remedies not only promote the secretion of urine, bnt act gently on the bowels, and thus, especially when conjoined with the exercise and free air enjoyed at a watering-place, increase in a remarkable degree the powers of digestion, and so prove beneficial to the scrofulous invalid. In their specific effects we have no confidence. Muriate of barytes is now very rarely prescribed; and muriate of lime almost as seldom, excepting in the combined form in which it is furnished by nature at various mineral springs.

The opinions which we have already expressed regarding the nature of scrofula may have prepared our readers to look for the most valuable remedies in this disease under the head of *tonics*. Even inflammation, which in most cases requires depletory measures, is, when combined with scrofula, and thus rendered indolent in character, often successfully treated by tonic remedies; this is especially true of those inflammatory affections which are attended with little or no constitutional disturbance, as in strumous inflammation of the conjunctiva, where the efficacy of cinchona has so long been acknowledged. This admirable drug is, without doubt, the most efficacious of all the tonics used in scrofula, and, from the concentrated form in which it can now be exhibited, the most generally available. The virtues of cinchona in strumous diseases were first brought into notice by Dr. Fordyce, (Medical Obs. and Enquiries, vol. i. p. 184; see also *Fothergill*, ibid. p. 303,) and from that time until now it has enjoyed more or less favour. Sulphate of quinia has now very generally superseded it, having become a remedy of every day prescription. It is one, however, which requires to be carefully watched and immediately intermitted when it produces, as it often does, a degree of feverishness. Other vegetable tonics and bitters have been administered with

advantage in scrofula, such as calumba, gentian, and hop; and in Germany, coffee made from roasted acorns has found many advocates, although, as Benedict (Handbuch der Practish. Augenheilkunde) informs us, it often proves constipating and induces a feverish state.

[Of late, different preparations of the leaves of *Juglans Regia*, walnut tree, and especially the extract, have been highly extolled by M. Négrier as anti-scrofulous remedies. (*Archiv. Général. de Méd.* x. 399, Paris, 1841.)]

Of the metallic tonics used in scrofula, iron is that which has been found the most beneficial. The best forms of exhibiting it are the vinum ferri, the muriated tincture, and the subcarbonate in powder: the chalybeate mineral waters also have often proved eminently serviceable in this disease.

Arsenic is a metal of much more questionable efficacy; but we have known it productive of great benefit in allaying the pain attending strumous affections of the bones and periosteum. Gold was given by Lalouette in scrofula, and its use has lately been revived by Chrestien as a remedy for syphilis. [From recent trials, it would not seem to be possessed of such efficacy as to recommend it to great confidence.]

In the advanced stages of scrofulous affections, one of the most permanent and exhausting symptoms is profuse perspiration; for the purpose of checking which, the mineral acids, particularly the sulphuric and nitric, have been given with great benefit: their use, however, is apt to cause irritation of the bowels, and thus we are forced to alternate them with opium, or altogether to abandon their employment. The root of the tormentil has been recommended as a substitute, but it seems to possess very feeble powers of repressing either perspiration or diarrhœa. The mineral acids are also useful in restoring the tone of the stomach, and thus they frequently prove of great service in the treatment of scrofula.

Scrofula as a chronic disease, often accompanied with febrile action of the stomach, and indeed, of all the assimilative organs of the system, seems naturally to require the exhibition of stimulating remedies. In regard to dietetic stimulants, animal food, as we have already stated, is proper in a large proportion of strumous cases, and in some ale and wine may be given with great advantage. Of these, ale is the more nutritious and less heating, and when sound and well seasoned with hops, it proves in many cases a valuable auxiliary to the medicinal treatment of scrofula,—an opinion which is not given on theoretical grounds, or the mere authority of others, but from what we have had frequent occasion to observe. Bitter tinctures have been prescribed in this disease, and that of Peyrhile, which contains also a proportion of alkali, was long a favourite among the French. Its effects, however, are known to have been often injurious, because too stimulating; and in the present day it is seldom or never employed.

Iodine, a powerful stimulant of the alimentary mucous membrane, and of the whole absorbent system, has lately been added to the catalogue of anti-strumous remedies; and as yet it can scarcely be said that a just estimate has been formed of its real virtues. The evidence contained in the writings of numerous authors, and the results of our own experience, prove satisfactorily that iodine possesses a very considerable efficacy in removing scrofulous swellings of the lymphatic glands; and there is some reason even to believe that it is capable also of inducing the absorption of tuberculous deposits. (*Gairdner*, On Iodine, pp. 52 & seq.; also, Baron's Inquiry.) This remedy is successfully employed both internally and locally, in each of which modes it increases the action of the absorbents; and in the latter it likewise often induces suppuration of strumous tumours, and thus hastens their removal. After attracting for a time the attention of the medical profession, iodine was beginning to experience a degree of neglect, when the appearance of M. Lugol's Memoirs restored its reputation. (*Lugol*, Mémoires sur l'Iode, Paris, 1829, 1830; and Dr. O'Shaughnessy's Translation, with Appendix.) His extensive series of experiments in the employment of this substance have placed in a very clear and convincing light the powers which it possesses of controlling and even curing scrofula. The trials which we have made of it serve to confirm the representations of M. Lugol; but we are ready to admit that his strong partiality in its favour may in some instances, perhaps, have led him a little beyond the limits of legitimate induction. For farther information regarding the employment of iodine in scrofula, we beg to refer to M. Lugol's last memoir, where a full account will be found of his most improved method of administering this powerful drug. Iodine, like arsenic and some of the mercurial preparations, is apt to cause pain of stomach, and in some instances headach; and when taken in excess, to produce an inflammatory condition of the alimentary mucous membrane, diarrhœa, and even bloody motions. The first of these symptoms is relieved by wine of cinchona, but the others require that the remedy be discontinued; and when resumed, that the dose be reduced. In cases where iodine has produced debility and loss of appetite while manifestly reducing the scrofulous swellings, we have obtained a return of health and continued diminution of the tumours, by administering in its place sulphate of quinia with extract of sarsaparilla and aromatic sulphuric acid. The evidence of many practitioners, whose veracity and correctness of observation are above suspicion, proves that iodine, when long continued in full doses, frequently produces great weakness and emaciation; but M. Lugol is disposed to throw doubt on this opinion, and he even asserts that in his experience, thin females have not become emaciated, nor corpulent ones lost flesh. It ought to be remarked in explanation of this discrepancy, that the doses which he prescribes are usually small, always moderate, and much diluted; and that he endeavours to accomplish by long perseverance what others have attempted by rapidly pushing the remedy to its utmost limit. In these particulars, we conceive, consists the superiority of M. Lugol's mode of treatment. It is proper to state here, that he also avails himself in the treatment of scrofula, of the auxiliary means of air, exercise, warm clothing, and good diet; and employs, besides, baths of watery vapour, of iodine, and of sulphureous water.

[The general condition of the system in scrofulosis might appear to suggest more especially the iodide of iron, in which eutrophic and tonic properties are combined. Accordingly, it has been extensively used, and with valuable results. Of this, a grain may be given three times a day, and the dose may be gradually raised to three grains.

Codliver oil—*oleum jecoris aselli*—which has been found to contain iodine, has been given largely in various forms of scrofulosis, and there is much testimony in favour of it. One writer, Schenck, (Hufeland's *Journal der Praktisch. Heil kunde*, May, 1838,) esteems it as certain a remedy in scrofula and rickets, as cinchona is in intermittent fever. The writer has had no experience with it. Recently, skateliver oil has been recommended as preferable to codliver oil. In Holland and Belgium, the oils obtained from the livers of *Raia clavata* and *R. batis* have been used in place of the latter, on account of their being less disagreeable to the taste, and even more efficacious as a therapeutical agent. It is said by MM. Girardin and Preisser to contain a per centage more of iodide of potassium; and in point of purity and other properties, appeared to be superior to it. (*Edinb. Med. and Surg. Journ.*, Oct. 1842, p. 504.)

Dr. Ure has suggested the use of codliver as a diet for those for whom the oil is considered to be indicated. (*Pharmaceutical Journ.*, Nov. 1, 1842, or Braithwaite's *Retrospect*, vi. 104, Lond. 1843.)

Bromine, whose properties resemble those of iodine, has been given in the same cases, but it possesses no advantage over the other, and is by no means as easily attainable.]

The use of *baths* in the treatment of strumous affections is of great value, the kind of bath made choice of being determined by the existing state of the patient. Sudden immersion in cold water, and especially sea-water, has long been an approved remedy in scrofula; but when the strength of the patient is so reduced that no kindly glow follows, and when there is decided feverishness, the cold plunge bath is not admissible. In such cases the warm-water bath, and still more that of vapour, will be found highly soothing and restorative. To weak scrofulous invalids, the well-managed application of steam has very often proved signally beneficial. A greater degree of excitement may be communicated to the cutaneous surface, when the general torpor of the system or the indolence of the diseased parts demands it, by the employment of warm saline water, or impregnating the water or steam with irritating gases, such as sulphuretted hydrogen, carbonic acid, (see the Remarks of Prof. Osann on the Gaseous Baths at Eger. Osann und Trommsdorf Die Mineral Guellen, etc., Berlin, 1822,) chlorine or iodine. The use of baths of every kind ought always to be followed by friction, and this alone is a valuable mean of restoring the healthy actions of the skin, and furnishing a substitute for that bodily exercise which the condition of the scrofulous patient often disables him from using. In cases of abdominal obstruction and affections of the spine and joints of the extremities, the great benefit derived from friction is attested by all who have seen it carefully practised.

Other modes of stimulating the scrofulous patient are afforded by electricity and galvanism: hitherto these have been employed principally as local remedies for the dispersion of strumous swellings, and with excellent effects; (*Underwood*, Surgical Tracts.—*Birch*, on the Medical Application of Electricity;) but they will be found equally, if not more beneficial, as general means of exalting the nervous energy, and improving the tone of the whole frame.

Like all diseases occasionally attended with pain, scrofula requires at such times the use of narcotics, and, among these, opium under various forms of preparation certainly holds the first place. Hyoscyamus, belladonna, and conium, are also used with advantage; and the last obtained at one period, through the writings of Dr. Stöeck, a particular celebrity for its anti-strumous virtues. It has both as an internal and external remedy a considerable power of relieving pain; but none which we have observed of a truly discutient nature.

Topical Treatment.—Of the local treatment of scrofula, it may be supposed that the physicians ought not to speak; but, although this branch of the subject falls immediately within the province of surgery, we may yet be permitted to state generally our views regarding this matter. Long observation of scrofulous diseases has convinced us that much active surgical interference is usually injurious, and that mild and soothing modes of treatment are, on the whole, more generally successful. Thus the laying open of sinuses, the cutting away of undermined integument, and the application of strong escharotic ointments, often exasperate instead of improving the case; while small counter-openings, moderate pressure, brushishing the integuments around ulcers and fistulous openings lightly with nitrate of silver; and the application to strumous sores of bread-and-water poultices, astringent washes, lime-water, and the black mercurial lotion, proves very serviceable. When a scrofulous ulcer is highly irritable and painful, the bruised fresh leaves of the hemlock applied as a poultice seldom fail to give relief. In ulcers of the tongue, carrot pulp and Peruvian balsam are the best applications.

Indolent scrofulous tumours, when the health is little reduced, may be dispersed or made to suppurate by continued pressure or by blistering, which can be employed when the situation of the swelling will not admit of pressure. As soon as suppuration has taken place, and the matter approaches the surface, it ought to be evacuated by a small puncture, which will hasten the cure and diminish the chance of an unseemly scar. When the parts continue inflamed and hardened, poultices of bread and water, or rags dipped in cooling lotions, are the best applications; but when the discharge is considerable, finely carded cotton with gentle pressure checks the profuse secretion, and gives comfort to the patient. In those sudden depositions of fluid which sometimes occur in strumous cases, it is not always prudent to make an opening as soon as fluctuation can be detected; for by a little delay and soothing means we have not unfrequently known the fluid to be wholly absorbed.

[When the strumous swellings are very indolent, along with the internal remedies, and re-

gimen inculcated above, many local applications may be made use of to discuss them. Chlorinated lime has been applied with advantage in the form of ointment, as well as the aqua chlorini. Iodine has been used advantageously in the form of tincture, applied repeatedly by means of a camel's-hair pencil. The ointment of iodine, of iodide of potassium, of the iodurетted iodide of potassium, and of the iodide of lead, have likewise been used with advantage, rubbed on the part night and morning, and the iodo-hydrargyrate of potassium has been prescribed both internally and externally. An ointment of veratria has likewise been strongly recommended, but it has not been much employed.]

The eczematous and impetiginous eruptions which occur in scrofulous individuals are greatly benefited by astringent applications, such as the liquor subacetatis plumbi and liquor aluminis compositus; and when these diseases have proved obstinate, the unguentum picis will often completely remove them. This last application we have found particularly efficacious in those crops of psydracious pustules and extensive exfoliations of the cuticle which are so frequently seen on the fingers of scrofulous females and delicate children.

The tumid upper lip, so distinctive of scrofula, and often amounting to a deformity, may be greatly reduced or altogether removed by the repeated application of nitrate of silver. When the ulcerated fissures of the lip are very painful, relief will be obtained from the hemlock poultice, and nitrate of silver can be afterwards had recourse to.

Strumous enlargements of the tonsils were formerly treated by excision, and cases requiring this procedure do sometimes occur: the practice is as old as Celsus, and is still a favourite with the Baron Dupuytren; Dr. Hosack of New York has also lately borne testimony to the safety and advantage of this operation, [and it is now frequently — perhaps too frequently — practised.] When it is not absolutely demanded, the employment of iodine, leeches to the throat, the light application of nitrate of silver to the tumours, and a gargle of oak-bark, will generally prove sufficient, if not for a complete cure, at least to keep the swellings within moderate bounds.

Scrofulous diseases of the bones and joints require, in their first stage, local depletion, and at a more advanced period counter-irritation by croton oil, blisters, tartar-emetic ointment, caustic issues, or moxa. The warm-water douche and careful friction are also eminently useful in indolent cases. A very successful plan of managing diseased joints has of late been made public by Mr. Scott, (Observations on the Treatment of Chronic Inflammation, &c.,) — consisting of the application of camphorated mercurial ointment, pressure, and complete rest of the affected articulation without confinement of the patient.

When all hope of recovering a diseased portion of the body is at an end, the question immediately presents itself whether such part ought not to be removed by an operation, and the patient thus freed from what is in itself useless, perhaps burdensome, the cause of constant irritation, and in many cases of exhausting discharge. Scrofulous bones and joints are peculiarly of this description, and the question of their amputation is seldom determined without the concurrence of the physician. It has been asserted that amputation in such cases merely puts off the evil day, and that the patient, at no distant period, is destroyed by scrofulous disease of some other and more important organ; but the futility of this opinion is daily attested by the numerous living instances, not only of those who have suffered amputation for scrofulous affections in early life, but of multitudes of others who have survived with contracted and distorted limbs from the ravages of the disease. In considering the propriety of amputation, it is necessary to determine how far the continuance of the affection brings the patient's life into hazard, and whether he has still sufficient strength left to undergo the operation. It is truly surprising to observe how small a degree of vital force is adequate to carry a patient safely through an operation under such circumstances; but it must be remembered that amputation, severe as it certainly is, removes the very sources of irritation and exhaustion which are rapidly undermining life. This operation is nugatory when another joint, or a vital organ, as the lungs or bowels, is already the seat of incurable disease; and in such cases unquestionably it should not be performed. Great caution, however, is required in making our final decision; for every practitioner of experience has seen instances where the symptoms of visceral disease appeared almost to preclude hope, and yet have yielded on the removal of the local irritation, and a cure has been the happy result.

W. Cumin.

SEDATIVES, from *sedare*, to calm. These are medicines which directly depress the energy of the nervous system, and diminish preternaturally increased action. They exert an immediate influence over the nervous system, by which its energy is either greatly weakened or wholly destroyed. They thus have a twofold action, first, upon the nervous system, and, secondly, through it upon the muscular: if the dose be large, the individual quickly loses his volition and becomes vertiginous; the nerves of sensation cease to respond to ordinary impressions; consciousness fails; syncope supervenes, and in a few seconds life is extinct.

With the exception of Dr. Young (Introduction to Medical Literature,) and Dr. Billing,* medical authors in general have confounded sedatives with narcotics. There is no doubt, however, that the distinctive characteristics of both classes are well marked, and that the boundaries of each may be readily traced. The only circumstance, indeed, which has prevented the distinction from being at all times perceived, is the transitory nature of the excitement which follows a large dose of a narcotic, and the rapidity with which the symptoms of diminished sensibility and mobility supervene, as if they were induced without any previous increased action. In the operation of every narcotic the depressing effect, therefore, is preceded by increased action; and both the degree of the collapse and the rapidity of its appearance depend on the extent of the previous excitement. In

* First Principles of Medicine, p. 44. [The separation is made by the writer in his *General Therapeutics*, Philadelphia, 1836 & 1843.]

small or moderate doses, narcotics augment the force and increase the frequency of the pulse, promote the secretions, and elevate the powers both of the body and the mind, and if these doses be repeated at proper intervals, this excitant effect is maintained; but, if the dose be not repeated, the transitory nature of this excitement becomes conspicuous, and a state of depression or collapse follows, in which languor, dullness of sensation, and sleep ensue.

Such are the effects of a narcotic. The administration of a sedative, on the contrary, whatever be the dose, is not followed by any perceptible quickening or augmentation of the pulse, but by an immediate diminution both of its force and frequency, and by a general feeling of depression, too decided to be overlooked. It is, indeed, evident that this effect is exactly the opposite of that of an excitant: and if the dose be large, not only is the sensibility diminished, but the whole power of the sensorium is at once completely paralyzed. We are perfectly aware that Magendie and others regard the sedative influence of one of the most efficient of this class of medicines, the hydrocyanic acid, as that of transient excitement, followed by an immediate state of collapse; but the result of our own experiments on living animals is adverse to this supposition: the instantaneous diminution of the general powers of the system, the prostration of strength, the stupor, numbness, sleepiness, vertigo, and depression of the animal spirits, all indicate an immediate influence on the nervous energy. With these observations in view, and with the experiments of Mr. [Sir B.] Brodie on some poisonous substances before us, we may venture to assert that it is upon the nerves of sensation chiefly that *direct* sedatives operate.

When sedatives are taken into the stomach, if they do not destroy life, their influence is much weakened after a certain time has elapsed, and soon afterwards it altogether ceases. It may, however, be maintained in the same manner as that of narcotics, by the repetition of the dose at moderate intervals; but the impression becomes weaker after each renewal of it, until it is almost lost, unless the dose be greatly augmented. If these statements be correct, it is evident that sedatives operate directly on the nerves of sensation, and that this effect is not the result of a stimulus rapidly exhausting the excitability of the nerves, but of a direct impression of a peculiar kind on the nervous system, which instantaneously destroys the susceptibility of the nerves for receiving impressions from external stimulants.

Owing to the ideas which we acquire in early life, the effects of excitants are connected with mechanical impressions, and, therefore, the mind has less difficulty in admitting the hypothesis that every instance of collapse must be preceded by a previous state of excitement, than that something is either abstracted from the nerves, or that some alteration takes place in these organs, which diminishes their faculty of receiving impressions. It is true that no organic change can be detected in the nerves of animals killed by sedative poisons, and we are equally unable to affirm from inspection that any thing has been abstracted from them, yet that some change has occurred is undoubted, as they are no longer susceptible of being excited.

Whether we can assume that the sedative effect is immediate, not secondary, is questionable: but we imply its direct character from the local effect of powerful sedatives where they are applied in small quantity to a limited portion of the surface of the body; as for example, if the finger be held over the mouth of a bottle of hydrocyanic acid, it is numbed, and it continues so for a considerable time without any extension of this effect to the rest of the body. When the quantity is larger, their influence ceases to be partial, and is extended over the system: and when it is very large, the same rapid destruction of life follows as when the sedative is taken into the stomach. Sedatives consequently differ from many of the other classes of medicines, in their effects being more regulated by the extent of the dose than by the state of the body. Upon the whole we conceive that there are sufficient reasons for separating sedatives from narcotics, and allotting to each a distinct place in the arrangement of the materia medica.

Let us examine their influence, as physiological agents, on the different organs of the living system.

1. **On the Digestive Organs.**—No sensation in the stomach is experienced when a sedative is taken into it, except occasionally that of nausea: the influence of the sedative is rendered obvious rather by the change which follows in the state of the digestive function than by anything which can be referred to the condition of the organ itself. If the viscus be morbidly irritable, the influence of the sedative is acknowledged by the diminished susceptibility of the gastric nerves, by the improvement of digestion from the lessened irritability favouring the formation of a more healthy, because more slowly secreted, gastric juice.

In this respect, when the dose is moderate, the direct influence of the sedative is local and confined to a certain set of nerves, although the general system ultimately benefits by the change thus affected, a fact daily illustrated in the administration of hydrocyanic acid in dyspepsia; whereas the influence of narcotics is invariably propagated over the system, even when they are administered in small doses.

If the dose of the sedative, however, be increased, the impression then extends to the brain, and is manifested by slight vertigo, transient insensibility, sinking of the pulse, failure of the muscular energy, particularly in the thighs, general lassitude, and mental depression. If the dose be larger, but within the limit of a poison, it must be admitted that sensations, for example weight and an obtuse pain in the forehead, are superadded, which seem to indicate previous excitement; but that this has not existed is highly probable, since we know that coma may proceed from inanition as well as from increased action in the brain, and that stimulants are frequently requisite to relieve symptoms closely resembling those requiring venesection and depleting remedies. Taken into the stomach, therefore, sedatives operate directly upon the nerves of that organ, and, within a certain limit with respect to dose, the effect which follows is strictly local.

2. **On the Circulating and Respiratory Organs.**—When the influence of a sedative extends to the general system, the action of the

heart and arteries is diminished, but not in the ratio of the impression on the nervous system. Schubarth asserts that the heart loses its contractility, but the experiments of Coullon, (Researches, &c. p. 146,) with which those of the author accord, lead to an opposite opinion. In poisoning by hydrocyanic acid, the heart continues to pulsate, and the intestines continue to display their peristaltic and vermicular movements after the death of the animal, and they do not lose their contractility for some time; at least such is the case when hydrocyanic acid is taken, and it is probable that the same occurs when other sedatives are employed. As far as relates to the lungs, if sedatives be applied directly to them either in the form of gas or of vapour, the effect is both more rapid and more decisive than when they are swallowed; the respiratory function is almost instantaneously suspended; no change takes place in the blood, which retains its venous character, and, on examining the organs, nothing is perceived which can authorize the idea of excitement having existed: death, in fact, is the result of the complete destruction of muscular irritability. When taken into the stomach, the action of sedatives on the lungs is greatly modified; the blood, however, remains dark-coloured and retains its fluidity.

3. **On the Nervous System.** — It is unnecessary to repeat that the nerves are the organs on which the influence of sedatives is chiefly and directly exerted; but little is known with regard to the nature of the impression, except that it is different from that of any exciting agent; and after the most minute inspections of the brain, the spinal cord, and the nerves, in cases of death from poisoning by sedatives, no other conclusion has been arrived at. Whatever may be the impression, it is assuredly not that which is followed by excitement.

4. **On the Secerning System.** — Sedatives produce effects which, to an ordinary observer, might seem almost at variance with the foregoing opinions: thus, salivation has occasionally followed the employment of hydrocyanic acid; (Lond. Med. Journ. Feb. 1823, p. 128,) and the secretion of urine is not unfrequently greatly augmented by whatever produces a sedative effect on the system. But such results do not necessarily imply previously increased vascular action in the salivary glands and the kidneys: thus we know that in the lowest condition of the nervous excitability in fatuity, salivation is one of the most ordinary attendants, and under the influence of fear and other depressing passions, nothing is more common than a sudden and copious secretion of urine. Upon the whole, we have sufficient reason for concluding that there are powers which can destroy excitability and life without causing previous excitement, or, at least, without any signs of its being discoverable. This is not the result of the administration of narcotics, and therefore we feel authorized in forming a distinct class of sedatives.

In treating of sedatives employed as therapeutical agents, we may arrange them under two heads; 1. *direct*, or those which operate by their immediate influence on the nervous system; and, 2. *indirect*, those which operate through the medium of the vascular system.

1. The first and most powerful of the direct sedatives is *hydrocyanic acid*.* This acid, as prepared for medicinal use, is one-sixth only of the strength of the concentrated acid, but it differs from it in no other particular. It is colourless, limpid, and has a penetrating odour, which causes headach, nausea, and fainting, when inhaled in considerable quantity by the nostrils. This odour has been erroneously compared to that of the peach-blossom,—an error originating from the odour of the volatile oil, which is, in some instances, as in the peach kernels, blossom, and leaves, and in the bitter almond, mingled with this acid. The odour of the free acid, when well examined, cannot be confounded with that of the peach-blossom.†

The pure acid is extremely volatile, and even the diluted or medicinal acid is so much so as to be greatly weakened when not carefully preserved. It is also spontaneously decomposed when it is not kept in a cool place: the best method of preventing this decomposition is to place the bottles containing it in water, or in porous jars saturated with moisture. In prescribing hydrocyanic acid, it is essential to know that it is decomposed by the aqueous solutions of chlorine and the oxides of antimony, and is precipitated by nitrate of silver and sulphate of copper. These substances are, therefore, incompatible in prescriptions with hydrocyanic acid, but it may be combined with the salts of iron if no alkali be present. This acid is the active principle of laurel-water, the distilled water of the leaves of the prunus *lauro-cerasus*; cherry-water, distilled from the bark of the cluster cherry, prunus *padus*; the kirsch-wasser of the Germans, which is a spirit distilled from the fruit of the same species of prunus; and the oil of

* This name is a compound of ὑδῶρ, water, and *cyanogen*, (a compound substance, named from κύανος, *blue*, and γένναω, *to produce*,) signifying a produce of blue, as it gives the blue colour to the ferrocyanate of peroxide of iron, or Prussian blue.

† The plan of this work forbids any detailed account of the various methods proposed by Vauquelin, Gay, Lussac, Robiquet, Pessinau, Frantwain, and others, for preparing the medicinal hydrocyanic acid; but it may be useful to describe the following processes, by which any practitioner can readily prepare it for himself.

1. Put into a wide-mouthed phial a solution of one part of bicyanide of mercury, dissolved in eight parts of distilled water, and pass through it a stream of sulphuretted hydrogen gas, extricated in another phial from a mixture of equal weights of sulphuret of iron, and strong sulphuric acid, diluted with two parts of water. The gas must be passed as long as any sulphuret of mercury in the form of black powder is formed; the fluids then filtered, and any excess of sulphuretted hydrogen removed by agitating the solution with a little carbonate of lead, and filtering a second time.

2. Put into a phial twenty-two grains of cyanuret of potassium, and pour over it a solution of fifty grains of pure tartaric acid in six fluidrachms of distilled water, and eight of rectified spirit. After agitating the phial occasionally, secure the stopper, and set it aside until the precipitate falls to the bottom: then decant the clear acid. The acid thus formed should contain one grain of hydrocyanic acid in every fluidrachm, which is easily ascertained by adding in small quantities to a given portion of it peroxide of mercury finely levigated, as long as agitation enables the acid to take it up. By dividing the weight of the peroxide dissolved by four, the quotient expresses the quantity of real acid contained in the diluted acid. No heat should be employed. [See the form for the preparation of hydrocyanic acid, in the Pharmocopœia of the United States.]

bitter almonds, now occasionally employed as a medicine, and very generally in confectionary.* But along with the acid in these and similar preparations, there is a volatile oil, the odour of which, as we have already stated, is very distinct from that of the hydrocyanic acid, is stimulant, and possesses poisonous properties nearly equal to those of the acid.† It is, however, not a direct sedative, but resembles a narcotic in its operation: thence the effects of the oil of bitter almonds and laurel-water differ considerably from those of free hydrocyanic acid.

Concentrated hydrocyanic acid cannot be employed as a medicine.‡ The same circumstance, the powerful influence of this acid on the nerves of sensation, which renders it so awfully formidable when it is taken in doses sufficient to produce its poisonous effects, renders it in the hands of the prudent and well-informed practitioner, when its dose is judiciously regulated, its administration properly timed, and its effects are carefully watched, a remedy possessed of powers which cannot be obtained from any other substance, and it is therefore extensively employed.

The use of hydrocyanic acid is indicated in diseases connected with a state of excessive or morbid sensibility, and those depending on a highly irritable state of the nervous system. This general statement is not solely influenced by the opinion which we maintain of its direct sedative power, and were the assertion that it produces at first a transient excitement capable of demonstration, it would not affect in any degree the administration of the acid; for as this excitement is said to be of a very transitory nature, it need not be taken into account in estimating the sedative powers of the remedy. In idiopathic fever, hydrocyanic acid has been rarely if ever employed: it has, however, been supposed to act beneficially in hectic, moderating the force of the circulation and suspending the night-sweats which always accompany this symptomatic fever;§ but, in reference to phthisis, the eulogy bestowed by some practitioners on this acid has not been merited. Neither, with the exception, perhaps, of phrenitis, is it calculated for the relief of the diseases classed by nosologists under the title Phlegmasiæ: even in phrenitis we have had no experience of its utility, but knowing that the inflammation of the membranes of the brain morbidly augments the general sensibility, as illustrated by the impatience of light and of sound, we are disposed to recommend its employment as an adjuvant to other remedies in this state of the brain. In pleurisy it has been found beneficial in moderating the cough, one source of exasperation of the inflammation of the serous membrane; but beyond this it has no pretensions to be regarded as a remedy in this disease.

In the exanthemata, except as an external application, hydrocyanic acid holds forth no prospect of benefit. In the state in which it is found in the bitter almond, it was employed as an external sedative so early as the time of Celsus in several external diseases; his formula in a painful pustular disease, which he describes as peculiar to infants, is the following: "lapidis, quem pyriten vocant, partes octo, cum quinquaginta amaris nucibus miscetur, adjiciunturque olei cyathi tres." (De Medicina, lib. v. c. 28, § 16.) But even as an external application, the volatile oil of bitter almonds requires to be used with much caution, and Coullen has recorded the case of a child killed by the leaves of the prunus *lauro-cerasus*, applied to a sore on the neck. (Researches, &c.) The free acid has been recommended by the author of this article in the proportion of f.ʒiii to f.ʒvi of bitter almond emulsion, as a lotion in impetigo or running tetter. In such cases also, when the irritability is very considerable, it may be combined with the acetate of lead according to the following formula:

R. Acid. hydrocyan. f.ʒiv.
Acet. plumbi, gr. xvi.
Alcoholis, f.ʒi.
Aquæ destillatæ f.ʒviiiss. M.

This lotion not only soothes the irritability of the diseased surface, but also disposes the skin to renew its healthy action, and is productive of the greatest comfort to the patient: it has been found very useful in prurigo *inveterata*, in the various forms of psoriasis, and several other skin diseases attended with itching and tingling.

In passive hemorrhages no advantage can be expected from hydrocyanic acid; but in active forms of the disorder, much confidence may be placed on the internal use of it. In hemoptysis, by rapidly augmenting the dose from three minims (the medium dose) to twelve minims, or until the pulse begin to afford indications of the deleterious influence of the medicine, we have seen the most happy results in the absence of any organic affection. In phthisis, as we have said, the powers of hydrocyanic acid have been much overrated; nevertheless as a palliative it is not without its value. In small doses frequently repeated, it diminishes the hardness and frequency of the cough, and lessens the general hectic tendency: but more is not to be expected from it in this respect than from some of the narcotics. It has, however, one advantage over narcotics, namely, that, besides moderating the cough, it frequently favours sleep

* Hydrocyanic acid is found in the leaves and kernels of almost all the plants of the natural order Amygdaleæ, and in the pips of some of the Pomaceæ and Aurantiaceæ; it is formed when copaiba is distilled with diluted nitric acid.

† When the volatile oil of bitter almonds is redistilled, the first portion which comes over smells strongly of hydrocyanic acid, and affords indications of its presence when tested; but it smells very faintly of the peach-blossom: the second portion exhales a more powerful odour of the peach-blossom than the first, but less of that of the hydrocyanic acid. The first portion operates as a powerful direct sedative in the same manner as free hydrocyanic acid; the second, besides operating primarily as an excitant, produces violent convulsions when it poisons. What remains in the retort, if the distillation have been carried far enough, crystallizes on exposure to the air, and absorbing oxygen, acquires all the properties of an acid: this is completely inert on the living system. Vogel has suggested that these changes depend on the process, and he supports his opinion by the fact that a quantity of bitter almonds, which, if made into an emulsion, may be swallowed with impunity, when distilled would yield a product more than sufficient to destroy the life of one individual.

‡ For an account of its poisonous influence on the animal system, as well as that of the diluted acid, the oil of bitter almonds, and laurel-water, with the modes of detecting these poisons and of counteracting their effects, we must refer our readers to the article Toxicology.

§ Historical and practical Treatise on the Internal Use of the Hydrocyanic Acid, &c. By A. B. Granville, M. D. &c. p. 59, 1820.

without exciting those sweats which are too often augmented when opium is employed. At the same time, as its tendency is to lower the powers of the system, it is in the early stages only of this disease that it can be regarded as likely to prove beneficial even as a palliative. Its employment in phthisis, in the combined state in which it is found in laurel-water, is, indeed, of no recent date, most of the old works on consumption enumerating laurel-water amongst the means to be employed for soothing the cough. From some experiments made by M. Jorg, at Leipsig, we might infer that it would prove injurious in the early stage of the disease, as well as in every inflammatory affection. This physician exhibited the cherry laurel-water in doses progressively increased from five to twenty-five, and finally to one hundred and twelve minims. He states that the symptoms were those of concentrated action of the brain, a sensation of weight in the head, drowsiness and torpor of the intellectual functions, lassitude, retardation of the pulse, and headach, preceded by a dull pungent pain of the head, chiefly in the region of the optic nerve. It also was attended with symptoms not unlike those of bronchitis. M. Jorg refers these symptoms to plethora of the cerebral vessels, but they may depend on paralysis of the brain itself. These observations are at variance with our own experience. We have found the laurel-water and also free hydrocyanic acid almost specific in that affection of the trachea which has been termed phthisis trachealis, and which is often as fatal as tubercular phthisis. The natural combination of hydrocyanic acid in the bitter almond emulsion is also an excellent vehicle for the administration of the compound powder of ipecacuanha in the above-mentioned disease.

In affections of the mucous membrane, hydrocyanic acid is a much less equivocal remedy than in the diseases already mentioned. In chronic catarrh, and under certain circumstances in dysentery, sufficient proofs of its efficacy have been recorded. In the latter disease, when given at the same time with full doses of calomel, to the extent of four or five minims for a dose, in the bitter almond emulsion, and repeated at short intervals, it allays irritation and improves the secretions and excretions of the intestinal canal. On the same principle its power of allaying irritability, and thereby favouring a slower and consequently more healthy secretion of the gastric juice, the author of this article was induced to recommend its employment as a sedative in dyspepsia. (See Granville's Historical and Practical Treatise on the Internal Use of the Hydrocyanic Acid. First Edition, 1819.) Dr. Elliotson prosecuted this suggestion, and laid the results of a very extended trial of its powers in St. Thomas's Hospital before the profession. (Numerous Cases illustrative of the Efficacy of Hydrocyanic or Prussic Acid in Affections of the Stomach, &c. 8vo. 1820.) In dyspeptic affections it may be combined with the decoction of Iceland liverwort, infusion of calumba, or the extract of sarsaparilla; or it may be administered in water, from three to five minims for a dose, with the addition of f.ʒi of tincture of calumba or of any simple bitter. In pyrosis it affords relief on the same principle, by allaying the morbid irritability of the stomach.

It is in spasmodic affections, however, as may be readily conceived, that the sedative powers of the hydrocyanic acid are most conspicuous. In spasmodic asthma, even when the pulse is small, irregular, and often not easily distinguished, we have seen it act almost instantaneously, relieving the oppressed state of the pulmonary circulation, and restoring the free action of the respiratory organ. In hooping-cough, also, this acid displays the most striking influence when early resorted to and judiciously administered. After emptying the stomach with an emetic, and purging briskly, it may be immediately administered three or four times a day, in doses of one or two minims, according to the age of the patient, in f.ʒiss of the bitter almond emulsion, sweetened with a few drops of syrup of tolu. It is seldom necessary to change the prescription, except to increase the dose of the acid, until the cough ceases, which generally occurs in less than a month or six weeks after commencing the use of the remedy. It is requisite to confine the patients to a graduated temperature, and to restrict them to a milk and vegetable diet.

[The writer has often used hydrocyanic acid in hooping-cough, and endeavoured to observe its effects carefully; but the results have not been such as to enable him to place much reliance upon it. It certainly has not answered, in his hands, in the very cases mentioned by Dr. Thomson, half as well as narcotics employed so as to produce a sedative influence.]

In epilepsy, chorea, hysteria, and tetanus, the results of the trials of hydrocyanic acid have been of a description which do not admit of any decisive opinion of its value in these diseases. In hydrophobia it has been tried both in this country and on the continent; in few instances it appeared to allay the violence of the paroxysms; (see Transactions of the Medico-Chirurgical Society of London, vol. xiii. p. 298;) but, as may be supposed, the effect was transitory, and in no instance has it warded off the fatal termination of the attack.

The essential oil of bitter almonds has been proposed as a substitute for hydrocyanic acid, on the plea that the strength of the medicine can be more certainly determined, and that it is less likely to suffer decomposition than the free acid from the influence of air, light, and variations of temperature. Twelve minims of the volatile oil of bitter almonds, dissolved in a fluidrachm of olive oil, and formed into an emulsion with mucilage, are regarded as equivalent to four minims of the ordinary medicinal hydrocyanic acid. An objection, however, to the use of this oil is the excitant property of the volatile oil with which the hydrocyanic acid that it contains, is mixed; it also produces an uncomfortable effect on individuals of a peculiar idiosyncrasy. Some people cannot eat even a single bitter almond without suffering severely from nettle-rash, attended with vomiting and vertigo; a circumstance, as we have already stated, depending on something in the kernels independent of the hydrocyanic acid, which is further demonstrated by the fact that the sweet almond sometimes causes the same inconvenience, although no hydrocyanic acid has been detected in it.

A more useful substitute for the hydrocyanic

acid than the volatile oil of the bitter almond, is the *cyanide of potassium*, which, although it does not hold a place in any of the British pharmacopœias, yet possesses sedative properties equal to those of the free hydrocyanic acid. In solution it is a hydrocyanate; but in this change it loses none of its sedative properties. One part of the cyanide and eight parts of water form a solution which may be administered in the same doses as the hydrocyanic acid; and in this state it has been successfully employed in neuralgic affections by Dr. Buttigny and Dr. Lombard of Geneva. They have also used in the same disease an ointment compounded of five grains of the cyanide and one ounce of lard. The cyanide has also proved useful in rheumatism.*

In closing our account of this powerful sedative, candour obliges us to notice some experiments and facts which have been published on the opposite side of the question, with regard to the mode in which its influence on the nervous system is effected. The author of this article supports the opinion that it operates directly on the nervous system, whilst Magendie, Orfila, and others contend that it is previously absorbed. The only experiments we shall notice are those of Dr. Krimer of Aix-la-Chapelle, who found that when it is applied directly to the neurilema of the nerves, or to the surface of the brain and spinal cord, it displays no activity. He also supposes that he has ascertained that it does not kill, even when applied to the tongue, until it is evaporated by the heat of the mouth, and is absorbed into the pulmonary circulation; destroying life first by diminishing the action of the heart and arteries, and then by extinguishing the energy of the spinal cord. Dr. Krimer found that when the arteries and veins of a part are tied and the nerves left free, if the acid be applied to a wound it produces no effect; but the instant the ligatures are removed, it displays its power: on the other hand, also, death occurs when the nerves are divided if it be introduced into the vessels. When all the vessels of the stomach, says Dr. Krimer, are tied, although the nerves remain entire, hydrocyanic acid when introduced into the stomach does not produce its usual effect; but it operates immediately when placed on the tongue, and in thirty-six minutes it can be detected in the blood by reagents: such is the case, also, when it is inhaled, without the vapour coming in contact with the nerves of the tongue.

Notwithstanding the apparent conclusiveness of these experiments, we cannot accord with the inferences deduced from them. For instance, we cannot conceive how the acid can be taken into the pulmonary circulation, and yet not act on the nerves in its vicinity; and an assumption is made respecting pulmonary absorption, which requires to be proved. On these accounts, and from having witnessed the instantaneous effect of this acid when taken in large doses, we see no reasons sufficient to alter our formerly expressed opinion regarding its mode of action.

Tobacco is another sedative of great power. The experiments of Mr. [Sir B.] Brodie have rendered it probable that there are two efficient principles in tobacco; one an *empyreumatic volatile oil*, which operates directly on the brain and the nerves of sensation, or on the sensibility of the system; the other a saline substance, (*nicotina*,) which appears to influence chiefly the motor nerves, confining its sphere of action particularly to the heart, which it renders insensible to its natural stimulus, the blood, and thereby causing death. In whatever manner this volatile oil is procured, its effects are so powerful on the animal economy, that, when it is applied to an abraded surface, or introduced into the rectum, it causes almost instant death.† When tobacco is infused in boiling water, this volatile oil is partially taken up by the liquid, and produces the sedative effects which always more or less result from the exhibition of tobacco enemata; but the greater part of the influence of the tobacco clyster is due to the nicotina, which, in the tobacco, is probably combined with some acid that increases its solubility. The sedative influence of nicotina is such that the action of the heart ceases even before that of the diaphragm,—an effect directly the opposite of that which occurs from the administration of hydrocyanic acid. The influence of both the components of tobacco is evidently directly sedative, without even the most transient stimulant effect, whether the infusion be introduced into the stomach or into the rectum.

It is remarkable, with the knowledge which the profession possesses of the sedative influence of the tobacco clyster, that it should ever have been employed in cases of suspended animation: it is indicated and has been successfully used in cases of incarcerated hernia. If one drachm of the dried plant infused in a pint of boiling water and strained, be thrown into the rectum, great muscular debility, partial insensibility, and sometimes cold clammy sweats almost immediately supervene; relaxation of the spasms follows, during which the gut is replaced. But occasionally the aid thus afforded to the taxis is not unattended with hazard; and in certain states of the system of some individuals which are not obvious, but greatly influence the action of the remedy, it is evident that it must not be inconsiderately resorted to, nor indeed at all whilst the least chance of any other means proving useful remains.‡ When it does not succeed, and the operation must be performed, the patients do not recover so well as those who have not been subjected to its use. The sedative influence of tobacco has also been taken advantage of, in smoking the plant for the relief of spasmodic asthma, violent tooth-ache, and some painful affections of the face.

[*Digitalis*, classed by Dr. Thomson under NARCOTICS, (q. v.) is more worthy of a place among sedatives. It is an important agent with

* A method of obtaining this cyanide in a state of great purity has been lately discovered by Mr. R. Lamins.

† This oil is gradually deposited in the wooden stems of the pipes of the Hottentots, who employ it for destroying serpents. Mr. Barrow mentions having witnessed its effects when applied to the tongue of a poisonous snake; the reptile stretched itself out, became stiff, and died in an instant.

‡ When the tobacco clyster produces deleterious effects, they should be immediately obviated by throwing into the rectum a strong infusion of nut-galls, or any other substance containing a large proportion of tannin and gallic acid, so as to combine with the nicotina, and by destroying its solubility, to render it inert. Brandy, ammonia, and other stimulants, should also be administered by the mouth, and an artificial respiration maintained for some time, or until the sedative influence of the medicine begins to disappear.

the contra-stimulant school. *Colchicum, veratria, album, veratrum, viride, cimicifuga*, and perhaps *ergota* might likewise be considered, with propriety, under this head, as their main action is one of sedation.]

The *hydrosulphuret of ammonia*, although less frequently employed than either hydrocyanic acid or tobacco, is a most powerful sedative, depressing the action of the heart and arteries by operating directly on the nervous system. In very moderate doses, namely five minims in a tumbler of water, it causes nausea and vomiting; and, when the dose is increased, drowsiness and vertigo supervene. It was employed and strongly recommended by Mr. Cruickshanks in diabetes mellitus, for destroying the ravenous appetite and morbid action of the digestive organs which always accompany that disease; but it has been very little used.

Two gaseous compounds of hydrogen, *sulphuretted hydrogen* and *carburetted hydrogen gas*, exert a powerful sedative influence on the animal economy, which proves rapidly fatal to animal life, if breathed, even when largely diluted with air. The former is noticed here rather with the view of alluding to the share which it has in causing the depression that always occurs in those febrile affections in which it is extricated largely in the intestinal canal, than to refer to its therapeutical properties, although its employment in phthisis has been suggested. There is undoubtedly a copious evolution of it in all low fevers, and its direct sedative influence on the intestinal nerves is the chief cause of the collapse which attends these diseases; to obviate this, is therefore, of much consequence, and the influence of chlorine in decomposing this gas by forming muriatic acid in combining with the hydrogen whilst the sulphur is deposited, points out an easy and effectual method of doing so. Either the aqueous solution of chlorine, or of the chloride of soda, should be administered in these cases. The presence of the gas is detected by the extremely offensive odour of the fæces; and still more decidedly by holding slips of paper covered with carbonate of lead over the vessels containing them. If sulphuretted hydrogen be exhaled, the carbonate will be immediately blackened.

The second of the above-mentioned gases, *carburetted hydrogen*, has been employed for medicinal purposes, as a sedative in phthisis; but its use requires much caution, as even when diluted with twenty or thirty times its bulk of common air, it cannot be respired for more than a minute or two without causing nausea, dizziness, and other symptoms of dangerous nervous depression. Although so destructive to animal life that it cannot be taken into the lungs undiluted without producing instantaneous death, yet to no gas does the system become so soon habituated; consequently the degree of dilution which is at first requisite, may be gradually reduced with impunity. The trials, however, which have been made of it as a remedy in phthisis are as yet far from sufficient to determine accurately its influence in that disease.

2. The *indirect* sedatives operate on the nervous system through the medium of the blood, either by altering the properties of that fluid so as to unfit it for affording the requisite stimulus to the brain and nervous centre, or by extracting it in quantity sufficient to bring the brain into a similar state from defect of stimulus, or, as it were, from inanition.

The first of the sedative agents belonging to this division of the class which requires to be noticed, is *carbonic acid gas*. The influence of this gas in causing suffocation when it is attempted to be breathed undiluted, as it never enters the lungs, but causes a constriction of the muscles of the glottis, so that no air can enter the lungs, and no change take place in the blood passing through them, is supposed to be negative; thence the question, whether this gas is positively or negatively sedative? But although this gas is never admitted into the lungs in attempts to respire it, and therefore may be regarded as negatively sedative, yet there are facts which demonstrate its positive sedative properties. Thus, if the body of an animal be immersed in an atmosphere of carbonic acid gas, whilst atmospherical air is freely admitted to the lungs, sedative symptoms occur, such as weight in the head, dimness of sight, singing in the ears, vertigo, &c.; and that it even exerts a local influence on the nerves, was demonstrated by an experiment of Dr. Priestley, who, having excited pain in a blistered hand by immersing it in oxygen, relieved the pain instantly by plunging the hand into a jar of carbonic acid gas. It is also a well-known fact that the pain of a cancerous ulcer is allayed by directing upon it a stream of carbonic acid gas which has passed through water; and it is to the presence of this gas in the carrot and other fermenting poultices, that they are indebted for their sedative properties. On these accounts, although we have arranged carbonic acid gas among the *indirect* sedatives, yet it in some measure belongs also to the former division of *direct* sedatives.

Carbonic acid gas was at one time much employed as a sedative in phthisis: Dr. Percival introduced it as an antiseptic, and from the result of thirty cases concluded that it abates the hectic and improves the expectoration; (Percival's Essays, vol. ii. p. 308;) and Dr. Withering, who also looked upon it merely as an antiseptic, found that similar effects resulted from its administration. Favourable opinions of it were given by Dr. Dobson, (Medical Commentary on fixed Air. London, 1779,) Dr. Hulme, Dr. Beddoes, and Dr. Fenwick of Durham: on the contrary, the experiments of Dr. Muehry, (Inaugural Dissert. Gott. 1797,) who gave it a fair trial in five cases without material benefit, and our own experience, have led us to place little confidence in it, even as a sedative. When it is employed, it should be largely diluted with common air; the best proportions are four parts of the air to one part of the gas.

The only other indirect sedative which requires to be noticed is *bloodletting*. It is scarcely necessary to remark that a certain quantity of the circulating fluid is required to be present in the blood-vessels, in order to support the energy of the brain and nervous centres; and, therefore, that when this proportion is diminished, the result is a sedative effect on the system. In man the average quantity of blood in proportion to the weight of the body, in a healthy adult subject, is as *one*

to *five*; when a greater relative proportion exists, a diseased state of the body, plethora, takes place; when a smaller, the body becomes emaciated. If blood be suddenly abstracted from the vessels, a series of phenomena occur which demonstrate a diminished state of vitality; and if the quantity taken away be greater than a certain proportion of the whole, then death almost immediately ensues. But these effects do not depend altogether upon the quantity of blood contained in the vessels or abstracted from them, but partly upon other circumstances, which ought always to be kept in view when bloodletting is intended to operate as a sedative.

If these phenomena depend on the state of the vascular system in health, it is evident that a powerful effect must result, in disease, from the abstraction of blood, whether this be effected by opening a vein, by cupping, or by leeches. The immediate depression of the vital powers which follows this abstraction must have been early rendered obvious, from the effects of hemorrhages arising from the accidental rupture of vessels; and thence artificial means were adopted to diminish excitement by opening a vein. The syncope which succeeds is much regulated by the habit of the patient, the nature of the disease, and the manner in which the blood is abstracted; but as a particular inquiry into the morbid effects of bloodletting and the methods of obviating these are given in detail in other parts of this work, we think it unnecessary to enter into minute details, referring the reader to the articles Bloodletting, Fever, Inflammation, and Plethora.

A. T. Thomson.

[Under the head of sedatives may be included a set of therapeutical agents, now much used, in Italy more especially, but also adopted in France and in Great Britain,—rarely in this country;—agents which, by removing excitation, might be termed *sedatives*, but which, by their propounders, have been called *contra-stimulants*, and the theory which suggests them, the *theory of contro-stimulus* or *contra-stimulus*,—the *new medical doctrine of Italy*,—*La nuova Dottrina*, &c.

Prior to the termination of the last century, the doctrines of Brown were universally embraced in Italy, and they continued in vogue until Rasori, on the occasion of a petechial fever making its appearance in Genoa, subjected the prevalent views to considerable modification; and, as in most similar cases, ended by embracing views diametrically opposite. Rasori maintained that most diseases, to which mankind are liable, are owing either to an augmentation of excitability, or to an excess of stimulus; and he conceived that there are certain medicinal agents which possess a peculiar debilitant power, and which act upon the excitability of the frame in a manner directly opposed to that in which stimulus acts upon it. To this power he gave the name *contro-stimulus*.

The mode in which the different contra-stimulants have acquired their reputation, appears to have been as simple as it must frequently have been fallacious. Every agent which succeeded in removing a sthenic disease, could do so only, it was presumed, by diminishing the excitability, or removing the stimulus. Accordingly, it was a contra-stimulant. Substances were therefore classed together, which bore no relation to each other, either in their immediate properties, or in their secondary effects—as regarded the physiological phenomena they induced. We find, in the lists, emollients—as milk and gum; astringents—as acetate of lead; tonics—as gentian, simarouba, iron, and, according to some, even cinchona; excitants—as turpentine, squill, and arnica; emetics—as tartrate of antimony and potassa, and ipecacuanha; narcotics—as stramonium and belladonna; acrid poisons—as arsenic, nux vomica, cantharides; and a host of other animal, vegetable, and mineral substances, which had no kind of analogy to each other. It has been properly observed, that this manner of considering the effects of medicines tends essentially to bring together the most dissimilar substances, as well as to separate such as are closely allied, and, consequently, to confound all.

In the case of this theory, however, as of every other, the practice built upon it has added valuable facts to therapeutics; and not the least of these is the knowledge, that tartrate of antimony and potassa may be administered in large doses in inflammatory affections, not only with impunity, but with marked advantage. This potent emetic may be given to the extent of ten or twenty grains or more, in divided doses, during the day, without either producing vomiting or purging; or, if the first doses prove emetic, a tolerance is soon acquired, and the subsequent doses may be followed by no marked effect, except the diminution of the febrile symptoms. At other times, the urinary and cutaneous depurations appear to be largely augmented, and rapid emaciation succeeds to its administration. The contra-stimulant physicians maintain, that the exaltation of the vital manifestations in febrile and inflammatory diseases, enables the system to bear the large doses of this and other contra-stimulants, and they say that the tolerance vanishes with the disorder that communicated it; but this assertion is not confirmed by experience. There is certainly a greater resistance to the action of these agents, as there is to bloodletting, when all is exaltation, but the power of resistance does not cease, although it is diminished, when the exaltation ceases. Some individuals, too, never possess the necessary tolerance; so that with them the tartrate of antimony and potassa does not produce its contra-stimulant effects; and it would seem that there are, also, what the French term *medical constitutions* or *epidemic conditions*, which forbid its employment. Thus, according to Bricheteau, (Clinique Médicale de l'Hôpital Neckar, Paris, 1835; or the writer's translation in the *Amer. Med. Lib.* Philad. 1838,) although it was so successfully used in 1831, it could not be beneficially administered at the end of 1832, and the beginning of 1833. Not until the autumn of this last year, could it be resumed advantageously. On one occasion it was given in the hospital, by an *Elève de garde*, during the choleric epidemy. The most violent symptoms supervened, and the patient died of cholera morbus, no sign of which existed before the tartrate was taken.

Of the different phlegmasiæ, acute rheumatism and pneumonia are those that are considered to

have been most successfully combated by this agent, in a large dose. (See art. Inflammation, vol. ii, p. 795.) "Emetic tartar," says M. Bricheteau, "should generally be preceded by bloodletting; and commonly it is advisable not to have recourse to the former, unless the latter is insufficient, except in cases in which bloodletting is contra-indicated or impossible, owing to some special circumstances,—as happened to me once in the case of a rickety individual, who had no veins proper for phlebotomy. The medical constitution of the season is, also, occasionally opposed to the abstraction of blood: in such cases, the tartrate of antimony and potassa is a valuable agent. Recourse may, likewise, be had unhesitatingly to tartar-emetic at the very first, when the patient is exhausted by age or other causes, and appears to be too weak to bear the abstraction of blood; or in cases where a positive refusal is given to the proposition for phlebotomy." "This agent," he adds, "must also be of great advantage and of convenient employment in country situations, where the physician can rarely pay his visits at an early period. It may be practicable, by this method, and with the aid of an intelligent person, to regulate the treatment of a case of pneumonia or of rheumatism for several days after having premised a copious abstraction of blood, if it be considered desirable." The fact, however, referred to by Bricheteau—that it is not every one who presents the necessary tolerance—would render this agent by no means as easy of application by the *laity* as he presumes.

Granting—and it would seem it must be granted—that the tartrate of antimony and potassa is a sedative agent, it becomes interesting to inquire into the mode in which such agency is exerted. It is, as is well known, one of our best suppurants, when we are desirous of establishing a centre of fluxion on some part of the cutaneous surface, with the view of removing an internal disease. Experience, too, has sufficiently shown that, when given in large doses, it produces pustulation in the mouth and fauces, if not lower down in the alimentary tube. In a case which occurred under the author's care in the Baltimore Infirmary, this effect of the antimonial was signally evidenced. Bricheteau—who has administered it largely as a contra-stimulant—says its local action is exerted more particularly on the mouth, tongue, and pharynx, where false membranes and pustules are occasioned by it; but these lesions, he thinks, are by no means common. The œsophagus, he says, never participates in them, and they are more frequent in the intestinal canal than in the stomach: and in the former, the lower part of the small intestines, and the commencement of the large, exhibit themselves more sensible to the action of the antimony than other portions of the tube; but it cannot be said that sufficient opportunities have occurred for testing the effects of the remedy, and for separating the morbid appearances which have presented themselves, and which may have proceeded from other causes. Bricheteau is of opinion, that the lesions which may be referred, with the greatest probability, to the use of the tartrate of antimony and potassa,—although he admits they are frequently owing to other inappreciable causes,—are, injection or infiltration of the submucous tissue of the intestines, and softening of the mucous membrane. In the mouth, considerable inflammation—either pustular or ulcerous—is sometimes observed, which speedily disappears after the discontinuance of the antimony.

The contra-stimulant virtues of tartrate of antimony and potassa may, then, be dependent upon its revulsive properties; this revulsion being produced in the lining membrane of the alimentary canal; so that when it is accomplished, the excited actions, going on elsewhere, may become diminished, and more or less nervous and vascular concentration takes place towards the seat of the artificial revulsion. Rasori thought that the remedy lessens stimulation, or augmented excitability, directly: Laënnec maintained that it invigorates the action of the absorbents; whilst Vaidy,—a French practitioner, who embraced the precepts of the followers of the "*Nuova Dottrina*,"—is of opinion, that its influence extends immediately to the circulation of the blood, restoring its harmony, and subduing the febrile excitement. Bégin (*Traité de Thérapeutique*, Paris, 1825) asserts that none of these hypotheses can stand the test of attentive inquiry, and that they are not founded on well-observed facts. "They are all in contradiction to experiments made on living animals, which prove that tartar-emetic, whilst it stimulates, and tends to inflame the mucous coat of the alimentary canal, from the cardia to the lower portion of the rectum, irritates the nervous system, and produces more or less inflammatory engorgement of the lungs:" and he adds—"this remedy acts chiefly as a revulsive in the treatment of pneumonia, and we shall have occasion to develop this truth, when treating of the revulsions produced on the gastro-intestinal system."

Robley Dunglison.]

SEX, DOUBTFUL, [*Sexual Ambiguity.*]—Among the freaks of nature, there is none which has given rise to more erroneous ideas or more barbarous practices than those varieties in the formation of the organs of generation, which have given origin to the term *hermaphrodite*. This word, derived from Ἑρμῆς, Mercury, and Ἀφροδίτη, Venus, conveys the notion of an individual partaking of both sexes, and capable of both begetting and conceiving. The ancients believed in the possibility of such a combination in the human body; and enactments existed, both in Greece and Rome, ordering the destruction of infants born with confusion of the sexual organs. At Athens all the unfortunate beings considered to be hermaphrodites were thrown into the sea, and at Rome into the Tiber. In modern times it is admitted that no such phenomenon ever existed in the human species as a perfect hermaphrodite; although there are numerous instances of preternatural structure which gives the appearance of a double sex. In the lower orders of organized bodies, hermaphrodism is common; thus in vegetables it is so prevalent as to have led some to suppose it to be an attribute of the order; and the more nearly the other classes of beings approach the vegetable, the more common is this combination of sex among them. Of this zoophytes, mollusca, acephali, and gasteropodes are examples.

In these animals two kinds of hermaphrodism exist: in some it is absolute, that is, the animal is capable of impregnating itself, as in some of the bivalves, as oysters and mussels; but in others, as the univalves, this power is not possessed, but a union of two individuals is necessary, both, however, becoming impregnated at the same time.

We look in vain for any such admixture in the higher orders of animals, though some extraordinary approaches towards it are recorded. According to Sir. E. Home (Phil. Trans. 1799,) and J. Hunter (Anim. Econ.,) such combination is most frequently met with in neat cattle, the individuals so circumstanced being known by the name of free martins. In these, however, the testes and ovaria are always too imperfect to perform their functions. Instances are not wanting in the human species in which, either from malformation of the genital organs in one or other of the sexes, or from a real attempt at mixture of the two in the same individual, considerable difficulty arises in deciding on the proper sex. This is the point to which the present article is more particularly directed, and it should be recollected that it is one of material importance; for upon the opinion pronounced by medical examiners may depend the employment in life of an individual, the right of inheritance to property, and the judicial decisions concerning impotence and sterility.

[In an able article by Dr. J. Y. Simpson, (Hermaphroditism, in *Cyclopædia of Anatomy and Physiology*, ii. 685, Lond. 1839,) hermaphroditic malformations, considered as a class, are divided into two orders—*spurious* and *true*,—the spurious comprehending such malformations of the genital organs of one sex as make these organs approximate in appearance and form to those of the opposite sexual type; and the true comprising all cases in which there is an actual admixture or blending together, upon the same individual of more or fewer of both the male and female organs. The following is Dr. Simpson's classification:

CLASSIFICATION OF HERMAPHRODITIC MALFORMATIONS.

- Hermaphroditism.
  - Spurious.
    - In the Female....
      - From excessive development of the clitoris, &c.
      - From prolapsus of the uterus.

Sir E. Home (Loc. cit,) considers that all the monstrous productions hitherto noticed and described as hermaphrodites may be reduced to one of the four following classes:—1. malformations of the male; 2. malformations of the female; 3. males with such a deficiency in their organs that they have not the character and general properties of the male, and may be called neuters; 4. where there exists a real mixture of the organs of both sexes, although not sufficiently complete to constitute the double organ.

Malformation of the Urinary and ...ive Organs of the Male.—Cases of ...lly depend upon imperfection of the ...ra; there is no deficiency of the ...ition of foreign parts, but the ... from the scrotum being split a... ...h half containing a testicle, an... ...be labia majora of the female. ... these parallel folds of skin ver... ...ulva, and the similarity is he... stance of the urethra being ... in these cases, and opening in ... which having a red and tender appea... easily mistaken for the vagina. In consequence of the urethra terminating at the perineum, the penis is imperforate; and thus, if it be of small size, it may be supposed to be the clitoris. It is this malformation of the male organs which more than any other has given origin to mistakes respecting the mixture of the sexes. The case of the negro described by Cheselden (Anat. of the Human Body, p. 314,) was of this kind. In him the scrotum was divided into two separate bags, with a deep slit between them, representing the labia majora and commencement of the vagina. Over these hung down the penis; the imperfection of the scrotum extended to the canal of the urethra,—a circumstance appropriately compared to the fissure of the hare-lip being continued through the bony palate. The penis was united by its under surface, through its whole length, to the folds of skin containing the testicles, resembling an enlarged clitoris, to which resemblance the absence of the urethra contributed. The urethra opened with a large aperture in the perineum, between the divisions of the scrotum, and from its size was mistaken for a vagina. Cheselden describes another case similar to the preceding, which he met with in the person of an European.

Persons afflicted with such malformation as we have described have not only been taken for females but have been married as such. Adélaide Preville was married, and lived the last ten years of her life in Paris, and died in the Hôtel Dieu ... that city. Giraud discovered by examination ... body after death that it was of the mascu... except a false vagina, which co... ...ac placed between the rectum a... ...al presented no resemblance ... ...ecueil périad. de la Soc. de Méd. Paris.) ...here is a very remarkable case related by Marc, (Dict. des Sciences Méd. t. xxi. p. 91 et Jour. de Méd. Chirurg. et Pharm. Paris, Feb. 1806,) in which an individual after having passed for a female for many years, was at length discovered to belong to the male sex, and was restored

by public ordinance to his proper station. On the 19th of January, 1792, the curé of the parish of Ber certified the birth of a girl, and gave her the name of Marie Marguerite. This child arrived at the age of 14 without having particularly attracted the attention of the parents. It shared the bed of a younger sister, and grew up among other young persons with whom it was associated by education, exercise, and childish amusements. At this time Marie complained of pain in the right groin, where a tumour soon manifested itself. The village surgeon took it for a hernia, and applied a truss. This instrument gave too much pain to be borne, and was soon laid aside. The tumour descended and the pains ceased. Some months afterwards, the left groin was affected in a similar manner, and on the supposition of the tumour in it being also a hernia, a double truss was put on, which was as speedily thrown off as the former. At 16 years of age an offer of marriage was made, but refused by the parents as an unsuitable match for their daughter. Three years afterwards another proposal was made and broken off after having been accepted of. Nevertheless, as Marie advanced in age, the graces of her person began to disappear; her clothes did not fit as well as before; her air and carriage had something extraordinary; from day to day her tastes changed and became more masculine; indoor occupations seemed to interest her less, and she preferred field-work to her former duties. These masculine dispositions, and the report of the surgeon that Marie had been hurt in such a manner as to prevent her ever marrying, did not prevent a third lover from aspiring to her hand. This match was much desired by the friends on both sides; but the parents of Marie, knowing that she was not formed as other women, and recollecting that she had never menstruated, did not wish to deceive the son of an old friend, and determined on having a medical examination of their daughter. Worbe was requested to perform this office. The surprise of all was great indeed when he declared Marie to be a man. She (or he) shed tears at the announcement, and was for some months before she could be reconciled to the idea of not being a woman. At last he took the resolution of petitioning the authorities to alter the registry, and declare him of the male sex. A commission was accordingly appointed consisting of three medical men, to inquire into the circumstances of the case, who reported that on examination they found the scrotum divided through its whole extent, each division containing a rounded body, which they recognised as true testicles. Between these parts a fleshy prolongation was observed, having a cleft at its extremity, but imperforate, covered by a process of skin, which was in reality the prepuce. The penis was but little developed; and beneath it, at about an inch and a half from the margin of the anus, an opening was discovered, caused by the abrupt termination of the urethra in the perineum. As to the rest of the body they found nothing remarkable, except a considerable development of the breasts, resulting, as they imagined, from the form of clothing usually worn. They therefore gave it as their opinion that Marie belonged to the male sex; and the authorities declared it to be so, and ordered that the registry of birth and baptism should be altered. Dr. Worbe states that in 1816, this individual was 23 years of age, hair and eyebrows auburn, a light beard appearing on the upper lip and chin, the sound of the voice masculine, height four feet eleven inches French measure, skin very white, constitution robust, and the limbs round but muscular. The form of the pelvis did not differ from that of a male, the knees were not inclined inwards, and the hands and feet were large and strong. A year had not elapsed from the time of his metamorphosis when he was considered as one of the best farmers in the canton. On being questioned with respect to what he felt when sleeping with females, whether he had not desires different from those of others, and if curiosity had not prompted him to discover what opportunity permitted him so easily to observe, he answered, blushing, "quelquefois, mais je n'osais pas."

Dr. Schweikard (Hufeland's Journal, t. xvii. No. 18,) has published the history of an individual who up to the age of manhood was esteemed to belong to the female sex. He had been baptized as a girl, and regarded as such, until to the astonishment of all he demanded permission to marry a girl then pregnant by him. He submitted to an examination, when it was found that the penis was situated lower than ordinary, not quite two inches long, and a little less bulky than usual. The imperforate glans offered a slight curve towards the lower part; the inferior surface of the corpora cavernosa was deprived of urethra, but presented a channel or groove along its middle line. Behind and under the corpora cavernosa, between their root and the anterior superior part of the scrotum, a prominent oval opening was remarked; this was the orifice of the urethra, through which the urine flowed, and in consequence of its vicinity to the penis, the stream was conducted along the under surface of that organ so as to appear to issue from its orifice. The scrotum, situated below this opening, contained the right testicle only, that of the left being probably retained in the abdomen. In all other respects the physical constitution of this individual was perfectly masculine. According to his account, the desire for women and the secretion of semen were observed at puberty. He had frequently performed coition, and had, besides a child born before marriage, two other children well formed, born in wedlock. This case was evidently only an instance of hypospadias, of which malformation we have already spoken in the article Impotence; and it is a further confirmation of the opinion there advanced, that persons labouring under it are not to be considered as incompetent to procreation. It is most probable that the semen during the act of coition was conducted along the penis, as the urine is stated to have been, at least so far as to enter the vagina. A case similar to that just mentioned is detailed by Dr. Wageler. (Annales de Méd. Politique de Kopp. v. 129.)

The malformation of which we have now spoken is that which most frequently causes mistakes in the male, but by a careful examination of the individual the obscurity must be easily removed. There are other degrees of imperfection

which are sometimes observed, but can never lead to much confusion. One of these consists in a close application of the penis to the anterior surface of the scrotum, by a continuation of the skin of the latter over the former. In such a case the penis is bound down in its unnatural situation, and the urine passes downwards; the erection of the organ cannot take place; it may become turgid, but never erect, and intromission is of course impossible. A case of this description occurred to Mr. Brand, (Vide Brewster's Edinburgh Encyclop. art. *Hermaphrodites*, and Beck's Med. Jur. by Darwall, p. 45,) in the person of a child seven years of age, who had been baptized and brought up as a girl; he found a malformation of the male sexual organs consisting of the presence of such an unnatural integument. By a slight incision he liberated the restricted part, and proved to the parents that they had mistaken a boy for a girl.

Another form of lusus which has given rise to mistake of sex, is that in which the urinary bladder, or rather the rudiment of it, opens directly above the pubis, through a deficiency of the abdominal muscles and integuments at that part. In these cases the bladder can scarcely be said to exist; all that appears of it is a red fungous mass protruding through the integuments, consisting of the mucous lining of the viscus, with the uterus opening on it together with the vesiculæ seminales and vasa deferentia. The penis is always very short, scarcely exceeding two inches, and, from deficiency of the urethra, imperforate. The testicles are generally well formed, but are sometimes retained in the abdomen. Persons with this malformation are observed to vary in their sexual appetites; some being totally deficient in sexual desire, others exhibiting it in a trifling degree, while others have it strong. It may readily be supposed that persons constructed in this manner are impotent; but it sometimes happens that the vasa deferentia open in a small tubercle at the root of the penis, in which case it is possible that impregnation may be effected by the individual. It is only by such a disposition of parts we can explain the pregnancy of a young girl in Linlithgow in Scotland, stated to have resulted from her sleeping with a young person, who from a malformation, such as we have described, was supposed to be a female. (Vide Piscottie's History of Scotland, p. 104.) It is plain that if the seminal ducts opened externally above the pubis, such an event could not have taken place.

2. Malformation of the Female Generative Organs.—There are two sorts of malformation in women which may lead to error in judging of the sex. The first consists in excessive dimensions of the clitoris. Although hypertrophy of this organ occurs most frequently in warm countries, it has also been observed in cold. Sir E. Home doubts that it ever takes place in these latitudes, and also is of opinion that even in those situations where it is most frequently observed, the enlargement never proceeds to such a length as to lead to any serious doubt. There are, however, some instances on record in which the increase in size was such as to cause the clitoris to resemble and be mistaken for the male organ. Columbus notices an instance in which it was the size of a finger. Haller observed one case in which he states that it was seven inches in length; and it has been said to reach the extent of twelve inches. (Dict. des Sciences Méd. art. *Clitoris*.) However, notwithstanding any excessive dimensions of the clitoris, an attentive observer will readily discover the difference between the genital organs of a female with such a development, and those of a male. Thus, for instance, in a celebrated hermaphrodite exhibited in Paris and London in 1777, named Marie Auge, the clitoris was found to resemble perfectly the male organ, but it was unprovided with a urethra, and imperforate: it was situated above the other parts of generation, which presented no peculiarity, except an unusual contraction of the vagina. Schneider met with an instance in a child of two years old still more likely to mislead; he examined it after death, and found neither labia majora nor minora, nor the usual cleft between them; the clitoris was an inch and a half long, resembling a penis, with a well-formed glans and prepuce, but it was imperforate, a small spot occupying the situation at which the male urethra terminates. Some lines below this organ there was an opening, by which the urine was transmitted; but this passage seemed also destined to perform the functions of a vagina, for it led directly to the uterus, and was of a length proportionate to the age of the subject; the vaginal rugæ were distinct, and at the upper part of the orifice a small opening was observed which led to the bladder, and was in fact the orifice of the true urethra. In Sir E. Home's (Loc. cit.) paper on hermaphrodites he gives an account of a Mandingo negress whose clitoris was two inches long, and of the thickness of an ordinary thumb: at first view the extremity seemed formed like a glans, but on more minute examination it was found imperforate, and not so round as a true glans, but more pointed; the clitoris was capable of erection, during which state its size increased to three inches. The other parts of generation were well formed, the urethra was situated just beneath the clitoris, which obstructed the flow of urine so much as to compel her to raise it when about to evacuate the bladder. Her person was very masculine, the mammæ were little developed, the voice was rough, and the countenance resembled that of a man. Beclard (Jour. de Med. Chir. et Phar. Mars, 1815,) has given a very detailed account of a female who was exhibited in Paris, in 1814, as an hermaphrodite, from which we extract the following. Marie Madeline Lefort was the name of the individual; she was then sixteen years of age, and in the general form of her body resembled a male; the voice was masculine, a beard appeared on the upper lip and chin, the breasts were developed, and the limbs were slightly hairy. The external genitals presented a rounded mons veneris, covered with hair, but the symphisis pubis was elongated as in the male; beneath it protruded a conoid-shaped body, twenty-seven centimetres in length, when flaccid, but more when erect; this was surmounted by an imperforate glans, covered for three-fourths of its extent by a prepuce. Inferiorily this enlarged clitoris was furnished with a canal, which, however, did not run the whole length, but was pierced in the middle line with five small holes,

capable of admitting a small probe. Beneath and behind the clitoris, there was a sulcus, bordered on each side by a narrow and short labium, which on being handled gave no sensation of containing any body like a testicle. This sulcus or fissure was very superficial, being blocked up by a dense membrane, but which gave, when pressed by the finger near the anus, the idea that it was spread over a cavity. At the anterior superior part, near the clitoris, this membrane was pierced by a round opening, which readily admitted a moderate-sized catheter. The external abdominal rings were very small, and gave no indication of containing testicles. The urine was passed partly through the opening in the membrane described, and partly through the small cribriform openings in the canal extending along the under surface of the clitoris. This was taken from her own account, as she found it impossible to void urine in the presence of the examiners. The bladder could not be reached by a catheter introduced through the large opening, but the instrument could be easily passed upwards and backwards, and in this manner it glided along the posterior surface of the membrane closing the vagina, which, being felt between the point of the instrument and the finger, seemed about twice as thick as the skin. She had menstruated regularly from the age of eight years, and on one occasion when Beclard examined her during menstruation, he observed the fluid to pass through the opening already described, and the catheter then introduced was withdrawn full of menstrual blood. She considered herself a woman, and preferred the society of men, and was persuaded that a trifling operation would render her fit for matrimony. This individual belonged decidedly to the female sex; she had many and the most essential of the female organs of generation, the vagina and uterus, the latter organ moreover performing its natural function with regularity; and those characters of the male which she exhibited were only of a secondary class, such as the proportions of the limbs and body, shoulders and pelvis, the size of the larynx, tone of voice, development of hair, and the prolongation of the urethra beyond the symphisis pubis: this, however, was not complete, for the canal did not extend to the extremity of the mimic penis.

The second kind of malformation of the female generative organs likely to mislead as to the sex of the individual, is a protrusion of the internal parts. The uterus when prolapsed has at times assumed so close a resemblance to the penis that it has actually been mistaken for it by medical men of the highest character. The following case came under the observation of Sir E. Home, who has given the particulars in his paper on hermaphrodites. "A French woman had a prolapsus uteri at an early age, which increased as she grew up. The cervix uteri was uncommonly narrow, and at the time I saw her (when she was about twenty-five years old) projected several inches beyond the external opening of the vagina: the surface of the internal parts, from constant exposure, had lost its natural appearance, and resembled the external skin of the penis; the orifice of the os tincæ was mistaken for the orifice of the urethra. This woman was shown as a curiosity in London, and in the course of a few weeks made four hundred pounds. I was induced by curiosity to visit her, and on the first inspection discovered the deception, which, although very complete to a common observer, must have been readily detected by any person intimately acquainted with anatomy. To render herself still more an object of curiosity, she pretended to have the powers of a male: as soon as the deception was found out, she was obliged to go away." There is in the Philosophical Transactions the history of an hermaphrodite which seems to be exactly similar to this, as is fully proved by the menses flowing regularly through the orifice of the supposed penis. The French physicians were, however, so perfectly convinced of her manhood, that they made her change her dress and learn a trade. To this she readily submitted, and the account says she could perform very well the functions of a man, but not those of the other sex.

3. Males with such a deficiency in their organs that they have not the character and general properties of the male, and may be called Neuters.

This form of hermaphrodism usually takes place in individuals originally intended for the male sex, and is nothing more than the effect produced by atrophy, or absence of the testicles,—a circumstance to which is frequently joined a defective development of the penis. The genital organs do not appear to grow with the rest of the body, but continue in the same state as at birth. In many the characters of both sexes seem mixed; in others there is a slight predominance of one or the other, discoverable chiefly by moral circumstances, such as the kind of life, habits and pursuits of the individual. An instance of this kind of deformity occurred to Hufeland at Koningsberg. An individual named Marie Dorothée Duriée, aged twenty-three years, was examined by him and Mursinna, who both declared the sex to be female, while Stark and Martens were of opinion that the same person belonged to the male sex.

A marine soldier, aged twenty-three years, in the year 1779 was admitted a patient into the Royal Naval Hospital at Plymouth, under the care of Sir E. Home. He had been there only a few days when a suspicion arose of his being a woman, which induced Sir E. Home to examine into the circumstances. He proved to have no beard, his breasts were fully as large as those of a woman at that age; he was inclined to be corpulent; his skin uncommonly soft for a man; his hands fat and short; his thighs and legs very much like those of a woman; the quantity of fat upon the os pubis resembled the mons veneris; the penis was unusually small as well as short, and not liable to erections; the testicles were not larger in size than we commonly find them in the fœtal state; and he had never felt any passion for women. In this case the testicles had been imperfectly formed, and the constitution was deprived of the influence which it naturally receives from them. The two following cases show a still greater degree of imperfection in the male organs; they are mentioned by Sir E. Home.

A woman near Modbury, in Devonshire, the wife of a day-labourer, had three children; the first was considered to be an hermaphrodite; the

second was a perfectly-formed girl; and the third an hermaphrodite similar to the first. In the year 1779 the eldest was thirteen years of age, and of a most uncommon bulk, which seemed to be almost wholly composed of fat; he was four feet high; his breasts as large as those of a fat woman; mons veneris loaded with fat; no penis; a prepuce one-sixth of an inch long, and under it the meatus urinarius, but no vagina. There was an imperfect scrotum with a smooth surface, without a rapha in the middle, but in its place an indented line; it contained two testicles of the size they are met with in the fœtus. The younger one was six years old, uncommonly fat and large for his age: the external parts of generation differed in nothing from those just described except in the prepuce being an inch long. Both were nearly idiots. The immense accumulation of fat, and the uncommon size of these children, accords with the disposition to become fat so commonly met with in the free martin.

4. Where there exists a real mixture of the Organs of both Sexes, although not sufficiently complete to constitute the Double Organ.—Cases of this description which most nearly approach the absolute hermaphrodite are less common than those we have mentioned. A remarkable instance is mentioned in Dr. Baillie's Morbid Anatomy, (3d edit. p. 410.) The person was twenty-four years of age, and bore the name and dress of a woman, had the breasts of a female, and no beard, and yet had a very masculine appearance. The clitoris and meatus urinarius had the natural appearance, but there were no nymphæ, and the labia pudendi were unusually pendulous, resembling a split scrotum, and contained a testicle each. The vagina was found to terminate in a cul-de-sac, two inches from the external surface of the labia. She had no partiality for either sex, and had never menstruated.

The Memoirs of the Academy of Dijon contain the following case, communicated by M. Maret. (*Mahon*, t. i. p. 190, and Beck by Darwall, p. 43.) Hubert J. Pierre died at the hospital in October 1767, aged 17 years. Particular circumstances had led to a suspicion of his sex, and these induced an examination after death. His general appearance was more delicate than that of the male, and there was no down on his chin or upper lip. The breasts were of the middle size, and had each a large areola. The bust resembled a female's, but the lower part of the body had not that enlargement about the hips which is usually observed at his age. On examining the sexual organs, a body four inches in length and of proportionate thickness, resembling the penis, was found at the symphisis pubis. It was furnished with a prepuce to cover the glans, and at its extremity, where the urethra usually opens, was an indentation. On raising this penis, it was observed to cover a large fissure, the sides of which resembled the labia of a female. At the left side of this opening there was a small round body like a testicle, but none on the right. However, if the abdomen was pressed, a similar body descended through the ring. When the labia were pushed aside, spongy bodies resembling the nymphæ were seen, and between these and at their upper part the urethra opened as in a female, while below these was a very narrow aperture covered with a semilunar membrane. A small excrescence, placed laterally, and having the appearance of a caruncula myrtiformis, completed the similarity of this fissure to the orifice of the vagina. On further examination the penis was found to be imperforate; the testicle of the left side had its spermatic vessels and vas deferens which led to the vesiculæ seminales. By making an incision into the semilunar membrane, a canal one inch in length and half an inch in diameter was seen, situated between the rectum and bladder. Its identity with a vagina was, however, destroyed by finding at its lower part the verumontanum and the seminal orifices, from which, by pressure, a fluid, resembling semen in all its properties, flowed. The most remarkable discovery was, however, yet to be made. The supposed vagina, together with the bladder and testicles, was removed. An incision was made down to the body noticed on the right side. It was contained in a sac, filled with a limpid and red-coloured liquor. From its upper part on the right side, a Fallopian tube passed off, which was prepared to embrace an ovarium placed near it. It seemed thus proved that the body in question was a uterus, though a very small and imperfect one, and on blowing into it, air passed through the tube.

In April 1807, an individual was exhibited at Lisbon, uniting the organs of both sexes in the highest degree of perfection that has probably been ever seen. This person was twenty-eight years of age, and possessed of the male organs, a penis, or what represented one, capable of erection, covered by a prepuce, and pierced for a third of its length by a canal, and testicles. The air and appearance were masculine, the colour dark, and a light beard covered the chin. The female organs were labia, vulva, and vagina, well formed, but very small; the larynx and voice were feminine, and so were all the dispositions; she menstruated regularly, and was twice pregnant, but was prematurely delivered each time, once at three, the other at five months. (Dict. des Sc. Méd., art. *Hermaphrodite.*) This, if the account respecting the testicles be correct, is the nearest approach to a true hermaphrodite with which we are acquainted in the human subject.

In the Memoirs of the Royal Academy of Sciences of Paris (An. 1720) there is a very accurate description by M. Petit, of a similar mixture of organs. The person had wholly the character of a man, but was of a delicate constitution; he was a soldier, and died of his wounds. The appearance of the penis is passed over; but the scrotum not containing testicles drew M. Petit's attention, and in the dissection he found testicles in the situation of the ovaria, attached to two processes, continued from an imperfect vagina, but having vasa deferentia, which passed in the usual manner to the vesiculæ seminales; the vagina communicated with the urethra between the neck of the bladder and of the prostate gland.

[A number of cases in which there was a mixture of the organs of the two sexes are now on record. (Simpson, *op. cit.* See also, Guy, *Principles of Forensic Medicine*, p. 36. Lond. 1843; and the writer's *Human Physiology*, 5th edit. ii. 351. Philad. 1844.)]

With respect to the formation of such monsters as we have spoken of, Sir E. Home was of opinion that the only mode in which it can be explained is by supposing the ovum, previous to impregnation, to have no distinction of sex, but to be so formed as to be equally fitted to become a male or a female fœtus; and that it is the process of impregnation which marks the distinction, and conduces to produce either testicles or ovaria out of the same materials. The following circumstances are in favour of this opinion. The testicles and ovaria are formed originally in the same situation, although the testicles even before the fœtus has advanced to the eighth month, are to change their situation to a part at a considerable distance. The clitoris in fœtuses under four months is so large as to be often mistaken for a penis, and serves to explain an erroneous opinion at one time maintained in France, that the greater number of miscarriages between three and four months have been remarked to be males; which mistake arose from the above circumstance. The clitoris originally appears, therefore, equally fitted to be a clitoris or a penis, as it may be influenced by the ovarium or testicle. In considering this subject, it is curious to observe the number of secondary parts, which appear so contrived that they may be equally adapted to the organs of the male or female. In those quadrupeds whose females have mammæ inguinales, the males have also teats in the same situation; so that the same bag which contains the testicles of the male is adapted to the mammæ of the female. In the human species, which has the mammæ pectorales, the scrotum of the male serves the purpose of forming the labia pudendi of the female, and the prepuce makes the nymphæ. The male has pectoral nipples as well as the female; and in many infants, milk, or a fluid analogous to it, is secreted, which proves the existence of a glandular structure under the nipple. This view of the subject throws some light on those cases where the testicles are substituted for the ovaria; since, whenever the impregnation fails in stamping the ovum with a perfect impression of either sex, the part formed will neither be an ovarium nor a testicle, sometimes bearing a greater resemblance to one, sometimes to the other; and may, according to circumstances, either remain in the natural situation of the ovaria, or pass into the situation proper to the testicle, whether it is the scrotum of the male or the labia pudendi of the female. [On the causes of hermaphroditic malformation, see J. St. Hilaire, *Hist. des Anomalies de l'Organiz.* ii. 58; and Simpson, *op. cit.*]

Means of ascertaining the true sex of a supposed Hermaphrodite. — We say supposed, because, as has been already stated, we do not acknowledge the existence of a true hermaphrodite in the human species. Some cases no doubt have occurred in which it was very difficult to assign the proper sex; but even the most perfect of these complications of the genital organs did not give the individual in whom they existed the power of double copulation. Thus in the case of Hubert Pierre it is not easy to decide to which sex he really belonged: again, we must admit that great difficulty existed in coming to a conclusion when we find such men as Hufeland, Mursinna, Stack, Martens, and Metyger disagreeing. From these and other cases that might be quoted, we must agree that cases do occur in which the greatest difficulty must be felt, and the greatest caution should be used in forming an opinion. These cases of great difficulty all belong to the last class of malformations: in the other classes the solution is not so difficult. In proceeding to make an examination for the purpose of ascertaining the sex of an individual, the greatest care should be taken not to mistake appearances, and these should be all accurately noted down. The different openings that present themselves should be all explored with appropriate instruments, (taking care not to inflict any wound or cause pain,) in order that their direction may be ascertained. An accurate inspection of the whole body should be made, to elicit any predominance of the constitutional characters of either sex that may exist. These examinations should not be made hurriedly, but should continue for a length of time, and be frequently repeated, before a positive opinion is given; for the tastes, habits, and propensities of the individual must be taken into account, as well as the physical conformation in doubtful cases. It is of importance to be informed whether a discharge of blood has ever escaped from any of the openings, and if repeated, whether it has been periodical; as that circumstance alone will be sufficient to decide us in coming to a conclusion. In the case of young children, it is best to wait until the parts become more fully developed, as it has happened that instances of confusion of sex when young have at the age of puberty taken a decided leaning to one or the other sex. Above all, it is necessary to be most cautious in believing all that is stated by the individual or the friends, as, from interested motives, they may misrepresent facts in such a way as to lead us into error.

T. E. Beatty.

SMALL-POX. — The most approved authors concur in the belief that the disease known to us by the name of *small-pox* or *variola*, was not described by any of the writers of antiquity. From their silence, therefore, respecting a disorder so fatal, and possessing such very peculiar characters, we may reasonably presume that its origin was subsequent to their times, and that the world had existed some thousand years before it was visited with this dreadful pestilence. Etymology comes here in aid of history. The first authentic passage in which the words *variola* and *pocca* occur is to be found in the Bertinian Chronicle of the date 961. (Moore's History of Small-pox, p. 87.) There being no term for the disease in the Greek or Roman authors, variola was coined in the middle ages from the Latin *varus*, a pimple, or *varius*, spotted, and for several succeeding centuries was applied to designate measles as well as small-pox. From variola are derived the Italian vaiuolo, and the French vérole. The term *poc* is of Saxon origin, and signifies a bag or pouch. The Anglo-Saxons early adopted this word, which was variously spelt, and became pock, pocks, and pox. The epithet *small* in England, and *petite* in France, were added in the fifteenth century.

From very early times attempts have been made to prove the antiquity of small-pox, and even in

our days this doctrine has found supporters. Dr. Baron, of Gloucester, the latest writer on the subject, entertains the opinion that small-pox is to be traced in the earliest writings of the Hebrews and Greeks; that it was seen by Hippocrates, and commented upon by Galen. According to this author, the account of the plague of Athens, as given by Thucydides, "presents as accurate an account of the leading symptoms of variola as could possibly be expected from any historian not medical." (Life of Jenner, p. 177.) In this opinion Dr. Baron is countenanced by Salmasius, Hahn, and more recently by Dr. Willan, in a posthumous dissertation "On the Antiquity of Small-pox." Rhazes, an Arabian physician, and the first acknowledged writer on this disease, laboured to prove that Galen had seen it, but with all his enthusiasm for his master, he acknowledged and was surprised at the unwonted brevity and inaccuracy of his description. This alone may be considered as decisive of the question; but we may further state that Friend and Mead, authors of the highest repute, after devoting great attention to the subject, agreed that there was no foundation for such a notion. We shall be fully justified, therefore, in adhering to the generally received opinion that small-pox is a disease of modern origin.

The first notices of a disorder which exhibits the well-marked features of small-pox, are to be found in the historical writings of Procopius (De Bello Gothico, lib. ii.), who flourished during the reign of Justinian the First. The obscurity of its origin, the difficulty of its cure, the universality of its devastations, and above all, the complete immunity from second attacks which are mentioned as characteristic of this epidemic, bespeak it to have been truly small-pox. It began A. D. 544, at Pelusium in Egypt, from whence it spread to Constantinople. This corresponds closely with the era commonly assigned in medical books to the first appearance of small-pox, viz. A. D. 569, the year of the birth of Mahomet. In that year an Abyssinian army, under Abrahah the viceroy, appeared before Mecca, and was unexpectedly compelled to raise the siege. Several circumstances concur to render it probable that the sudden retreat of the army was owing to the breaking out of small-pox, and the dreadful mortality which it occasioned. Bruce, in his travels (Travels to discover the Source of the Nile, vol. i. p. 514), met with a manuscript account of this war, which confirms this story, and strengthens the opinion that small-pox first appeared in Egypt and Arabia about the middle of the sixth century.

A further question has been raised and keenly agitated, whether the small-pox really began in Egypt, or was conveyed to the shores of the Red Sea from India. Attempts have been made to establish the existence of this disease in China and Hindostan at very remote periods. Mr. Moore, in his history of small-pox, advocates this opinion. He finds in the mythology, the religious institutions, the sacred and historical records, the medical works, and uniform tradition of those countries, abundant proofs that small-pox existed there at a period antecedent even to Hippocrates. (Moore's History of Small-pox, p. 35.) He then enters into an investigation of the circumstances which may have prevented the spread of the infection from Asia to Europe and Africa. It must be acknowledged, however, that the facts on which Mr. Moore relies in support of this opinion rest on very questionable authority; and as the opinion itself has not met with many supporters, it is not necessary in a practical work like the present to bestow on it more particular examination.

The small-pox, and with it the measles, certainly burst forth in Arabia under circumstances most fatally favourable to their dissemination. It was in the year 622, when Mahomet began to collect the wandering tribes of Arabs whom he led forth, inflamed with religious zeal, against the neighbouring nations. To the devastations of war were now added the ravages of a new and most intractable disorder. But if we owe the introduction of small-pox to the Arabian armies, it is to the physicians of the same nation that we are indebted for the earliest accounts of it. Rhazes, an Arabian physician, who practised at Bagdad about the beginning of the tenth century, is the first author who treats expressly of small-pox. He quotes, however, several of his predecessors, of whom the most ancient is Ahron, a physician of Alexandria, who is supposed to have flourished about the year 622, the era of the Hegira, when Mahomet first went forth as a conqueror and a prophet. The treatise of Rhazes "De Variolis et Morbillis," deserves especial mention for the accurate description which is given of the several kinds of small-pox. His theory of the disease, however, is childish and scarcely intelligible, and his treatment lamentably deficient. He abounds, indeed, with directions for the management of every symptom, and more especially for that of the pustules in their several stages, which is very complicated, consisting of fomentations, fumigations, dry powders, ointments, and other applications chiefly intended to prevent pitting. In most of those instances his prescriptions are harmless, but this merit does not belong to his recommendation of free bloodletting and of the most powerful narcotics in all stages, and even in the confluent forms of the disease. Avicenna, another Arabian physician, gives also a very full and excellent account of the symptoms of small-pox, and he improves upon the treatment suggested by Rhazes, by restricting bleeding to plethoric habits, and to the three first days of the disease. Both Rhazes and Avicenna concur in the opinion that measles and small-pox are only modifications of the same disorder. Avicenna considered measles as a sort of bilious small-pox.

Hali Abbas, a third Arabian author on small-pox, deserves to be mentioned as having made an approach to the doctrine of contagious origin. The theory of small-pox adopted by him, as by all the Arabian physicians, was founded on the commotion and putrefaction of the humours of the body; but Hali observed that one of the accidental causes which excited the movement of the distempered humours to the skin was being in the same place with persons affected with the small-pox, or breathing air contaminated with the pestilential vapour of small-pox pustules. All the Arabian authors believed in the occasional occurrence of small-pox twice in the same person.

The successes of the Saracen arms in Spain and Sicily, during the eighth century, contributed

doubtless to the gradual extension of small-pox through the different countries of Europe, but on this subject very little is known. We read that on several occasions a pestilence of fire raged, the body dissolving away as if burnt, with an intolerable fœtor of the putrid flesh. It is reasonable to suppose that some at least of these epidemics were the small-pox: others may have been the true Egyptian plague with buboes.

The researches of antiquarians lead to the belief that small-pox reached England early in the tenth century (907). There is preserved in the British Museum a curious Anglo-Saxon manuscript, supposed to have been written in that century, containing an exorcism or supplication against the small-pox. (Moore's History of Small-pox, p. 94.) Nicasius was the saint especially addressed on these occasions. All that we read serves to show how great were the terrors inspired by the small-pox in every period of its career.

The discovery of America by Columbus, which so wonderfully extended the boundaries of human knowledge, was the occasion also of scenes of desolation at which the heart sickens. Among all the calamities incident to that event none can surpass the introduction of small-pox into that continent, which took place in 1517, twenty-five years after its discovery. It is stated, on the authority of the Spanish historians, that in a very short time after the infection reached Mexico, three millions and a half of people were destroyed by it in that kingdom alone. Among the victims was the emperor, the brother and successor of the brave but unfortunate Montezuma. (Robertson's History of America, vol. iv. b. viii.)

From the revival of learning to the present period, no subject has attracted the attention of physicians, both speculative and practical, more than small-pox. Every medical writer has treated of it, and some have devoted themselves exclusively to its study. It would be vain, therefore, to attempt more than a brief allusion to those who have distinguished themselves in this department of medical inquiry.

The humoral doctrines which prevailed in the schools during the sixteenth century led to the universal adoption of the hot or alexipharmic mode of treating pestilential and malignant diseases, including small-pox. Sennertus gives the following account of the practice pursued in his time (1628). The great object was to expel the noxious humour by perspiration, to accomplish which various decoctions of warm seeds are directed, containing mithridate, bezoar, and other drugs, denominated alexipharmic and sudorific. "While using these, every attention is to be paid, especially in winter, to prevent the admission of cold air. The patient is therefore to be tended in a warm chamber, and carefully covered up, lest by closing the pores of the skin the efforts of nature should be impeded, the humours driven upon internal organs, and matters which ought to be expelled retained within the body, to the imminent danger of the patient, and the certainty of increasing restlessness, fever, and other symptoms." (De Variolis et Morbillis, t. vi.)

Such had long been, and such was the state in which Sydenham in 1667 found the theory and practice of small-pox. Bad as that practice was, it yet had the support of all the learning and all the prejudices of the age. It required, therefore, talent and boldness successfully to oppose it. Sydenham began by separating for ever small-pox from measles, with which, from the days of Rhazes, it had been so strangely yet so obstinately associated. He divided small-pox into two kinds, the distinct and confluent, traced with the greatest accuracy the usual course of both, and added many important remarks to the detail of symptoms given by others, particularly with reference to prognosis. Of the intimate nature or essence of small-pox he professed his ignorance in common with the rest of mankind, but adds immediately afterwards his suspicion that it consists of a specific inflammation of the blood and other humours, and that the inflamed particles, when duly digested and concocted, are expelled from the body in the form of little abscesses. The chief merit of Sydenham consists in his criticisms on the prevailing treatment of small-pox. These, though worded with the most scrupulous care, and an anxious wish to avoid hurting the feelings of his professional brethren, yet exposed him to much obloquy, and he was calumniated as an innovator and a homicide. He introduced what is now called the cooling regimen, including fresh air, light bed-coverings, and abstinence from wine and all cordial and sweating medicines. The remedies on which he chiefly relied were moderate bleedings, acidulated drinks, and opiates. His principal faults consisted in the timid employment of purgatives, and his fondness for blisters.

Boerhaave, who was born when Sydenham was at the height of his fame (1668,) entertained the highest admiration of him, and was contented to adopt almost without alteration the description and treatment of small-pox given in his works. But Boerhaave has the great merit of first putting prominently forward *contagion* as its direct exciting cause. He acknowledges "that as the first man who suffered from small-pox must necessarily have received it without contagion, so may it still be occasionally engendered by causes of which we are ignorant. Nevertheless, as a general law it may be stated that the contagion once generated multiplies itself without any assignable limit, as the smallest spark may spread the widest conflagration." (Van Swieten's Commentaries, vol. v. p. 18.)

The theory and treatment of natural small-pox, placed thus, by the combined labours of Sydenham and Boerhaave, upon their proper footing, underwent no important changes during the last century; the attention of authors was then directed almost exclusively to the new discovery of inoculation, of which we shall treat more fully in a subsequent page.

We now proceed to give a description of small-pox, and have to remark, in the first place, how singularly diversified are the appearances which it presents. A variety of causes contribute to this, but none more remarkably than the previous habit or condition of the body with reference to the contagion of small-pox. It will be useful, therefore, to begin by considering the disease under three different aspects:—

First, as it occurs, casually and for the first time, to those who have undergone no preparatory process. This is called the casual or *natural* small-pox.

Secondly, as it occurs to those who in early life have undergone the process of vaccination. This is called the mitigated or *modified* small-pox.

Thirdly, as it occurs to those who have been inoculated with the variolous virus: the *inoculated* small-pox.

Natural Small-pox.

This disease is characterized by a long train of phenomena, some of which are peculiar to it, while others are common to it with other acute disorders. From very early times it was observed that these admit of a division into three *stages*. Such an arrangement is strictly natural, and admits of no improvement. These are, the stages of incubation, maturation, and decline; and they will require separate investigation.

I. **Stage of Incubation.** — Under this head is included the whole period that elapses from the reception of the variolous germ, or virus, into the human body, until the appearance of eruption. Rayear (Treatise on Diseases of the Skin, translated by W. B. Dickinson, p. 108, London, 1833) subdivides it into the two stages of incubation and invasion, the former comprising the interval between the reception of the germ and the *sickening*; the latter extending from the sickening to the appearance of eruption. In very many cases, however, this distinction cannot be made, the two periods running into each other by insensible degrees.

The reception of the variolous poison into the human body casually by the mode of *infection*, (that is, through the medium of respiration,) takes place in most instances imperceptibly and without symptoms. Occasionally, however, the patient experiences at the moment of imbibing the germ of disease some unpleasant sensation, such as a disagreeable odour, or a feeling of giddiness, or sickness at stomach, or, what is perhaps more common still, an inward sense of alarm or fright. The duration of this stage is subject to some variety. Fourteen days may be stated as the average period that elapses from exposure to contagion to the appearance of eruption. The extremes may be set down as one week and three weeks. This interval is passed differently in different cases. Sometimes the patient, during the whole or greater part of this period, has been weak, languid, low-spirited, and inactive, with impaired digestion and unquiet nights. He has felt poorly, without any assignable cause. In the greater number of instances, however, no uneasiness whatever is experienced until the eleventh or twelth day after exposure to contagion, when an unexpected and perhaps severe rigor announces the commencement of the initiatory, or, as it is sometimes called, the *eruptive* fever. This is accompanied in some cases with severe pain or weakness of the back, so that the patient has dropped down; in other cases with acute pain of the epigastrium, aggravated on pressure, and hence sometimes mistaken for gastritis; with nausea, vomiting, giddiness or headach. Children are often very drowsy at this period. The nervous system sometimes participates in a more marked manner. There is extreme prostration of strength. The patient staggers in his walk, and the expression of countenance is anxious and haggard: children have an epileptic fit: adults become delirious. These more urgent symptoms generally indicate the approach of a severe form of the disease. Of this there can be no doubt, when, in addition to the symptoms already enumerated, we observe such as denote that the fluids of the body are implicated in the mischief which is going on—that is to say, when petechiæ appear in different parts, or large patches of subcutaneous ecchymosis, with hemorrhage from the nose, mouth, stomach, bowels, or uterus. Under these circumstances death has been known to take place prior to any unequivocal appearances on the skin. Here the real nature of the disease must always remain in some degree doubtful, but it can often be inferred by tracing carefully the history of the case. It will be found to have succeeded exposure to small-pox contagion within the reasonable limit of time, or it may in its turn have communicated contagion to others. Several well-marked instances have occurred, rendering it almost certain that contagious emanations are thrown off from the lungs and skin even at this early period of the disease.

The duration of the initiatory or eruptive fever of small-pox has been a fruitful source of discussion among authors. Prior to the time of Sydenham the object of physicians was to shorten the period as much as possible, and to promote an early eruption, which they attempted to effect by powerful diaphoretics. Sydenham, on the other hand, maintained that the more tardy the eruption the lighter was the subsequent disease. This observation is not borne out by the results of our own experience; and it is not improbable that Sydenham's judgment might have been in some degree warped by his anxiety to dissuade from that heating regimen of whose injurious effects he was so well convinced. The fact appears to be that the period of the initiatory fever is most remarkably uniform. The eruption in a vast majority of cases shows itself at the end of forty-eight hours from the occurrence of rigor or headach, whether the subsequent disease be mild or malignant, confluent or distinct: in other words, one complete day intervenes. Sometimes, from accidental circumstances, (such as great weakness of constitution,) this period is protracted to seventy-two hours, but never, so far as we have observed, is it shortened. This may be looked upon as a remarkable law of the variolous disease, and a most important means of distinguishing small-pox from other exanthemata, particularly scarlatina, lichen, and measles. In the two former disorders, the duration of the premonitory symptoms is less than in small-pox; in measles it is greater.

II. **Stage of Maturation.**—The eruption of small-pox shows itself in the first instance in almost all cases on the face and wrists, and thence gradually extends over the rest of the body. In a very few cases only has it been first observed on the inferior extremities. It consists of minute papulæ sensibly elevated above the general surface of the skin. In some instances the eruption is fully developed over the whole body in the course of twenty-four hours. In other cases, two and even three days elapse before the process is

completed on the legs and feet. When the papulæ are few in number, and separate from each other, the disease is called *distinct*; when the eruption is close set and profuse, *confluent*. To the intermediate varieties the old authors gave the name of *contiguous* or *coherent*, but the term *semiconfluent* is preferable. We apply it to designate those cases where the eruption is confluent in one part and distinct in another, as well as those where the papulæ are numerous without actually running into each other.

Arrangement and structure of the pock.—This branch of the subject has excited much attention at various times, and in particular was investigated diligently by Cotugno, (better known under his Latin name of Cotunnius,) an Italian physician, in the year 1771. (De Sedibus Variolarum. Vienna, 1771.) When the papulæ are few in number, they will not be found indiscriminately diffused over the body, but arranged in groups of three or five, and assuming a crescentic or semicircular form. When two groups coalesce, a complete circle of papulæ may sometimes be observed. The papulæ have their seat in the true skin; and upon the third or fourth day from their first appearance are converted into vesicles, containing a thin transparent lymph. These vesicles are very curiously organized, being divided into six or eight cells tied together in the centre, which for several days is depressed. This central depression, or *umbilicated* form of vesicle (as it is sometimes called), is very characteristic of small-pox. It is exhibited only in one other disease—cow-pox. The specific matter or poison of small-pox is secreted by the parietes of the minute cells, and the progress of inflammation in the papula is denoted by the inflammatory circle (called areola) which about the fourth day begins to surround it. As the colour of this areola changes to a bright crimson, the lymph in the vesicle is converted into a thick opaque matter, of a white or straw colour. This distends the cells, and gradually increasing in quantity, breaks down the central band, in consequence of which the pustule *acuminates*. In favourable cases this process is usually completed in seven, or at furthest in eight days: occasionally it occupies only five or six days.

During the maturation of the pustules there is always some degree of fever present, varying, of course, in violence, with the quantity of eruption, the habit of the patient, and the circumstances in which he may happen to be placed. If the habit of body be good, the season mild, the apartment cool, the diet duly restricted, and the mind free from anxiety, there will be very little fever, even though several hundred pustules are in the process of maturation. There is generally more or less tenderness of the skin present. Occasionally this tenderness is excessive, and productive of the greatest distress.

Confluent form of small-pox.—When the eruption is very copious over the whole or greater part of the body, this, its regular or normal progress, undergoes several important modifications, which are next to be described. In some cases, indeed, the confluent small-pox runs the same course as the mildest forms of the distinct disease. The vesicles are small, and each is surrounded by a minute areola, while the constitutional excitement is moderate. Such a form of small-pox may be characterized as the *confluent superficial*. The most familiar instances of it are presented when the disease is taken after vaccination, but it is sometimes witnessed among persons wholly unprotected.

Analysis of the symptoms of confluent small-pox.—1. The first peculiarity of confluent small-pox, as generally met with, is, that from a very early period it involves not only the cutis vera, but the subjacent cellular membrane in extensive and often violent inflammation. The eye-lids are swollen, and by the fifth day the patient is unable to see. The scalp is tense and tender. The parotid glands participate in the increased action of the surrounding cellular membrane, and salivation takes place, with great turgescence of the cheeks. The limbs are tumid, and an erythematous redness often occupies such parts as are free from variolous papulæ. In the most aggravated cases, buboes form in the groin, often with intense pain. The skin being almost wholly occupied with vesicles, there is no areola. The pustules do not acuminate, but appear flat and doughy, and upon the face especially they coalesce into one large sore, which discharges a copious thin ichor. The constitutional symptoms accompanying this kind of small-pox are very severe. The pulse is rapid, with extreme debility, restlessness, and total want of sleep.

2. The second peculiarity of the confluent small-pox is, that the eruption occupies not only the skin but the mucous expansions of the mouth, nose, pharynx, larynx and trachea to below its bifurcation. The tongue is also occupied with vesicles. The precise structure of the mucous vesicle has not been determined with the same accuracy as that of the cutaneous vesicle; but it runs a course in all respects similar. This complication of mucous inflammation adds immeasurably to the danger of the disease, besides that it modifies some of the other symptoms. Heat of the mouth, pain of the throat, difficulty of swallowing, hoarseness, dyspnœa, and more or less mucous expectoration, are the first symptoms that it occasions. These increase in severity until the eighth day, from which time a copious secretion takes place from all the structures so affected. In a large proportion of cases the swelling occasioned by the inflammation so narrows the opening of the larynx, and the effused matter so blocks up the air-passages, that suffocation is produced. Before this takes place, however, the respiration has been impeded to such a degree as materially to interfere with the due oxygenation of the blood. Hence arises a long and frightful train of symptoms, among which we may particularly enumerate gradually increasing dyspnœa, coldness and paleness of the extremities, lividity of the areola, especially in parts distant from the centre of circulation, a swelled and purple tongue, great restlessness, and a low muttering delirium.

Cases of the confluent form of small-pox are sometimes met with, which are altogether devoid of mucous complication, but they are very rare. The extent of mucous and of cutaneous inflammation, however, are not always and necessarily proportioned to each other. A case may be very

confluent on the surface, with but few vesicles in the throat.

3. A third circumstance influencing materially the character of the symptoms in the confluent variety of small-pox, is the early and deep implication of the brain and nervous system. This fortunately is but a rare occurrence. The chief symptom by which it is characterized is early and violent delirium, (the delirium *ferox* of old authors,) attended in many cases with such a strong disposition to self-destruction that the utmost care should always be taken to guard against the possibility of accident. Variolous delirium is accompanied with redness of the conjunctiva, contraction of the pupil, and a wild expression of countenance. It generally shows itself at the very commencement of the initiatory fever, but is sometimes delayed until the second or third day from the appearance of the eruption. Excessive restlessness, anxiety, and despondency may be viewed as lighter evidences of the same specific affection of the brain. Nothing indicates its absence so certainly as a calm and collected manner, with a succession of quiet nights, and a confident hope of recovery. Variolous delirium is always most violent in the early periods of the disorder. When the areola begins to form, still more when external inflammation is fully developed, delirium for the most part ceases. Cases of confluent small-pox complicated with delirium are extremely dangerous. A large proportion of them terminate unfavourably, sometimes by affection of the head, (coma,) sometimes by acute inflammation of some other internal part, especially the pleura, brought on or determined by the general derangement of the nervous system. We have stated, as a general rule, that the peculiar affection of the brain and nervous system now adverted to, is associated with a full confluent form of eruption, but occasionally it is found to accompany, and of course very materially to aggravate the danger of distinct and semi-confluent cases.

4. The fourth circumstance which characterizes and modifies the phenomena of the confluent forms of small-pox, is the implication of the *fluids* of the body,—in other words, the concurrence of that state of the blood called by the old writers *dissolved* or putrescent. To these, the most aggravated of all cases, the terms *malignant* or petechial small-pox are generally applied. They are thus distinguished. From the earliest period of the disease, petechiæ are observed in different parts of the skin. Sometimes the extent of subcutaneous ecchymosis is immense. As the vesicles advance to maturation, they fill, not with pus, but with a thin ichor tinged with blood. Hemorrhages break forth from all the mucous structures of the body. The gums bleed often very profusely. There is epistaxis, spitting of blood, vomiting of blood, and the passage of blood by stool. Females suffer from violent menorrhagia, and abortion never fails to occur to such as are pregnant. There is bloody urine in some cases. All this occasionally happens without delirium, or any other well-marked evidence of cerebral affection. More commonly, however, these conditions, viz. disturbed brain and dissolved fluids, are found associated together. From this appalling variety of small-pox, recovery is scarcely ever met with. Death usually takes place between the fifth and seventh days of the eruption.

Complications.—Such are the ordinary phenomena of the natural small-pox in its distinct and confluent forms, when it occurs to persons previously in good health and of sound constitution. But it must be remembered that this disorder may attack those who may be labouring, at the time of seizure, under some other disease, such as pneumonia, hooping-cough, hepatitis, or consumption; and further, that these and other disorders may come on, unexpectedly, at any period, early or late, during the progress of small-pox. An infinite variety of *accidental* symptoms may thus be superadded to those regular symptoms now enumerated. Besides which, small-pox may occur to persons of a weak habit, or in constitutions exceedingly exhausted, and unable to cope with a disease of such severity. It may occur, for instance, to those who have but recently recovered from a severe typhous or scarlet fever. Under these circumstances, we observe a very tardy eruption; collapse without advance of eruption; or in cases somewhat more favourable, an abundant formation of large blebs, containing a thin ichor, with a very tedious and hazardous period of convalescence. To this latter form of the disease the old writers gave the name of the watery or bladder pock.

III. **Stage of Decline.**—If the maturating stage of small-pox exhibits great diversity of symptoms, so also, even in a more eminent degree, does the stage of decline. The mildness and rapid progress to recovery which some cases present, contrast strongly with the severity, obduracy, and varied dangers of others.

In the distinct and mild form of small-pox the pustules burst and discharge their contents on the sixth, seventh, or eighth day. A scab succeeds, cicatrization commences, and in vigorous constitutions is completed in about eight or ten days. In the very mildest cases of all, which approach to the character of chicken-pox, there is very little discharge of matter, but the pustules harden, and the small portion of pus which they do contain is apparently absorbed. This variety of the disease has been called the dry or horny pock, and it is the most common form in which small-pox shows itself after previous vaccination.

In cases of greater severity, as well in the truly confluent as in those which we have distinguished as the semi-confluent variety, where the eruption is copius, but where the vesicles do not actually coalesce except in a few places, the decline of the disorder is attended with some remarkable phenomena, of which the most important are pitting and secondary fever. Cicatrization is tedious and ultimately effected with such a loss of substance in the true skin as occasions pits and scars, which continue during the remainder of life. From the great vascularity of the face, there is always greater confluence and a higher degree of inflammation there than in other parts. Hence, pitting is chiefly met with in the face, disfiguring and often completely altering the countenance of the sufferer.

Secondary fever.—The febrile symptoms subside entirely in all cases where the pustules have maturated kindly over the whole body; but in all

severe cases, that is to say, where the cellular membrane and glands which it envelopes have become involved with the skin in inflammation, the fever, so far from subsiding on the ninth or tenth day, when the maturative stage has closed, is aggravated. The surface of the skin at this time becomes hot and dry, the tongue white, the pustules hard and scaly, the pulse increases in frequency, the patient is tormented with a great, sometimes inextinguishable thirst. Secondary fever is now said to have set in, and the variety of symptoms observed during its progress almost baffles description. The following attempt to enumerate some of the leading phenomena of secondary fever will serve at least to point out the character of this very singular condition.

1. In a large proportion of cases, secondary fever is accompanied with some form of inflammatory action on the surface. An efflorescence identical with that of scarlatina occupies the trunk and extremities. Trails of erythematous redness appear in several parts, or a genuine erysipelas attacks the head, trunk, or limbs. In other cases the cutaneous and cellular inflammation is more circumscribed, leading to the formation of abscesses, often of great extent, of boils and carbuncles, and ulceration of those parts which are especially liable to pressure, such as the elbows, hips, and sacrum. In those situations sloughing sores are often met with, which from their extent and depth bring life into danger. In some cases the scalp is the part which receives the violence of the fever. Abscesses form there, or a diffuse cellular inflammation takes place, which is followed by purulent infiltration. Lastly, in a few instances the whole surface is occupied with pustules of *ecthyma cachecticum*, accompanied with fever of the hectic kind, which is with great difficulty subdued.

2. Secondary fever is accompanied in a certain proportion of cases with ophthalmia. The subject of variolous ophthalmia is one of great extent and importance. In the early periods of the disease it is not uncommon to observe a considerable degree of conjunctival inflammation, and sometimes a pustule forms at the edge of the cornea; but it is reserved for the decline of the disease to exhibit the aggravated form of this affection. In some desperate cases an intense form of ophthalmia sets in about the tenth day, which rapidly involves all the structures of the eye, and in the course of a few days destroys its entire organization. In other cases the sloughing is confined to a portion of the cornea, and this is followed by a staphylomatous protrusion of the iris. It is rare to observe more than one eye involved in this very destructive form of inflammation, but still in all countries, and from the earliest periods at which we read of this disease, a large proportion of the blind have been found to owe their misfortune to the secondary fever of small-pox.

3. Another frequent occurrence in the progress of secondary fever is gangrenous inflammation of the genitals. This shows itself in the first instance on the scrotum or prepuce, runs on rapidly to mortification, and in almost all instances ends in the loss of life.

4. The destructive effects of secondary fever, however, are by no means confined to the surface of the body. It frequently happens that without any obvious cause some internal organ receives the violence of the febrile shock. Acute inflammation is set up, and the result is in almost all cases suppuration. The *pleura* is the part peculiarly disposed to suffer under these circumstances. Variolous pleurisy comes on about the eleventh or twelfth day of eruption, for the most part very suddenly, and proceeds rapidly to empyema. We have seen it prove fatal in thirty-six hours. In general, the pleuritic symptoms are violent and well marked. The pain of side is excruciating, and the shortness of breath equally unequivocal; but sometimes there is a latent form of pleurisy. The patient dies without making any complaint of the side, and on dissection one of the cavities of the thorax is found gorged with a sero-purulent fluid. In all cases of secondary fever, a strict attention to the respiratory organs, with such aid as the stethoscope can afford, should never be omitted. In a few cases the substance of the lungs is the seat of an intense form of inflammation, tending to abscess. Children are sometimes attacked with symptoms indicating laryngitis or croup.

5. Affections of the abdominal viscera are very uncommon. Inflammation of the liver and of the mucous membrane of the bowels have been noticed, but they are among the rarest forms of internal disease observable in the progress of small-pox.

6. The brain sometimes suffers during the presence of secondary fever. Phrenitis with delirium occurs in children; and in adults of plethoric habit a state of coma or lethargy is not unusual. But what is most worthy of attention in this respect, is that singular state of the nervous system which accompanies the destruction of large portions of skin, and which is so well known to surgeons as a consequence of extensive burns and scalds. It is characterized by severe and repeated rigors, succeeded by general tremors, low delirium, a weak and rapid pulse, a dry brown tongue, and collapse of the features terminating in death.

7. The evils attending secondary fever are aggravated by the concurrence of the strumous habit. Nothing develops it more certainly than protracted small-pox. Accordingly, in scrofulous constitutions we see secondary fever complicated with strumous ophthalmia, characterized as well by its complete intolerance of light and abundant secretion of tears as by its obstinate resistance to every kind of remedial treatment. Irritable ulcers form under the lower eyelid, and around the knee, ankle, and elbow-joints, and are found very difficult to heal. Glandular enlargements of the neck take place, which sometimes suppurate, but oftener continue indolent and of stony hardness. Children frequently suffer from otitis.

8. To all this must be added the danger of contracting during the stage of decline, common fever of the typhoid or erysipelatous kind. At the Small-pox Hospital, it is not uncommon to find even the milder cases attacked during apparent convalescence, with fever, irritable stomach, sore throat and erysipelas of the face or extremities. This *superadded* disease has in many instances brought life into hazard, and in some has proved fatal. The great peculiarity of it is the concur-

rence of severe inflammation of the tonsils and subjacent cellular membrane with erysipelas of the head, neck, or back. It appears to have its origin in that vitiation of the air which is almost inseparable from the very nature of an hospital, and which any accumulation of malignant cases, more especially in a disease like small-pox, must necessarily tend to augment. This form of disease might be appropriately designated *hospital fever*. When it has once shown itself, there is abundant reason for believing that such a fever, whether exhibiting anginose or erysipelatous symptoms or their combination, is truly contagious.

Prognosis. — The following are the chief grounds on which the prognosis in small-pox should rest.

1. Confluence is always unfavourable, because it necessarily occasions a large drain on the system; but if the pustules acuminate well, and the areola on the extremities be of a good, that is, crimson, colour, a reasonable ground of hope exists. Confluence on the face is more to be dreaded than in any other part. When the vesicles on the trunk of the body are flat, when the eruption on the face is white and pasty, when the extremities appear of a clarety or livid colour, little or no hope of recovery can be entertained.

2. With reference to prognosis, great attention is due to the state of the larynx. Hoarseness, with copious spitting, occurring at an early period is very unfavourable, as indicating the extent of mischief in that important organ. On the other hand, a natural tone of the voice is a favourable sign, and with a good constitution gives a fair ground of hope, even though the eruption be full and confluent.

3. Quiet nights, composure of mind, a collected manner, and confident hope of recovery are good omens, because they indicate the comparative freedom of the brain and nervous system from all serious complication. Patients who from an early period of the disease are restless, delirious, moaning, and desponding, rarely recover. There is not a worse symptom in children than grinding of the teeth: very few recover in whom it is observed.

4. In estimating the danger of confluent and semi-confluent cases, the age of the patient merits particular attention. Persons above forty years of age seldom recover from any of the severer forms of small-pox. Infants also are in danger even from a moderate quantity of eruption. In both cases the reparative process is attended with great exhaustion of nervous power, the result of which is that the brain, larynx, or some other important organ loses its tone, takes on acute inflammation, and by its disorganization life is destroyed. The most favourable age for taking small-pox is from the seventh to the fifteenth year, when the powers of life are in the greatest vigour, with the least chance of plethora.

5. The habit of body is likewise to be taken into account. In the middle periods of life the danger of small-pox is much increased by its concurrence with a *plethoric* habit. Great weakness of constitution is equally a source of danger. Of the additional risk which a strumous habit entails, we have already had occasion to treat.

6. Every thing indicating a dissolved or putrescent state of the fluids is of course most unfavourable, such as petechiæ, menorrhagia, and epistaxis. Recovery from the petechial or malignant form of small-pox, indeed, is so rare as scarcely to enter into calculation.

Mortality of Small-pox. — It is commonly stated that one-fourth of those who are attacked by small-pox in the natural way perish. The records of the Small-pox Hospital indicate a somewhat higher proportion. The deaths during the last fifty years at that institution have averaged thirty per cent., the extremes being eighteen and forty-one per cent. The days of greatest mortality, or critical days, as they are called by the old authors, have been much commented upon, and in all ages it has been observed that the eighth (counting from the day of eruption) is the day of greatest danger. The following table, extracted from the register of the Small-pox Hospital for the years 1828 and 1829, illustrates this fact, while it shows at the same time that small-pox proves fatal at various periods, from the third to the thirty-eighth days of eruption. From this table it also appears that nearly two-thirds of the total number of deaths take place during the second week of eruption.

	Total	168	

[Prior to the introduction of vaccination, according to Dr. Gregory, (Tweedie's *Library of Practical Medicine*, 2d Amer. edit. ii. 324, Philad, 1842,) the deaths by small-pox were, to the total deaths in town and country, in the ratio of 16 to 100, or about one-sixth. Of those attacked, the mortality is usually stated at 1 in 4. This,

according to Dr. Stewardson, was the mortality at the Small-pox Hospital of Philadelphia during the years 1840, '41, and '42,—a much smaller proportion than in the epidemic of 1823 and 1824, described by Drs. J. K. Mitchell and J. Bell, (*North American Med. and Surg. Journal*, vol. ii. 1826,) in which more than one-half the unprotected cases died. In an epidemic small-pox, which visited Malta and Gogo in 1830 and 1831, the mortality amongst those not vaccinated was, according to Dr. John Davy, 1 in 4.7. (*Notes and Observations on the Ionian Islands, &c.*, Lond. 1842.)

The numerical method has not, however, been extensively and rigorously applied to this subject. The mortality seems to vary in different places; thus, from primary small-pox in London it has been estimated by Dr. George Gregory at 36 per cent.; whilst in Germany, according to Heim, it was only 20 per cent. From accurate statistical accounts, taken by the Registrar-General of England, it would appear that, in 1837, there were only five diseases more fatal in England; and that the deaths by it throughout England and Wales amounted to about 12,000 annually. Since then, the number has fluctuated from 16,268 in 1838, to 9,131 in 1839. (Mr. W. Farr, in *Third Report of Registrar-General*, 1841.)

At times, during special epidemic influences, the mortality from small-pox is terrific.]

Causes of death in Small-pox.—It may not be irrelevant to recapitulate the several causes of death in small-pox. 1. Prior to the maturation of the pustules, that is, between the second and seventh days of eruption, patients die of malignant fever; of that peculiar condition of the fluids and nervous system to which the name of *acute malignancy* may properly be given. 2. Between the eighth and thirteenth days of eruption, the chief cause of death is to be found in affection of the throat, and consequent *suffocation*. 3. In the state of secondary fever, that is, between the fourteenth and twenty-first days of the eruption, death may take place in three ways—either by violent febrile excitement with effusion on the brain; or by sloughing, gangrene, and destruction of large portions of the surface; or lastly, by supervening pleurisy, peripneumony, or laryngitis. 4. At a still later period, that is, after the third week from the appearance of eruption, death may take place from mere exhaustion, or from erysipelas and superadded fever.

Morbid Appearances.—It has been remarked from the earliest periods that the internal organs do not suffer in small-pox so extensively or so frequently as might be expected. In a large proportion of cases, the condition of the surface is the sole cause of death. In the throat, however, some very characteristic appearances present themselves, provided death has taken place between the seventh and twelfth days of the eruption. The pharynx, larynx, and trachea are then found covered with a copious, viscid, puriform, or purulent secretion of a grey or brownish colour, thrown out by the numerous vesicles which had formed upon the mucous membrane of those organs. The mucous membrane itself appears thickened, pulpy, and in the worst cases black and sloughy.

There is no point wherein pathologists have more widely differed than in this, whether the specific inflammation of small-pox invades the internal parts? The phenomenon has been asserted as a matter of fact by some, while others have, with equal confidence, denied it. Cotunnius (De Sedibus Variolarum, passim) made a vast number of dissections with a special view to ascertain whether any of the viscera were the seat of variolous pustules. His conclusion is, that they are exclusively confined to the skin, and those mucous membranes which are in direct contact with the external air. There can be no doubt that this opinion of Cotunnius is strictly correct. Inflammation may originate from accidental causes in any internal organ during the progress of small-pox, and its effects will be seen after death; but these are not to be confounded with, or mistaken for, the specific effects of small-pox on the skin, and mucous expansion of the throat and chest.

When death has taken place in the third week from the appearance of eruption, the pleura will sometimes be found inflamed, and coated with layers of coagulable lymph, while in the corresponding cavity of the thorax, purulent matter or a sero-purulent fluid will be collected, often in enormous quantity, compressing by its bulk the lung of that side into a small space. Occasionally a portion of the lung itself is found infiltrated with pus.

In some cases, where great determination of blood to the head has been indicated during life by swelling of the head and face, delirium, headach, and high fever, the blood-vessels of the brain and its meninges are found turgid, with more or less of effusion into the ventricles.

Nothing is more worthy of notice than the freedom of the abdominal viscera from all traces of disease in those who die of small-pox. Among the numerous dissections made at the Small-pox Hospital, we have never been able to detect variolous pustules on the mucous membrane of the intestinal canal. Ulceration of the bowels indeed sometimes takes place in children during the violence of the secondary fever, but differing in no respect from that which occurs in other and more familiar forms of hectic fever.

[See, on this subject, Dr. Petzholdt, in *Brit. and For. Med. Rev.* v. 479.]

Pathology.—For more than a thousand years after the first appearance of small-pox, this disease was considered by physicians to have its origin, like other fevers, either first, in some state of the atmosphere, or secondly, in some vitiated condition of the humours of the body. A large portion of the community at the present day are of the same opinion, and confidently believe that the small-pox is, to use their own expression, bred in the blood. The pathologists of the last century, however, from the time of Boerhaave, reasoning from the very peculiar train of symptoms observed in small-pox, and from the comparatively recent date at which it became known, adopted the notion that this disease is in all cases the product of a specific poison or contagion, received into the blood from without. Such is still the general opinion of the best informed physicians. It cannot indeed be denied, that great difficulties are experienced in tracing the source of contagion in numberless cases, and that the doctrine of *spontaneous* origin admits of being

supported by some ingenious and plausible arguments; but the weight of evidence is decidedly in favour of the invariable origin of small-pox by *contagion*. How the variolous poison was first generated is wholly unknown. A tradition has been handed down by the Arabian physicians (See Baron's Life of Jenner, p. 522,) that it was originally derived from the camel, but no substantial reasons for such an opinion have ever been advanced.

The peculiar miasm or morbid matter of small-pox is receivable into the human body in three modes: first, by the lungs through the medium of the respiration: this is called the mode of *infection*. Secondly, by application of the matter to the unbroken surface of the skin or mucous membrane of the nose. This is properly denominated *contagion*, although the terms infection and contagion are generally made synonymous. Thirdly, by application of matter to the wounded surface, which is the mode of *inoculation*.

The diffusion of small-pox by the air in the mode of infection, as thus defined, presents many interesting peculiarities. It takes place much more energetically in certain states of the air than in others. Occasionally the atmosphere appears to be altogether incapable of disseminating the poison. That peculiar, or as it is sometimes called, *epidemic*, constitution of the air which is so favourable to the propagation of small-pox is not at all understood. It is neither appreciable by the thermometer, the hygrometer, nor the barometer. Small-pox spreads sometimes in a dry and warm, sometimes in a cold and moist state of atmosphere. The phenomenon may possibly depend upon some electrical state of the air, which has hitherto eluded the researches of philosophers, but which time and closer observation may perhaps eventually succeed in discovering. It has been supposed that the peculiar condition of the atmosphere predisposing to the dissemination of the variolous germ recurs every five or seven years, but no adequate grounds for this opinion appear to exist. Dr. Haygarth (Inquiry how to prevent the Small-pox, p. 78, 1801,) has taken great pains to ascertain the sphere of contagious influence in the case of small-pox — in other words, the distance to which the contagion extends beyond the person of the individual affected. He inclined to the opinion that it was very limited, not exceeding a few feet. There is reason to believe, however, that some fallacy exists in the experiments made to determine this point, and that the distance at which the poison ceases to be energetic is much greater, varying, however, according to the condition of the atmosphere.

Effluvia capable of communicating small-pox are generally considered to be given off by the lungs as well as by the skin, and at every period of the disease from the earliest to the latest. Drs. Haygarth and Heberden maintained (Ibid. p. 47 and 216,) that prior to the appearance of eruption, and even for the first two or three days after, a patient is seldom if ever found to communicate infection. We have already, however, expressed our belief, founded on facts within our own knowledge, that even prior to the occurrence of eruption, while the body is labouring under the premonitory fever, the secretions are infectious. It is admitted by all that the contagious property hangs about the body as long as any scabs remain, which may be said to contain the poison in a concentrated form. Again, it has been well ascertained (see cases detailed by Mr. Hawkins, in the London Medical Gazette, vol. iii. p. 282,) that for some considerable period after death the matter of the pustules continues energetic, and that a confluent case will so taint the air as to spread the disease, by infection, for at least ten or twelve days after death.

All mankind, with few exceptions, are susceptible of the variolous poison at some period of their lives. It has been received by the fœtus in utero, by the infant immediately after birth, and by the adult up to the most advanced period of human life. As a general law, it may be stated that the susceptibility of small-pox is equally great at all ages, but it often happens that a particular individual shall resist infection at one period of his life and receive it at another. Some constitutions imbibe this morbid germ mildly, others with great alarm. In such cases the nervous system may truly be said to be *poisoned* by it. A full and plethoric habit predisposes to a confluent and malignant form of the disease. Huxham has well remarked that the ebullition of the fluids consequent on the circulation of the poison in such persons is, *cæteris paribus*, most severe and dangerous. (On Fevers, p. 126 et seq.) Hence the great mortality of the disease in that class of adults who indulge in full living, with a large allowance of ale and porter. At the same time it must be remembered that the opposite state of body, extreme weakness, is equally unfavourable for the quiet reception and safe elimination of the variolous poison.

The *quantity* of eruption is sensibly influenced by the state of the surface at the period of its development. Great heat of the apartment, the warm bath, the use of strong diaphoretics, abundance of bed-clothes, and the local irritation of blisters, all favour confluence. It might be expected that cold would possess some power in diminishing the number of papulæ. It must be confessed, however, that though by injudicious measures we may often aggravate the quantity of eruption, we possess few or no means of lessening it. The character of the disease is not with any certainty influenced by the source whence the infection was derived. The mildest form of what is called varioloid eruption will communicate to another the most confluent and malignant disorder.

Variolous effluvia are very volatile. A free ventilation, therefore, is the most effectual means which we possess of diminishing the danger of contagion. The clothes and bedding of a small-pox patient, if closely wrapped up, will retain and give out the disease to others at great distances of time; while medical men who visit small-pox patients and subsequently go into the open air, seldom if ever communicate the disorder. Dr. Haygarth is of opinion that they never do. Be this as it may, variolous effluvia are rendered comparatively innocuous by dilution.

A few persons pass through a long life, apparently insensible to, or unsusceptible of, the

small-pox virus. It is a curious and important circumstance that, so far as is yet known, such constitutions exhibit a like inaptitude to receive and nourish the vaccine disease. (See London Medical Gazette, vol. viii. p. 494.)

Recurrent Small-pox.—Few facts in medicine are better ascertained than that once undergoing small-pox gives to the individual through life complete immunity from future attacks. Exceptions to this law, however, have undoubtedly occurred. They have been noticed in all ages, and stand recorded in the writings of almost all authors who have treated of small-pox. (See Medico-Chirurgical Transactions, vol. ii. p. 31. Also Edin. Med. and Surg. Journal, vol. iv. p. 460.) They are, nevertheless, comparatively rare occurrences, and many persons practising extensively, have never seen even a single case of the kind. There is no instance recorded of a patient being received twice into the Small-pox Hospital. Second attacks of small-pox, when they do occur, are generally, so far as our own experience extends, different in their character from the first: when the first attack, that is to say, has been severe and unequivocal, the second has been light and trivial, and *vice versâ*. Sir Gilbert Blane remarks, (Blane's Select Dissertations, p. 209,) that "almost all the well-authenticated cases of second small-pox have been of those persons who in the first instance had undergone it in its most severe and dangerous form." This would seem to connect the occurrence of small-pox with a peculiar proneness in such a constitution to suffer under the variolous germ. Others, again, have attempted to explain this phenomenon on the supposition that the first attack did not perfectly saturate the system. Instances of death from recurrent small-pox are not common, but they are to be found recorded in authors of undoubted veracity. It has been alleged that second attacks of small-pox are more frequent after the inoculated than after the casual disease; but Baron Dimsdale, a high authority on such matters, denies this. A predisposition to receive small-pox more than once has been stated to exist in certain families.

Concurrence of Small-pox with other Exanthemata.—Among the peculiarities of the contagion of small-pox, the possibility of its simultaneous occurrence with other exanthematous diseases deserves mention. Several cases have been recorded wherein measles and small-pox have appeared together,* and both diseases have run their regular course uninfluencing each other. Such cases, however, are very rare. It has occurred to us to see at the Small-pox Hospital several unequivocal cases of the simultaneous existence of small-pox and scarlatina anginosa. Small-pox and cow-pox may sometimes be seen together, each running its natural course, but in general, under such circumstances, one or other disease is modified. This subject will be more fully discussed when treating of vaccination.

Communication of Small-pox to the fœtus in utero.—A number of facts illustrating this very curious subject have been collected together by Dr. George Pearson. (Duncan's Medical Commentaries, vol. xix. p. 213.) From them it appears that the small-pox does not often extend from the mother to the fœtus; that whenever it is so taken, it is fatal in almost all cases to the fœtus; that inoculating a pregnant woman generally destroys the life of the fœtus, and, lastly, that the disease in the fœtus and mother is scarcely ever in the same degree of intensity. Dr. Jenner has published two cases (Medico-Chirurgical Transactions, vol. i. p. 269) in which the fœtus in utero took the disease from the mother, without the mother being herself affected, though exposed, of course, to the contagion. Mead entertained the fanciful notion, that if a pregnant woman underwent small-pox without aborting, the child would remain through life unsusceptible of small-pox.

Treatment.—1. It is seldom that opportunities offer of treating this disease in its initiatory stage, for its existence is generally unsuspected until the eruption manifests itself. The eruptive fever of small-pox, therefore, supposing its nature unknown, would be managed like other forms of inflammatory fever. Blood would be taken from the arm, when the pain of the epigastrium or of the head were urgent. Saline medicines in a state of effervescence would be given to lessen the feverish excitement and to allay the irritable state of the stomach. Coldness of the extremities would be met by hot bottles to the feet, sinapisms, and the pediluvium. When from concurrent circumstances, especially a known exposure to contagion, the real nature of the disease should be ascertained or very strongly suspected, the plan of treatment would not be materially different from this. Bloodletting would not then be repeated under a confident expectation that the appearance of eruption would speedily relieve the symptoms. Leeches to the temples would be advisable, provided the headach continued urgent. The bowels should be relieved by injections and the milder kinds of aperients. All drastic purgatives should be then avoided. The saline diaphoretics might be advantageously directed, with the addition of an opiate at night, in cases accompanied by much delirium. Bleeding from the arm is not found to afford relief to that specific affection of the brain and nervous system which ushers in a certain proportion of the severe cases, and accompanies their maturative stage for the first three or four days. Leeches cold lotions to the head, aperients, and an anodyne at night, offer a better prospect of relief. The antiphlogistic regimen is to be pursued in all its details.

2. During the period of maturation the following plan of treatment is to be recommended. When the stomach remains irritable with a tardiness of eruption on the extremities, a blister may be applied to the epigastrium, and frequent pediluvia administered, made more stimulating by the addition of mustard-powder. Pain of the fauces with difficulty of swallowing is benefited by the application of leeches to the throat, followed by fomentations made of camomile-flowers or poppy-heads. The bowels are to be duly regulated by aperient draughts, consisting of senna and salts, castor oil, or jalap with cream of tartar, in sufficient doses to insure one motion daily, or two motions, if the degree of fever requires it. The

* Dr. Russell in Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, vol. i. p. 90.—Mr. Delagarde in Medico-Chirurgical Transactions, vol. xiii. p. 163.

action of the kidneys in like manner is to be encouraged by frequent doses of the citrate of potash, the liquor ammoniæ acetatis, or any similar mild diuretic. An opiate consisting either of laudanum, of the liquor opii sedativus, or of Dover's powder, may be given at bedtime, if there be any considerable degree of restlessness or of irritation of the skin.

When the surface is tender and painful to the touch, with much heat, cooling lotions may be applied with considerable advantage. Under all circumstances the diet is to be regulated as in other cases of inflammatory fever. Lemonade may be given for common drink, and Sydenham's strong recommendation of small-beer may be unhesitatingly adopted.

Symptoms indicating local inflammation must be met by appropriate means. When cough and copious expectoration of a puriform mucus occur, and give evidence that inflammatory action has spread to the smaller branches of the bronchi, blood should be taken from the arm to the extent of twelve ounces, and repeated according to the exigencies of the case, bearing always in mind the drain upon the system which an extensive pustulation will ultimately occasion. When headach, a flushed face, redness of the eye, and activity of the carotid and temporal arteries denote the presence or probable approach of phrenitic inflammation, particularly in persons of plethoric habit, blood must be taken from the arm freely. In the same habit of body it is sometimes advisable to take blood from the arm to moderate the violence of inflammatory action upon the surface, and to lessen the danger during the state of secondary fever. In all these cases the blood will be found buffy, and generally in a high degree. Ophthalmia occurring during the maturative stage is generally relieved by leeches to the temples, a strong purgative of calomel and rhubarb, and lotions containing Goulard and the extract of poppies. In all cases of small-pox it is desirable to keep the chamber darkened to guard as far as possible against this occurrence, and for the same purpose, as well as for the general comfort of the patient, the hair should be taken off at an early period of the disease.

3. The treatment of small-pox during the stage of decline and secondary fever is to be regulated on the following principles. When the disease is mild, a few doses of purgative medicine are useful, to keep down feverish excitement, and to carry off foul secretions, or, in the language of the vulgar, to get rid of the dregs of the disorder. Where the disease has been more severe, and secondary fever has set in, the excitement is to be allayed by occasional doses of antimonial powder with calomel, followed by an active aperient. The propriety of purging during the secondary fever of small-pox was for a long period the subject of keen controversy, but the question was satisfactorily settled in its favour. Calomel and rhubarb, senna and salts, and castor oil are the forms of purgative which will generally be found to answer best.

Bleeding from the arm is seldom advisable in the course of secondary fever, unless accidental and superadded symptoms, such as pleurisy or coma, occur to render it necessary. When the face continues swollen, with tendency to delirium and a very dry skin, leeches should be applied to the temples. In those aggravated cases accompanied with the destructive form of ophthalmia already described, little can be done for the assistance of the patient. The loss of blood which the intensity of the symptoms indicates would be followed by great and rapid exhaustion. To save the patient's life, therefore, the eye must sometimes be sacrificed.

The period of secondary fever is frequently accompanied with symptoms of debility, which call for the employment of tonic and cordial remedies. If there be a cold surface, a trembling hand, and dry tongue, wine should be administered, together with cordial draughts, consisting of camphor julep, ether, and the subcarbonate of ammonia. When the pustulation is profuse over the whole body, and the consequent drain upon the system great, beef-tea should be given freely, with a liberal allowance of porter, wine, or brandy. In this condition of the surface, it is extremely useful to absorb the matter by frequently and largely sprinkling the body with some simple dry powder, such as hair-powder, dried flour, the powder of starch, or of calamine. Starch-powder is the best. When sloughy and gangrenous sores have taken place upon the hips or extremities, reliance must chiefly be placed on the administration of wine and brandy, assisted by cordial draughts containing quinine, camphor, the aromatic confection, and laudanum.

Particular symptoms must be met, as they arise, by appropriate remedies. Pains of legs are best relieved by warm fomentations made of the decoction of poppy-heads. Extreme debility and night-sweats call for the administration of bark and acid. An ecthymatous state of the surface, with languor and loss of appetite, will sometimes yield, and cicatrization advance, under the use of sarsaparilla and small doses of the pilula hydrargyri. In many cases, however, this troublesome sequela of the disease will not give way except to change of air, the beneficial influence of which is very manifest in the convalescence from all the severer forms of small-pox. Erysipelas is to be treated by purgatives of calomel and rhubarb, followed by castor oil; by lotions to the surface, applied either warm or cold according to the feelings of the patient, and the internal administration of saline diuretics, aided towards the decline of the complaint by the decoction of bark.

When small-pox has called into activity the dormant seeds of scrofula, the tonic and alterative treatment usually pursued in the management of that disorder is demanded, although the most scientific efforts of the physician will then too frequently be baffled. The abscesses and ulcers, as well indolent as irritable, which are so often left by small-pox, are to be treated according to the ordinary rules of surgery. There is no peculiar method which can be devised for the prevention of pits and scars. The masks and ointments formerly in use for that purpose, and so highly vaunted, are in reality more hurtful than beneficial. The application of a little cold cream to the hardened scabs is all that can be recommended.

The greatest attention should be paid during the latter stages of confluent small-pox to the state of the scalp. The matting together of the pustules is apt in this situation to occasion extensive

abscesses, which are very troublesome and difficult to heal. To obviate these evils, the hair should be kept close cut, the scalp, when hot, should be covered with cold lotions, and purgative medicines administered, to relieve that determination of blood to the head on which the occurrence mainly depends.

[The "ectrotic method" of treating the eruption has been much recommended of late years. (Rilliet & Barthez, *Traité Clinique et Pratique des Maladies des Enfants*, ii. 544, Paris, 1843.) It has been advised to cauterize the pustules, within the first two or three days, or even somewhat later, with the view of abridging their duration, and preventing pitting. The best mode of applying the caustic is to cut it to a fine point, and pierce the centre of each pustule with it. Mercurial plasters, composed of calomel or corrosive sublimate, are said to have the power, when applied to the skin, of so modifying its condition as to prevent the maturation of the pustules; and wetting the face frequently with spirit of hartshorn is said by Dr. Morton, (Amer. edit. of Mackintosh's *Principles of Pathology*, &c.,) to have kept down the inflammation, and prevented the pustules from becoming either large or irritable. Keeping the patient with his face covered with a linen mask smeared on the under surface with mercurial ointment, seems to have prevented pitting. (See, on this subject, Dr. Stewardson, in *Amer. Journ. of the Med. Sciences*, Jan. 1843.) Baron Larrey, however, affirms, that he has found nearly the same benefit to follow the repeated anointing of the patient's face with olive oil.

In addition to the plans already mentioned, it has been proposed, of late, to pass over the eruption a pencil dipped in a solution of nitrate of silver in the proportion of from 15 to 45 grains to the ounce of distilled water. It would seem to be necessary, that the plan should be adopted before the fourth day, or before the eruption assumes the pustular form. Frictions with sulphur ointment, made of from a drachm and a half to two drachms to an ounce of lard—the first proportion for varioloid,—the second for cases of confluent small-pox—over the face and the other parts that are covered with pustules, have been followed by equally favourable results.

Light has certainly an effect in favouring the development of the pustules: hence, the patient has been kept with advantage in a dark room. With the view also of preventing the contact of light, the face has been masked with advantage; and, according to Baron Larrey, the Egyptians and Arabians are accustomed to cover the exposed parts of the body—as the face, hands, and feet—with gold-leaf, as soon as the eruption makes its appearance.]

Modified Small-pox.

Small-pox taken casually by those who have undergone no preparatory process of any kind, is sometimes of an exceedingly mild character. The pustules, though perhaps very numerous and close set, do not run into each other, but maturate separately, and *turn*, as it is called, on the fifth day. The eruption feels hard to the touch, and is of the kind commonly denominated seedy or horny. In the works of the oldest authors on small-pox, a description of the variety called *horn-pock* or stone-pock may be found. (Van Swieten's Commentaries, vol. v. p. 10.) It is a fair presumption that such natural mildness of disorder is attributable to some fortunate peculiarity in the constitution of the patient.

When small-pox occurs a second time, whether after inoculation, or after the disease casually taken, the second attack is very often of a spurious or anomalous kind. The papulæ are prematurely surrounded with an imperfectly-formed areola; some are developed and pustulate; others harden and die away. The eruption is limited to the face, or, at furthest, extends only to the face and trunk. Such instances of a spurious or modified small-pox are recorded in all the old writers, and do not appear to have been of unfrequent occurrence. Their close resemblance to cases of common chicken-pox gave occasion to much ambiguity, and even dispute concerning the identity and relations of these diseases.

Since the discovery of vaccination, the milder varieties of small-pox have greatly increased in frequency, so as at the present time to be familiar to every one engaged in practice. Vaccination may be said to have multiplied prodigiously the number of constitutions that imbibe the small-pox mildly. It has generated a sort of artificial habit favourable to the peaceful reception of the variolous virus. It becomes now, therefore, an object of considerable importance to investigate carefully the phenomena of the mitigated or modified small-pox [*Varioloid.*] It is reserved for a future opportunity (see Vaccination,) to explain the circumstances under which small-pox occurs after cow-pox, and the presumed causes of such an occurrence. All that we now propose is to state the appearances which small-pox presents at some considerable interval of time after vaccination, as for instance, ten or twenty years.

In a certain limited number of such cases, even when the proofs of correct vaccination have been most undeniable, the small-pox has been found to run its regular course unaltered in its symptoms, and unmodified in any of its features. We cannot, therefore, be surprised if it has sometimes, when so occurring, proved fatal. In an infinitely larger proportion of cases, however, the small-pox, when it attacks an individual who in the early period of life has felt the full influence of vaccination, is altered or modified, as well in its primary aspect as in its subsequent development and progress. No reasonable doubt can be entertained, from the abundance of facts now before the world, that such modification is the *law* of the animal economy, and that the regular or normal progress is the *exception*.

It does not appear, however, that the modifying power of vaccination displays itself in the incubative stage. In the modified, as in the natural disease, the same interval of time elapses between the reception of the variolous germ, the first development of symptoms, and the subsequent appearance of eruption. The same pain of back attends the initiatory fever. The same constitutional disturbance, as well in kind as in degree, precedes the eruption. But though the primary fever rages uncontrolled by vaccination, its influence is often perceptibly seen at the very first appearance of the papulæ. The eruption is both

less in quantity, and more limited in extent than in the common forms of the disease. It shows itself in the face and breast, and not at all, or very scantily, on the extremities.

In many cases, indeed, this description does not apply. The eruption is profuse, and equals, both in extent of surface affected and in quantity, the worst cases of natural confluent small-pox. The modifying power, however, begins to show itself almost immediately afterwards. The feverish excitement, which with such a state of surface might be expected to run high, subsides entirely. Some of the papulæ never advance at all towards maturation, while around others an imperfect attempt to form areolæ may be observed as early as the second or third day. The course of the disease is then so rapid, that by the fifth day the pustules on the face have maturated. The pocks are horny and speedily desiccate, leaving, however, for a considerable time afterwards, tubercular elevations of the skin surrounded often by a mottled redness. During the progress of this imperfect maturation the patient is generally able to walk about. He enjoys a good appetite and sound sleep. The unsightliness of the eruption alone disturbs him. No inflammation of the cellular membrane interrupts the period of convalescence. No pits remain to attest the violence of the disorder.

We are warranted, as well by etymology as by the custom of old authors, in applying to this mild form of small-pox the term varicella; but to distinguish it from another disease which has received the same name, (the genuine or infantile chicken-pox,) we may with propriety call this the *varicella variolodes*. It resembles the true chicken-pox in the mildness of the external inflammation and the absence of all severe constitutional excitement. It differs from it, however, in its undoubted origin from the variolous germ, and in its power of communicating the most perfect small-pox to others, as well by inoculation as by infection.

In some cases, especially where the interval from the date of vaccination has been short, small-pox in the vaccinated shows itself in a form so singularly mild that the real nature of the disorder can be with difficulty ascertained. In fact, none but those who are in the constant habit of seeing such cases, of tracing them to their source, and observing the minute gradations by which the several kinds of small-pox run into each other, could recognise them. A few scattered pimples perhaps are all that exist to attest the fact; but these pimples, in their progress to maturation, will be found to exhibit (with or without the aid of the microscope) that great and undoubted criterion of variolous origin, *depression of their centres*. The diagnosis is aided by carefully inquiring into the history of the initiatory fever, and observing if forty-eight hours had elapsed between the occurrence of rigor and the development of papulæ. It is put beyond dispute by tracing the source of the disorder to some case of undoubted variola, at the distance of eight to fourteen days, or by its simultaneous occurrence with other cases in which the character of the disease is unequivocally displayed.

Such are the phenomena of small-pox as it usually presents itself in those who have undergone regular vaccination in early life. It remains to state that every intermediate degree between the thoroughly confluent and the mildest varioloid will sometimes be seen. It is seldom, however, that any severe affection of the bronchial passages is witnessed. A few vesicles may be observed on the tongue and soft palate, but they seldom extend to the larynx. Affection of the brain and nervous system is more common. Intense delirium may often be found accompanying a very modified aspect of eruption, giving rise to much anxiety and some real danger. The cause of this anomaly generally exists in the peculiar habit of the individual. He will be found to be a person of an irritable or nervous temperament, and who has probably displayed, on some former occasion, a similar occurrence under the pressure of acute disease.

Small-pox after vaccination very rarely exhibits dissolution of the fluids, hemorrhages, and the other phenomena of malignancy. Such an occurrence has been witnessed, and followed too by a fatal result, but it must be looked upon as the most rare of all observed deviations from the ordinary course of the modified disease.

Inoculated Small-pox.

Small-pox existed in the world, and had been studied by physicians for at least a thousand years, before any idea prevailed that its course could be controlled and its virulence assuaged by any artificial means. When, where, and by whom this great discovery was first made is not accurately known. It has been conjectured that it had its origin in the countries bordering on the Caspian sea, Circassia, and Georgia; but the opinion rests upon no adequate authority. Nor can we place much more reliance on the statements which have been made as to the antiquity of inoculation in China and Hindostan. Our first accounts of it are derived from Constantinople, and there, towards the close of the seventeenth century, inoculation must be considered as having had its origin.

About the year 1703, rumours of the great success of this operation attracted the attention of Dr. Emanuel Timoni, a Greek physician, who had studied and graduated at Oxford. He subsequently settled in Constantinople, and being convinced of the importance of the discovery, wrote an account of it in 1713 to his English correspondent Dr. Woodward, which in the following year was published in the Philosophical Transactions. In 1715, Dr. Pylarini, the Venetian consul at Smyrna, having also learnt the success of this Turkish practice, published an account of it at Venice. A notice of this work appeared in the Philosophical Transactions for 1716, and these favourable accounts were fully corroborated by the reports of Mr. Kennedy, (an English surgeon, who had travelled in Turkey) in his "Essay on External Remedies," published in London in 1715.

No notice, however, was taken of these important facts by any English physician, and the idea of transplanting or engrafting small-pox (as the process was called) was well-nigh forgotten in London when the celebrated letter of Lady Mary Wortley Montagu appeared, which described the practice in so lively a manner as to attract public attention. (Vol. ii. Letter 31, dated April 1, 1717.) "The small-pox," she writes, "so general and so fatal amongst us, is here entirely harmless by the

invention of *engrafting*, which is the term they give it. There is a set of old women who make it their business to perform the operation. Every year thousands undergo it, and the French ambassador observes pleasantly that they take the small-pox here by way of diversion, as they take the waters in other countries. There is no example of any one that has died in it, and you may believe I am well satisfied of the safety of the experiment, since I intend to try it on my dear little son. I am patriot enough to take pains to bring this careful invention into fashion in England." She kept her word, and to the spirit and enterprise of this lady the introduction of inoculation into this country is altogether due. It was not until her return to London that any attempt was made to profit by a discovery which had been announced for five years; and her own daughter was reserved to be the first example of inoculation in England. This event occurred in April 1721, and as its success was complete, Dr. Keith, who had been witness to the experiment, submitted his child to the same process, and with a like happy result. Several months elapsed, but the medical profession in London still remained sceptical; some, because the practice originated with ignorant old women, and others from inability to understand the rationale of the process.

The next step was to obtain a pardon from King George I. for six condemned criminals, on condition of their submitting, by way of experiment, to inoculation. This was effected through the agency of the Princess of Wales, who was anxious to follow Lady Mary's example, and to secure her own children by the new process. These and some other trials having been deemed satisfactory, the Princesses Amelia and Caroline were inoculated on the 19th April, 1722, the former being then eleven and the latter nine years of age. Both of them passed through the small-pox favourably; but the new practice, begun under such brilliant auspices, received a severe check in the death of three persons, (one of them a child of the Earl of Sunderland,) which happened within a few days afterwards.

Contemporaneous with these experiments in London were those performed at Boston in North America, by Dr. Boylston, on the authority of Timoni and Pylarini. 244 persons were inoculated by him in Boston and its neighbourhood between June, 1721, and January, 1722, of which number six died. The subjects, however, were ill chosen, and the operator betrayed both ignorance and rashness. Dr. Boylston, however, deserves credit for having been the first to remark that the period of incubation is shorter in the inoculated than in the natural small-pox, and that the former may be employed to supersede the latter.

When these occurrences at Boston became known in London, the clamour against inoculation increased. Objections were made to it both in a medical and moral point of view. By Dr. Wagstaffe it was declared to be unsafe, and by the Rev. Mr. Massey impious. Under these discouraging circumstances, it is hardly to be wondered at that the practice of inoculation advanced but slowly. Prejudice and mismanagement combined to throw obstacles in its way. It was calculated that during the first eight years only 897 persons were inoculated throughout the whole of Great Britain, of whom seventeen died.

By slow degrees the medical profession became convinced of the advantages of inoculation, but it was not until the middle of the last century that it was practised in England to any considerable extent. Several circumstances contributed about this period to bring it into repute. In the year 1746 the Small-Pox and Inoculation Hospital of London was founded, for the express purpose of extending to the poor the benefits which had hitherto been almost exclusively confined to the rich. The results of the practice in the hospital were eminently favourable to the cause of inoculation. In 1747, Dr. Mead, then in the zenith of his fame, published his work *De Variolis et Morbillis*, and in a chapter expressly treating of inoculation, adduced many cogent arguments in support of it. In 1754, the Royal College of Physicians of London put forth a strong approbation of inoculation; but the popularity which it ultimately acquired is mainly attributable to the improvements which, in 1763, the Suttons introduced in the mode of conducting the process.

Robert and Daniel Sutton were sons of Mr. Robert Sutton, surgeon, of Debenham, in Suffolk, who had acquired some celebrity as an inoculator. Both followed their father's profession. The former established himself as a professed inoculator at Bury St. Edmunds, and the latter at Ingatestone in Essex. The success which attended Daniel (the cleverest of the family) at Ingatestone was unparalleled, but he fairly earned it by the boldness and dexterity of his management. The peculiarities in his system of inoculation were chiefly the following:—he reduced the preparatory process from a month to a week; he employed very freely, during the whole period, a strong purgative powder, containing calomel and emetic tartar: he inoculated by means of a single puncture; he exposed his patients freely to the coldest air prior to and during the eruption, and prescribed cooling drinks and a spare diet. There was nothing new in the plan. Lady Mary Wortley Montagu had stated that the Turkish children were suffered to play about in the open air during the period of eruption; Sydenham taught the value of the cool regimen; and the purgative powder had been introduced from North America. The merit of the inoculator consisted in the skill with which he selected what was beneficial in the several plans already known.

The system of Daniel Sutton was ably followed up by Baron Dimsdale, who enjoyed a high reputation and extensive practice, and whose admirable treatise on inoculation (The present Method of Inoculating for the Small-Pox, by Thomas Dimsdale, M.D. seventh edition, 1779) contains every thing then known on the subject. Nor was any further improvement attempted. For twenty years the mode of practice recommended in Dimsdale's work was adhered to, and the result was, that in every succeeding year inoculation became both more popular and more successful. The close of the century, however, which saw the rise of inoculation, was destined to witness its fall. In 1798 Dr. Jenner announced the discovery of vaccination, almost immediately after which the ge-

neral practice of inoculation declined, and has never since been revived.

Theory of Inoculation.—The object of inoculation is to secure a mild form of the disease, and this result follows in a very large proportion of cases. No adequate explanation has ever been offered of the singular fact, that mildness of the disease should be occasioned by the germ being received into the system by means of the cutaneous vessels. Something, it has been said, may be attributed to the influence of the preparative process, but this explanation will not go far when we reflect that the same means applied during the incubation of the natural disorder are not productive of the same effects.

The beneficial influence of inoculation is displayed not only in moderating the quantity of eruption, but in determining the whole force of the disease upon the surface. In a very large proportion of inoculated cases, the eruption is of the distinct sort, and moreover widely scattered. An efflorescence (roseola exanthematica) frequently precedes for one or two days the development of the true variolous papulæ. Sometimes a full and confluent crop is produced, but under these circumstances it is very seldom that the mucous membrane of the pharynx and larynx become implicated to any dangerous extent. The cellular membrane, in like manner, is rarely involved in the inflammatory action, so that the disease is then properly characterized as *confluent superficial.* Secondary fever, therefore, is rarely met with in the latter stages of inoculated small-pox; and further, that affection of the fluids which constitutes the leading feature of acute malignancy is almost or altogether unknown as a consequence of inoculation. The result of all this is, that the mortality by inoculated small-pox is very small indeed, and bears no sort of proportion to that of the casual disease. The average number of deaths at the Inoculation Hospital was only three in a thousand. In the wards appropriated to the casual disease the deaths were (and continued to be) three in ten.

Practice of Inoculation.—According to the statement of Lady Mary Wortley Montagu, the old women of Constantinople "opened with a large needle one or more of the veins of the arm or leg, and put into the wound as much matter as would lie on the head of the needle, afterwards binding it up with a hollow bit of shell. This simple mode was first followed in England, but it was afterwards supposed more desirable to have large wounds, which might ensure a more plentiful discharge of matter. For this purpus incisions were made three quarters of an inch in length, and deep enough to penetrate through the skin; and some cotton charged with variolous matter was laid on them for twenty-four hours, and retained there by means of a plaster. (Woodville's History of Inoculation, p. 99.) Another mode of giving the small-pox, said to have been first practised in China, consisted in inserting crusts or cotton charged with variolous matter in the nostrils. These rude practices were very injurious to the cause of inoculation, and they have long since yielded to the simple expedient of making a *single* wound with a lancet armed with fresh variolous matter in any convenient part; and, by a sort of general consent, the arm, at the insertion of the deltoid muscle, has been selected for the purpose.

It is of little moment at what period of the disease the matter for inoculation is taken; but thin, limpid, or *crude* lymph of the fourth and fifth days is generally preferred to the purulent or well concocted matter of the eighth and ninth days. It is of as little importance whether the matter be supplied by a distinct or a confluent, a casual or an inoculated case. The Suttons preferred the crude lymph of a *primary* inoculated vesicle. Common sense would dictate the propriety of rejecting a case of extreme malignancy.

The best age for inoculation is from the third to the sixth month from birth, and again, after the period of dentition is passed. Adult persons in the middle periods of life may be inoculated with perfect safety, due attention being paid to the habit of body. Season has but little influence upon the results of inoculation, but, *cæteris paribus*, the extremes of heat and cold should be avoided. The spring season was generally preferred by the professed inoculators in England. At Constantinople the month of September was the period usually selected.

The circumstance chiefly to be dreaded in inoculated small-pox is an inflammatory state of the blood. Hence it is that the only preparatory measures of any importance are such as have for their object to repress this tendency. A dose of purgative medicine should be given prior to the observation, and two or three more during the period of *incubation.* The purgative should consist of calomel, combined either with antimonial powder, emetic tartar, or powder of jalap. The patient is to be restricted to a spare vegetable diet. He should sleep in a large airy apartment, without a fire, and during the day should be exposed freely to the cold air. The influence of cold in repressing the quantity of eruption was strikingly manifested in the practice of the Suttons, and constituted, in fact, the principal peculiarity of the Suttonian system.

Phenomena of Inoculation.—On the second day after the operation, if the part be viewed with a lens, there appears an orange-coloured stain about the incision, and the surrounding skin seems contracted. On the following day a minute papular elevation of the skin is perceptible, which on the fourth day is transformed into a vesicle with a depressed centre. The patient perceives an itching in the part. On the sixth day, some pain and stiffness are felt in the axilla, proving the absorption of the virus into the general mass of blood. Occasionally on the seventh, but oftener on the eighth day, rigors occur, accompanied sometimes with faintishness, sometimes with pain of the back, headach, or vomiting. The patient complains of a disagreeable taste in the mouth, and the breath is offensive, soon after which the eruption shows itself.

The incision in the arm, when viewed through a glass, now appears surrounded with an infinite number of small confluent papulæ, which daily increase in size. On the tenth day an areola or circle of inflammation forms around the inoculated point, now distended with matter. This areola is irregular in shape, and in its progress becomes

interspersed with numerous minute vesicles. By the fifteenth day the primary pustule has scabbed, and the eruption on the body generally has begun to maturate. By the twenty-first day, in the great majority of cases, the disease is wholly at an end. The number of papulæ dispersed over the body is subject to great variety. In some cases not more than two or three are perceived. It is important to know that an eruption is not indispensable to the success of inoculation. In some cases the full change has been produced upon the frame, and a complete insusceptibility to future attacks given, by means of the single pustule excited artificially upon the arm.

Treatment of inoculated small-pox.—In mild cases nothing is required but one or two doses of simple aperient medicine, such as the infusion of senna, with manna and Epsom salts. In cases of greater severity, we are to proceed in the manner already directed for the natural small-pox.

The objections which have been urged against inoculating for the small-pox, and which have caused the abandonment of the operation, are the following. Although in many instances the subsequent disorder be slight, still it is sometimes severe, and occasionally brings life into hazard. It often proves the exciting cause of other disorders, and more especially calls into activity the scrofulous taint. But more than all, it is urged against small-pox inoculation that it adds to the danger of the public by multiplying the foci of variolous contagion,—that it preserves one life at the risk of many. This objection to inoculation, which has been so strongly insisted on of late years by almost all writers, was long since fully appreciated. Dr. Watkinson, Dr. Schwencke, and others, in the year 1777, attempted to obviate it by showing that the diffusion of variolous contagion takes place only in certain epidemical states of the air; that when such a condition of atmosphere prevails, the disease would propagate itself quite as widely, independent of all cases artificially excited; and when it was not present, inoculation would be perfectly harmless. The argument is ingenious, and certainly calculated to show that this charge against inoculation has been overstated. It might seem easy to determine the point at once by reference to the Bills of Mortality, where a gradual augmentation of deaths, in proportion as the practice of inoculation extended, will at first sight appear. Dr. Adams, however, very justly remarks (Inquiry into the Laws of different Epidemic Diseases, by Joseph Adams, M. D. 1809, p. 144,) that this argument is more plausible than solid; for in the first place, admitting the fact to be as stated, there has been a corresponding increase in other diseases, not communicable by inoculation; and, secondly, the statements may be so put as to show a diminution rather than an increase. Thus, in the thirty years between 1741 and 1770, there died of small-pox, according to the Bills of Mortality, 63,308; whereas in the next thirty years (viz. from 1771 to 1800,) there only died 57,268.

Although, then, it would be difficult to support this objection against inoculation by a reference to statistical tables, it is obvious that it must necessarily contribute to diffuse the contagion, and so far therefore is an evil. Notwithstanding this defect, however, and others already adverted to, inoculation must still be viewed as a most valuable discovery, and a merciful provision of nature against the ravages of a dreadful pestilence.

GEORGE GREGORY.

SOFTENING OF ORGANS.—The term *softening* [*Ramollissement*] is employed to designate a diminution of the natural and healthy consistence of organs. It is only of late years that this change has been investigated and described as a special morbid condition; and whether we consider the frequency of its occurrence, the variety which it presents as to degree and extent, the serious and often fatal effects to which it gives rise, or the wide difference of its nature in the same or in different organs, it constitutes a subject of great interest and importance.

Before proceeding to describe softening of particular organs and tissues, we shall take a summary view of the opinions which are entertained regarding the nature of this lesion. Two opinions prevail regarding the nature of softening of the brain, an organ in which this change of consistence frequently occurs and often proceeds to a great extent. The first of these opinions is, that it is always a consequence of inflammation; the second, that it is a disease *sui generis*, entirely opposite in its nature to inflammation, and, consequently, that it ought to have a distinct place in the nomenclature of diseases. It is surprising that opinions so opposite should have received the exclusive support of pathologists of great merit, and whose extensive opportunities of studying the disease put them in full possession of the means of determining how far one or both of these opinions should be received as the truth.

It may not be altogether out of place to notice here what we conceive to have been the circumstances which led to the adoption of these two opinions on the nature of softening of the brain. M. Rostan, who may be regarded as the first who directed the attention of pathologists to softening of the brain, was one of the physicians of the Salpêtrière of Paris, an hospital destined exclusively for the reception of females, the greater number of whom are very old. These old women, varying from sixty to upwards of eighty years of age, were the patients in whom he observed softening of this organ. In such patients, ossification and other diseased states of the arteries of the brain which give rise to obliteration of these vessels, and consequently to cessation of nutrition in the part to which they are distributed, may be said to be a frequent occurrence. The consequence of this state of the arteries is, as we shall afterwards endeavour to show, softening of the cerebral substance. But M. Rostan having overlooked this pathological state of the arteries, and not observing in the greater number of his patients, either the phenomena which generally accompany acute inflammation of the brain during life, or some of its least equivocal effects, such as various degrees of vascularity, and the presence of pus or coagulable lymph in this organ, after death, was led to believe, and to announce it as his belief in the work which he published on softening of the brain, that the disease in question is not the consequence of inflammation, but, as

we have already said, a disease *sui generis*, resembling *gangrena senilis* more than any other disease with which we are acquainted. (Recherches sur le Ramollissement du Cerveau.) The facts brought forward by Rostan in support of this opinion are far from being conclusive. He maintains rather than proves that the disease is not the consequence of inflammation, and has not attempted to elucidate its nature, with regard to which he seems satisfied by saying that it resembles gangrena senilis, which disease is the result of cessation of nutrition from ossification of the arteries; but what is most remarkable is, that, after having made such a statement, he brings forward no evidence to show that softening of the brain is produced by a similar state of these vessels. Nay, among the great number of cases of softening of the brain, the histories of which are detailed in his work, there is not one in which ossification of the arteries of this organ is mentioned as having been observed at the autopsy. Such being the case, the opinion of M. Rostan on the nature of softening of the brain is at most but a plausible conjecture, in so far as the evidence which he has brought forward in support of it is concerned. But the fact is, these researches were imperfect; for we have had frequent opportunity of examining the state of the arteries of the brain in softening of this organ in the old women of the Salpêtrière, and in the great majority of cases we have found ossification or other morbid states of these vessels. Had this anatomical fact been stated by M. Rostan, and shown to have the same relation to softening of the brain as it has to gangrena senilis, he would have proved that there is at least one form of softening of this organ, the origin of which is independent of inflammation: —that it is the consequence of a cessation of nutrition from an interruption to the arterial circulation, a state of gangrene or local death from this cause.

The chief supporter of the opposite opinion is Lallemand of Montpellier. This able pathologist seems to have studied softening of the brain for the most part in young and middle-aged persons, and in several of his cases it occurred in consequence of external injury. Under these circumstances he had a full display of the inflammatory phenomena which precede softening of this organ. He has traced, if not in all, at least in the greater number of the cases he has related, its inflammatory origin and progress; that is to say, he has shown its connection with vascular injection of various degrees, with the presence of coagulable lymph, or with pus either infiltrated or collected in the form of an abscess. (Recherches Anatomico-Pathologiques sur l'Encéphale et Ses Dépendances. Paris, 1820.) Indeed, the researches of Lallemand on the nature of softening of the brain are so conclusive, that even Rostan himself tacitly admits, in the second edition of his work already referred to, that this lesion may occur under two forms—the inflammatory and the non-inflammatory, or that which he compares to *gangræna senilis*.

[A similar opinion has been strongly expressed of late by Durand-Fardel, (*Traité du Ramollissement du Cerveau*, Paris, 1843.)]

Dr. Abercrombie describes softening of the brain as the consequence of chronic or acute inflammation, but he thinks it may also occur from obliteration of the arteries, as supposed by Rostan. (Pathological Researches on Diseases of the Brain and the Spinal Cord. Edin. 1828.)

Softening of the mucous membrane of the digestive organs, a much more frequent occurrence than softening of the brain, has for a long time engaged the attention of pathologists. But it is more especially softening of the mucous membrane and other tunics of the stomach which has been made the subject of pathological investigation. The great extent to which softening often proceeds in this organ, and its occurrence under conditions of the most opposite kind, as relates to the state of the stomach individually or to that of the economy in general, are circumstances which have given rise to great diversity of opinion regarding the nature or softening of this organ. The following are the chief opinions which have prevailed on this point. 1st. That softening of the stomach is the consequence of irritation or inflammation. 2d. That it is produced by the operation of an acid and corrosive fluid, formed in consequence of irritation of the mucous membrane of the stomach. 3d. That it is a change effected after death by the gastric juice, this fluid having been previously modified by disease of the stomach. 4th. That it is produced after death by the dissolvent property of the gastric juice, this fluid as well as the stomach itself being in the natural state.

Of these opinions, two only appear to us to merit attention, viz. the first, which ascribes softening of the stomach to an inflammatory condition of this organ; and the fourth, which refers this change to the natural dissolvent property of the gastric juice acting on the stomach after death. We have, therefore, the same lesion said to be produced by two agents, and under circumstances of the most opposite nature. In the first case, softening of the stomach is a pathological condition—a disease; in the second, it is not a disease, it is merely a *post-mortem* lesion. But although occurring after death, softening of the stomach from the chemical action of the gastric juice requires to be particularly noticed in the present article, because of its having been described by many eminent pathologists as a diseased state. We shall, therefore, endeavour to demonstrate in another part of this article the separate existence of these two forms of softening of the stomach, and more particularly the characters by means of which the one may be distinguished from the other.

The forms of softening which we have noticed are confined to particular organs or tissues. But there are other forms of this lesion of a much more general character, and which are also very different in their nature from the former. In the first of these forms the softening occurs in almost all the textures of the body at the same time, although it may be so slight in some as hardly to be observable; whilst in others, even the hardest, it may be greatly marked. It is never observed unless in individuals in whom nutrition in general is strongly modified. The modification of nutriment which precedes the softening process is, however, very different in kind in different in-

dividuals—a difference which obviously exercises a great influence in determining the seat and severity of the disease. Thus, in children born in a state of debility and emaciation, and in those who have been long deprived of the wholesome necessaries of life, we find all the tissues and organs of the body more or less soft, and easily injured by external causes. This general diminution of cohesion is always accompanied by universal pallor, a watery, scanty, and aplastic state of the blood. Such, also, is the case in advanced stages of scrofula and scorbutus; the bones as well as the other textures being found in those who die of these diseases, soft, spongy, and infiltrated with a sero-albuminous or sero-sanguinolent fluid. In another class of patients, the softening, while it pervades to a certain extent all the tissues of the body, exists in a much greater degree in the bones, and from the superincumbent weight which they have to support, or the impulse which they receive from the action of neighbouring muscles, they lose their natural forms, and become bent or flattened to an extraordinary degree. It is this form of softening which has been termed *rachitis*, *mollities ossium*, or *osteo-malacia*. Great softening and pliancy of the bones constitute what is most frequently termed mollities ossium, whereas a degree of fragility, a want of cohesion, accompanied with softness, are more generally regarded as constituting rachitis. (See Rickets.)

There is another form of softening, or rather flaccidity, which only requires to be noticed. It is best seen in the skin and cellular tissue when these textures, after having been greatly distended by an accumulation of fluid in the abdomen, are left unsupported by the removal of the distending cause. The looseness and flaccidity of these tissues is also very conspicuous in old people: in persons who, from a state of obesity, become lean, and in persons in general who become rapidly emaciated, particularly from disease.

Lastly, softening of organs and tissues may take place from maceration and putrefaction after death. With regard to softening produced by these causes, we shall only observe that it should be kept in mind by the physician in his *post-mortem* researches, lest it should be confounded with the pathological forms of this lesion.

From these general considerations, it would appear that the several forms of softening to which the different tissues and organs of the body are subject, may be ranged under two groups, the first comprehending those forms which occur during life; the second, those which are effected after death.

I.—*Occurring during life.*

1. Softening from inflammation.
2. Softening from obliteration of arteries.
3. Softening from a modification of nutrition.

II.—*Occurring after death.*

1. Softening from the chemical action of the gastric juice.
2. Softening from maceration and putrefaction.

We shall treat of three only of these forms of softening,—viz. the first and second of the first group, and the first of the second group,—because of the two former being special pathological states, and because of the latter occurring under circumstances which have often deceived the practical pathologist, and led him to describe it as a morbid alteration of the gravest character.

I. **Softening from Inflammation.**—Before proceeding to describe inflammatory softening, it may be well to make a few remarks as to the manner in which the consistence of a tissue becomes diminished or entirely destroyed by inflammation. Two causes appear to co-operate in producing this change. The first is of a mechanical, the second of a physiological nature. Serosity or pus, when in considerable quantity, appear to effect, mechanically, a diminution of the cohesion of the tissue in which they are contained. The pressure which they exercise arrests the circulation, and it would appear, absorption also; for if this function were performed, we should have an excavation or ulcer formed instead of a mass of soft pulpy tissue. The circulation being thus arrested, nutrition ceases to be accomplished, and the molecules of the tissue are disunited and detached. If, while these changes are going on, or at some subsequent period, the function of absorption be resumed, the softened tissue is partially or wholly absorbed, and solutions of continuity of various extent are formed. The physiological cause of softening is referable to a change in the vital properties of the affected tissue. We are unable to say in what this change consists, but its effects on circulation and nutrition are sufficiently obvious, both these functions ceasing to be performed at an early period of the inflammatory process. Softening or dissolution of the affected tissue then takes place in the same manner as when produced mechanically. It is necessary to observe that the presence of serosity in a tissue from a mechanical obstacle to the return of the venous blood, as œdema of the inferior extremities from disease of the heart, does not give rise to softening; and for this reason, that it does not arrest, but only impedes the capillary circulation.

Locality of inflammatory softening.—There is no tissue in which softening may not occur as the mediate or immediate consequence of inflammation. It occurs in tissues which are never the seat of inflammation, as cartilage, tendon, fibrous tissues, &c. Thus, when inflammation exists in the immediate vicinity of these tissues, they are soon deprived of the materials of their nutrition, and, consequently, lose their natural consistence, become soft and pulpy, and even slough. The cellular tissue is by far the most frequent seat of inflammatory softening. The diminution of cohesion which follows inflammation of parenchymatous organs, is owing to softening of the interstitial cellular tissue. Slight pressure with the point of the finger lacerates or breaks down a portion of hepatized lung. Muscular tissue is also easily torn or separated into shreds in consequence of softening of the interstitial cellular texture by which its fibres are united, examples of which are sometimes met with in the heart, but more frequently in the muscles of voluntary motion.

Softening of the subcutaneous, submucous, and subserous cellular tissues, is often great in degree and extent in erysipelas phlegmonodes, enteritis, and peritonitis. The easy separation of these

coverings, particularly the serous and mucous, from the subjacent tissues after death, is always the consequence of inflammatory softening of their cellular tissue, and the degree of facility with which their separation is effected affords a ready means of determining the degree and extent of the inflammation to which this tissue had been subjected. Cases of peritonitis and meningitis occur which would escape the *post-mortem* researches of the pathologist but for this state of softening of the cellular tissue. In such cases there may be little increase of vascularity, and perhaps only a slight serous effusion, both of which may be overlooked, or, if observed, can afford no idea of the degree or extent of this morbid condition of the cellular tissue.

Softening of mucous membranes from inflammation is a frequent occurrence, and is often great in degree and extent. Softening of this tissue is more frequently met with in the digestive organs than in the respiratory, urinary, or generative organs. It is not, however, either so frequent or extensive in the mucous membrane of the digestive organs as has been supposed, for the reasons to which we have already alluded, and which we shall afterwards explain. Softening of the osseous tissue is seldom observed as a consequence of inflammation, unless in surgical diseases. It is, however, a change which always follows inflammation of this tissue, and is frequently so considerable that the hardest bones become as soft as cartilage or muscle.

Softening of the blood-vessels as a consequence of inflammation does not take place till after the destruction of their cellular sheath from the same cause. Softening of this sheath is a serious accident in surgical diseases of the arteries requiring the application of the ligature.

It has often been said that softening of the spleen, which is sometimes so great that this organ is transformed into a uniform pulpy mass, is the consequence of inflammation. We are, however, of the opinion of those who ascribe this state of softness of the spleen to a morbid condition of the blood with which it is filled, this fluid being in a state of extreme fluidity.

Inflammatory softening is no where so conspicuous, either as regards its physical characters, or the functional derangement to which it gives rise, as in the brain and spinal cord. Obvious functional derangement, as the direct consequence of inflammatory softening, is indeed not observed, unless when the brain or spinal cord is the seat of this lesion. We shall therefore commence with the medical pathology of inflammatory softening as it occurs in these organs.

Physical characters of inflammatory softening of the brain and spinal chord.—The *degree* of softening of the cerebral substance may vary from a slight diminution of the natural consistence of the part affected to that of cream or even of thin milk. The first stage of softening of this substance is often so slight, that it is hardly perceptible to the touch, and may, even when considerable, if not accompanied by some peculiarity of colour, be altogether overlooked. In the first case a gentle stream of water allowed to fall upon the cerebral substance, is the best means of determining whether a portion of it has lost its natural consistence; and in the second case, the only way of detecting the presence of softening unaccompanied by any obvious change of form or colour of the affected part, is to submit the whole of the cerebral substance to a careful inspection, by removing it piecemeal in the form of thin slices.

In the first stage the cerebral substance is not yet broken down; it has only lost a certain degree of its cohesion, for it is still continuous with that by which it is surrounded. In the second stage the diminution of consistence is so great that it may be recognised at first sight, owing to the change of form by which it is accompanied. The cerebral substance is so soft that it sinks by its own weight beneath the level of the cut surface; and prominent parts, such as the thalami, corpora striata, and convolutions, become more or less flattened. In the third stage, a solution of continuity has been effected by the separation of the softened cerebral substance. It is now of the consistence of cream or milk, contained in an excavation of variable extent, situated in the substance of the brain, or confined between the membranes and convolutions of this organ.

The *colour* of inflammatory softening of the cerebral substance presents considerable variety. The principal varieties of colour depend on the quantity of blood contained in the affected part, on changes which this fluid undergoes some time after its accumulation or effusion, and on the presence of serosity and pus. Redness and vascularity are, in general, greater in the first than in the second stage, but the degree and extent of either greatly depend on the quantity of blood in the cerebral vascular system. In some cases a gradual increase of redness and vascularity can be traced to a considerable extent beyond the softened part; in others, these changes are limited to the immediate vicinity of the latter. The vascularity of the softened cerebral substance has frequently a hemorrhagic character. When this substance is divided, it presents a number of red points, streaks, or patches, produced by the blood accumulated in the veins, or effusion of this fluid. In some cases the effused blood is small in quantity compared with the extent of the softening; in others it pervades the whole of the softened substance, and presents the same appearance as hemorrhagic apoplexy. The redness, vascularity, and hemorrhagic character of inflammatory softening, are never so conspicuous as when this lesion occupies the brown substance, as that of the corpora striata, thalami, and convolutions. Inflammatory softening of the cerebral substance is not always accompanied by those changes of colour which we have just described. The affected part may have preserved its natural colour, or it may be much paler than natural. Thus the septum lucidum may be converted into a mere pulp, without its colour being perceptibly altered; and the same degree of softening may take place in the brown or cortical substance, which has become so pale as hardly to be distinguished from the medullary substance in its vicinity. Pale softening in either of these situations, viz. in the medullary or cortical substance of the brain, is a frequent occurrence in hydrocephalus, and it is also this variety of softening which is sometimes met with in those fevers in which the brain is primarily or secondarily affected. Mons. Recamier described this pale softening of the brain in his

clinical lectures at the Hotel Dieu of Paris, long before Rostan, Lallemand, or Abercrombie published on softening of this organ. This author regarded the pale softening as a primary condition of nervous or malignant fevers, and therefore he called it *ramollissement ou dégénérescence ataxique; foyer ataxique*. In such cases of softening of the medullary or cortical substance, we always find the brain in general pale, its vascular system containing but a small quantity of blood, and its membranes infiltrated with serosity. It is, in fact, owing to the pressure which the effused serosity exercises on the blood-vessels, that the anæmic condition of the brain in general, and of the softened portion of it in particular, is to be attributed.

When the redness which accompanies softening arises from the presence of effused blood, it may always be regarded as evidence that the softening is of recent occurrence. But there are other modifications of colour which accompany softening of the cerebral substance, and which for various reasons require particular notice. They indicate that the disease has existed for a considerable time — several weeks, or two or three months. The principal modifications of colour consist of brown, yellow, and orange colours, either separately or combined, and occupy either the softened substance, the part of the brain contiguous to it, or both at the same time. They are not observed unless the softening has been accompanied by effusion, and originate in changes taking place in the effused blood. Such are the modifications of colour to which we allude, so frequently observed to take place in the blood effused in the subcutaneous cellular tissue in consequence of external violence. The brown colour appears first, and is very limited in extent when compared with the orange and yellow, by which it is succeeded,— circumstances which enable us to form a tolerably accurate opinion regarding the extent of the sanguineous effusion by which the softening had been accompanied. Knowing that these colours accompany cerebral softening, the pathologist will be put on his guard, and not confound this disease with hemorrhagic apoplexy, in which the same colours are present.

A pale yellow straw-coloured tinge of the softened cerebral substance arises also from the presence of pus. But this is rarely observed unless the softened substance be in contact with the membranes of the brain. The presence of serosity in the softened cerebral substance produces, as we have already observed, a diminution of the red colour alluded to; but it likewise communicates a glossy albuminous aspect to softening, which it does not present in any other circumstances.

When softening of the brain is accompanied by an increase of bulk, it is generally owing to the softened part being infiltrated with serosity.

The *situation* of softening, or those portions of the brain in which this change of consistence occurs, requires to be pointed out. Thus, it has been found in the central portions of the medullary substance and in the convolutions of the anterior, posterior, and middle lobes of the brain; in the corpora striata and thalami; in the corpus callosum, septum lucidum, and fornix; in the pons Varolii, crura cerebri and cerebelli; in the cerebellum and the surface of the lateral, third and fourth ventricles. It is much more frequent in the brown than in the medullary substance, and more so in the brown substance of the convolutions than in that of the thalami or corpora striata. Softening may occur in both substances at the same time, which is generally the case when it occupies the two latter situations. It may also occupy several portions of the brain at the same time, as the septum lucidum, fornix, and walls of the lateral ventricles; the corpora striata and thalami; one or more lobes; a portion of one or both hemispheres; the brain and cerebellum; and is rarely met with in the latter organ without its being present in the former, — circumstances which give great variety and complexity to the functional derangement by which it is accompanied.

In all the portions of the brain which we have named, the softening may be confined to a very limited spot, or pervade the greater part of their entire substance. There are examples of nearly the whole of one of the hemispheres of the brain having undergone this change of consistence; and in children, probably on account of the natural softness of this organ in them, both hemispheres have been found reduced almost to a pulpy or fluid consistence.

[Softening of the brain occurs with nearly the same frequency in both hemispheres. In 169 cases, the right hemisphere was concerned 73 times; the left, 63 times; and both hemispheres, 33 times. (Andral, *Clinique Médicale*, v. 545.) In 150 brains, the softening of the whole of the hemispheres was observed 4 times; of almost the whole of one hemisphere, 13 times; of the convolutions, 14 times; of the convolutions and other parts, 9 times; of the anterior lobes, 27 times; of the middle lobes, 37 times; of the posterior, 16 times; of the corpora striata, 28 times; of the thalami optici, 15 times; of the parietes of the ventricles, 2 times; of the peduncles, once; and in disseminated points, 5 times.

M. Durand-Fardel (*Op. cit.*) found acute softening by far most frequently in the convolutions. Of 33 cases, 31 were examples of this seat of the disease; and in 9 the convolutions were alone affected. Fifty-three cases, collected from various sources, gave the following results as regards the seat of the lesion:—

Convolutions and medullary substance,	22
Convolutions alone,	6
Medullary substance alone,	5
Corpus striatum and thalamus opticus,	6
Corpus striatum alone,	11
Thalamus opticus alone,	4
Pons varolii,	3
Crus cerebri,	1
Corpus callosum,	1
Walls of the ventricles, septum,	1
Fornix,	1
Cerebellum,	1]

Such is a general description of the physical characters of inflammatory softening of the brain. Whatever may have given rise to the inflammation of the cerebral substance or its membranes, which terminates in softening, the physical characters of this lesion are always such as we have described them. It is, however, of great practical importance to make a distinction between softening from idiopathic inflammation, and that which follows the presence of foreign bodies, such as

bony and fibrous tumours, tubercles, carcinoma, melanoma, hydatids, &c., formed in the brain or its membranes, and foreign bodies forced into it from without, which, at some period of their development, or after their introduction, excite inflammation and softening.

The description which we have just given of inflammatory softening of the brain, applies generally to the same lesion of the spinal cord. In this organ the softening may be confined to the medullary or cortical substance, or may occupy both at the same time. The whole of the cord may be softened, or only particular portions of it, as the cervical, dorsal, and lumbar,—differences of situation which are accompanied by corresponding differences in the seat of the functional derangement to which this lesion gives rise. The nature of the functional derangement, especially of sensation and motion, it is now well known depends on the situation of the softening, the former being deranged when the softening occupies the posterior surface, and the latter being affected when it occupies the anterior surface of the cord. Softening of the cord may, like softening of the brain, be the consequence of idiopathic inflammation, or of this pathological state succeeding to the presence of foreign substances, or arising from external injury.

The simultaneous occurrence of inflammatory softening in the brain,—cerebrum, cerebellum, and spinal cord, is rarely observed, unless in infants. Of thirty cases of softening of the cerebral substance observed by M. Billard in infants, in ten these three divisions of the nervous system were simultaneously affected. In these children, softening of the cord was rarely observed to occur without softening of the brain; and on the contrary, softening of the brain was frequently considerable without any similar change being present in the cord. (C. Billard, Traité des Maladies des Enfans, &c. Paris, 1828.)

Before proceeding farther in the description of inflammatory softening of the brain, we shall point out the physical characters of this lesion when produced by obliteration of the arteries, as it will be more advantageous to treat of the causes, symptomatology, diagnosis, prognosis, and treatment of both forms of the disease at the same time.

Softening of the brain from obliteration of the arteries of this organ.—This form of softening depends on the presence of osseous, cartilaginous, and fibrous substances formed in the interior of the arteries or between their coats. These accidental products may exist in the form of cylinders occupying the entire calibre of arteries of considerable size, and also the smaller branches; or they may form patches or small masses projecting internally, which obstruct the circulation of the blood. The obliterated arteries may occupy the softened cerebral substance, and can be seen ramifying through it; and when this substance is removed by pouring water upon it, the solidified vessels retain their situation, and feel sometimes as hard as fine wires. If the obliteration be confined to a limited portion of an artery whose branches terminate in the softened part of the brain, the cause of the softening may be overlooked. In the case of obliteration of minute arteries, or of a single small arterial trunk, the softening is generally limited to a space not exceeding an inch or two inches in breadth; but if several large contiguous branches be obliterated at the same time, the extent of the softening is considerably increased; and if the obliteration takes place in the carotid or one of its principal divisions within the brain, the greater part or the whole of a hemisphere may be completely softened. This form of softening is, like the inflammatory, not confined to any particular portion of the brain. Like it also, it occurs far more frequently in the brown than in the medullary substance, or in those parts most abundantly supplied with blood-vessels, as in the optic thalami, corpora striata, and cortical substance of the convolutions. If the obliteration has taken place in the minute arteries or small branches, the softening is generally confined to the brown substance; and when a large trunk or several small trunks are obliterated, both the brown and medullary substances are softened.

Softening, from obliteration, of the corpus callosum, septum lucidum, and fornix, is extremely rare, and we have only met with one example of it in the pons Varolii. We have not observed it in the spinal cord.

The degree of softening from obliteration, as well as the various colours which this change presents, are very similar to those observed in inflammatory softening. It is necessary, however, to observe that redness is seldom considerable, and vascularity and effusion of blood are generally wanting on account of the impervious state of the arteries. When it does happen that blood is effused, it is probably the consequence of rupture of the obliterated vessels, or some of the small arteries in the softened part having remained pervious, and yielding to the increased momentum of the blood.

Before concluding this part of our subject, it may be well to observe that the sanguineous effusion which succeeds to softening of the brain is sometimes so extensive that it is extremely difficult to distinguish such cases from sanguineous apoplexy. Nor should it be overlooked that softening of the brain is occasionally the cause of apoplexy, as apoplexy may be the cause of softening, although some authors have maintained that apoplexy is always preceded by softening. It is only when the softening extends considerably beyond the effused blood, or when this fluid has been thrown out in several points of the softened cerebral substance, that we can feel authorized to say that apoplexy has occurred subsequently to the softening. That apoplexy may occur without previous softening is as true as the occurrence of hemorrhage in other tissues, such as the cutaneous, mucous, and cellular, where it is not preceded by any such alteration. That hemorrhage may take place under similar circumstances in the brain is obvious from what is observed in many cases of apoplexy, in which the only change consists in the presence of effused blood. Nor are the portions of brain which have been broken down and mixed up with this fluid always softened. In those cases where death has taken place suddenly, such portions of brain are found to have lost very little of their natural consistence.

[It appears to the writer, however, to be taking too restricted a view of softening, when we refer

it either to an inflammatory process or to obliteration of arteries. It certainly remains to be proved, as M. Calmeil has remarked, (Art. *Ramollissement Cérébral*, in *Dict. de Méd.* xxvii. 220, Paris, 1843,) that white softening, with anæmia, and without purulent infiltration, has been really preceded by active hyperæmia of the softened tissue. It is clearly an altered state of nutrition of the organ, occurring under the influence of morbid causes of very different character. "To endeavour," says M. Andral, "to discover these various conditions is the great but difficult object,—an object of far more importance than that on which observers have exhausted themselves in recent times, when they have been desirous of referring every cerebral softening to some form or degree of inflammation of the nervous centres," (*Clinique Médicale*, iv. 527).

In the obscurity of the subject M. Calmeil (*op. cit.*) suggests, that the softening may be owing to the action of some kind of menstruum, which, he supposes, may be formed by the reaction of the chemical elements upon each other,—"a menstruum, which hereafter perhaps the chemists may be able to demonstrate to the pathologist!"]

To distinguish softening from obliteration from softening produced by inflammation, it is only necessary to ascertain the presence of the morbid state of the arteries which we have described.

We shall conclude the pathological anatomy of softening of the brain with a short description of the changes which occur in those cases in which this lesion does not prove fatal. It is now well known that blood effused into the substance of the brain may be absorbed, and the solution of continuity which it had occasioned become cicatrized. The softened cerebral substance may also be removed by absorption; but we have never seen a case in which its removal was followed by cicatrization.

The first change which indicates the removal of the softened cerebral substance is the formation of an excavation containing a milky, greyish, reddish, or yellowish fluid matter, with sometimes a small quantity of loose cellular tissue. By-and-bye this matter becomes fluid and limpid, and the cellular tissue is found transformed into a serous membrane which lines the surface of the excavation. This cystiform membrane is very delicate, and when the excavation which it lines is situated near the surface of the brain, it may acquire a large size. We have met with a cyst of this kind which would have contained an orange. It occupied one of the thalami and a portion of the corpus striatum on the same side, and extended to the surface of the brain, where it was covered only by the pia mater and arachnoid. It is only in the inflammatory form of softening that we have met with examples of this mode of cure. In three cases in which we have seen it, the patients, from thirty to forty years of age, could not afford us any particulars of their respective cases, but they had been paralytic of both extremities of one side from an early period of life.

Causes of softening of the cerebral substance.—The exciting causes of the two forms of softening which we have described are, as we have seen, inflammation and obliteration of the arteries of the brain. The predisposing causes of the first form of this lesion will be found enumerated under the article Brain. Those of the second form have as yet received no elucidation, further than that the ossification which gives rise to the obliteration of the arteries and softening, consists in a modification of nutrition peculiar to an advanced period of life. It is, therefore, between seventy and eighty years of age that softening from ossification and obliteration of the arteries of the brain is most frequent. The inflammatory softening occurs at every age. It has been met with in infants a few days after birth, in children, adults, and old persons.

Symptoms and progress of softening of the brain and spinal cord.—In both forms of softening of the brain it is necessary to distinguish *two periods;* the first period comprehending the symptoms which accompany or follow the existence of this lesion.

1. *Symptoms of inflammatory softening of the brain and spinal cord.*—As the symptoms of the *first period* of inflammatory softening of the *brain* must necessarily be those of inflammation of this organ, its membranes, or both, it would be superfluous to describe them here. (See Brain, Inflammation of.) It may, however, be observed that the severity of these symptoms does not always indicate a corresponding condition as to the degree and extent of the softening which they precede; nor do they present any one character which can be regarded as a sign that the inflammation on which they depend will terminate in softening. When, however, they are taken in conjunction with those of the second period, they are frequently of great value, as they afford us the means of establishing our diagnosis in cases where it would otherwise be impossible. We shall, therefore, as we proceed, allude to the more important of these the precursory symptoms of softening of the brain.

The symptoms of the *second period* of inflammatory softening of the brain are, generally speaking, of an entirely opposite character to those of the first period. Those of the first depending on the presence of irritation or a morbid stimulus, are characterized by a state of excitement; whereas those of the second being the consequence of the softening or disorganization of the cerebral substance, are necessarily marked by a state of prostration, collapsus, or paralysis. They are announced by the gradual or sudden diminution of the intellectual powers; by the occurrence of stupor or coma; by paralysis, difficulty or loss of speech, and diminution of the sensibility of the skin, eye, and ear. The relative frequency, degree, and extent of these symptoms, as well as the order of their occurrence, present considerable variety. Thus, the derangement of the *intellectual faculties*, such as their diminution, suspension, or abolition, is always present at the commencement of the second period, that is, so soon as the softening of the cerebral substance has taken place. In some cases the derangement which they manifest is at first slight, increases gradually or rapidly, and terminates in their entire abolition. In others, these faculties are, from the commencement, gravely compromised and give no signs whatever of their existence. It is not rare to meet with cases in which their derangement is marked by

remissions and exacerbations, or the occurrence of lucid intervals succeeded by profound stupor. The delirium which accompanies the first period of inflammatory softening either disappears or diminishes greatly in intensity when the second period is announced by the derangement of the intellectual faculties to which we have alluded. It diminishes with the diminution of these faculties, and ceases when their suspension or abolition is indicated by the presence of coma and complete paralysis.

An imperfect state or the entire loss of memory and speech are necessary consequences of these latter conditions of the intellectual faculties. But the absence of any derangement of these faculties is not necessarily unaccompanied by derangement of memory and speech, particularly the latter, for a patient may recover the consciousness of his existence, perceive and comprehend what is passing around him, and yet be incapable of expressing himself in words, on account of paralysis of the muscles by means of which the act of speech is accomplished. The diminution, suspension, or abolition of the intellectual functions, are always accompanied with *paralysis* of the muscles of voluntary motion, and the degree of the paralysis is, generally, in the direct ratio of the extent of the derangement manifested by these functions.

The paralysis is rarely complete at the commencement. It is generally progressive, with occasional alternations of increase and decrease, before it becomes ultimately complete. The situation and extent of the paralysis present considerable variety, and in many cases seem to correspond with the situation and extent of the softening, in the same manner as in apoplexy. The paralysis occupies one or both extremities of the same side, when the softening is limited to one of the hemispheres of the brain, and paraplegia or universal paralysis is produced when both hemispheres, the pons Varolii, &c., are the seat of this lesion. It has been said that paralysis occurs more frequently in the superior than in the inferior extremities; that the seat of the lesion in paralysis of the former is the corpus striatum, and of the latter, the optic thalamus of the opposite side of the brain.

Softening of certain parts of the brain may, however, exist without occasioning paralysis. Such cases are observed in softening of the septum lucidum, fornix, and corpus callosum.

[Still, according to M. Calmeil, (*Op. cit.*) the most precious symptom in the diagnosis of local softening of the brain is local paralysis seated in the side of the body opposite to the softened hemisphere. "Without being invariably present, the abolition or quasi-abolition of motion is so rarely absent, that, whenever the premonitory symptoms of softening are noticed, we should hasten to explore the movements of the limbs."

In 32 cases of acute softening, recorded by M. Durand-Fardel, (*Op. cit.*) paralysis was present in 23 cases. In two, it was general; in one there was simply weakened powers of motion; in 6 the paralysis was limited to the arm, and in 14 it affected one entire side.]

Paralysis of the muscles of the face, of the eye, of the tongue, and of deglutition, depends likewise on the situation of the softening. Paralysis of the bladder and rectum is a frequent consequence of softening of the brain, and gives rise, in the first place, to an accumulation of the contents of these organs, and afterwards to their involuntary escape, more particularly of the urine, from the distension of the bladder and the subsequent dilatation of its sphincter. The difficulty with which vomiting is sometimes effected in this affection of the brain is also, no doubt, owing to a similar state of the muscles which participate in the accomplishment of this act. The state of stupor of the intellectual faculties will, however, explain, in great part, why the urine and fæces are retained, and why emetics as well as purgatives frequently fail to produce their usual effects. For in this state of the brain the impressions of external objects are feebly or not at all perceived. It is under similar circumstances of the brain that the organs of hearing and of sight, which in the first or inflammatory period of softening are highly susceptible, are rendered obtuse to a degree that a strong light or loud sounds impressed on the eye and ear pass unperceived.

One of the most constant symptoms of inflammatory softening of the brain is a state of permanent *contraction* of the flexor muscles of the extremities. This state is well described by Lallemand. (Loc. cit. p. 252.) In some cases the contraction of these muscles amounts only to a slight degree of stiffness; in others it is carried to such an extent that the hand is clenched and remains pressed against the shoulder, and the heel against the hip. The spasmodic contraction of the muscles is sometimes so great that it is not possible to extend the affected limb. The muscles themselves are prominent, feel hard, and the projecting tendons resemble cords stretched beneath the skin. Acute pain is frequently the imdiate consequence of an attempt to overcome the contraction of the muscles. A prickling sensation or even lancinating pains, more marked in the superior than in the inferior extremities, sometimes precede the contraction of the muscles, which, according to Lallemand, always commences in one of the superior extremities, in which, unless it be already carried to the utmost extent, it is always greater than in the inferior extremities. It is sometimes limited to the former, or does not extend to the latter until a considerable time after.

It is of importance to note the presence of this state of the muscles of the face and eyes, as it produces changes peculiarly characteristic of paralysis from softening. We have seen that a paralysed extremity may be contracted and held in a state of permanent flexion. The same thing happens in the paralysed side of the face. The muscles of this side, spasmodically contracted, are drawn upwards and backwards, and produce that deviation in the form and situation of the mouth observed in this disease as well as in apoplexy. But the fact to be noticed in the present case is the deviation of the mouth to the paralytic side, the opposite of what is observed in apoplexy, in which disease it is drawn towards the healthy side. When, however, the spasmodic state of the muscle has ceased, the mouth immediately assumes the position which it occupies in the latter disease. As the spasmodic contraction of the muscles depends on the presence or irritation

around the softened cerebral substance, the former coincides, diminishes, increases, or disappears with the latter. Hence it is that these contractions have an intermittent character, precede the paralysis, and seldom accompany it till the fatal termination of the disease. The paralysis is not otherwise recognised during the spasmodic contraction than by the immobility of the paralysed limb, which is not under the command of the will. When the contraction ceases, the limb becomes flaccid, and remains in a state of immovable extension. If the spasmodic state of the muscles returns, the limb is again contracted, and thus the stiffness and flaccidity, the flexion and extension of the muscles, occur at irregular intervals of time. Slight convulsive motions, referable to the same cause as the contractions, viz. the presence of irritation of the brain, the degree of which is suddenly increased and diminished, accompany sometimes the contraction of the muscles, or agitate the paralysed limb.

The spasmodic contraction of the orbicular muscle of the eye is also not unfrequently very marked. When the eyelids are raised by the finger, they immediately return to their former position, and cover the entire surface of the eyeball; and when the motor muscles of this organ are affected, there is strabismus. The pupil, too, undergoes marked changes of contraction and dilatation. It is contracted only during the first period of the softening, or when this change is accompanied by irritation of the brain; and during the second period, or when there is softening without subsequent irritation, it is dilated. This state of the pupil is also intermittent, and its permanent dilatation does not occur until the paralysis is complete. It is observed by Lallemand that the pupil is contracted only in those patients in whom the muscles are spasmodically contracted; that when the disease exists only on one side of the body, it is the eye of the same side that is affected; that when the spasmodic convulsions make their appearance by successive attacks, it is during these attacks that the pupil is contracted; and lastly, that in proportion as the paralysis increases, the pupil becomes more and more dilated; and, as we have seen, that as patients are unable to use their limbs although the action of the muscles is increased, so are they incapable of perceiving external objects, although the contraction of the pupil announces an augmentation of the sensibility of the retina.

In some cases the spasmodic contractions are confined to the paralysed extremity, a circumstance which depends on the irritation being limited to the same portion or side of the brain in which the softening exists. In other cases, the paralysed and healthy extremities are both spasmodically contracted from the irritation occupying both hemispheres of the brain. Such is frequently the case when the softening occupies the convolutions of the brain, or when it is preceded by meningitis of both hemispheres. In this latter instance too, the rigidity, contraction, and convulsive movements of the muscles, precede the paralysis. Lastly, one side of the body may be in a state of complete paralysis, and the other the seat of spasm or convulsive contraction, when one hemisphere of the brain is affected with softening, and the other or its membranes in a state of inflammatory excitement.

The precedence of spasmodic contractions to paralysis is not a constant character in inflammatory softening. We have seen two marked cases of paralysis from inflammatory softening which, so far as information could be obtained from the relatives of the patients regarding the previous history of both, appeared to have taken place suddenly without any precursory symptoms, such at least as were calculated to prevent the patients from carrying on their daily occupations.

The last symptom of inflammatory softening of importance to be noticed, is pain. It is obvious that this symptom cannot depend on the state of softening of the cerebral substance. It is the consequence of irritation or morbid excitement of the brain, the disorganization of which has not yet taken place. It is therefore generally most severe when it occurs as a precursory symptom; but it frequently accompanies the first period of the disease, and presents remissions and exacerbations, variable in duration and degree. It is seldom that it exists to the same extent in the second period as in the first; on the contrary, it generally diminishes or disappears as the paralysis and the derangement of the intellectual faculties increase. The depressed state of these faculties not unfrequently prevents the patient from manifesting the existence of pain; and it is not until he is roused from the state of stupor in which he is plunged, that he gives signs of suffering by carrying the hand to that part of the head which is the seat of pain. We have already alluded to the pain which accompanies the spasmodic contraction of the muscles. It is hardly necessary to remark that pain can be present in those cases only in which the sensibility of the paralysed part remains unaffected.

Such are the modifications of function which are generally observed to accompany inflammatory softening of the brain, and which appear to be the immediate consequences of this lesion. We shall now notice briefly those which are observed in the functions of respiration, circulation, and digestion. Respiration is seldom much affected till near the termination of the disease, when it becomes embarrassed, afterwards hurried or irregular, and lastly stertorous. The pulse is sometimes frequent, full, and strong; sometimes quick, or feeble and intermittent, but more frequently it does not present any very remarkable alteration. There is in general little or no appetite; sometimes nausea or even vomiting; thirst, and, as we have already noticed, difficulty or even impossibility of swallowing. The temperature of the skin is sometimes not much increased; at other times it is considerably so; the tongue and lips become dry, fissured, and covered with a brown or black sordes. It is at this period that the respiration becomes stertorous, the pulse sinks and intermits, and announces the approaching death of the patient, which takes place in the midst of the most profound stupor, and in a state of universal paralysis and prostration.

The *progress* of inflammatory softening of the brain is generally rapid. It is seldom stationary except during the first period. The second period is marked by a progressive increase of the principal

symptoms, which, although sometimes observed for a short interval, re-appear under a worse form, and hasten towards a fatal termination. The average *duration* of the disease, or of the second period, is from five to seven days; death may supervene on the second or third day, or not until the third or fourth week, or even at a later period; but cases of the latter kind are extremely rare.

The symptoms of inflammatory softening of the *spinal cord* consist in modifications of sensation and motion, as the increase, diminution, or abolition of the former, the diminution or cessation of the latter. If the posterior portion of the cord be softened, sensation only is modified; if the anterior, motion only is modified; and when both portions are the seat of this alteration, both sensation and motion are modified. The lesion of sensation and motion, separately, does not so frequently happen as that of both; and when it does occur is seldom of long continuance, both soon becoming affected. The situation, degree, and extent of the functional derangement are determined chiefly by the seat of the softening. If the softening has taken place in the cervical region, the functions of all the organs situated inferiorly, in so far as their accomplishment depends on the integrity of the cord, are altered. Paralysis of the superior and inferior extremities of one or both sides; diminution or increase of the sensibility in the same parts; difficulty of respiration; retention or involuntary discharge of the fæces and urine, are produced, according as the softening occupies the anterior or posterior portions of the cord or both. The latter symptoms only are present when the dorsal or lumbar region of the cord is affected. Pain may or may not be present in the affected portion of the cord. It may exist as a consequence of the disease, or may not be perceived until it is developed by pressure or the direct application of heat or cold.

We formerly alluded to the simultaneous occurrence of softening of the brain and spinal cord. This complication rarely happens, however, in adults; and in the cases which we have seen, the softening of the cord being confined to the lumbar region, the general symptoms did not present any peculiarity worthy of notice. The same may be said of softening of the cerebellum, which we have never seen unaccompanied by softening of the brain.

2. *Symptoms of softening of the brain from obliteration of the arteries.*—This form of softening of the brain has, like the former, been divided into two periods. The symptoms of the *first period* consist of pain referable to a particular part of the brain. The pain may be slight or severe, of short or long duration, generally remittent or intermittent. The intellectual functions are often sensibly modified; memory is impaired, speech embarrassed; there is frequently drowsiness, an unwillingness to every exertion; sometimes numbness or stiffness of the extremities, a prickling sensation or an increase of the sensibility to such a degree that even slight pressure occasions acute pain. The functions of the organs of sense are generally impaired; sight in one or both eyes may be less acute or entirely lost, and the pupil may retain its natural dimensions or be dilated; hearing may also be more or less imperfect, and taste and smell, when altered, are less acute than natural. The state of the digestive functions does not present any remarkable alteration, except inappetence, or constipation; the latter symptom being generally accompanied with retention or a difficulty of voiding the urine.

These are the symptoms which generally occur during the first period, but they are not constant; they are seldom all equally manifest; several of them may be absent, or only one, two, or more of them may be so marked as to attract the attention of the physician, or excite the fears of the patient. The local symptoms, or those of the brain, may prevail, particularly pain, loss of memory or confusion of ideas; or it may be the general symptoms, or those which indicate derangement of the functions of those organs which we have enumerated, especially the sensation of numbness and prickling felt in the muscles of the extremities or face, and difficulty of speech. It is, however, important to note that all the symptoms of this period may be regarded as denoting a diminution rather than an increase of function, the opposite of what is observed in the first period of inflammatory softening of the brain.

The symptoms of the *second period* are generally ushered in by a sudden aggravation of those of the first period, but chiefly by the occurrence of complete paralysis and the suspension or abolition of the intellectual faculties. The extent and situation of the paralysis, the modifications of the sensibility and contractility of the affected parts, and the ulterior progress of the disease, are so similar to those observed in the second period of inflammatory softening, that a description of them would be nearly a repetition of the latter. The important exceptions which they present will be more appropriately introduced when treating of the diagnostic symptoms of both forms of softening.

The *progress* and *duration* of softening of the brain from obliteration of the arteries do not essentially differ from those of inflammatory softening. In its progress it is, perhaps, less rapid than the latter. Although it may sometimes appear stationary, it is essentially progressive. The paralysis, if not complete at the commencement, increases till it becomes so, and the recovery of speech or of the intellectual faculties seldom insures more than a short suspension of the progressive increase of this form of softening. The duration of this lesion is very various. We have seen death take place as early as the second day, and not before the fourth or sixth week.

Diagnosis of softening of the brain and of the spinal cord.—We have here to distinguish, first, the symptoms of softening of the brain produced by inflammation, from those which accompany softening from obliteration of the arteries; and, secondly, the symptoms of both these forms of softening from those of other diseases between which and the former there is a greater or less resemblance.

First, the necessity of distinguishing between the two forms of softening of the brain can arise only when this disease affects persons after the decline of life. We shall not enter minutely into the description of the distinctive characters of the two forms of softening, as the treatment required in both is essentially the same, and as the impor-

tance of an accurate diagnosis diminishes in proportion as the disease approaches to that stage or period which constitutes the lesion of which we are now treating.

We have already observed that the two forms of softening of the brain are distinguishable from each other more by the phenomena of the first than by those of the second period; by the symptoms which precede rather than by those which accompany the state of softening. Inflammatory softening is preceded by local and general excitement; there is present, from the commencement, an increased development as it were of the functions of the brain, and of those organs comprised within the sphere of its morbid activity. This state of local and general excitement does not occur in the non-inflammatory softening at the commencement. It takes place after this lesion is produced; is, in general, slight at first, and afterwards increases in severity, the opposite of what happens in the former. The delirium, the spasmodic contractions and convulsions, the contraction of the pupil, and increased sensibility of the eye and ear to their natural stimuli, which precede the former, are absent at the commencement of the latter, and do not occur until some time after the softening has taken place and is followed by irritation or inflammation of the substance of the brain or its membranes.

When the second period of softening of the brain has arrived, there are few if any symptoms which indicate the kind of softening on which they depend, if those of the first period cannot be ascertained, or, as sometimes happens, have been wanting. The spasmodic contraction or convulsive twitchings of the muscles of the extremities and contraction of the pupils are, under these circumstances, the symptoms on which most reliance is to be placed. The presence or absence of these symptoms may, as a general rule, be regarded as indicating the presence, the former of inflammatory, the latter of non-inflammatory, softening.

Secondly, the diseases the most likely to be confounded with softening of the brain are serous effusion, congestion, and apoplexy. The *serous effusion* which gives rise to symptoms resembling those of softening of the brain, occurs as a termination of meningitis. The delirium, derangement of the intellectual faculties, and febrile excitement which accompany the first stage of the latter disease, together with gradual and sometimes sudden supervention of paralysis occasioned by the effused serosity, render it, in some cases, very difficult to distinguish this termination of meningitis from inflammatory softening. There are, however, two features in particular, in the symptoms of meningitis, of considerable diagnostic value, — namely, the prevalence of convulsions during the first stage, and the general character of the paralysis in the second stage, the latter symptom being seldom confined to one extremity or one side of the body in this disease. Paralysis from this cause is not likely to be confounded with non-inflammatory softening.

The symptoms of *congestion* are, generally speaking, very characteristic of the kind of lesion on which they depend. The ringing of the ears, dimness of the sight, the sensation of a weight within the cranium, giddiness, stupor, and the turgidity of the veins of the face and neck and conjunctiva, followed by the sudden diminution or suspension of the intellectual faculties, of sensation and motion, are symptoms referable to a rapid accumulation of blood in the vascular system of the brain. And if this disease does not suddenly prove fatal, the disappearance of all these symptoms under the use of the ordinary remedies, and the rapid recovery of the patient, very soon put its nature beyond doubt.

The difficulty of distinguishing between inflammatory softening of the brain and *apoplexy* from sanguineous effusion is, in the great majority of cases, by no means great. The progressive character of the former, and the sudden invasion of the latter, constitute, in a general point of view, a marked difference between the two diseases. The state of excitement which precedes and accompanies inflammatory softening occurs in apoplexy only as a consecutive symptom, and is, perhaps, never equal in degree or extent to that observed in the former disease. The state of coma and collapse does not make its appearance till towards the termination of softening from inflammation, whereas it is the first symptom which indicates the existence of apoplexy. Inflammatory softening tends progressively to this state; whereas in apoplexy the most profound stupor may be of short duration; consciousness and the exercise of the intellectual faculties return, and, if the disease be curable, may regain the same degree of integrity which they possessed before the attack. The subsequent contraction and convulsive motions of the muscles, and the contraction of the pupil — conditions the opposite of those observed at first, namely, relaxation and dilatation, — present the same differential importance as the symptoms just alluded to. It is in those cases of apoplexy in which the stimulus of the effused blood gives rise to irritation of the cerebral substance with which it is in contact, that the difficulty of distinguishing between this disease and inflammatory softening is greatest, particularly if the inflammation which has preceded the latter has been slight, and confined to the cerebral substance.

It would be difficult to lay down even a general rule whereby to determine the distinctive characters of softening of the brain originating in obliteration of the arteries, from those of hemorrhagic apoplexy. Apoplexy is certainly, in general, more sudden in its occurrence and less frequently preceded by precursory symptoms than non-inflammatory softening. But it must not be forgotten that the former may be preceded by symptoms similar to those which precede the latter; and, *vice versâ*, the latter may occur with all the rapidity of the former, and without its being announced by any marked modification of function.

Softening of the spinal cord will not readily be confounded with apoplexy of this organ. Apoplexy is a rare affection of the cord compared with softening; and its effects, loss of sensation and motion, are sudden, from the first complete, and without being announced by any precursory symptoms. In inflammatory softening, sensation and motion are gradually lost, are preceded by excitement, generally by local pain, although it may be slight; by an increase of the sensibility and con-

tractility of the affected extremities, and sometimes by convulsions of the same parts.

Prognosis of softening of the brain and spinal cord.—We formerly observed that we had not met with a case of cure of non-inflammatory softening of the brain, and that, on the contrary, we had seen cases of the inflammatory kind in which the evidence of complete recovery was rendered obvious by the state of the brain examined some years after the attack. Rostan (Loc. cit. p. 462,) says that the cure of softening of the brain, when it has attained the second period, must be regarded as problematical, and if he alludes to the non-inflammatory form of the disease, his opinion is in accordance with our own. Lallemand (Loc. cit. p. 287,) and Abercrombie (Loc. cit. p. 158,) both agree in opinion as to the curability of inflammatory softening of the brain, or, more correctly, of the curability of inflammation of this organ when the symptoms have been of the worst kind, and those too which accompany the second period. But at the same time they remark that this favourable termination of the disease is, under such circumstances, of rare occurrence. When, therefore, the symptoms of the second period of inflammation of the brain, or those ascribed to softening of this organ, manifest themselves, our prognosis must always be unfavourable, and the more so in proportion to the rapidity of the progress of the symptoms of the second period, and the degree of coma and paralysis by which they are succeeded. The progress of softening of the spinal cord is, if possible, more unfavourable than that of the brain.

Treatment of softening of the brain and spinal cord.—It would appear from the preceding remarks that the fatal termination of this disease has seldom been prevented by any mode of treatment hitherto adopted. There are no successful cases recorded of softening from obliteration of the arteries, and in the few cases of the inflammatory form of the disease which have terminated favourably, it is more than probable that the softening was very limited in extent, and affected the superficial or less important parts of the brain. As regards the state of softening, which, in point of fact, consists in a *solution of continuity* of the cerebral substance, it must be obvious that we possess no remedial agent capable of obviating such a change. The diseased state, therefore, of which we are treating, is incurable; that is to say, the solution of continuity which it constitutes will remain, even though the patient should recover. The essential part of the treatment of softening of the brain relates, consequently, to the local morbid conditions which immediately precede this change,—namely, the diseased state of the arteries on the one hand, and inflammation of the brain on the other. This state of the arteries, like the softening to which it gives rise, is, so far as we yet know, beyond the control of remedial agents. When, therefore, it is ascertained that the softening is the consequence of this state of the arteries, the only hope that can be indulged is partial relief, and the prolongation of life for a short period beyond that at which the disease would have proved fatal had it been allowed to run its natural course. It is possible that the attack may be delayed by judicious treatment, employed when the first symptoms of cerebral derangement are perceived, such as pain in a particular part of the head, confusion of ideas, giddiness or unusual drowsiness and listlessness, together with a prickling sensation, or numbness in the muscles of the extremities, face, or tongue.

Bleeding from the temples, cupping in the nape of the neck, or small general bleedings, repeated from time to time as circumstances may require, may, by diminishing the quantity of the blood, facilitate the circulation of this fluid through the brain. But, perhaps, greater advantage would be derived by keeping the bowels freely open without inducing excitement or debility, chiefly by means of the neutral salts. The compound aloetic pill will be advantageously employed in those cases in which the disease occurs after the cessation of the catamenia, or suppression of a hemorrhoidal discharge. A diminution of the circulating fluids, as well as their equalization, will be effected likewise by promoting all the secretions, particularly the secretion of the urine and bile. The food and drink of the patient should be particularly attended to. His diet should consist of those kinds of food which are most easily digested by him, and which affords the greatest quantity of nourishment in the smallest bulk. Ardent spirits, strong wines, fermented liquors, even strong coffee or tea, and all stimulating potions should be avoided as more or less injurious. The occasional use of warm and rubefacient pediluvia, constant warmth to the feet and lower extremities, an elevated posture of the head, residence in a cool atmosphere, and tranquillity of mind, will greatly favour the operation of the other means, and afford the patient a chance of escaping the fatal termination of the disease.

It is with reluctance that we allude to any kind of treatment to be employed when softening has once taken place. Rostan recommends that the use of all debilitating means be avoided, when the softening does not present the inflammatory character, which kind of softening, we presume, is that of which we are now treating. He recommends the prompt use of rubefacients, irritating lavements, and those internal medicines which exert their influence on the large intestines; and the administration even of tonics, aromatics, and internal stimuli.

It is also by the early, prompt, and vigorous application of those means which have been found most efficacious in arresting the progress of inflammation of the brain and its membranes, that the termination of this pathological state in softening is to be prevented. As the treatment of inflammation of the brain and its membranes has been given in detail in another article, (see BRAIN AND ITS MEMBRANES, INFLAMMATION OF,) we shall, in this place, only allude to it generally. The principal are bloodletting, purgatives, and cold. The bloodletting may be either local or general, or both; and in this respect, as well as quantity, we must be regulated by the violence of the attack, the age, habits, and constitution of the patient.

Drastic purgatives have been found the most beneficial, but in their employment the physician must be guided by the state of the stomach and intestines. With these, the tartar-emetic may be

combined, or given alone in such quantity as to keep up a state of nausea, but ought never to be carried so as to produce vomiting. As a purgative, Dr. Abercrombie strongly recommends the croton oil. The same author highly extols the beneficial effects of cold applied to the head, by means of pounded ice contained in a bladder; or a stream of cold water directed against the crown of the head, and continued until the desired effect be produced: but this is so powerful a remedy that it requires to be used with much discretion.

The treatment of the second period, or that of softening from inflammation, is the same in principle as that of the former, in so far as it regards the state of excitement with which this morbid change is generally accompanied. But if the paralysis be fairly established, and, notwithstanding the depletory and sedative measures which have been employed, continues to increase, neither our own observation nor the recorded experience of others would recommend a hardy perseverance in the means, the debilitating effects of which have not been sufficient to overcome the inflammatory excitement of the first period. Bleeding and active purgatives should now be laid aside; blisters or sinapisms should be applied to the inferior extremities, the nape of the neck, and superior part of the spine; the head should be kept cool by the constant application of evaporating lotions; the bowels evacuated once or twice a day by means of castor oil or any mild aperient if it can be swallowed, or by injections; the secretion of the urine and the cutaneous perspiration should also be promoted by remedies of the least stimulating qualities. The retention of the urine is a complication which must be sedulously watched, that this fluid may be removed before it accumulates to a degree to prove injurious. Stimuli or tonics should now be employed with a view to support the strength of the patient, but they ought never to be employed to such an extent as to produce excitement, as the powers of life are already greatly exhausted by the stimulus of the disease.

Should the patient recover from this dangerous and so frequently fatal disease, every attempt to restore the functions of the paralysed limb should be deprecated in the strongest terms. There are, however, cases in which the paralysis is extremely slight, consisting in a slight degree of weakness, which disappears gradually of itself in the course of a few weeks. But in the former, the paralysis is from the commencement complete, the member remains in a state of flaccidity and immobility, from which it does not recover until after a considerable length of time, and, perhaps, never to such a degree as to be of much use to the patient. In such cases there must be a solution of continuity, which being permanent and the cause of the paralysis, the paralysis must be permanent also.

With regard to the treatment of inflammatory softening of the *spinal cord*, it is only necessary to observe that it is in every respect the same as that of softening of the brain. Topical bloodletting, however, the actual cautery or the moxa, may be employed according as the disease may be acute or chronic in its progress, and the more so that it is much more frequently the consequence of disease of the spine, which also requires this treatment, than of idiopathic inflammation.

Softening of the Mucous Membranes.—Softening of the mucous membranes may, as we have already remarked in the introductory part of this article, occur either as a *pathological* or *post-mortem* lesion. The first, being the consequence of inflammation, is met with in mucous membranes in general; but the second being the effect of the chemical action of the gastric juice, is observed only in the digestive organs. It is a remarkable fact that softening of the mucous membrane is much more frequent and infinitely more extensive in the stomach and intestines than in any other organ; a circumstance deserving of particular notice, inasmuch as it indicates some peculiarity in this portion of the mucous system considered in itself, or in its relations with external agents. It is, therefore, not surprising that softening of the mucous membrane of these organs should have attracted in a special manner the attention of pathologists, but more particularly after it was discovered that this membrane undergoes so frequently this change in various forms of fever, or when the seat of inflammation as a primary or secondary disease.

Before proceeding to describe softening of the mucous membrane of the stomach and intestines from inflammation and from the chemical action of the gastric juice, we shall make a few general observations on the natural consistence of this membrane in these organs, and the diminution of consistence which it undergoes from maceration and putrefaction. The importance and intricacy of this part of our subject render it absolutely necessary to possess an accurate acquaintance with the modifications which the mucous membrane presents in these respects.

The *natural consistence* of the mucous membrane of the digestive organs is always in proportion to its thickness. Thus it is found to be thickest in the duodenum and pyloric portion of the stomach, and in these situations it is most consistent; it is thinnest in the colon and fundus of the stomach, and there also its consistence is least. Its thickness progressively diminishes in the rectum, jejunum, and ileum, and in the same descending ratio its consistence. If where it is thickest it be cut through, it may be torn from its connection with the cellular tissue, in pieces varying from a quarter of an inch to half an inch in length. This can be done in the pyloric portion of the stomach and rectum, but not in the duodenum, on account of the mode of attachment of this membrane in this portion of the intestinal tube. At the fundus of the stomach and in the colon it can be detached in very small portions only; and in all cases of great emaciation, this membrane becomes so thin throughout the whole of the stomach and intestines, that it breaks whenever an attempt is made to raise it.

The relative degrees of the normal consistence of the mucous membrane in different portions of the digestive tube are nearly the same at every period of life. It is hardly necessary to remark that the consistence of this membrane, as well as that of the other tunics of the stomach and intestines, is much less in the infant than in the adult.

When a portion of intestine is submitted to *maceration*, the mucous membrane does not lose its consistence until after a considerable lapse of time. Billard made this experiment, and found that softening did not commence till towards the expiration of two months. (De la Membrane Muqueuse Gastro-Intestinale. Paris, 1825.) When exposed to the air, it does not begin to soften until about the commencement of the third week. But in both cases it would appear that putrefaction always precedes the softening, as the latter is not perceived until the former is announced by the peculiarity of its smell. Hence it has been suggested that as softening of the mucous membrane, from these causes, does not take place until at a period greatly beyond that at which the body is usually submitted to inspection, we ought not to regard as *post-mortem* examples of softening those which are met with in this membrane, say twenty or thirty hours after death. This, however, we shall find, is far from the truth, as we shall afterwards show that complete softening of all the tunics of the stomach and intestines may take place in a much less space of time.

With regard to the influence of putrefaction in producing softening, it would not by any means be correct to say that it does not produce this change of the mucous membrane till after the expiration of weeks or months. Such appears to be the expression of the fact as regards the influence of putrefaction in modifying the consistence of healthy mucous membrane; but when this membrane has been the seat of disease before death, and more particularly when the disease has been of such a kind as to deprive this membrane suddenly of its vital properties, a few hours will suffice for its complete decomposition. This fact is illustrated in a general point of view by those cases of sudden death in which the nervous system, the blood, or both, are the vehicles of the destructive agent or of its influence, as in death from lightning and certain poisons. In such cases all the tissues run rapidly into putrefaction.

Having made these general remarks on softening from maceration and putrefaction, we shall now confine our attention to softening of the mucous membrane from inflammation and the chemical action of the gastric juice.

Softening of the Mucous Membrane of the Stomach and Intestines from Inflammation.—It is said that the mucous membrane of the stomach is much more frequently affected with softening than that of the intestines. Now this statement is true only in so far as expressive of the occurrence of softening without reference to its nature. It is not true as regards inflammatory softening, while it is quite true if applied to softening as a chemical effect of the gastric juice. It is also said that the mucous membrane is most frequently found softened where it lines the fundus of the stomach. This circumstance does not, however, decide the locality of inflammatory softening in this organ. For it is precisely at the fundus of the stomach that the mucous membrane is almost always acted upon by the gastric juice after death. Softening of the mucous membrane from inflammation is, we should say, most frequently observed at the termination of the ileum; in the depending or fixed portions of the colon, or the cœcum, in the right and left hypochondriac regions and sigmoid flexure of this intestine. Although such are the parts in which inflammatory softening is most frequently observed, it may occur not only in any definite portion of the intestinal tube, but also throughout its whole extent, that is to say, from the cardiac orifice to the anus; but such cases are very rare. These remarks apply to inflammatory softening of the mucous membrane considered as a whole; but as this membrane is composed of distinct elements,—the mucous tissue properly so called, villosities and follicles,—this morbid alteration may take place in each of these parts separately, or in all of them at the same time. Softening of the mucous membrane in general, or of these its elements in particular, presents various degrees. In the first degree the mucous membrane, instead of possessing that degree of cohesion which permits of its being detached from the submucous tissue, breaks as soon as it is seized between the fingers or forceps; in the second degree the edge of a scalpel or the finger passed lightly over its surface converts it into a soft, somewhat opaque, creamy-looking pulp; and in the third or last degree it is so soft that it is removed by a stream of water poured upon it from the height of a few inches. In this stage portions of it are found partially or entirely destroyed, and, having been removed by the fluid contents of the stomach or intestines during life, the submucous or cellular tissue is thus found deprived of its mucous covering. It is in this manner that various forms of softening are produced, as irregular or round patches of various sizes. It is important to notice this circumstance, for when the softening is limited to the glandulæ solitariæ, particularly in the large intestines, as is frequently the case in dysentery, it might be altogether overlooked. These bodies being very small, and their entire destruction from softening being often unaccompanied by any obvious alteration of the mucous membrane itself, the seat and nature of the intestinal affection might not be ascertained were it not for the presence of a number of minute circular patches, which, when narrowly examined, are found to be the result of softening of these follicles; for it often happens that enlarged follicles are seen intermixed with the patches, and which, when a scalpel is carried over the surface of the mucous membrane, break down or are removed, and thus other patches are formed similar to the former. These circular patches, which have the submucous tissue for their basis, are often described as ulcerations of the mucous membrane; but in all cases of doubt the use of the scalpel, as noticed above, will enable us to determine their nature. Softening of the mucous membrane in the form of stripes and bands has been described with great care and precision by Louis, and has been much insisted upon as characteristic of inflammatory softening. But for reasons which we shall afterwards assign, we are disposed to ascribe a very different origin to these forms of softening of the mucous membrane of the stomach, viz. the chemical action of the gastric juice.

Softening of the mucous membranes of the digestive organs may present various degrees of redness, or it may be quite pale. The redness may

be confined to the softened part, or it may extend to the neighbouring parts at the same time, or the latter may be red and the former pale. The redness of the softened membrane may vary from a slight rose red, bright or dark red, to purple or brown,—varieties of colour, the value of which it is by no means easy to estimate, inasmuch as the quantity of blood in an inflamed tissue cannot be taken as the measure of the degree of inflammation which had caused the accumulation of this fluid. The pale inflammatory softening presents also some variety of tint which requires to be noticed. The softened mucous membrane is of a pale greyish or yellowish grey tint, being little altered from its natural colour; or it may be paler than natural, when it generally presents a milky aspect, owing to the colour of the submucous tissue being seen through it. The pale softening is very common in phthisical subjects, in tubercular disease of the mesenteric glands, as in all diseases followed by great emaciation, although the existence of this important lesion was not known to pathologists till very lately, owing to the imperfect mode of examination to which the digestive mucous membrane was subjected.

Instead of constituting the only disease of the mucous membrane, softening may be complicated with various other diseased states, such as thickening of this membrane, enlargement of its follicles, and ulceration; but its general characters do not, under these circumstances, differ from those we have just described.

Inflammatory softening has been described as affecting all the tunics of the stomach and intestines. It is said to proceed from the mucous membrane to the submucous tissue, and from the latter to the muscular coat and peritoneum, all of which it destroys in succession, and terminates in perforation of these organs. We, however, disbelieve this statement. Softening of all the coats of the stomach or intestines, carried to the extent of perforation of these organs, does not arise in inflammation. It depends on the chemical action of the gastric juice.

Much has been said of the *symptoms* of softening of the gastro-intestinal mucous membrane, but it would serve no useful purpose to give an exposition of them in this place, inasmuch as when this lesion is the consequence of inflammation, the symptoms are those of gastritis or gastro-enteritis, and which will be found detailed under these heads respectively. It need hardly be observed that there are no symptoms referable to the states of softening which we have described, considered in itself, and as a termination of inflammation of the mucous membrane.

It may, however, be reasonable to suppose that, if a person recovers from gastritis or enteritis, followed by complete softening of the mucous membrane to a considerable extent, nutrition will be considerably modified, at least in degree. But how far this actually takes place has not been ascertained; and although we find the mucous membrane in some individuals, after death, presenting a very indistinct villous structure, either generally or in particular parts, it is easy to conceive how great must be the difficulty of deciding on the nature of such an appearance, the more especially as it has not been found to be connected with any peculiar modification of function.

The description, therefore, which we have given, of softening of the digestive mucous membrane, is valuable only in so far as it becomes a *test* of the previous existence of inflammation. It is, in fact, only in this point of view that we can consider it in this place. It is a lesion of the mucous membrane which belongs exclusively to the pathologist, as it furnishes the physician with no sign of its existence. It puts him, however, in possession of the important facts to which we have alluded, viz. the frequency, extent, and consequences of inflammation in organs to which it had so long escaped his researches, thereby leaving him without the means of judging of the propriety of his practice, or of giving to it that stability and scientific character which it is more capable of receiving.

2. *Softening of the stomach and intestines from the chemical action of the gastric juice.*—The chemical dissolution of the mucous membrane and other tunics of the stomach was discovered by John Hunter, while engaged in a series of experiments on digestion. (J. Hunter, on the digestion of the stomach after death, Phil. Trans. vol. lxii. p. 444; and Observ. on certain Parts of the Animal Economy, 2d edit. p. 226.) He described it as *digestion of the walls of the stomach after death*, and as the immediate consequence of the solvent property of the gastric juice. As he had observed it only in healthy animals, and in persons who had been suddenly deprived of life by external violence, he believed that a perfect state of health, immediately before death, was absolutely necessary to its production. The opinions of Hunter on the dissolvent property of the gastric juice after death, were soon after confirmed by Spallanzani (On the Natural History of Animals and Vegetables, Dissert. 5,) and Dr. Adams, (On Morbid Poisons, &c. and London Med. Jour. vol. xxiii. p. 399); and Mr. Allan Burns (Observations on the Digestion of the Stomach after Death; Edin. Med. & Chir. Jour. vol. vi. p. 129,) contributed some important information on the subject, more particularly relating to the chemical dissolution of the stomach in individuals who had died in a state of great debility and emaciation from chronic disease, and also the occurrence of this lesion in portions of the stomach in which it had not before been observed.

Although the experiments and observations of Hunter, modified and extended by the contributions of Spallanzani, Adams, and Burns, clearly demonstrated the occurrence of softening and perforation of the walls of the stomach in certain animals, as fishes, rabbits, and dogs, and in man, in consequence of the chemical action of the gastric juice after death, British pathologists appear to have entirely overlooked the importance of the subject in relation to those morbid conditions of the stomach which bear a greater or less resemblance to the *post-mortem* effects of the gastric juice upon this organ. In France, the opinions of Hunter were at first received with doubt, afterwards turned into ridicule, and the most vague and absurd hypotheses set up in their place. French pathologists, instead of regarding the lesions pointed out by Hunter as *post-mortem* effects of the gastric juice, described them as grave

alterations of the stomach during life by the direct operation of morbific agents. Chaussier (Bulletins des Sciences Médicales du Département de l'Eure, No. 53, p. 7,) whose description of the appearances produced by the gastric juice accords with that of Hunter, ascribes the softening and perforation of the walls of the stomach to the presence of an *acrid* and *corrosive* fluid produced by a *special* irritation of this organ, and which turns its activity even against the tissue whence it is derived, as well as other tissues with which it is brought in contact. Morin (Considér. générales sur l'Erosion, Paris, 1806,) Laisné (Considér. Medico-légales sur les Erosions et Perforations spontanées de l'estomac, dans le recueil intitulé Méd. Lég. No. 104, p. 135,) and several others referred the same alterations of the stomach to the sudden development of a *high degree of local irritation*, terminating in the partial or complete destruction of the affected part of this organ, by a process similar to that of erosion or ulceration.

The researches of Jæger* in Germany revived the opinions of Hunter, and directed the attention of pathologists anew to the experimental investigation of this interesting subject. The experiments and observations of this author led him to the conclusion that the softening and perforation of the stomach occur after death, but that these changes are not the result of the chemical action of the healthy gastric juice. He believes, on the contrary, that this fluid must have been altered by disease, the nature of which he does not explain, but supposes it to consist in some peculiar change taking place in the functions of the nervous system, and a consequent modification of the secretion of the digestive organs. Dr. J. Gairdner† has arrived at the following conclusions as the result of his observations on softening and perforation of the alimentary canal, viz. that these lesions are produced after death by the action of the fluids contained in the stomach and intestines; that these lesions probably occur in some cases without previous disease of the parts in which they are found to exist; but that they also take place in consequence of a peculiar disease of the alimentary canal, whereby portions of it are rendered more easily soluble by the action of its contents.

Such are the principal opinions of those who have adopted, rejected, or modified the views of John Hunter on softening and perforation of the alimentary canal. We may now allude briefly to those of Cruveilhier and Louis, who have described these *post-mortem* lesions as pathological alterations of the stomach and intestines, and as constituting a disease not hitherto observed by pathologists. Louis‡ has detailed, with great precision and accuracy, the symptoms and *post-mortem* appearances observed by him in a considerable number of cases in which the mucous membrane of the stomach was found more or less softened or destroyed. He considers this state of the stomach as produced during life, and referable to a state of irritation of the mucous membrane, the symptoms of which, although generally conspicuous, are sometimes wanting. In Cruveilhier's (Médecine Pratique éclairée par l'Anatomie et la Physiologie Pathologique) memoir, we find this author describing the same lesion of the alimentary canal as it occurs in infants and children, and ascribing it to a high state of irritation of the mucous membrane, which, being followed by the repeated effusion of serosity, the delicate textures of the stomach and intestines become infiltrated, distended, and ultimately disorganized, thus producing, as it were mechanically, what he calls the *ramollissement gelatiniform* of the walls of this organ, and perforation.

Such is a brief outline of the several opinions which have been entertained regarding the nature of the lesion now under consideration. Impressed with the importance of the subject when considered in connection with several morbid conditions of the stomach, more especially those produced by inflammation of this organ, the author of the present article instituted a series of experiments, modified in every possible way, with a view to obtain a satisfactory solution of the following questions. (Journ. Hebdom. de Méd. Nos. 87 and 91, 1830.) Are the lesions described by various authors under the appellations of softening, erosion, perforation, gelatiniform softening, and digestion of the walls of the stomach, the same or different lesions? Are these lesions produced during life or after death? If in the latter case, are they the effects of the chemical action of the gastric juice? and what are the conditions and properties of this fluid to which they are to be ascribed? The following summary of the experiments alluded to appears to us to afford a satisfactory solution of these queries.

Softening, erosion, and perforation of the stomach and intestines from the chemical action of the gastric juice after death, in inferior animals.—When an animal, such as a rabbit or dog, in the most perfect state of health, is killed during the act of digestion, the following appearances are observed in the stomach if examined four, six, or eight hours after. In one series of cases, the mucous membrane of the most depending portion of the stomach, or this membrane, the submucous, and muscular coat, are softened or broken down into a pulpy substance. In a second series, the serous or peritoneal covering is also destroyed, or the stomach is perforated, and a quantity of digested food projects through the opening, and lies in contact with the liver, spleen, diaphragm, or intestines, one or all of which may present, to a greater or less extent, the same kind of softening as that observed in the stomach. In a third series, the diaphragm or œsophagus is perforated, and the liquid part of the digested food has passed into the cavity of the thorax, and all the parts with which it is in contact, as the pleura pulmonalis and costalis, and even the substance of the lungs, are softened or entirely dissolved. The colour of the softened parts was generally pale, sometimes of a yellowish tinge; and whenever vessels filled with blood traversed these parts, this fluid presented a brown or black colour. The

† Cases of Infantile Disease, in which Erosions and Perforations of the Alimentary Canal were found after death. Trans. of Edin. Med. Chir. Soc. vol. i. p. 311.

‡ Ramollissement avec Amincissement, et de la Destruction de la Membrane Muqueuse de l'Estomac. Archiv. Génér. de Méd. tom. v. p. 5; and, Recherches Anatomico-Pathol. sur diverses Maladies, Paris, 1826.

softened mucous membrane of the stomach, when removed by passing a scalpel over its surface, appeared like a solution of starch in hot water. It was frequently found in this state covering the submucous coat like a thin layer of jelly, and could be carried away by a stream of water, leaving a large irregular grey or pale coloured patch, formed by the denuded submucous coat. Sometimes several of these patches were observed, and presented those appearances termed erosions. These alterations of the mucous membrane were always limited to, or most marked in, the fundus or most depending portion of the stomach; they became gradually less perceptible towards the body or pyloric portion of the stomach, where they were lost in the healthy state of this membrane. The same characters were observed in the other tunics of the stomach, and the borders of the perforation were irregular, ragged, thin, pulpy, and transparent, and consisted principally of the peritoneum.

The fundus of the stomach was the part primarily and exclusively affected. It was also in this portion of the stomach that the food was found most completely digested,—a circumstance which depended on the depending position of the fundus, at least in those cases in which the food was in a state of fluidity, or the gastric juice considerable in quantity. The same may be said of those organs alluded to, those of them being most softened that were nearest the fundus of the stomach, or in the direction in which the fluid contents of this organ were made to pass, from the position given to the body of the animal after death. From these facts it will not be difficult to perceive in these changes the effects of a common cause, having its seat in the stomach, and extending its influence to other organs in the manner we have described. That this cause was the healthy gastric juice must be obvious, since this fluid was formed in animals in a perfect state of health. It was, besides, only when these animals were killed during the act of digestion, or when the stomach contained gastric juice, that any lesion of this organ was observed. We shall not at present attempt to identify the effects of the healthy gastric juice with those described by Cruveilhier, and others observed in children, as we shall afterwards have an opportunity of showing that the gelatiniform softening of the stomach and intestines met with in children is of the same nature as that we have just described.

The next fact satisfactorily determined by these experiments was the *property* of the gastric juice, by means of which the dissolution of the stomach or other organs is effected after death. On laying open the softened or perforated stomach of a healthy animal, we are at once struck with the sour smell that arises from its contents. It is precisely similar to that which we perceive on opening the stomach of a living animal containing a quantity of digested food. When litmus paper is placed in contact with this food, or the more fluid contents of the stomach, it becomes immediately red, the degree of redness, or the rapidity with which it takes place, varying with the stage of the digestive process and the fluidity of the contents of the stomach. The *acidity* of the gastric juice always accompanied the softening and perforation of the stomach in the animals subjected to our experiments; and hence we concluded that it is to this property—acidity, that the production of these changes is to be attributed; a conclusion, the accuracy of which was confirmed by introducing into the stomach of a rabbit that had just been killed, a quantity of magnesia sufficient to neutralize the acid contents of this organ. In this experiment there was no appearance of softening.

In order to show that the softening and perforation of the stomach are the immediate effects of the gastric juice, or, more correctly speaking, the *gastric acid*, and in no way dependent on any morbid state of the stomach or other organ of the body, the stomach of a healthy rabbit, containing digested food, was removed, and placed under a glass globe. It was kept moist by a little tepid water placed beneath it. In a short time the fundus became pale, afterwards soft, thin, and transparent, and at the end of four hours dissolution of all the coats of this depending portion of the stomach took place, and was followed by the escape of the food. Softening and perforation of the stomach, intestines, and urinary bladder, are produced under similar circumstances—that is to say, when the gastric acid or digested food is taken from the stomach of a healthy animal, and introduced into one or other of these organs, removed from another animal, or left *in situ*. We have repeatedly observed, and reproduced as stated above, all the varieties of softening, erosion, perforation, &c. described by the authors whose opinions we have quoted as pathological states.

Softening, erosion, and perforation of the stomach from the chemical action of the gastric juice after death, in persons suddenly deprived of life while in the enjoyment of perfect health.—It were weak and futile to argue that the *post-mortem* effects of the gastric acid, although observed to take place in inferior animals, do not prove their occurrence in man; for the gastric acid has been found to be of the same nature in all animals in which it has been examined, as in man. Moreover, all the chemical *post-mortem* effects of this acid have often been observed to occur in individuals suddenly deprived of life soon after a meal, and at the time in the enjoyment of perfect health. We have seen one case of this kind which occurred in a healthy young man who fell from a considerable height soon after breakfast, and died a few hours after. All the coats of the fundus of the stomach, except the peritoneal, were converted into a soft gelatinous pulp, resembling in every respect the same change observed in our experiments on rabbits, as well as the contents of the stomach in this case, these having been found, by means of their smell and the chemical test, to be acid. There cannot, therefore, remain the slightest doubt that softening of the walls of the stomach occurs after death from the chemical action of the healthy gastric acid in individuals suddenly deprived of life.

Softening, erosion, and perforation of the stomach, of this organ and the intestines, the œsophagus, diaphragm, &c. from the chemical action of the gastric acid after death, in persons who die of various diseases.—These lesions have been met with of every possible degree, extent, and

form, whatever may have been the nature of the disease by which they had been preceded. Thus they have been observed in the bodies of those who have died of acute and chronic diseases, whether of one or of several organs, whether the stomach and intestines have manifested any signs of disease during life or not; in the most robust as in the most feeble and emaciated, and at every period of life. Before alluding farther to the symptoms ascribed to the present form of softening of the stomach, by those who regard it as a pathological lesion, we shall point out the situation which it occupies in this organ, the degree and extent to which it proceeds, and the form and colour which it presents, in order to determine how far it resembles in these respects this change of consistence, such as we have described it to occur in animals and in man, as the consequence of the chemical action of the healthy gastric juice after death.

The *situation* of softening, as well as that of erosion and perforation of the stomach, in individuals who die from disease, is precisely the same as in our experiments, viz. the fundus of that organ. It is to this part of the stomach that these lesions are almost always either exclusively confined, or in which they are greatest in degree. Their occurrence in any other portion of the stomach may be explained by the presence of certain physical conditions of this organ, which we shall presently notice more particularly.

The *degree* of softening presents the same variety observed in our experiments. The mucous membrane or other tunics of the stomach present, in the first stage, a slight diminution of consistence, and have acquired a certain degree of transparency. When seized, they break immediately, or are crushed between the fingers into a soft pulp. In the second stage, the mucous membrane is seen lying like a quantity of albumen covering the submucous coat, and can be wiped off or removed with a bit of cloth or a stream of water. In the last stage, this membrane has entirely disappeared in several portions of the stomach, thus leaving the submucous coat denuded, and presenting the grey silvery aspect by which it is characterized.

The *extent* of the softening is very various, being either limited to a small portion of the fundus, or occupying the whole surface of the stomach. When perforation either of the stomach or œsophagus has taken place, we find, as in our experiments, softening of the liver, spleen, intestines, diaphragm, pleura, and lungs, all of which organs may be affected in the same individual, and present various degrees of dissolution.

The *form* of softening presents several important varieties. If the softening be confined to the mucous membrane of the fundus, the form which it presents is that of small or large patches. These are generally irregular, the borders of them being formed by the mucous membrane, and the bottom of each by the submucous coat. The edges of the patches, besides being irregular, are thin, soft, and somewhat transparent. If the softening has penetrated the submucous and muscular coats, the edges of these are beveled outwards, and terminate in thin irregular prolongations, which are seen to float like shreds of transparent coagulable lymph when water is poured upon them. Softening and perforation of the peritoneal coat present precisely the same characters as to form and consistence. These, then, are the varieties of form of softening observed in the fundus of the stomach, and when this lesion extends beyond the fundus, it still presents the same appearances so long as the mucous membrane is smooth or stretched out. But when this membrane is thrown into folds or forms plicæ, the softening no longer occurs in patches, but presents those remarkable appearances so minutely and accurately described by Louis, as indicating the existence of pathological alterations. The forms of the softening in this case are those of stripes or bands of various dimensions, having the situation and distribution of the plicæ. Wherever these stripes and bands exist, we find that the mucous membrane has been completely destroyed, and the submucous coat laid bare. They have thus a bluish or silvery grey aspect, while the mucous membrane which they enclose may be of its natural colour, red or otherwise modified, and appears in isolated patches of various forms and extent. It was the isolated and defined character of this form of softening which made it be considered as indisputably of a pathological nature. But the following explanation will show that it is a *post-mortem* lesion, and the consequence of the chemical action of the gastric juice. The mucous membrane possessing only in a very limited degree the power of diminishing its bulk, is always thrown into the form of plicæ when the muscular coat has contracted so as to diminish considerably the capacity of the stomach. When a quantity of gastric acid is collected on the surface of the mucous membrane in this state, it is obvious that the dissolvent property of this fluid will be exerted principally, if not exclusively, on the borders of the plicæ, their lateral surfaces being in contact with one another, or covered with mucus. Hence it follows, that when the stomach is removed from the body, emptied of its contents and spread out, the plicæ are effaced, and the stripes and bands, not before observed, make their appearance. That such is the manner in which this form of softening is produced is demonstrated by the following experiment, which we have frequently repeated. If the stomach of an animal, or of the human subject, in which the plicæ are well marked, be taken, and a quantity of gastric acid or digested food be placed over its mucous surface, we find that after a few hours the projecting borders of the plicæ are dissolved, while their lateral surfaces remain unchanged.

We have said that softening of the stomach, the erosion and perforation by which it is followed, almost always takes place in the fundus of this organ, in consequence of its depending position favouring the accumulation of the gastric acid. But there are various circumstances which, operating after death, give rise to important varieties in the situation, form, and extent of the softening of the mucous and other coats of the stomach. Great enlargement of the spleen may elevate or compress the fundus of the stomach so as to prevent the gastric acid from collecting within it, while at the same time this fluid accumulates in some other portion of the stomach, as the pyloric, which may have become the most depending part;

great distension of the transverse arch of the colon may throw the great curvature of the stomach upwards and forwards, when the fluid contents of this organ collect along the small curvature; or tumours in the liver, retro-peritoneal cellular tissue, &c. may be so situated as to produce considerable variation in the position and form of the stomach, and, consequently, in the situation of the softening.

Under all these circumstances the form of softening is likewise considerably modified. But the presence of gas in the stomach gives rise to a particular variety of form of softening which requires to be noticed. The softening terminates in a well-defined, abrupt margin, beyond which the mucous membrane is found to present (so far, at least, as the gastric acid is concerned) its natural colour and consistence. This regular and defined margin of the softening is determined by the gas acting as a foreign body, equalizing the distribution of the gastric acid, and confining its operation to a circumscribed portion of the mucous membrane. The quantity of the gastric acid generally regulates the extent of the softening of the mucous membrane. If considerable, the whole of the gastric mucous membrane may be destroyed, and it is also in cases of this kind that the cardiac orifice becomes dilated, and the gastric acid passes into the œsophagus, the cuticular lining, mucous and muscular coats of which it dissolves, and forms a communication between the cavity and this tube and that of the chest.

The *colour* of the mucous membrane in softening, erosion, and perforation of the stomach, presents several important modifications, and which depend essentially on the quantity of blood contained in this organ after death. If the quantity of this fluid be very small, or such as it is generally found to be in what is considered the healthy state of the stomach, the natural colour of the mucous membrane is not altered except where it is softened, where it is of a dull-yellow or orange-tint. This colour increases with the quantity of blood, and is accompanied with shades of brown and black, which assume a variety of forms, the description of which will be found in the article Melanosis, and also the experimental evidence which demonstrates that these changes of colour are produced by the gastric acid. An opposite state, or extreme paleness of the softened mucous membrane, is that form of *post-mortem* softening which is generally observed in infants and young children, and in emaciated, cachectic, and leucophlegmatic persons, in whom the blood is not only small in quantity, but contains a great disproportion of serum. In such individuals the whole stomach appears as if macerated; is, indeed, sometimes infiltrated with serosity, and is so completely deprived of blood that no trace of this fluid is perceived except in some of the large venous branches.

Redness of the softened mucous membrane is never observed. Its existence is incompatible with the chemical action of the gastric acid, and the red colour of the blood is instantaneously destroyed by this fluid.

Although the general characters of the chemical dissolution of the *intestines* agree in every respect with those which accompany this lesion of the stomach, there are a few circumstances which require to be noticed, in order to refute the opinion that softening of this part of the digestive apparatus is, in an especial manner, the consequence of disease. We have already stated that softening of the intestines was a frequent occurrence in those animals submitted to our experiments. The portions of intestines softened or perforated were invariably those situated in the epigastric or left hypochondriac region; and it is most important to note that complete dissolution of the coats of the intestines was sometimes observed, even when the stomach was not perforated, and, consequently, when the former were not in immediate contact with the gastric acid contained within the stomach. As the intestine occupied the superior surface of the stomach, presented no trace of disease, nor contained any acid fluid, the softening must obviously have been produced by the gastric acid having been transported from the stomach by imbibition. Hence it follows that softening, and even perforation, *from without inwards*, of the intestines, may take place after death from the chemical action of the gastric acid, and without perforation of the stomach as a previous and necessary occurrence. It is an interesting fact that in almost all the cases of softening, (gelatiniform softening,) or softening with perforation of the intestines that have been published, the large intestines, situated in the epigastric or left hypochondriac region, were exclusively the seat of one or both of these lesions. Such, also, has been the result of our own observations in all the cases of softening of the intestines which we have examined in the dead body. The locality of this lesion and its physical characters being precisely the same in man as those observed in animals, and having traced it in both to the mediate or immediate influence of the gastric acid, we must necessarily regard it in the former, as it was shown to be in the latter case, a *post-mortem* alteration. Cases of softening and perforation of the intestines, *from within outwards*, occur after death, from the presence of an acid fluid, either formed within them, or brought into them from the stomach.

From the evidence we have brought forward to prove that the softening, erosion, and perforation of the stomach and intestines, described as pathological lesions by the authors to whom we have referred, are the effects of a chemical agent—the *healthy* gastric acid—and produced after death, it would, in our opinion, be a waste of time to attempt a refutation of the several theories which have been offered on this subject. We have already remarked that all these lesions have frequently been found to occur in individuals, whatever may have been the seat or nature of the functional derangement by which they may have been preceded, whether death may have been the consequence of disease or of accidental injury. But why, it may be asked, do these lesions frequently occur, particularly in children, in whom the only symptoms observed are referable to a greater or less derangement of the functions of the stomach and intestines? This question may be met by the following. How does it happen that these lesions *do not occur* in cases in every respect the same as the former as regards the derangement of function and the organs affected?

The answer is simply this—the presence in the former, and the absence in the latter case, of the chemical cause of these lesions. Gastritis or gastro-enteritis is the disease which exists in both cases, and would never have been described as any thing else but for the presence of those *post-mortem* lesions which we have described. It is, indeed, surprising that any divergency of opinion should exist on this subject, seeing that no such changes exist in any other organ supplied with a mucous membrane; seeing, on the contrary, that inflammation produces quite a different kind of softening of the mucous membrane from that which we have described. The mucous membrane softened by inflammation, instead of being transparent, is more or less opaque, and even when it is completely disorganised, it resembles a mixture of flour and water or milk, rather than an albuminous or a gelatinous fluid. Such is, in fact, the principal character of inflammatory softening of the mucous membrane, in whatever organ it occurs; whereas the transparent gelatiniform softening is never observed except where the chemical agent is formed by which it is produced, viz. in the alimentary canal, and in some of the neighbouring organs, for the reasons which we have already given. We shall only further observe, that were the gelatiniform softening, erosion, and perforation of the stomach the consequences of inflammation, we should in every case find, either in the stomach or external to it, one or more of the products of this pathological state. But this we never find; even the perforation of the stomach, of the intestines, diaphragm, with the accompanying destruction of the spleen, liver, &c., may exist all in the same individual without any trace of serous effusion, of coagulable lymph or pus. There is no trace of peritonitis, even when the contents of the stomach, of the most stimulating quality, are lying in contact with the peritoneum. Lastly, the stomach is frequently found perforated without its contents having escaped into the cavity of the abdomen.

From all the facts brought forward on this part of our subject, the following principles may be established:—

1st. That the softening, erosion, and perforation of the walls of the stomach, attributed by the greater number of pathologists to morbid conditions of this organ, may be produced, whatever may be their form, degree, extent, or situation, by the gastric acid.

2. That no pathological condition of the stomach or of any other organ is necessary to the production of these lesions.

3d. That all of them are met with in individuals who, in the full enjoyment of health, are suddenly deprived of life; and in those who die from various diseases.

4th. That all of them are met with, after death, in healthy and diseased stomachs, which contain gastric acid.

5th. That they are produced by introducing this fluid into a healthy dead stomach.

6th. That the varieties observed in the form, degree, extent, and seat of these lesions, depend on modifications of the gastric acid, the action of which on the stomach is regulated by a certain number of physical conditions in which this organ may be placed.

7th. That softening, erosion, and perforation from the action of the gastric acid, are observed in other organs besides the stomach, viz. in the œsophagus and intestines, from the direct communication which exists between them and the former organ; and the peritoneum, liver, spleen, diaphragm, pleuræ, and lungs, in consequence of the perforation of the stomach and œsophagus.

8th. That all these lesions of the stomach, intestines, and of the other organs, are produced after death.

R. Carswell.

SOMNAMBULISM AND ANIMAL MAGNETISM.

I.—Of Proper Somnambulism.

Somnambulism or sleep-walking is one manifestation of a state of the nervous system which, in different degrees and under several forms, coexists with various general conditions of the living body. It is characterized by a suspension more or less complete of external feeling, while the imagination is in activity, but the individual is not conscious of his real state, and fancies himself to exist under different circumstances from those which actually surround him. Dreaming is one modification of this state, but it does not afford so great a variety of phenomena as somnambulism, or display so many peculiar signs of the real condition of the faculties. Many forms of delirium, catalepsy, trance or ecstacy, and some cases of madness — those, for example, in which the patient on recovery is found to have lost suddenly all recollection of what had passed during the period of his disease — belong to the same class of affections, for which we have as yet no collective term. An inquiry into the real character and pathology of somnambulism may afford us an opportunity of throwing some light on a variety of obscure phenomena which display themselves in the state of the system above described, and it will be found interesting, and, as we trust, useful in some other points of view.

There is an obvious relation between the state of the faculties in somnambulism and that which exists during dreams. It is, indeed, probable that somnambulism is dreaming in a manner so modified, that the will recovers its usual power over muscular motion, and likewise becomes endued with a peculiar control over the organs of sense and perception. This power, which gives rise to the most curious phenomena of somnambulism, is of such a kind that, while the senses are in general obscured, as in sleep, and all other objects are unperceived, the somnambulator manifests a faculty of seeing, feeling, or otherwise discovering those particular objects of which he is in pursuit, towards which his attention is by inward movement directed, or with which the internal operations of his mind bring him into relation.

The near connection between somnambulism and dreams is established by the following considerations:—

1. Sleep-walkers, after they have awakened from the slumbers which ushered in and continued after somnambulation, have sometimes remembered the circumstances or adventures of the period, and

have correctly related them as the impressions of a dream. This fact has been noticed by Sylvius and by Hoffmann : " Somniantibus et somniorum ratione obvenire hominibus somnambulorum affectum patet exipsorum evigilantium relatu, putantium se somniâsse duntaxat, quæ actu fecerunt." A striking instance of this kind is related by Horstius. A young nobleman in the citadel of Brenstein was observed by his brothers, who occupied the same room, to rise in his sleep, put on his cloak, and having opened the casement, to mount, by the help of a pulley, to the roof of the building. There he was seen to tear in pieces a magpie's nest, and wrap the young birds in his cloak. He returned to his apartment, and went to bed, having placed his cloak by him with the birds in it. In the morning he awoke, and related the adventure as having occurred in a dream, and was greatly surprised when he was led to the roof of the tower and shown the remains of the nest, as well as the magpies concealed in his cloak. A similar observation as to the occasional remembrance of the impressions made on the mind during somnambulism, was made long ago by Muratori, to whose work we shall again have occasion to refer.

2. As in dreams, so likewise in somnambulism the individual is intent on the pursuit of objects towards which his mind had been previously directed in a powerful manner, and his attention strongly roused; he is in both states impelled by habit, under the influence of which he repeats the routine of his daily observances. A somnambulator is a dreamer who is able to act his dreams.

Many facts may be cited in proof of this remark. A man (known to the writer of this article), who was accustomed to attend a weekly market, rose from his bed, saddled his horse, and actually proceeded on his journey as far as a turnpike, which being closed during the night, he was awakened by the circumstance. Another individual who had been in the habit of frequenting a public promenade, where he used to meet his acquaintances, was seen to rise from his bed at night and walk in his shirt along the same path, which extended for a mile on the brow of a hill, stopping very frequently and greeting different individuals whom he had been accustomed to see in the same place. Hoffmann relates the case of a somnambulator who dreamed that he was going to set out on a journey, rose and put on his clothes, shoes, and spurs, and then striding across the sill of an open window, began to kick with his heels and to exert his voice, supposing that he was exciting his horse to speed. Henricus ab Heer mentions another person, a student at an university in Germany, who having been very intent on the composition of some verses which he could not complete to his satisfaction, rose in his sleep, and opening his desk, sat down with great earnestness to renew his attempt. At length having succeeded, he returned to bed, after reciting his composition aloud, and setting his papers in order as before. Martinet gives the case of a man who was accustomed to rise in his sleep and pursue his business as a saddler.

M. Bertrand considers it to be a peculiar feature of somnambulism that the individual, though on waking he is generally found to have lost all recollection of what passed during his sleep, yet recalls, when the periods of this state return, the whole train of obliterated ideas. " Somnambulism," as the same writer says, " thus constitutes really a new life, returning at unequal intervals, connected together by a new species of memory." (Traité du Somnambulisme, par A. Bertrand, Paris, 1823.) We may observe that something of this kind is perceived in the instance of dreams. A person strongly impressed by a dream, on again falling asleep, experiences not unfrequently a recurrence of the same impressions, and the imagination will even take up the dream at the precise point where it was before interrupted.

These observations seem to prove that somnambulism is a modification of dreaming, and this conclusion appears so probable, that it will perhaps be admitted without hesitation; yet there are many writers of great research and ability who maintain a different opinion. Bertrand, who has investigated the circumstances connected with the history of sleep-walking with great pains and accuracy, considers the state in question to be something entirely different from dreaming. The same opinion is expressed in the most positive manner by Professor Heinroth, who says that somnambulists are to be reckoned as awake, since their perceptive power is in some respects even more acute than during the ordinary waking state; and that this condition bears no relation to dreaming, inasmuch as dreamers exist in an ideal world, whereas night-wanderers are conversant with actually existing and material objects. (Lehrbuch der Stoerungen des Seelenlebens, und ihrer Behandlung, von Professor J. C. A. Heinroth, Leipzig, 1818, B. ii. p. 270.) Both of these writers maintain an opinion which is very prevalent in France and Germany, that somnambulists have the ordinary channels of sensation entirely closed, that they neither see with their eyes nor hear with their ears, but are endowed with a peculiar mode of sensation, which, in its highest degree, constitutes what is termed *clairvoyance*. This is supposed to be diffused over the whole surface of the body, but to be especially seated in the epigastrium and fingers' ends. It is not exactly sight or hearing, but fulfils all the functions of both these modes of perception.

An opinion so improbable will be thought by some scarcely worthy of consideration. Its extensive reception, however, among a large number of continental writers, together with some other reasons which will become apparent, must prevent our passing it over as an idle speculation. The facts, also, of somnambulism are, as we have above remarked, deserving of further attention on account of their relation to a variety of obscure pathological phenomena, with which we shall have to compare them. For these reasons we deem it necessary to call the attention of our readers to some of the most remarkable of the cases of somnambulism which have been recorded in different countries, and which are occasionally appealed to as affording evidence on controverted points.

Somnambulism was known to Hippocrates and Aristotle, and to Galen by his own experience, but is briefly mentioned by them. Diogenes Laertius has recorded two cases of this affection. One

was that of a stoic philosopher, who in this state used to compose works, read, and correct them. Such actions, as M. Bertrand observes, under the ordinary circumstances would imply the possession of sight; still this writer is inclined to maintain that somnambulists have rather a new faculty which supplies the place of sight, though he admits that the supposition should not be adopted without incontestable proof. Gassendi has related in a more detailed manner several cases of somnambulism. These are extracted by Muratori in his work on The Imagination, in which are also to be found some of the most interesting facts on record connected with this and other mental phenomena.* One of Gassendi's somnambulists used to rise and dress himself in his sleep, go down to the cellar and draw wine from a cask: he appeared to see in the dark as well as in a clear day; but when he awoke either in the street or cellar, he was obliged to grope and feel his way back to his bed. He always answered his wife as if awake, but in the morning recollected nothing of what had passed. It often seemed to him as if there was not light enough, and he thought he had risen before day. He then struck fire, and lighted a candle. Another sleep-walker, a countryman of Gassendi, passed on stilts over a swollen torrent in the night, but on waking was afraid to return before daylight, or until the water had subsided. Two of the most curious and best related cases on record are those of Signor Augustin Forari and John Baptist Negretti; both of these are given by Muratori, from whom we shall take a brief extract of them.

"Signor Augustin was an Italian nobleman, dark, thin, melancholic, and cold-blooded, addicted to the study of the abstract sciences. His attacks occurred at the waning of the moon, and were stronger in autumn and winter than in the summer. An eye-witness, Vigneul Marville, gave the following description of them.

"One evening towards the end of October, we played at various games after dinner; Signor Augustin took a part in them along with the rest of the company, and afterwards retired to repose. At eleven o'clock his servant told us that his master would walk that night, and that we might come and watch him. I examined him after some time with a candle in my hand. He was lying upon his back, and sleeping with open, staring, unmoved eyes. We were told that this was a sure sign that he would walk in his sleep. I felt his hands and found them extremely cold, and his pulse beat so slowly that his blood appeared not to circulate. We played a trictrac until the spectacle began. It was about midnight, when Signor Augustin drew aside the bed-curtains with violence, arose, and put on his clothes. I went up to him and held the light under his eyes. He took no notice of it, although his eyes were open and staring. Before he put on his hat, he fastened on his sword-belt, which hung on the bed-post: the sword had been removed. Signor Augustin then went in and out of several rooms, approached the fire, warmed himself in an arm-chair, and went thence into a closet where was his wardrobe. He sought something in it, put all the things into disorder, and having set them right again locked the door and put the key into his pocket. He went to the door of the chamber, opened it, and stepped out on the staircase. When he came below, one of us made a noise by accident: he appeared frightened, and hastened his steps. His servant desired us to move softly and not to speak, or he would become out of his mind; and sometimes he ran as if he were pursued, if the least noise was made by those standing round him. He then went into a large court and to the stable, stroked his horse, bridled it, and looked for the saddle to put on it. As he did not find it in the accustomed place, he appeared confused. He then mounted his horse, and galloped to the house door. He found this shut; dismounted, and knocked with a stone which he picked up, several times at the door. After many unsuccessful efforts he remounted, and led his horse to the watering-place, which was at the other end of the court, let him drink, tied him to a post, and went quietly to the house. Upon hearing a noise which the servants made in the kitchen, he listened attentively, went to the door, and held his ear to the keyhole. After some time he went to the other side, and into a parlour in which was a billiard-table. He walked round it several times, and acted the motions of a players. He then went to a harpsichord on which he was accustomed to practise, and played a few irregular airs. After having moved about for two hours, he went to his room and threw himself upon his bed clothed as he was, and the next morning we found him in the same state; for as often as his attack came on, he slept afterwards from eight to ten hours. The servants declared that they could only put an end to his paroxysms either by tickling him under the soles of his feet, or by blowing a trumpet in his ears."

The history of Negretti was published separately by two physicians, Righellini and Pigatti, who were both eye-witnesses of the curious facts which they relate. The former corresponded with Muratori, and gave replies to his questions as to particular circumstances. Negretti was about twenty-four years old, was a sleep-walker from his eleventh year, but his attacks only occurred in the month of March, lasting at farthest till the month of April. He was a servant of Marquis Luigi Sale. On the evening of the 16th of March, 1740, after going to sleep on a bench in the kitchen, he began first to talk, then walked about, went to the dining-room and spread a table for dinner, placed himself behind a chair with a plate in his hand, as if waiting on his master. After waiting until he thought his master had dined, he uncovered the table, put away all the materials in a basket, which he locked in a cupboard. He afterwards warmed a bed, locked up the house, and prepared for his nightly rest. Being then awakened and asked if he remembered what he had been doing, he answered, no. This, however, was not always: he often recollected what he had been doing. Pigatti says that he would awake when water was thrown into his face, or when his eyes were forcibly opened. Ac-

*L. A. Muratori, della forza della Fantasia Umana, Venez. 1766. It is singular that this treatise has not been translated into either French or English. The German translation is a very valuable work, containing various notes and additions by the editor, Richertz of Göttingen.

cording to Maffei, he then remained some time faint and stupid. Righellini assured Muratori that his eyes were firmly closed during the paroxysm, and that, when a candle was put near to them, he took no notice of it. Sometimes he struck himself against the wall, and even hurt himself severely. Hence it would seem that he was directed in his movements by habit, and had no actual perception of external objects. This is confirmed by the assurance that if any body pushed him he got out of the way, and moved his arms rapidly about on every side, and that when he was in a place of which he had no distinct knowledge, he felt with his hands all the objects about him, and displayed much inaccuracy in his proceedings; but in places to which he had been accustomed, he was under no confusion, but went through his business very cleverly. Pigatti shut a door through which he had just passed: he struck himself against it on returning. The writer last mentioned was confident that Negretti could not see. He sometimes carried about with him a candle, as if to give him light in his employment; but on a bottle being substituted, took it and carried it, fancying that it was a candle. He once said during his sleep that he must go and hold a light to his master in his coach. Righellini followed him closely, and remarked that he stood still at the corners of the streets with his torch in his hand not lighted, and waited a while in order that the coach which he supposed to be following might pass through the place where light was required. On the 18th of March he went through nearly the same process as before, in laying a table, &c. and then went to the kitchen and sat down to supper. Signor Righellini observed him in company with many other cavalieri very curious to see him eat. At once he said, as recollecting himself, 'How can I so forget? To-day is Friday, and I must not dine." He then locked up every thing and went to bed. On another occasion he ate several cakes of bread and some salad, which he had just before demanded of the cook. He then went with a lighted candle into the cellar and drew wine, which he drank. All these acts he performed as usual, and carried a tray upon which were wine-glasses and knives, turning it obliquely on passing through a narrow doorway, but avoiding any accident.

Our limits prevent us from extracting the further details which relate to the history of this night-wanderer. The preceding relations, to which we shall incidentally add a few other particulars from the same sources, furnish a body of facts sufficient for displaying, as far as these individual cases are concerned, the state of the faculties in somnambulism. In the analysis of these we shall now attempt to discover some general principle which may serve as a clue to the variety of analogous phenomena on record. To begin with the inferior senses. Pigatti says that Negretti sat down to eat a bowl of salad which he had prepared. It was taken from him, and some strongly seasoned cabbage put in its place; this he eat without perceiving the difference, as he did also some pudding which was presently substituted. At another time, having asked for wine, he drank water which was given to him. He sniffed ground coffee instead of snuff, which he had demanded. Other sleep-walkers are well known to have detected similar deceptions, as it will appear from a case hereafter to be related. The difference appears to be in the degree of attention: a more lively perception as to the qualities of the object desired existed in one case than in the other, the mind being more directed to particular sensations in the one case, and more distracted or diverted from them in the other.

The sense of hearing presents similar variations. In general, somnambulists do not hear persons who talk aloud in their presence. It has often been observed that very loud noises are unperceived by them,—that a trumpet must be sounded in their ears before their attention can be forcibly withdrawn from reverie to the perception of the real world, and to the waking state. At other times they converse and hear the lowest sounds. Signor Augustin repeatedly listened and heard slight noises at a distance. The difference seems here to depend upon the same principle as in the preceding instances which refer to smell and taste. When attention is by a voluntary act directed to the particular operations of sense, the perceptive faculty of the sleeper is perfect, even remarkably acute. But when his mind is distracted, his reverie presenting different objects, even loud sounds are imperceptible to him. Perhaps from the same consideration we shall obtain a clue to unravel the perplexing varieties of phenomena connected with the state of vision in some cases which will be presently mentioned. Negretti, as it seems, had his eyes shut and saw not. Habit guided him in places with which he was familiar, and in other places he frequently showed the want of accurate perception, and assisted himself by feeling and groping about. Etmuller observed that sleep-walkers go about "oculis clausis," but he adds that some have acted "oculis conniventibus." Haller says decidedly, that they get out of their beds fast asleep, their eyes being either firmly closed or otherwise sightless, since a strong light is unperceived, though held near. (Elem. Physiol. tom. v. p. 626.) The fact is doubtless, yet why may we not avail ourselves of the analogy presented by the sense of hearing, and allow the insensibility to light under the ordinary circumstances of sleep-walking to be compatible with the use of the same faculty in other instances where we can find no other explanation of the phenomena? Such cases will presently come under our notice. Negretti and Augustin did not see, and Richertz well observes that the want of vision seems to have been supplied by various means. Habit, as we have observed, is the principal guide. The sense of feeling, when under the guidance of attention, and even that of hearing in similar circumstances, appear to be remarkably acute. Then as to the hypothesis to which in the sequel we shall have further to advert, viz. that somnambulists have a new kind of sight independent of the eyes;—although we are not called upon to disprove such a position, yet many facts may be found in the history above related which would enable us to do so. The defect was not supplied in such a degree and manner as the hypothesis implies. Negretti stood behind his master's chair supposing him to be at dinner; he fancied that the torch which he held to guide

his coach was lighted, when it was not. In a variety of cases he displayed the total want of any sensation analogous to sight; he stumbled when he walked in places to which he had not been accustomed, felt his way on various sides, struck himself against a wall. In attempting to pass through a closed door, he hurt himself. Other histories of somnambulists supply parallel remarks. Galen mentions of himself that he once walked about a whole night in his sleep till he was awakened by striking himself against a stone which happened to be in his way. (De Motu Musculorum, lib. ii. cap. 5.)

There are facts which prove that even the sense of feeling, which is the principal guiding faculty in somnambulism, is limited in its sphere of action, and exists under a modification similar to that which affects the other perceptive powers, and which, according to the opinion above stated, explains the anomalies of their operation. Negretti seems not to have distinguished accurately even objects of feeling *when they were not particularly the objects of attention*. When struck a blow by a stick on the leg, he fancied that a dog had touched him, and scolded it. Being again struck, he threw a bit of bread, calling the hound by name. A muff was thrown at him, which he again took for the dog. (*Muratori*, ubi supra, p. 323.)

In other instances somnambulists have been known to write, and even to correct their compositions, and to do other acts which could not possibly be performed without sight.

Castelli, a sleep-walker, whose case is one of the most remarkable, was a pupil of Porati, an Italian apothecary. His history has been published by Francesco Soave, a physician, who personally observed him. He was found one night in the act of translating from Italian into French, and looked for words in a dictionary as usual, being asleep. His candle being extinguished, he found himself to be in the dark, groped for the candle, and went to light it again at the kitchen fire. Bertrand thinks that Castelli did not really experience the want of light, because the room was, as we are informed, actually illumined at the time by other candles. This is a most improbable supposition, and seems irreconcilable with the fact just related, that he perceived his candle to become extinguished. There are, indeed, many circumstances related of this somnambulist which prove to our entire conviction that he not only saw, but had his other organs of sense in a state capable of perception whenever his attention was excited, and he wished to avail himself of their operation. He used to leave his bed, go down to the shop and weigh out medicines to supposed customers, to whom he talked. When any one conversed with him on a subject on which his mind was bent, he gave rational answers. He had been reading Macquer's Chemistry, and somebody altered his marks to try if he would notice it. This puzzled him, and he said, "Bel piacere di sempre togliermi i segni." He found his place and read aloud, but his voice growing fainter, his master told him to raise it, which he did. Yet he perceived none of the persons standing round him, and "though he heard," says Soave, "any conversation which was in conformity with the train of his ideas, he heard nothing of the discourse which those persons held on other subjects." His eyes seemed to be very sensible to objects relating to his thoughts, but appeared to have no life in them, and so fixed were they, that when he read he was observed not to move his eyes but his whole head, from one side of the page to the other.*

Facts which appear even still more strongly to evince the possession of accurate sight, are related in a very curious case of somnambulism, which was published in the French Encyclopædia. The account has been copied by Bertrand, who endeavours to turn aside the evidence afforded by it, or to reconcile it with his own hypothesis. We shall conclude this part of our inquiry with an abstract of the most remarkable facts contained in the narrative, and request our readers to bear in mind the explanation of the phenomena which we have proposed.

This somnambulist was a young priest in a Catholic seminary; the witness and reporter of the facts, the archbishop of Bordeaux, who used to go into his chamber after the priest was gone to sleep, and observe his proceedings. He sometimes arose from bed, took paper, and wrote sermons. After finishing a page, he read (if the act was properly reading) the whole aloud; and, if necessary, erased words and wrote his corrections over the line with great accuracy. "I have seen the beginning of one of his sermons which he had written when asleep; it was well composed, but one correction surprised me: having written at first the words 'ce divin enfant,' he had afterwards effaced the word *divin*, and writtten over it *adorable*. Then perceiving that *ce* could not stand before the last word, he had dexterously inserted a *t*, so as to make the word *cet*." The witness, in order to ascertain whether he made use of his eyes, put a card under his chin, so as to intercept the sight of the paper which was on the table; but he continued to write without perceiving it. Wishing to know by what means he judged of the presence of objects which were under his eyes, the witness took from him the paper on which he was writing, and substituted others repeatedly. He always perceived this by the difference of size, for when a paper of exactly the same shape was given to him, he took it for his own, and wrote his corrections on places corresponding to those on the paper which had been taken away from him. The most astonishing thing is that he would write music with great exactness, tracing on it at equal distances the five lines, and putting upon them the clef, flats, and sharps. Afterwards he marked the notes, at first white, and then blackened those which were to be black; the words were written under, and once happening to make them too long, he quickly perceived that they were not exactly under the corresponding notes; he corrected this inaccuracy by rubbing out what he had written, and putting the line below with the greatest precision.

On one occasion, in the midst of winter, he fancied himself to be walking on the bank of a

* Riflessioni sopra il Somnambolismo; di Francesco Soave. Many of the particulars relating to this case of Castelli have been inserted by Mr. P. B. Duncan, fellow of New College, in a very ingenious essay on somnambulism.

river, and to see a child fall into it, in danger of drowning. He leaped into the river, as he thought, in order to rescue the child, and actually threw himself upon his bed with the action of a man swimming. He imitated the movements of a swimmer for some time, and at length feeling in a corner of the bed a bundle of the clothes, fancied that he had seized the child, held it in one hand, and with the other swam, as he supposed, to the bank of the river; he there put down the bundle, and came out shivering and chattering with his teeth, as if he really had just emerged from a cold stream. He said to the persons near him that it was freezing, and that he was almost dead with cold, and asked for a glass of brandy to warm him; as there was none at hand, they gave him water, but he knew the deception, and again demanded brandy, expressing the risk which he incurred. He drank a glass of strong liquor, and seemed refreshed, but, without awaking, lay down, and continued to sleep soundly.

The reporters of this curious story suggest, by way of comment, the following queries:—"1. How is it possible for a man buried in profound sleep, to hear, speak, write, see, and in short enjoy the use of his senses, and perform correctly different movements? To facilitate the solution of this problem, we shall add," say the writers, "that the somnambulist sees only those objects which he seeks, or which are present to his imagination. This individual composed sermons, saw his paper, his ink, pens, could distinguish whether they marked or not the paper. For the rest he did not suspect that any person was in his room, neither seeing nor hearing any body, unless when he had asked for any thing.

"2. How any person can experience sensation without the assistance of the organs of sense? The somnambulist above mentioned appeared evidently to see those objects which had relation to his own ideas. When he traced the notes of music, he knew exactly those which ought to be black and those that were to be left white, and without mistake blackened the former and omitted the others, and if the lines were not dry, he took the precaution to avoid blotting them. There is no reason to suspect that the other channels of sensation were less interrupted than the ordinary one of vision. This might have been ascertained by stopping his ears, &c.

"3. How did it happen that during the paroxysm of somnambulism he remembered what had occurred during former paroxysms, although, when awake, he lost all traces of such matters?

"4. How is it possible that, without any real cause, he was strongly affected by agents of which he had only imagined the existence, as by the coldness of the water, in which he supposed himself to be immersed?"

We shall leave these inquiries to the consideration of our readers, and now proceed to another division of the subject.

II.—Ecstatic or cataleptic Somnambulism.

A morbid affection analogous in many of its phenomena to sleep-walking, but occurring under different circumstances, has been well known to medical writers since the time of Sauvages and Lorry, who first described it. Sauvages gave it the designation of cataleptic somnambulism. According to this writer the attack is ushered in and followed by a complete fit of catalepsy. This happened in the case described by him, but in other instances the preceding symptoms are not so strongly marked: coma, or insensibility in various degrees, may, however, be considered universally present. The most correct idea of the phenomena of this affection will be conveyed by some examples. The following is the first case published by Sauvages. "In the month of April 1737, a female who had been for some time affected with fits of hysterical catalepsy, experienced in conjunction with these attacks other symptoms, of which she had more than fifty returns. The fits were divided into three periods; the beginning and termination had perfectly the character of catalepsy; the intermediate period, which sometimes lasted from the morning till the evening, was occupied by what the girls in the house called the *live fit*, while they termed the catalepsy the *dead fit*. I shall now describe the phenomena," says Sauvages, "which I should certainly have believed to be feigned if I had not become convinced of the contrary by numerous proofs. What I shall say respecting one attack may be understood to apply, with the variation of some circumstances, to all the rest. On the 5th of April 1737, visiting the hospital at ten o'clock in the morning, I found the patient in bed, which she kept on account of her debility and the pain in her head: the fit of catalepsy had just seized her, and it quitted her after five or six minutes; this was perceived by her yawning and raising herself into a sitting posture, the prelude to the following scene. She began to talk with a degree of animation and *esprit* never observed in her except when in this state. She sometimes changed her subject, and appeared to converse with some friends whom she saw around her bed. Her discourse had relation to what she had said during her attack on the preceding day. She repeated word for word an instruction in the form of a catechism, which she had heard on the evening before, and she made pointed applications of it to persons in the house, whom she took care to designate by invented names, accompanying the whole with gestures and movements of her eyes, which *she kept open*, and alluding to the circumstances and actions of the preceding evening. Yet she was all this time in deep sleep; a fact which was strongly averred, but which I should never have ventured to declare if I had not obtained satisfactory proof by a series of experiments on the organs of sense: when she began to talk, a blow of the hand inflicted smartly on her face, a finger moved rapidly towards her eyes, a lighted candle brought so near to the organ of vision as even to burn the hair of her eyebrows, a person unseen uttering suddenly a loud cry into her ear, and making a stunning noise with a stone struck forcibly against her bedstead, brandy and a solution of ammoniacal salt placed under her eyes and introduced into her mouth, the feather of a pen, and afterwards the extremity of a finger applied on the cornea, Spanish snuff blown into the nostrils, pricking by pins, twisting her fingers; all these means were tried without producing the least sign of feeling or perception. Soon afterwards she rose, and I expected to see her strike

herself against the neighbouring beds; but she passed between them and turned corners with the greatest exactness, avoiding chairs and other furniture that happened to be in her way, and having walked about the ward, returned between the beds without feeling her way, lay down, covered herself, and in a few minutes became again cataleptic. She afterwards awoke as if from a deep sleep, and perceiving by the looks of those about her that she had been in her fits, she became very confused and wept all the rest of the day, not having the least idea of what had passed during the paroxysm." Sauvages adds that this patient recovered; her fits became less frequent; she had some relapses, but the disorder at length nearly left her.*

Lorry has described the phenomena of two remarkable cases of ecstasis, of which he was an eye-witness. A woman in a state resembling somnambulism used to converse aloud with absent persons, supposing them to be present. She was so insensible to external impressions, that she could not be excited by pricking or pinching her body, yet she perceived objects to which the current of her thoughts directed her, or to which they had relation. Her arms and fingers retained the positions in which they were placed till they were changed by a voluntary movement of the limb. After the paroxysm she had lost all recollection of what had passed. The other case given by Lorry was that of a female who had deficient catamenia. During her paroxysms she used to address herself to some individual actually present, whom she evidently saw, while all that she said to him turned upon the subject of her reverie. In the mean time she appeared unconscious of the presence of others, and could not be made to hear them or perceive them. "This fact," says Lorry, "I witnessed with the utmost astonishment, but many other persons are living who can attest it. The mother of this female died unexpectedly; after which the daughter used to hold conversations with her as if she were present."

A remarkable circumstance in these cases is the fact that while the individual is insensible to all other impressions in a wonderful degree, he retains perception of all objects which fall in with the course of his ideas, or connect themselves with the thoughts and feelings which occupy his attention for the time being. This feature is common to the cases of ecstasis and somnambulism. It was observed in an example of the former kind, of which an account was published several years ago by the writer of this article. A boy, about thirteen or fourteen years of age, suddenly exclaimed that somebody was beating him on his head, and fell into a state of insensibility; he became subject afterwards to similar attacks. He first perceived a mist or darkness before his eyes, and would say that he was then going off. He became then unconscious of external impressions; had his eyes open, but did not perceive objects; used to hold conversations with absent persons, repeat his lessons, supposing himself to be at school, and play on a flute, during which action he evidently perceived that other boys accompanied him, and evidently directed his attention to them. He recovered from this state by starting as if from sleep, and never retained the slightest trace of any occurrence during the paroxysm. The circumstance above indicated, in reference to the state of the perceptive faculty, is important as illustrating the character of these affections, and as accounting for the phenomena.

Another striking characteristic of this affection is the instantaneous change which it occasions in the thoughts and state of consciousness, and in the whole catastasis of the mind, the total suspension of present ideas which takes place during an indefinite period, and the equally sudden and remarkable restoration of the former state of mind after the termination of the paroxysm. These facts are well illustrated by some cases published by Professor Silliman of Yale College, in the American Journal of Science, of which we shall give a brief abstract.

Case 1. A lady in New England, of respectable family, became subject to paroxysms of delirium, which came on suddenly, and after continuing an indefinite time, went off as suddenly, leaving her mind perfectly rational. It often happened that when she was engaged in conversation she would stop short in the midst of it, become in a moment delirious, and commence a conversation on some other subject not having the remotest connection with the previous one; nor would she advert to that during her delirium. "When she became natural again, she would pursue the same conversation in which she had been engaged during the lucid interval, beginning where she had left off. To such a degree was this carried, that she would complete an unfinished story or sentence, or even an unfinished word. When the next delirious paroxysms came on, she would continue the conversation which she had been pursuing in her preceding paroxysm; so that she appeared as a person might be supposed to do *who had two souls*, each occasionally dormant and occasionally active, and utterly ignorant of what the other was doing." It is evident, that, although this affection is termed delirium, it was neither that state in the ordinary acceptation of terms, nor any form of madness, but one of coherent reverie. We have no means of forming an opinion as to the state of mind which subsisted during the paroxysm in the succeeding cases.

Case 2. An intelligent lady, in the state of New York, undertook a piece of fine needle-work, to which she devoted her time almost constantly for many days. Before its completion she became suddenly delirious, and she continued in that state about seven years. She said not a word during this time about her needle-work, but, on recovering suddenly from the affection, immediately inquired respecting it.

Case 3. A farmer, in New England, became dejected and melancholy under the impression that he had made an unwise sale of his property. He was preparing for the enclosure of a lot of land, and began with a beetle and wedges to split timber; at night he put his tools into a hollow tree and went home. Here he was seized with delirium, which continued several years. He sud-

* Histoire de l'Académie des Sciences, an. 1742. Traité du Somnambulisme, par A. Bertrand, Paris, 1823. A very curious and remarkable case of ecstatic somnambulism is to be found in the German translation of Muratori. It is extracted by Richertz from the Breslau Sammlungen. See Muratori über die Einbildungskraft, band. i. p. 361.

denly recovered, and the first question which he asked was, whether his sons had brought in the beetle and wedges? He appeared to be wholly unconscious of the lapse of time from the commencement of his attack. His sons avoided any explanation, and simply replied that they had been unable to find the tools. He immediately rose from his bed, went into the field where he had been at work a number of years before, and found the wedges and the rings of the beetle where he had left them, the beetle itself having mouldered away.

The phenomenon of thought alternately interrupted and restored, or of *dipsychia*, as we might term it in following Professor Silliman's suggestion, though it reminds us of the old romantic tales of princes laid asleep in enchanted castles, is nevertheless confirmed by sufficient evidence, and may be considered as a well-established fact. An instance of this description has been reported in the Edin. Philosophical Transactions by Dr. Dyce,* and is cited by Dr. Abercrombie. The patient, who was a servant-girl, was first attacked by fits of somnolency during the day, which came on with a cloudiness before her eyes and a pain in her head. In these fits she talked of scenes and transactions which appeared to be as in a dream, used to follow her occupations, dressed herself and the children of the family, and laid out a table correctly for breakfast. Being taken to church during the attack, she behaved properly, evidently attended to and was affected by the preacher so as to shed tears. In the next paroxysm she gave a distinct account of the former, although during the interval she had no recollection of being at church. During the attack her eyelids were generally half shut; her eyes sometimes resembling those of a person affected with amaurosis, that is, with a dilated and insensible state of the pupil, but sometimes they were quite natural. She had a dull vacant look, but when excited knew what was said to her, though she often mistook the speaker: it was observed that she discerned objects which were but faintly illuminated. The paroxysms generally continued about an hour, but she could be roused out of them; and then she yawned and stretched herself, like a person awaking out of sleep. At one time she read distinctly a portion of a book that was presented to her, and she sang much better than in the waking state. After six months this affection ceased on the appearance of the catamenia.

However extraordinary are many of the phenomena presented by these cases, as to the different states of consciousness manifested in them, still there is nothing that establishes the opinion that sensation has taken place in any instance through unusual media. In many of the above instances of ecstasis or cataleptic somnambulism—for it is to them that we confine our reference at present—we are informed that the individuals affected had their eyes open and saw, and otherwise perceived objects by the ordinary instruments of sensation. This circumstance throws a great additional improbability on the opinion of some late writers to which we have already adverted, and shall direct our attention more fully in the sequel.

A series of cases remain to be noticed in which individuals are reported to have had the usual channels of perception entirely closed, while the sense of sight, or something analogous to it, was diffused over the whole surface of the body, or transferred to the fingers' ends, while smell and hearing obtained a new seat in the epigastrium. As these wonderful relations have been reported and admitted chiefly by the advocates of animal magnetism, and in connection with the evidence brought forward by them in proof of their doctrines, we have hitherto merely alluded to them, being unwilling to blend the consideration of facts which, though clearly authentic, are in themselves sufficiently extraordinary, with that of stories which most persons in this country look upon as entirely fabulous and absurd; while those who do not reject them in the mass find it extremely difficult to draw a line which may serve as a limit to the demands made upon their credulity. We must, however, proceed to this part of our subject, after laying before our readers what is a necessary prelude to it, namely, a brief outline of the history of animal magnetism, and the controversies to which its discovery or invention has given rise.

III.—Of Artificial Somnambulism. History of Animal Magnetism.

It is well known that the practisers of animal magnetism profess to have the power of calling forth, by the exercise of their art, a state of the system analogous to that of natural somnambulism, or to the ecstacy of cataleptic persons, and that surprising accounts are related of individuals in this state. They are said to become possessed of *clairvoyance*, a sort of second sight, or the power of seeing at an indefinite distance, of foretelling future events, discovering diseases in the interior of their own bodies and in those of others, knowing the unexpressed thoughts of persons by whom they are magnetised, or with whom they are brought into magnetic connection. Such testimonies are treated in this country with the ridicule which they seem at the first view of the subject to deserve; they are rejected in the mass; few persons give themselves the trouble to inquire whether there is any basis of truth on which a superstructure of such extraordinary pretensions has been raised. The Germans and French have treated the matter differently. Among the physiologists and other scientific men on the continent, many are persuaded that animal magnetism, though its powers have been greatly exaggerated, is not without a foundation in truth, and even contains in itself the discovery of some hitherto unknown and very important fact or series of facts in the animal economy. M. Cuvier expressed this opinion many years since, and long before the persuasion became so general as it is at present. He says, "We must confess that it is very difficult, in the experiments which have for their object the action that the nervous system of two different individuals can exercise one upon the other, to distinguish the effect of the imagination of the individual upon whom the experiment is tried, from the physical results produced by the

* Transactions of the Royal Society of Edinburgh, vol. ix. The case related by Dr. Dyce is very curious, and in some of its particulars bears resemblance to the history of Negretti.

person who acts upon him. The effects, however, obtained on persons ignorant of the agency, and upon individuals whom the operation itself has deprived of consciousness, and those which animals present, do not permit us to doubt that the proximity of two animated bodies in certain positions, combined with certain movements, *have a real effect*, independently of all participation of the fancy. It appears also clearly that these effects arise from some communication which is established between their nervous systems." Here we find Baron Cuvier giving a full assent to the fundamental doctrine of the animal magnetists.

M. De la Place, in his work entitled "Théorie Analytique du Calcul des Probabilités," says, "The singular phenomena which result from the extreme sensibility of the nerves of some individuals, have given rise to many opinions upon the existence of a new agent, that has been called animal magnetism. It is natural to suppose that the action of these causes is of a very delicate nature, and very easily disturbed by a number of accidental circumstances; thus, when in many cases it is not manifested, we must not conclude that it does not exist. We are so far from knowing all the agents of nature and their different modes of action, that it would be very unphilosophical to deny the existence of phenomena solely because they are inexplicable in the present state of our knowledge."

In Germany and other northern countries, animal magnetism has long had partisans among men celebrated for their attainments in science and rank in the medical profession. In Prussia, Hufeland, after opposing it, at length declared himself convinced by the evidence adduced in its support. At Berlin, M. Wohlfahrt; at Frankfort, Passavent; at Groningen, Baker; at Petersburg, Stoffresten, first physician to the empress of Russia, and Count Panin at Moscow, have admitted the reality and have pursued the practice of this art. At Stockholm it is customary for those who graduate in medicine to make animal magnetism the subject of inaugural dissertations. (*Bertrand*, Traité du Magnetisme Animal.)

It is unnecessary to multiply citations in order to evince the propriety of giving this subject a share of our attention. If so many intelligent persons in different countries, several of whom must be admitted to be competent to form correct opinions, and in general to be rather sceptical than credulous in their habits of judgment, have come, apparently under the guidance of evidence, to admit the existence of facts which among us are generally discredited, we have sufficient inducement to examine the real merits of the question, and to consider the statements made by the supporters of the new doctrine, before we determine finally to adhere to our own opinion.

We shall, without further apology, proceed to lay before our readers a brief statement of the history of animal magnetism, and refer those who wish for more ample information to the writings of Déleuze, Bertrand, Rostan, &c.

The supporters of animal magnetism carry back its history, as do the historians of freemasonry, to a period of high antiquity. Some of these writers persuade us that it was the great arcanum of the mysteries, the initiations, and secret ceremonies of the pagan world; that the vertigo of the Delphian priestess, the prophetic visions of the sibyls, the wonderful powers of magic, the raptures of eastern seers, and in fact all that is related of miraculous or portentous in former periods of the world, is to be explained by reference to this power, now for the first time developed and understood. Many passages have been discovered in the writings of the ancients which have appeared to afford some plausible ground for the supposition that animal magnetism was not unknown to the priests who ministered in the temples of Æsculapius, or in those of Apollo. Some of these passages bear allusions more or less obvious or probable to ceremonies not unlike those of the magnetisers. In none is the allusion in this sense more closely applicable than in a passage attributed to Solon, and preserved by Stobœus, which was first pointed out in a work very recently published:—

Πολλάχι δ'ἐξ ὀλιγῆς ὀδύνης μέγα γίγνεται ἄλγος,
Κοὐκ ἄν τις λύσαιτ' ἤπια φάρμακα δοῦς.
Τὸν δὲ κακαῖς νούσοισι κυκώμενον ἀργαλέαις τε
Ἁψαμένος χειροῖν αἶψα τίθησ' ὑγιῆ.

"The smallest hurts sometimes increase and rage
More than all art of physic can assuage.
Sometimes the fury of the worst disease
The hand by gentle stroking will appease."*

A passage in Plautus has been cited by the same writer. The poet means to express, in a humorous manner, "What if I knock him down!" *Quid si illum tractim tangam ut dormiat!* There seems to be an allusion to some method of setting persons asleep by a particular process of manipulation similar to that of the magnetisers.

It has been only in periods comparatively recent, and especially in the visionary times of Paracelsus and Van Helmont, that we find theories becoming general which approach very nearly to those of Mesmer, and in fact identify themselves with the very speculations which that singular person actually adopted and made the basis of his art. The doctrine of a subtile fluid universally diffused, which was supposed to be the agent in all the great movements of the heavenly bodies, was very long general, and served to account for the phenomena of electricity and of magnetism at the several periods of their discovery. By the chemical physiologists this fluid was imagined to have its chief seat in organized living bodies. Here a preparation was obviously made for pretensions such as those with which Mesmer began his career.

Bertrand says that Mesmer was born at Vienna; but another account, which is adopted by Mr. Colquhoun, states him to have been a Switzer by birth. However, he took his degree at Vienna in 1766, and wrote his inaugural dissertation, "*On the Influence of the Planets on the Human Body.*" According to his theory, all the phenomena of life depend upon a particular current of the universal magnetic fluid enclosed in each organized body. It can be increased or diminished in intensity by external agencies, and especially by the medium of magnetic instruments. According to Bertrand, Mesmer was a man of very

* See Mr. Colquhoun's Introduction to the Report on Animal Magnetism, by a Committee of the Royal Academy of Medicine of Paris.

moderate talents, but possessed with an ardent desire to distinguish himself by novelties, and by escaping from the beaten track of his contemporaries. Father Hell, a Jesuit, who was professor of astronomy at Vienna, had invented plates of a certain form for the purpose of performing experiments on the magnetic properties of different substances; these were applied by Mesmer to the bodies of his patients, and with results as marvellous as those which Perkins obtained in later times by his tractors. The effects of the magnetic remedy were published, but only drew on their author ridicule and contempt; and Mesmer quitted Vienna for Paris, as affording a more ample field. At the latter place he took up his residence in 1778; and here he soon became the object of general curiosity. Crowds of persons, of all ages and both sexes, resorted to him, in the hope of obtaining cures for their complaints; and his fame spread far and wide. He made some attempts to obtain the sanction of the Academy of Sciences and of the Royal Society of Medicine; but being treated with coldness, he expressed his contempt for such bodies, and declared that he sought patronage from the king, the father of his people, and not that "*d'un tas de petits importans.*" After some interval Mesmer addressed himself to the faculty of medicine, and became intimately associated with M. Deslon, a docteur-régent of that body, and physician to the Count d'Artois, who strongly espoused his part, notwithstanding the resolution of the faculty to expel any of its associates who refused to enter into a positive renunciation of Mesmer and his pretensions. Mesmer talked of leaving France and carrying his precious discovery into foreign countries; but the multitude of persons who placed a high value on his curative power prevailed upon the government to offer him a stipend of 30,000 livres in order to fix him among them. This he disdainfully refused, and went to Spa, where he was residing when the alarming intelligence was brought to him that Deslon had set up for himself, and was magnetising multitudes in Paris, and eclipsing his master. Mesmer returned to Paris, and engaged to communicate his secret to a certain number of persons, on condition of his receiving payment at the rate of 100 louis-d'or from each. By this arrangement he is said to have obtained the enormous sum of 340,000 livres. His pupils designated themselves as the Society "de l'harmonie." When they had acquired the instructions for which they had paid so considerable a sum, and were preparing to publish the same for the benefit of humanity, Mesmer complained indignantly of their conduct, declared that they were bound to secresy by an indenture, which appears to have been the fact; and being yet unable to prevent their proceeding, which interfered with his unbounded hopes of gain, left France, carrying with him the riches which he had acquired, and proclaiming that he had been cruelly treated and betrayed. (*Bertrand*, Traité du Magnetisme Animal.)

Animal magnetism was practised very extensively in France. Ladies of the first quality were among its most sanguine votaries, as well as crowds of all descriptions. At length the government interposed, it being evident that either good or mischievous results were likely to ensue from so popular an object of attention. The appointment of the celebrated royal commission to try the merits of Mesmerism is a great event in the history of this art. The commissioners were men of the highest authority in science; Franklin, Lavoisier, Bailly, and Jussieu were among the number. The report of their observations on the practices of animal magnetism, carried on at that time by M. Deslon, is an authentic and important document. It was drawn up by M. Bailly; and it is well observed by Bertrand, that no unprejudiced person who reads it can fail of partaking in the opinions of the celebrated men who were parties to its adoption.

The following is a description of the method in which Mesmer and his colleagues carried on their proceedings. According to this report, a little wooden tub, of different forms, round, oval, or square, raised one foot or one foot and a half, was placed in the middle of a large room. This tub was called "*the baquet;*" its covering was pierced with a certain number of holes, from out of which came branches of iron, jointed and flexible. The patients were placed in several rows round this "*baquet;*" and each person held his branch of iron, which, by means of the joints, could be applied directly to the part affected; a cord was placed round the bodies of the patients, which united them one to another. Sometimes a second chain was formed by communication with the hands, that is to say, by applying the thumb of one between the thumb and the first finger of the next person; the thumb thus held was then pressed, and the impression received on the left was returned by the right, and circulated all round. A piano-forte was placed in a corner of the room; different airs were played upon it; sometimes the sound of the voice in singing was added. All the magnetisers had in their hands a little rod of iron, ten or twelve inches long. This rod was looked upon as the conductor of magnetism; it possessed the advantage of concentrating it in its point, and of rendering the emanations more powerful. Sound, according to the principles of Mesmer, was also a conductor of magnetism; and, in order to communicate the fluid to the piano, it was sufficient to let the rod approach it. The cord with which the patients were surrounded was destined, as well as the chain of thumbs, to augment the effects by communication. The inside of the "*baquet*" was said to be so formed that it might concentrate the magnetic fluid; there was nothing, however, in reality, in its formation which could excite or retain magnetism or electricity.

The patients, ranged in great numbers and in several rows round the baquet, received magnetism by all the different ways: by the iron branches which come out of the tub; by the cord which was entangled round their bodies; by the union of the thumbs; by the sound of the piano, and agreeable voices which mingled with it. They were more directly magnetised by means of the finger and the iron rod, moved before the face, above or behind the head, and upon the diseased parts, always observing the distinction of the poles. They were acted upon by a fixed look, but, above all, they were magnetised by the appli-

cation of hands and by the pressure of fingers upon the hypochondria, and upon the abdominal region; an application often continued for a long time, sometimes during several hours. Such was the method of Mesmer, and to which was added a multitude of practices, much too long to describe. They magnetised in this manner several natural objects, and among others trees, which hence acquired magnetic virtue; so that persons who put themselves "en rapport" with them, fell into a crisis. They could likewise magnetise inanimate bodies, such as a bottle, a glass, or a cup.

The effects produced on the subjects of this strange ceremony are thus described :—

"Some remained calm and tranquil, others coughed, spat, felt some slight pain, a local or universal heat, and had sweats; others were agitated, tormented with convulsions, most extraordinary by their force, their number, and their duration.

"As soon as one began, another succeeded; the paroxysms lasted sometimes three hours; the patients spat a thick, viscous, and sometimes bloody fluid; the attacks were characterized by precipitate, violent, and involuntary movements of the members or the whole body, by constrictions of the throat, by spasms at the epigastrium and hypochondria, piercing cries, tears, hiccough, and immoderate laughter. Nothing could be more astonishing than the sight of these agitations and various seizures: the sympathies which established themselves between all these individuals struck us with amazement. We beheld the patients precipitating themselves one towards the other, smiling and talking to each other with affection, and mutually alleviating their agitations. Every thing depended upon the will of the magnetiser; were they in an apparently deep sleep, his voice, a look, a sign drew them out of it." "We cannot," say the commissioners of the king, "prevent ourselves from recognising in these constant effects a powerful agent, which acts upon patients, subdues them, and of which the person who magnetises them seems to be the depository."

The commissioners soon discovered that it was very difficult to ascertain to what point the results produced were the effects of imagination, to the excitement of which so many circumstances were adapted, and how far to any peculiar agency. They resorted to private trials of the same manipulations. Some of the most interesting of these experiments were performed at Passy, at the residence of Dr. Franklin, who could not be present at Paris at the public exhibition. Here M. Deslon tried his art in vain upon the obdurate American, as well as upon the members of his family, who, notwithstanding that some of them were ladies in delicate health, were found quite insensible to the whole ceremonial of magnetism. Neither of the other commissioners could perceive any effect in his own person. One of the experiments made at Passy is worthy of a particular recital. It consisted in the magnetising of a tree in Dr. Franklin's garden. M. Deslon affirmed that if this was done by himself and a youth introduced who should be purposely selected as an individual susceptible of the magnetic influence, the result would be manifest on his approaching the particular tree. A boy, aged twelve years, was chosen by M. Deslon, who insisted on the necessity of his presence and co-operation. Care, however, was taken to prevent collusion. The boy was made to approach four trees successively, without knowing which was the magnetised one, having his eyes covered with a bandage, and to embrace each tree for two minutes, according to the previous arrangement of M. Deslon. That gentleman stood in the garden, and kept his cane pointed at the magnetised tree, in order to maintain its magnetism. Under the first tree not magnetised, at the end of a minute the boy perspired in great drops, coughed, expectorated, felt a slight pain in his head; he was then twenty-seven feet distant from the magnetised tree. Under the second tree he felt stupor and the same pain in his head. Under the third tree these symptoms were greatly increased; he believed himself to be approaching the magnetised tree; he was, however, then at the distance of not less than thirty-eight feet from it. Under the fourth tree not magnetised, at the distance of twenty-four feet from the magnetised tree, the young man fell into a crisis. He lost all consciousness, was carried to a neighbouring grass-plot, where M. Deslon soon reanimated him. The operator accounted for this untoward phenomenon by saying that the trees had probably become spontaneously magnetic. "But," rejoined the commissioners, "if trees are in the dangerous habit of assuming this state of their own accord, a susceptible person walking in a garden must incur the continual risk of falling into a crisis."

The commissioners having repeated and varied the experiments in every way that seemed to afford an opportunity of arriving at the truth, at length came to the conclusion that the whole proceeding of the magnetisers was calculated in several ways to do injury; that it was devoid of any salutary or useful influence, and that the results were wholly to be attributed to imagination and other feelings, which were excited by the performances. M. Jussieu, however, refused to coincide in the report, and returned one of his own, which, though by no means favourable to Mesmer and his pretensions, and explaining most of the results in the same manner as M. Bailly had done, yet admitted that in four particular experiments, he could not account for the results by attributing them to imagination. He proposed an hypothesis of his own, viz., that animal heat, or, as he termed it, "*the electric fluid animalized*," directed and accumulated on certain parts, may be the cause of the effects produced.

Notwithstanding the unfavourable nature of this report, and the retirement of the principal from the scene, Mesmerism continued to be practised extensively in France. The members of the Society of Harmony, who were spread through the country, continued their operations in the provinces. Among them the Marquis Puységur was one of the most distinguished, and it was during his proceedings that the most remarkable phenomenon accompanying these exhibitions was first noticed. We allude to the production of that state which has been termed the magnetic or artificial somnambulism. The commissioners, in the report to which we have already alluded, had remarked that nothing was more astonishing than the spectacle which they witnessed in the operations of M. Deslon, and that they were equally

surprised at the profound repose of a part of the assembled group, and at the agitation of others. These opposite effects were produced by the same agency, according to the different predispositions of individuals. But as the method of display was gradually changed by later operators, the agitations in a great measure ceased to be observed, while the appearance of a state of somnolency became much more striking and general; and in numerous instances, though by no means in a great proportion of persons, a species of somnambulism displayed itself, of which we shall proceed below to examine the peculiar characters.

The political revolutions in France withdrew the public attention from animal magnetism. Many of the party interested in this pursuit perished, and others were exiled. It was not till the return of better times that the practice of this art was resumed, and its historians declare that on its revival animal magnetism was found to have retained very few features of its ancient character. The mode of treating patients was quite changed; the theory of the magnetisers was new; the only circumstances connecting the old magnetism of the age of Mesmer and his immediate disciples with the present method, is the appearance in both of somnolency and somnambulism.

We shall trace very rapidly the few remaining events in the history of animal magnetism, and then say a few words on its actual character.

In the year 1813, M. Déleuze, a writer highly respectable for his moral integrity, talents, and good sense, published his critical history of animal magnetism. The appearance of this work occasioned a favourable change in the opinion of many scientific men in respect to the new art, and some who had before concealed their opinions were now emboldened to speak more openly in defence of it. In 1820, M. Husson instituted a series of experiments at the Hôtel Dieu, which were attended by scientific men, and the result was a general conviction that some very powerful influence was brought into operation, though some difference of opinion existed as to the nature of this influence.

A series of experiments at the Salpêtrière was followed by similar effects, and it was now that animal magnetism obtained two highly distinguished proselytes, viz., M. Rostan, author of the essay on this art in the Dictionnaire de Médecine, and M. Georget, well known as a man of most acute penetration, who adopted with entire sincerity the whole doctrine.

In 1825, a letter was addressed by M. Foissac, an advocate for animal magnetism, to the Royal Academy of Medicine, urging that body to appoint a new commission to inquire into its merits. The proposal met with strong opposition, but was at length carried, and a number of individuals were requested to investigate the subject anew. The report of this body was drawn up by M. Husson, already well known as an advocate for animal magnetism. It is said by M. Bertrand to have produced a strong impression in favour of the art, but as this document has lately been translated and published in Scotland,* we shall say nothing further on the subject on the present occasion.

We have already observed that animal magnetism had some time ago obtained an extensive prevalence in the north of Europe, [and in Great Britain and this country it has, of late years, excited great interest.]

IV. — Present mode of operating in producing the phenomena of Animal Magnetism.

The person, as M. Rostan informs us, who is to be subject to this proceeding, is seated in a chair, and the operator places himself opposite in such a manner that their knees and the extremities of their feet may touch; then the magnetiser takes the thumbs of the subject and holds them till their temperature is brought into equilibrium with that of his own hands. He afterwards places his hands on the shoulders of the patient, and after some minutes draws them down the arms, taking care to direct the extremity of the fingers along the tract of the nerves which are there spread. This manipulation must be repeated several times, after which the hands must be applied to the epigastrium and held there for some instants of time, and then drawn down towards the knees and even to the feet. Afterwards the hands of the operator must be brought back to the head of the patient, care being taken to keep them in returning at a distance from his person; again they must be drawn down the arms, and as far as the feet. After this practice has been repeated several times, magnetic phenomena begin to display themselves. The patient experiences involuntary drawings of the limbs (tiraillemens), a sense of uneasiness (embarras) in the head, heaviness of the eyelids. After some repetitions of this performance, and sometimes even at the first sitting, he falls into a profound sleep.

M. Rostan adds that the magnetiser must not let his thoughts wander while he is performing the operation; his attention must be entirely concentrated upon it; any distraction of mind is incompatible with success. He informs us that the looks and the expression of countenance of the magnetiser powerfully contribute to the effect. We must observe that M. Rostan is one of those who suppose that the volition of the operator, his intense desire to bring about the result, the agency of *his* mind rather than any influence exerted on the mind of his patient, is the first and principal cause of the effects which ensue.

The effects of these proceedings are described by M. Bertrand nearly as follows.

The majority of persons subjected to magnetism experience results much less striking than somnambulism, and yet sufficiently remarkable.

Whatever may be the sex, temperament of the patient, or the nature of the disorder, the magnetic operation is generally followed by a singular calmness of feelings both physical and moral; the individual is conscious that the pains which he felt before the operation are gradually soothed; he experiences a desire of repose which it would be irksome to him to resist; his limbs become heavy, and his eyelids oppressed and drawn together. It is often declared by persons who have been subjected to this operation, that a sense

*Report of the Experiments on Animal Magnetism made by a Committee of the Royal Academy of Medicine of Paris, read at the Meetings of the 21st and 28th of June, 1831. Translated by J. C. Colquhoun, Esq. Edin. 1833.

of heat more or less strong follows, over the surface of the body, the hand of the magnetiser, though passing over the clothes, and even at the distance of some inches from the skin. In other instances the impression is rather of coldness than of warmth. This sensation is variously accounted for. The partisans of the art attribute it to the magnetic fluid ejected from the hand of the operator. This opinion seems to have been held long ago, since even Bailly thought it necessary to oppose it, and to contend that the heat felt was that of the hand, and the cold that of the atmospheric air displaced by its movement. Bertrand maintains that the effects, as well as all the results of magnetism, are to be attributed solely to the excited imagination of the person who submits himself to the operation; and he declares that the effects produced within his experience have always borne the most exact proportion to the conviction of the patient. The temperature of the body is generally increased, according to the same writer, in persons who undergo the magnetic treatment, and a tendency to perspiration follows; the pulse becomes in many instances increased in fulness. Some individuals experience a general tremor at every renewal of the manipulations, which has been as strongly marked as the rigor which belongs to the cold stage of an intermittent. Convulsions are not frequently produced under the present mode of magnetic treatment. Many persons who experience little or no effect from the proceedings of the magnetiser during his operation, yet feel, after the business is at an end, such weariness or numbness of the limbs that they fall back into their chairs in attempting to rise. This is attributed to the accumulation of the magnetic fluid in the lower extremities, and the operator relieves it by means of certain frictions, by which it is believed that the fluid is dissipated or drawn off. Bertrand supposes that the sensation has in general no other cause than the ordinary fatigue occasioned by remaining long in one posture.

The feelings above described are frequently followed by a sense of drowsiness, which is at the same time irresistible and agreeable. The patient then becomes plunged into a state of vague reverie. Individuals who have experienced this state describe it as affording some peculiar delight. This interval of dreaming repose is often followed by a sort of sleep, which, though not somnambulism, yet resembles it, and differs from ordinary sleep in this respect, that the patient can with great difficulty be roused from it before the period of its spontaneous cessation. The loudest noises are sometimes without effect, but the experiment is said to be occasionally dangerous, and to give rise to convulsions. After this follows somnambulism or the lucid state, which is in fact the characteristic peculiarity of the magnetic process. In some individuals all these phenomena display themselves in a very short time, and even during the first sitting; but in general it is not till after several repetitions of the proceeding that the full effects of animal magnetism are produced.

V.—Theory of Animal Magnetism.

How does the proceeding of the magnetisers operate in giving rise to these effects? The theory generally adopted by the partisans of this art is as follows. The instrument which is set in action is a peculiar vital fluid, secreted, or at least accumulated, in the brain, and to which the nerves perform the office of conductors. This fluid, which presides over all the movements of the body, is in an especial manner under the direction of the will, and may, under its influence, be propelled, or directed towards, and accumulated upon, any external body living or inert. If this theory is not clearly developed in the writings of all the magnetisers, it is at least implicitly adopted by them. The characteristic peculiarity of their doctrine is the admission of an influence, residing in the will of the magnetiser, on the emanation of the fluid alleged to exist, and on the consequent production of magnetic phenomena—an influence so great, according to the prevailing theory, that all magnetic action is regarded as subordinate to the exertion of will which sets the fluid in activity.

This hypothesis, which, as its supporters seem to be aware, must appear to the generality of persons very wild and visionary, has been supposed to derive some support from the conclusions of MM. Reil, Autenrieth, and Von Humboldt, who have attempted to prove the circulation of a nervous fluid, as well as the outward expansion of that fluid,—an expansion said to take place with a force and energy sufficient to form a sphere of activity resembling that of electrified bodies.

The doctrine thus stated, which has been with some trifling modifications adopted by MM. Georget, Rostan, Husson, and the generality of those who maintain the efficacy of animal magnetism in France, must, in the actual state of our knowledge, be considered at least as a very bold speculation. It soars so far above the region of observation and experiment that it cannot be subjected to proof, and it is at the same time impossible to determine whether, if conceded or established, it would be sufficient to account for the phenomena of which an explanation is sought. A much more probable opinion is that of M. Bertrand, who, after surveying with calmness and discrimination the whole history of magnetism, and witnessing with his own eyes the proceedings of the operators in this art, and practising them himself with considerable effect, comes at last to the conclusion that all the results of these operations are brought about through the influence of the mind; not by the will of the magnetiser, radiating forth his own vital spirit, and operating through this material or immaterial instrument on the vital spirits of other men, who are the passive recipients, but by the energy with which the feelings and imagination of the latter act upon themselves.

A strong confirmation of this opinion is derived by Bertrand, from the manner in which the Abbé Faria performed magnetisation, in which he brought about all the results of this agency in the persons subjected to his attempts without the instrumental methods used by Mesmer's earlier or later followers, and in a way which seems to preclude any other influence than that merely of the mind. Abbé Faria made no attempt to avoid the imputation of quackery, and actually received sums of money for his exhibitions. Yet in the opinion of M. Bertrand, he entertained much more correct notions of the real principles of magnetic phenomena than most of its partisans. Having been

taught by a long course of experiments that the cause of somnambulism, or, as he termed it, the *lucid sleep*, as well as of all the other magnetic phenomena, is connected with the state of the individual who is the subject of treatment, he varied his proceedings in such a manner as to render them expeditious. His method was as follows: He placed the patient in an arm-chair, and after telling him to shut his eyes and collect himself, suddenly pronounced, in a strong voice and imperative tone, the word "dormez," which generally produced on the individual an impression sufficiently strong to give a slight shock, and occasion warmth, transpiration, and sometimes somnambulism. If the first attempt failed, he tried the experiment a second, third, and even a fourth time, after which he declared the individual incapable of entering into the state of lucid sleep. Abbé Faria used to boast that he had put more than five thousand persons by this method into somnambulism, and though in this there may be some exaggeration, yet it is incontestable, as M. Bertrand observes, that he very often succeeded. A very considerable number of persons, removed from all suspicion of connivance, have experienced the influence of this method. The complete identity of the phenomena thus produced by a method which operated confessedly through the imagination, with those which display themselves under the ordinary treatment of the magnetisers, affords a strong reason for concluding that the results in other instances depend upon a similar principle. The state of crisis or insensibility produced in Dr. Franklin's garden, in the experiment above described, is sufficient of itself to prove that the influence ascribed to the imagination is not greater than the reality. We have here a cause proved to be sufficient for the phenomena, with which it is more philosophical to rest satisfied than to resort to the visionary hypothesis of the magnetic fluid radiated forth by the will of the operator upon surrounding persons and objects, or to confess the strange doctrine, that the volition of a human body is capable of exerting an immediate influence on other minds and bodies than his own. The generality of magnetisers persist, indeed, in the assertion that the manipulations of the performer have no effect upon the subject, unless accompanied by a powerful agency of the will, by continued, strong, intense volition to produce the result. This is denied by M. Bertrand, who declares that in trials made by himself precisely the same results followed, whether he WILLED to produce them or not, provided that the patient was inwardly persuaded that the whole ritual was duly observed.

A very important question refers to the curative powers of magnetism, and to the salutary effects which may be obtained from it in the treatment of disease. M. Bertrand declares that it is difficult to imagine with what facility the practisers of the art succeed in relieving the most severe affections of the nervous system. Attacks of epilepsy in particular are rendered considerably less frequent and severe by this method, skilfully employed; which displays in so remarkable a manner the influence of moral impressions on the physical state of the constitution. In some instances magnetism has been injurious by occasioning delay in the use of remedies of a more efficient class. and M. Déleuze enjoins the precept that a patient should never be consigned to the operation of a magnetiser without the advice of a physician. On the whole, when we consider the degree of suffering occasioned by disorders of the class over which magnetism exerts an influence through the medium of the imagination, and the little efficacy which ordinary remedies possess of alleviating or counteracting them, it is much to be wished that this art, notwithstanding the problematical nature of the theories connected with it, were better known to us in actual practice, and that some of the foreign operators would introduce it more extensively into this country.

VI.—Concluding Remarks on Animal Magnetism.

We shall briefly advert to the most remarkable phenomena which are said to characterise the lucid sleep of animal magnetism. Some of these far exceed the ordinary limits of belief, and seem to have been admitted on very imperfect evidence; others, which are sufficiently curious, though less wonderful than the former, are established by an accumulation of testimony which almost forces our assent.

1. *Phenomena referring to the state of consciousness and perception.*—Persons in magnetic somnambulism are said to be unconscious of external impressions in general, and yet to remain under the influence of the magnetiser, who is able to engage them in conversation, and without difficulty obtain replies to questions. Some facts already mentioned in connection with the preceding instances of cataleptic somnambulism or ecstasis, may tend to illustrate this peculiarity. In the relation of a case cited from Lorry, it appeared that a female who was the subject of that affection, held conversation with one person, and addressed herself constantly to him, while she was unaware of the presence of any other individual, and unconscious of her actual state. From this and other instances, it appears that certain individuals may become so connected with the reverie of the somnambulist, and so brought into relation with it, as to enter within his sphere of perception, while others are removed from it or separated by that mysterious veil which isolates the ecstatic person, and places him as it were in a world created by his own phantasy.

The degree of insensibility to external impressions which is said to exist in some cases of artificial somnambulism is altogether surprising. A lady has a scirrhous tumour in her breast which requires excision; she cannot summon courage to submit to the operation; she is thrown by a celebrated practitioner into magnetic sleep, undergoes the operation in that state, and on being awakened is surprised and sheds tears of joy on hearing that the much-dreaded business has been accomplished. Strange as this statement appears, it seems to have been credited by the committee appointed by the Royal Academy of Medicine. Few persons in this country will follow their example, and yet by rejecting it we do not extricate ourselves from the difficulties with which the subject is environed. The witnesses of the case are persons of undoubted veracity and reputation. It is hardly possible to conceive that the lady who was the subject of the

operation could be influenced by fondness for imposture and deceit to such an extent, as the supposition that she feigned or acted a part implies. On the other hand, if it is a matter of fact that a state is induced by animal magnetism such as we have seen described, a condition of the system is admitted to be present in persons subjected to its influence, in which ordinary sensation is suspended, and to what degree this suspension reaches we have no means of estimating. We are not justified in fixing arbitrarily any particular limit beyond which we will not believe the absence of feeling to extend. If the insensible state of the system induced, in some unintelligible way, but probably through the influence of the imagination, is analogous to natural or ecstatic somnambulism, we can only form an idea of its nature through this comparison; and when we refer to the cases above cited from Sauvages and others, we shall find reason to believe that the insensibility to outward impressions was in some of these instances very great, and almost insuperable by any stimuli whatever. Pricking by pins, irritating the ball of the eye, putting a solution of ammonia under the eyes and into the mouth, striking the face, and making all sorts of noises in the ears, produced no effect.

2. *Alleged transference and exaltation of feeling.*—But if we could admit that a state of the system takes place in persons subjected to animal magnetism characterized by a remarkable and even surprising insensibility to external impressions, we should still be far from being convinced of the alleged transference of specific sensations from their appropriate organs.

Some writers have endeavoured to illustrate this phenomenon, and afford a degree of probability to the statement respecting it, by bringing forward cases of natural somnambulism in which analogous facts are said by them to have been observed. The most remarkable of these were published by M. Pétetin, a physician of Lyons, in a work on what he entitled 'Animal Electricity.' In this the author detailed experiments made by him on eight cataleptic females,—a surprising number as occurring in the practice of one physician within a short space of time,—in which, according to the statement, the seat of sensation was transferred to the epigastrium. Young females, quite deaf to sounds in the ordinary way, heard plainly when M. Pétetin whispered to them close to the epigastrium. The great sympathetic had, it seems, taken up the suspended function of the auditory nerves. We shall not repeat the particulars from which this statement is deduced, but refer our readers to M. Pétetin and to M. Bertrand, who has given sufficient extracts. The latter writer also refers to the Annales de Chimie et de Physique, and to the Gazette de Santé, for December 1807, for the account of another female who saw with her fingers' ends; and to a publication in Germany, by Baron Strombeck, describing the case of a young woman, who had the still more admirable faculty of seeing through floors and walls, and even of discovering objects in an upper story of the house where she dwelt, and far removed from her own apartment. With respect to these cases, we may observe that they have been brought forward by professed supporters of animal magnetism, and that they occurred in places where that practice was at the time in vogue, and an object of lively interest.

Secondly, it is very important to remark that, whatever may be argued to the contrary by the votaries of magnetism, such phenomena have no parallel in the facts connected with natural somnambulism, as recorded before the period of magnetism, and uninfluenced by the representations of its professors. It was partly in order to establish this conclusion on a sufficient basis, that we were induced to investigate so fully the phenomena of somnambulism as recorded by the authors above cited. If this object has been accomplished, we are satisfied that the advocates of magnetism seek vainly in this quarter for facts which give countenance to their doctrine.

The powers of magnetism are variously estimated in their extent; but most practitioners maintain that the subjects of this art become endowed with the faculty of seeing, or in some way discovering the internal state of their own bodies. The sensibility of the ganglionic system, the nervous system of physical or organic life, being greatly exalted, the individual obtains an inward feeling, which in the natural state of the system has no existence, of the condition of his own viscera, whether healthy or morbid; he foreknows in some mysterious manner various changes which are destined to take place in it, and if indisposed foretels the event of his own case. This is the most moderate estimate of the faculty of prevision. With some it comes but little short of the gift of prophecy. The lucid sleeper is not limited to the contemplation of his own interior; he casts a penetrating glance into the body of his magnetiser, or of any person who is brought into magnetic relation with him; he has likewise an exalted or perfect instinct of remedies: in the enthusiastic language of a votary of magnetism, "he becomes inspired with the genius which animated Hippocrates!" (Lettre du Docteur Foissac à la Académie de Médecine. Août, 1825.)

Hippocrates made no pretension to an "*instinct of remedies*," otherwise we should not so often have heard the maxim, "Ars longa, vita brevis." But if we are invited to believe that certain *démoiselles* in Paris acquire, or recover—if it be a natural faculty of man—through magnetism, a sort of intuitive knowledge or instinctive appetency for remedies proper for diseases, as sick animals eat certain plants, we may fairly expect some decisive proof. Let the magnetisers obtain from their lucid patients remedies for some intractable disorders. If they learn to cure cancer, for example, all the world will make suitable acknowledgments. With respect to the power of prevision, as this faculty is very much lowered in its claims in the late report, and seems likely to dwindle to the mere foretelling of hysterical fits, any practitioner who has had much experience in hysteria will be ready to believe the fact, provided that the patients only remember their predictions at the period of fulfilment. As to the talent of seeing through stone walls, whether with the eyes or epigastrium, we do not think it can be turned to any practical advantage. Not so the inspection of living bodies, and the power of discovering morbid changes in the living thorax and abdo-

men. A magnetic nurse in each ward of an hospital, who could perform autopsy while the patients are alive, would save us a world of trouble in auscultation and percussion, and might even obviate the necessity of post-mortem examinations. But if she had the instinct of remedies, where would be the want of a physician?

[Of late, both in this country and in England, animal magnetism has experienced numerous revivals; all the phenomena previously ascribed to it having been produced and re-produced; and several extensions having been given to it, which we should be disposed to regard as eminently ridiculous, had not sober-minded men—sober-minded, that is, on many other matters—given their entire credence to them. But although we may hesitate as to the term to be applied to such credence, we must withhold our own in *toto*. Of the reality of certain of the effects ascribed to the manipulations of the animal magnetiser, no doubt, we think, ought to be entertained. The whole history of the art exhibits, that impressible individuals may have irregularities of nervous distribution induced through the medium of the senses, especially through those of sight and touch; and that somnambulism and hysteric sleep, with other phenomena referable to a like condition of the nervous system may be elicited; but that there is any thing like a magnetic fluid or agent, which may be communicated by the magnetiser to the subject of his experiments, is not only not proved, but is by no means presumable. There can be no doubt of the curious phenomena produced by this singular condition in the greatly developed sensibility to some irritants, and the total insensibility to others. The writer has seen different persons bear, without the slightest muscular action, the application of a straw or feather to the conjunctiva; the insertion of pointed bodies into various parts of the cutaneous surface; the extraction of a tooth, &c.; and yet start at the least puff of air made to come in contact with the face. These phenomena have been so often witnessed as not to admit of disbelief; and from what the writer has himself seen, he can readily credit the statements affirmed on respectable testimony, that even the major operations of surgery may have been executed whilst the patient was in this state of *mesmeric sleep*—if it may be so termed. As to the *Hellsehen*, *Clairvoyance*, or "lucidity of vision," said to have been possessed by the magnetised, could we assign our belief to it at all, it would only be on the ground—"*credo quiâ impossibile est*." When skilfully analysed, however, the phenomena have usually admitted of rational explanation.

One of the most startling of recent announcements is the statement, that if one of the compartments of the skull, as mapped out by the craniologist, be touched while a person is in the mesmeric state, he will immediately have his thoughts turned in the direction of the mental faculty that corresponds with the particular phrenological organ, and exhibit manifestations thereof in his actions and speech; yet it has been shown, that where the person operated upon has had no previous acquaintance of any kind with phrenology, not the slightest manifestation can be elicited, and whilst, by stating aloud, that the manipulator was about to touch a certain organ, although he touched another, the thoughts and actions corresponded with the organ mentioned, and not with the one over which the finger was placed; and moreover, that in no case could the phenomena be elicited in the child, who had never seen or heard of a phrenological chart or cast. (See on this subject, Dr. J. K. Mitchell, in *Quarterly Summary of the Transactions of the College of Physicians of Philadelphia* for May, Sept. and Oct. 1842, and the writer's *Medical Student*, p. 252, Philad. 1844.)]

We must now dismiss the subject of animal magnetism, and conclude this article, of which somnambulism is the proper subject, with some further observations on the pathology of that disorder.

VII.—Further observations on the Pathology of Somnambulism.

Richertz has observed that the tendency to somnambulism is to be reckoned among morbid conditions of the system, and he founds his opinion on the following reasons:—First, the relation of this affection to various diseases. He says that when somnambulism has continued long with frequent and severe returns, it is apt to pass into epilepsy, apoplexy, hypochondriasis, melancholy, and madness, to which last he thinks it has a near relation. (Zusätze des herausgebers von Muratori über die Einbildingskraft, th. i. p. 226, &c.) We shall presently consider the grounds of this opinion.

Secondly, he regards somnambulism as a disease, inasmuch as it is a phenomenon contrary to nature, which ordains sleep as a state of repose and refreshment from labour, whereas with night-wanderers it becomes an occasion of additional weariness and more than ordinary fatigue. Paroxysms of somnambulism are generally followed by a long and heavy sleep, and by a feeling of debility and lassitude on the ensuing day.

Among the predisponent causes of somnambulism, the most important, as it may be observed with respect to other diseases of the nervous system, is a peculiarity of constitution. This appears from the fact that the disease is hereditary. Negretti's son was subject to it from early boyhood. Dr. Willis knew a family in which the father and all the sons were afflicted with this troublesome complaint; the sons in their nightly discursions ran against and awakened each other.

Intemperance is said to be among the causes of somnambulism, and the analogy of facts prevents our doubting the assertion. Scipio Maffei, a correspondent of Mead, and one of the eye-witnesses of Negretti's adventures, attributed the disorder of that person to his immoderate fondness for wine.

Age and sex are to be taken into the account by those who investigate the etiology of any constitutional disease. According to Richertz, somnambulism is chiefly incident to the male sex and to the early period of manhood. It seldom appears in a strongly marked form in early youth, and generally lessens or ceases with the commencement of old age.

A plethoric state of the constitution, and whatever causes tend to induce fulness in the vessels of the head, increase the disposition to this disorder. Signor Pozzi, body-physician to his holiness Pope Benedict the 14th, assured Muratori, that he was obliged to have his hair cut at least every

second month, in order to prevent his becoming a somnambulist.

We have accumulated these somewhat quaint observations with the view of leaving nothing incomplete in the history of somnambulism as we find it upon record. To the practical physician the nature of this disease and the treatment which it requires must be almost self-evident.

Richertz was certainly correct in his opinion as to the pathological relations of somnambulism both to comatose and to maniacal diseases, and this is a consideration of some interest. In the first place, the symptoms which usher in and terminate the paroxysms of somnambulism, and the transitions from one disease to another, mark the connection between sleep-walking and comatose affections. These facts may be noticed in many of the cases above mentioned. There are frequent transitions from one form of disease to another. Ecstatic somnambulism, as being the most severe affection, has been most frequently connected with other disorders of the brain. In females it is often conjoined with catalepsy and hysteria, and in males with epilepsy. Dr. Darwin has related a case of ecstasis occurring in a boy, which was supposed to proceed from worms. It began with an epileptic aura, and terminated in stupor. Another instance recorded by the same writer was that of a female, and it was combined with uterine epilepsy, or perhaps with hysteria. In its phenomena it appears to have resembled the example related by Sauvages. Two cases are described by Martinet, in both of which epileptic fits formed a part of the disease. In one of these, somnambulism was vicarious of epilepsy: in the other, fits of ecstasis were ushered in by the usual symptoms of epilepsy.

The relation of ecstasis to insanity is in several of its phenomena still more apparent than that which it bears to comatose diseases. In the first place, it seems extremely probable that those affections termed cases of insanity, in which a patient is suddenly attacked by a peculiar kind of delirium, which holds him under its influence for a time, and then leaves him without any impression on his memory of what has taken place from its commencement, are truly examples of ecstacy, and similar in their nature to the fits of day-dreaming above described. Some of the cases cited from Dr. Silliman's American Journal of Science were considered as instances of insanity; and Dr. Haslam has recorded other examples of a similar description, which he also regarded as cases of that disease. (On Medical Jurisprudence in relation to Insanity.) In all these the impressions of the delirant period had entirely vanished from the memory of the individual affected. In such instances it is very probable that a relapse of the disease would have brought with it a renewal of the thoughts and feelings so entirely suspended during the interval. The phenomena, at least so far as they are described in these cases, are so analogous, that we may expect this analogy to extend even further than the facts recorded. In the next place we have seen that night-walkers and ecstatic persons are not found uniformly to have forgotten the visionary scenes presented to them during their paroxysms, and a recollection or retention of such impressions, blended with the waking state of consciousness, may bring these cases into a closer association with insanity. Indeed, Professor Heinroth has reckoned among the forms of madness one which he terms "*reiner wahnsinn*, or *ecstasis*," and identifies with the *melancholia attonita* of Chiaruggi. (Formenlehre in Heinroth's Störungen, b. ii.) Its essential character consists in intense reverie. Many instances of disease are upon record, and some well-marked cases have fallen under our own observation, in which the indisposition has appeared to commence with some ecstatic vision, and this has left a powerful impression on the mind of the individual, and has given its peculiar character to the series of morbid phenomena which ensued. We know the family of a clergyman who had been for some time in indifferent health, when standing one day at the corner of a street he saw a funeral procession approaching him. He waited till it came near to him, saw all the train pass him with black nodding plumes, and read his own name on the coffin, which was carried by and entered with the whole procession into the house where he resided. This was the commencement of an illness which put an end to his life in a few days. Vivid dreams and intense reverie occur in cases of insanity, but they mark a peculiar form of that disease, and are rather to be considered as the proper phenomena of ecstasis than of insanity in strict propriety so termed. There are, however, examples in which the symptoms are so mixed and blended, as to render the determination extremely difficult and even impossible to which head such examples should rather be referred. This remark may at least be applied without hesitation to a very striking and peculiar case, with a recital of which we shall terminate the present article.

A gentleman, about thirty-five years of age, of active habits and good constitution, living in the neighbourhood of London, had complained for about five weeks of slight headach. He was feverish, inattentive to his occupation, and negligent of his family. He had been cupped and had taken some purgative medicine, when he was visited by Dr. Arnould of Camberwell, who has favoured us with the following history. By that gentleman's advice he was sent to a private asylum, where he remained about two years; his delusions very gradually subsided, and he was afterwards restored to his family.

The account which he gave of himself was almost verbatim as follows. We insert the statement as we received it from his physician. "One afternoon in the month of May, feeling himself a little unsettled and not inclined to business, he thought he would take a walk into the city to amuse his mind; and having strolled into St. Paul's Church-yard, he stopped at the shop-window of Carrington and Bowles, and looked at the pictures, among which was one of the cathedral. He had not been long there before a short grave-looking elderly gentleman, dressed in dark brown clothes, came up and began to examine the prints, and occasionally casting a glance at him, very soon entered into conversation with him, and praising the view of St. Paul's which was exhibited at the window, told him many anecdotes of Sir Christopher Wren the architect, and asked him at the same time if he had ever ascended to the top

of the dome. He replied in the negative. The stranger then inquired if he had dined, and proposed that they should go to an eating-house in the neighbourhood, and said that after dinner he would accompany him up St. Paul's; 'it was a glorious afternoon for a view, and he was so familiar with the place that he could point out every object worthy of attention.' The kindness of the old gentleman's manner induced him to comply with the invitation, and they went to a tavern in some dark alley, the name of which he did not know. They dined, and very soon left the table, and ascended to the ball just below the cross, which they entered alone. They had not been there many minutes, when, while he was gazing on the extensive prospect, and delighted with the splendid scene below him, the grave gentleman pulled out from an inside coat-pocket something like a compass, having round the edges some curious figures; then having muttered some unintelligible words, he placed it in the centre of the ball. He felt a great trembling and a sort of horror come over him, which was increased by his companion asking him if he should like to see any friend at a distance, and to know what he was that moment doing, for if so the latter could show him any such person. It happened that his father had been for a long time in bad health, and for some weeks past he had not visited him. A sudden thought came into his mind, so powerful that it overcame his terror, that he should like to see his father. He had no sooner expressed the wish than the exact person of his father was immediately presented to his sight on the mirror, reclining in his arm-chair, and taking his afternoon sleep. Not having fully believed in the power of the stranger to make good his offer, he became overwhelmed with terror at the clearness and truth of the vision presented to him; and he entreated his mysterious companion that they might immediately descend, as he felt himself very ill. The request was complied with; and on parting under the portico of the northern entrance, the stranger said to him, 'Remember, you are the slave of the man of the mirror!' He returned in the evening to his home, he does not know exactly at what hour; felt himself unquiet, depressed, gloomy, apprehensive, and haunted with thoughts of the stranger. For the last three months he has been conscious of the power of the latter over him." Dr. Arnould adds, "I inquired in what way his power was exercised? He cast on me a look of suspicion mingled with confidence; took my arm, and after leading me through two or three rooms, and then into the garden, exclaimed, 'It is of no use—there is no concealment from him, for all places are alike open to him—he sees us and he hears us *now*.' I asked him where this being was who saw and heard us? He replied, in a voice of deep agitation, 'Have I not told you that he lives in the ball below the cross on the top of St. Paul's, and that he only comes down to take a walk in the church-yard and get his dinner at the house in the dark alley. Since that fatal interview with the necromancer,' he continued, 'for such I believe him to be, he is continually dragging me before him on his mirror, and he not only sees me every moment of the day, but he reads all my thoughts, and I have a dreadful consciousness that no action of my life is free from his inspection, and no place can afford me security from his power.' On my replying that the darkness of the night would afford him protection from these machinations, he said, 'I know what you mean, but you are quite mistaken. I have only told you of the mirror, but in some part of the building which we passed in coming away, he showed me what he called a great bell, and I heard sounds which came from it, and which went to it; sounds of laughter, and of anger, and of pain; there was a dreadful confusion of sounds, and as I listened with wonder and affright, he said, 'This is my organ of hearing; this great bell is in communication with all other bells within the circle of hieroglyphics, by which every word spoken by those under my control is made audible to me.' Seeing me look surprised at him, he said, 'I have not yet told you all; for he practises his spells by hieroglyphics on walls and houses, and wields his power, like a detestable tyrant as he is, over the minds of those whom he has enchanted, and who are the objects of his constant spite, within the circle of the hieroglyphics.' I asked him what these hieroglyphics were, and how he perceived them? He replied, 'Signs and symbols which you in your ignorance of their true meaning have taken for letters and words, and read as you have thought, '*Day and Martin* and *Warren's blacking*.' Oh! that is all nonsense! they are only the mysterious characters which he traces to mark the boundary of his dominion, and by which he prevents all escape from his tremendous power. How have I toiled and laboured to get beyond the limits of his influence! Once I walked for three days and three nights, till I fell down under a wall exhausted by fatigue, and dropped asleep; but on awaking I saw the dreadful signs before my eyes, and I felt myself as completely under his infernal spells at the end as at the beginning of my journey.'"

It is probable that this gentleman had actually ascended to the top of St. Paul's, and that impressions there received being afterwards renewed in his mind when in a state of vivid excitement, in a dream or ecstatic reverie, became so blended with the creations of fancy as to form one mysterious vision, in which the true and the imaginary were afterwards inseparable. Such at least is the best explanation of the phenomena that occurs to us.

J. C. Prichard.

[SPERMATORRHŒA. — The term spermatorrhœa was, at one time, used by many for an involuntary discharge of sperm without erection; but it has been employed, likewise, in a more extended signification, — to include too great a flow of sperm, whether produced by masturbation, or occurring during the night (*Gonorrhœa dormientium*) whilst the individual is asleep. These cases are extremely common: the writer is frequently consulted by persons suffering under the effects—as they conceive—of inordinate discharge of sperm, either from vicious habits, or in dreaming. That excessive secretion of sperm may act injuriously upon the nervous system, there can be little doubt; but the injurious physical consequences, that have been ascribed to it, have often been fabulous. Speaking of it in a medical point of view, there

can, in the writer's opinion, be no greater evil to the economy from a flow of semen accompanied by venereal desire, without sexual intercourse, than with it: but where vicious habits have been contracted, alarm is often excited by the perusal of cases of serious disease, ascribed to similar practices; and the individual becomes nervous and apprehensive, until ultimately his life is rendered miserable to him. He observes, in the advertisements of the empiric, the numerous mental and bodily evils that may be his lot; and it has happened, that he has not had courage enough to support his fancied afflictions, and has been led to commit suicide. This has more especially occurred if the person has been engaged in marriage, and has been impressed with the idea, that impotence must necessarily result.

It is proper to state, that of the many cases in which the writer has been consulted by young men thus circumstanced, and who have married subsequently, in no instance has he heard of any impediment to procreation existing subsequently; and, consequently, unless the spermatorrhœa occurs in the day-time, and without venereal desire; or, unless, along with such desire, it takes place immediately on the erection of the male organ, he has advised the fulfilment of the patient's matrimonial intentions, and has never heard a complaint afterwards.

Spermatorrhœa, in the form of *nocturnal pollution*, is common; and unless it occurs more than once in the course of the night, and every night, it ought scarcely in a young and robust individual to be esteemed a pathological condition. The presence of sperm in the seminal ducts or vesicles produces an excitement during sleep, which is appreciated by the brain, salacious dreams are the consequence, during which the seminal emission occurs.

These forms of spermatorrhœa cannot be mistaken. The patient either induces them by his own acts, or has full evidence of them from his sensations during sleep, and the appearances on awaking. Another form, however, is not so clear. In this, there is a discharge of a glairy, viscid fluid, whilst the last drops of urine are discharged, or on straining during the evacuation of the bowels. But the presence of such a fluid in those circumstances by no means shows that it is sperm. Indeed, it probably rarely is so, and is nothing more than the mucous fluid from the prostate or the glands of Cowper. It has been proposed to employ the microscope in our doubt; and that if proper animalcules be found in the fluid, we may pronounce the secretion to be seminal; but this would not be decisive, inasmuch as those animalcules have been found in the mucous secretions of the urethra, and even in the urine. Moreover, M. Lallemand (*Des Pertes seminales involontaires*, Paris and Montpelier, 1837–41) believes, that the seminal animalcules are deficient in these very cases, which ought certainly to be unfavourable to the idea that the fluid proceeds from the spermatic vessels. In most of the instances that have fallen under the care of the writer, he has been satisfied, that the glairy fluid was mucous and not seminal.

The general effects ascribed to spermatorrhœa are various: the functions of the alimentary canal are said to become gradually impaired, and to be irregularly accomplished; but the animal functions suffer chiefly; the mind especially feels the effects; and the individual becomes hypochondriacal, misanthropic, and may even fall into a state of dementia.

Elsewhere (*Practice of Medicine*, ii. 288, 2d edit. Philad. 1844,) the writer has inquired into the effect of spermatorrhœa in the causation of insanity, and has given ample reason to believe that it has been exaggerated. M. Lallemand has had an opportunity of examining the bodies of patients who had died, he conceived, of exhaustion caused by involuntary discharges of sperm, or had perished from some accidental affection during the continuance of such discharges, He found the orifices of the ejaculatory ducts dilated, the seminal vessels hardened and contracted, and the prostate generally diseased. In several subjects, the gland was filled with a multitude of small abscesses, and its whole tissue was pale and soft. The urethra was rarely free from disease; it was thickened, and a firm and extensive stricture was found in several patients; the bladder and kidneys, too, participated in the morbid condition.

Causes.—These are—gonorrhœa, which is very liable to leave behind it the lesions mentioned above; excessive sexual indulgence, or masturbation; affections of the rectum, that oppose a mechanical obstacle to the passage of the fæces, and occasion pressure on the vesiculæ seminales, and the prostate; and a fissure of the rectum, or hemorrhoids, by occasioning violent straining, may produce the same effect. Ascarides in the rectum would seem to have caused so much irritation as to react upon the urethra and vesiculæ seminales, and to give rise to profuse involuntary discharges of sperm. A case is given by M. Lallemand, of obstinate spermatorrhœa occurring chiefly during sleep, which resisted all methods of treatment until the ascarides were removed by large and repeated enemata of very cold water. It is not improbable, however, that the impression made indirectly by the cold on the parts implicated may have been salutary.

Treatment.—It need scarcely be said, that in all cases of spermatorrhœa, the treatment will have to be moral as well as physical. If the disease be kept up by vicious habits, these must be abandoned; and the mental effects resulting directly or indirectly therefrom must be modified by a change of all the influences surrounding the individual, like that advised under Hypochondriasis; attending, at the same time, to the physical aberrations that may present themselves. Of course, if the spermatorrhœa be owing to, or connected with, disease of the rectum, obstinate constipation, irritation from worms or any other appreciable cause, it will yield on the removal of these conditions; but if it be dependent upon an altered state of the urethra, ejaculatory ducts and prostate — as described above—it may not give way to any remedy except direct cauterization. This may be practised by passing solid nitrate of silver into the urethra, enclosed in an appropriate canula, and turning it very rapidly over the part to be cauterized, retaining it in contact as short a time as possible, and then rapidly withdrawing it. After the application of the caustic, the discharge of urine is excessively painful for a day or two, and

is sometimes a little tinged with blood; but after the pain has ceased, the spermatorrhœa is often suspended, and the whole of the local and general symptoms gradually pass away. (Lallemand, *op. cit.* and Raige-Delorme, art. *Spermatorrhée* in *Dict. de Méd.* xxviii. 518, Paris 1844.)

For the nervousness, or great impressibility often seen in these cases, the physician is sometimes called upon to prescribe; and he is led to combine tonics with astringents. Thus, the *tinctura ferri chloridi*, (gtt. x. ter die,) and the *liquor ferri iodidi*, (gtt. xv. ter die,) are not unfrequently prescribed; and they are as likely to prove serviceable as any therapeutical agent; but the writer has not derived any marked advantage from them. Where the mental distress is considerable, especially under the circumstances before mentioned, —where a matrimonial alliance is projected, and the individual is afraid he may prove impotent,— provided he is capable of erection, it may be proper to advise, that the alliance should be entered into; and although moral impotence may exist for a time, it will gradually wear off. As before remarked, the writer has never heard any complaint subsequently, where this course has been pursued; and he has recommended it in many instances.

ROBLEY DUNGLISON.]

SPINAL MARROW, DISEASES OF THE. —The abnormal states of the spinal marrow are not so numerous as those of the brain, whether we take into account their congenital malformations or morbid conditions. As regards the latter, it seems, upon a fair consideration of all the facts hitherto collected, that those of the brain predominate; and considering the greater vascularity of that organ, its proximity to the surface, the close adhesion of its fibrous covering to the interior of its bony case, and, in fine, the part which it plays in, or the connection which its functions have with, the phenomena of mind, we cannot but accede to the justice of this conclusion.

Passing to the consideration of these conditions, we shall first notice the congenital malformations, to little more than a bare enumeration of which our space restricts us. Total absence of the spinal marrow has been frequently observed accompanying acephalous or anencephalous monstrosities, but never otherwise. To this form of monstrosity Beclard has given the name of *amyélie*. It is a question whether its absence is attributable to a real defect of the development of the organ, or to its destruction while yet in a state of great delicacy by the formation of a dropsical effusion either around it, or in the canal or ventricle which exists in it at an early period of its development. Cases of this deficiency are recorded by some writers as having reached an advanced period of uterine life. (*Ollivier*, sur la Moelle Epinière, vol. i. p. 139.) One of the most complete cases of this kind is recorded by Lallemand. The fœtus had firm flesh, and the epidermis was sound; the testicles were situated at the orifices of the inguinal canals; the motions of the child were distinctly felt by the mother before birth; and, judging from the size of the limbs and the declaration of the mother as to the duration of her pregnancy, it was concluded that the fœtus had reached the period of between seven and eight months; yet it had neither brain, cerebellum, nor spinal marrow.* The spinal marrow is, moreover, found in various degrees of imperfection, constituting the *atelomyélie* of Beclard. These defects of form are thus enumerated by Ollivier, (Loc. cit. p. 153): 1. the malformation of various kinds of its upper extremity when the brain is absent, or when a variable portion of the upper part of the trunk is wanting; 2. its division, to a greater or less extent, into two portions; 3. its double form, as in cases where the spine is single to a certain extent, and then bifurcates at one extremity either to support two heads, or to form two trunks separated below and re-united above; 4. varieties in its length and breadth; 5. the existence of a canal in its interior; 6. its congenital dropsy, (*congenital hydrorachis,*) which in general is accompanied with an accumulation of fluid in the meningeal cavity of the spine.

Of all these varieties of congenital defect the last is that which is most frequently presented to the notice of the practitioner. The dropsy of the spine, called **hydrorachis,** consists of an accumulation of fluid [which, in health, has been estimated by Magendie (*Précis de Physiologie*, 2de édit. i. 181, Paris, 1825,) at two ounces, but often amounts to five,] in the substance of the spinal cord, in the subarachnoid cavity between the arachnoid and pia mater, or in the arachnoid sac. It very frequently happens that there co-exists with this disease a congenital deficiency of the posterior portions of the vertebral rings — the spinous processes and vertebral laminæ being absent—for a variable number of vertebræ. Hence the term hydrorachis has been constantly confounded with that of *spina bifida*, which merely has reference to the incomplete state of the bony canal. It cannot be denied that hydrorachis, or a superabundant quantity of fluid, may exist in the spinal cavity without the osseous deficiency; but it will be always important for the practitioner to remember that a natural fluid exists in this canal before he pronounces with certainty on the morbid character of an effusion. When a congenital hydrorachis, strictly so called, (or, as J. P. Frank terms it, *hydrorachia incolumis*, De Curandis Hominum Morbis, tom. vi. p. 374,) exists, it is generally only part of a dropsy affecting the whole cerebro-spinal axis, and therefore its symptoms are those of congenital hydrocephalus in an aggravated form, sense and motion being affected to a greater degree, and its treatment will be to be conducted on a similar plan. But that form of hydrorachis which is found along with a deficiency of the vertebræ (*hydrorachia dehiscens* of Frank) we decidedly think to be, in the majority of cases, an accumulation which the absence of the natural resistance from the posterior wall of the spinal canal allows to take place, and therefore this defect constitutes the essence of the peculiar affection under consideration. The presence, therefore, of this congenital defect is generally if not always indicated by the existence of a tumour proportionate in extent to the number of defective vertebræ, prominent in one or more regions of the spine. Such a tumour may occur in any region of the spine; but it is most frequently found in the lumber

* Observations Pathologiques propres à éclairer plusieurs points de Physiologie. See also a well-observed case by Morgagni, epist. 48. § 50.

region, next in the sacral, rarely in the dorsal, and least of all in the cervical; it may exist in two regions at the same time, or may occupy all the three regions, the whole spine being bifid. In the cervical region, spina bifida generally coexists with an open condition of the cranium posteriorly, resulting, as Isid. Geoffroy St. Hilaire remarks, from a sort of "*spina bifida cranien.*" There is a free communication between the tumour or tumours and the rest of the cavity of the spine, or even of the cranial cavity, as appears from the diminution in the size of the tumour produced by pressure, or by an alteration in the position of the infant, for when it is in the erect posture the tumour is tense, but if the head be placed lower than the rest of the trunk it becomes flaccid. It is said that respiration also causes remarkable changes in the tumour, that it swells during expiration, and falls during inspiration. (*Ollivier*, loc. cit.)

The coverings of these tumours vary, sometimes including the skin, and, when that fluid is accumulated in the marrow, the pia mater; but the dura mater and arachnoid — that is, one layer of it—will constantly be found among its coverings. The condition of these coverings is also variable, the skin being either sound, thickened, ulcerated, almost gangrenous, or covered with fungous growths or tufts of hair; and the membranes may likewise be congested or thickened. The fluid itself is generally of the same characters as that of hydrocephalus; it may vary in quantity from a few ounces to six or seven pints, and has been found to occupy various situations, of which Andral enumerates the following:—1. In the cavity of the arachnoid; 2. between the arachnoid and dura mater; 3. between the arachnoid and pia mater; 4. between the latter membrane and the osseous parietes of the spinal canal; 5. in a canal formed in the spinal cord; 6. in a cyst situated outside the dura mater, which latter, as well as the other membranes, was perfectly free from alteration. (Anat. Pathol. by Townsend, vol. ii.) Sometimes serous cysts filled with clear fluid have been found in the tumour. Fleischmann (De vitiis congenitis circa thoracem et abdomen, Erlangæ) reduces the defects of the vertebræ to three classes: — 1. When the whole vertebræ, body as well as processes, is divided; 2. where the lateral arches are imperfectly developed; 3. where, although the lateral arches are developed, they are not united. Of these the first and third are rarely observed. Lastly, the condition of the spinal cord demands attention. Otto says, "In the most severe forms the spinal marrow is entirely wanting, and we find merely the membranes fallen togegether, usually slit at one or more spots, or even more or less degenerated and adherent to each other, forming sometimes a closed sac filled with lymph." (Path. Anatomy, by South.) In the more ordinary cases it is, according to Ollivier, most frequently sound; but Meckel thinks otherwise, and that it is more frequently altered either in situation, being found in the cavity of the tumour, or in structure, being softened or reduced to a pulp and diminished in size, and sometimes imperfectly divided into two parts, or spread out into a kind of membrane. The nerves undergo some alteration in their mode of distribution. Sometimes the posterior branches do not pass beyond the tumour, but are distributed upon the internal surface of the walls of the tumour, and terminate there: in some cases they form a nervous net-work in their ramification on the internal surface of the tumour. (Stafford, in loc. cit. pp. 21, 22, 23.)

This affection is for the most part fatal in its termination, and has hitherto been deemed almost incurable, but very few cases having either recovered or been ameliorated by treatment. The lower limbs are generally paralysed, as well as the bladder and rectum, and sometimes there are convulsions and hydrocephalic symptoms. The hopelessness of a cure is of course increased, when, as is not unfrequently the case, there are other congenital defects, as deficiency of the abdominal walls, extroversion of the bladder, imperforate anus, &c. &c.

The duration of the life of the infant will depend on the size of the tumour — the larger the latter is, the shorter will be the former. On the other hand, however, it is abundantly proved that a state of integrity of all the functions may occasionally exist even with a tumour of considerable size, for many instances are recorded of children living several years, and even arriving at the respective ages of 17, 18, 19, 20, 21, or even 50 years, with such tumours. If the tumour burst suddenly, death almost certainly will immediately result, preceded by violent convulsions; and the same consequence is apt to follow the opening of the tumour by cutting instruments, even where its evacuation is effected slowly.

Various plans of treatment have been proposed by surgeons to remove or remedy this congenital defect. The application of a ligature round the base of the tumour, pressure by a truss, (*Benjamin Bell,*) the introduction of a seton, counter-irritants, (*Richter,*) have been justly discarded. Compression and puncture were originally proposed by Mr. Abernethy, and have been since successfully carried into effect. Compression was devised by Mr. Abernethy, from the idea that it would supply that which was wanting in consequence of the incomplete state of the vertebral canal. This, however, is only a palliative remedy, and requires to be constantly kept up in order to prevent the increase of the tumour. Sir A. Cooper applied pressure by means of plaster of Paris fitted to the tumour, and maintained by a roller applied with a moderate pressure round the waist. This was removed after a time, and its place supplied by an umbilical truss, which answered every purpose, and kept the tumour entirely within the channel of the spine. (Med.-Chir. Trans. vol. ii. p. 323.) Mr. North, so well known to the profession by his work on Infantile Convulsions, has related to us an equally successful case which occurred in his practice. The subject of it, a girl, is now arrived at adult age, and able to perform the duties of a servant in a family in London.

The plan of treatment by puncture also has been successful in the hands of Sir A. Cooper. The tumour was punctured by a needle, and its contents evacuated every fourth day, and a roller applied round the body: after some time the walls of the tumour became solid, and the child was relieved from all inconvenience. This mode of

treatment seems decidedly to be the only one likely to effect a permanent cure by the final consolidation of the tumour, and it is evident that its success will in great measure depend on the degree of perfection of the spinal marrow itself.

We may here allude to that peculiar yellow discoloration of the spinal marrow and of its serous covering which M. Lobstein has noticed in fœtuses at an early period, and which he has denominated "*kirronosis*." The colour is a golden yellow, and does not seem to be attributable to any particular extraneous colouring matter, for it resisted repeated washings and a prolonged immersion in alcohol. M. Lobstein has not found this discoloration at a more advanced period of life, and has always noticed it in the nervous tissue and serous membranes. (Répertoire Gén. d'Anat. et Phys. fasc. i. 1826; and Ollivier sur la Moelle, &c. v. i. p. 209.)

The morbid conditions of the contents of the spinal canal may be discussed in the following order: — 1. those of the spinal meninges; 2. spinal effusions; 3. the morbid states of the spinal marrow itself.

1. The Morbid States of the Spinal Meninges.—The membranes of the spine are so similar to those of the brain in the healthy state, that it is natural to expect their diseases should closely resemble each other. As in the case of the cerebral membranes, we rarely find one of the spinal coverings acutely affected without the others being more or less implicated. The anatomical characters of acute **Spinal Meningitis** may be thus enumerated:—increased arterial vascularity of the meninges and of the tissues immediately in the vicinity of them; slight increase of thickness of the dura mater, and an exudation of lymph upon the surface of the arachnoid, or according to Ollivier, more frequently between the arachnoid and pia mater, so as to give the marrow the appearance of being enlarged in circumference. Sometimes there is purulent effusion between these membranes, or considerable serous effusion into the arachnoid cavity, while that membrane itself is rendered opaque, probably by the thickening of the subjacent pia mater. If the arachnoid membrane appear red, it will be so from the turgescence of vessels subjacent to, not in it; for this membrane, like the other serous membranes, does not afford any signs of red vascularity. Where there is a morbid state of the bones, local or circumscribed inflammations are observed. Lallemand, (Lettres sur l'Encéphale, t. i. p. 309,) Ollivier, and, Bergamaschi, (Giornale della Soc. Med. Chir. di Parma. Guigno, 1810,) relate cases in which effusion existed on the exterior of the dura mater, between it and the osseous wall of the spinal canal.

When the lymph is thrown out upon that portion of the arachnoid which lines the dura mater, it gives an appearance of increased thickness to the latter membrane, which of course will vary with the quantity of effused lymph. Adhesion of the two layers, and consequent obliteration of the sac of the arachnoid, as well as opacities of the membrane itself, often produced by a close adhesion to the pia mater, may be regarded as consequences of inflammation. Ulceration and mortification are also spoken of by some writers.

The greater number of cases of spinal meningitis occur in connection with acute disease within the head, either antecedently or subsequently, and most frequently the inflammation spreads to the substance of the marrow itself; hence instances are rare where this affection has existed alone, and consequently those symptoms which exclusively depend on irritation of the membranes are imperfectly ascertained. Pain, sometimes extremely intense, occupying a greater or less portion of the spine; rigidity, or violent spasms of the muscles of the back, occasionally producing opisthotonos, and also of other muscles, as those of the neck, upper extremity, &c.; a peculiar sense of constriction either round the neck, back, or loins, according to the part of the spine affected; rigors, more or less of exalted sensibility, or paralysis of motion; dysuria, or even retention of urine from paralysis of the bladder, and constipation of the bowels, are among the most prominent symptoms. The locality of the paralytic symptoms, as well as of the muscular rigidity, varies with the situation of the spinal disease. On the first invasion of the disease, there are generally some obscure symptoms about the patient; pains resembling those of rheumatism, attended with lassitude, and a feeling of weight about some part of the spine. The tetanic contraction is, as Ollivier remarks, particularly manifested when the patient is moved. In some instances the rigidity is continued and permanent until death, but most frequently there are remissions of a more or less complete character. Dr. Tweedie has related to us a case, the symptoms of which there is strong reason to think resulted from partial spinal meningitis. A young lady, in the advanced stage of a severe attack of fever, during which the brain had been severely affected, was seized rather suddenly with violent muscular contractions of the extremities, so that the arms were alternately thrown out from and drawn back to the trunk with great violence; while, at another, similar contractions of the muscles of the lower extremities occurred. These violent and irregular motions ceased almost immediately after large detraction of blood from the region of the spine, followed by counter-irritation, and the patient completely recovered. In another case, that occurred to Dr. Tweedie, in which the early symptoms assumed the form of cerebral fever, the muscles of the lower jaw became so rigidly contracted, that medicines and nourishment were with the utmost difficulty administered. The muscles of the trunk became next affected, complete opisthotonos being induced. This lady died, and on examining the spinal cord, the dorsal portion bore traces of violent inflammation; the investing membrane was intensely injected, and the substances of the spinal marrow, for the space of an inch, reduced to a softened pulpy mass.

The exalted sensibility is, according to Ollivier, a constant phenomenon in spinal meningitis, and may serve, as he thinks, to distinguish it from inflammation of the marrow itself, which is in general attended with diminished sensibility. The respiration is sometimes difficult and oppressed; the pulse preserves its regularity, but gradually becomes weak, and the patient dies exhausted by the severity of the spasms, or the intensity of the pain, or from convulsions, which are sometimes

accompanied with trismus. The bladder is sometimes inflamed, either in consequence of the loss of its protecting sensibility or of the acrid nature of the urine, which becomes decomposed in the bladder. The causes of spinal meningitis are not always discoverable. It may arise from disease of the bones — from violence applied to the spine externally; it may appear consecutively to a similar inflammation within the cranium, as in Dr. Tweedie's case just related, or, as some think, it may be caused by a suppression of the menses or of a hemorrhoidal flux; it may be the effect of cold, or on the contrary of a prolonged exposure to great heat, as from the sun's rays. It is generally fatal.

Treatment.—Copious local or general bleeding is obviously indicated as the first step of the treatment. Goss recommends free and deep incisions along each side of the vertebral spine, with a view of opening the veins which communicate so freely with those of the spinal marrow. The warm or vapour bath may be advantageously employed. Ollivier recommends the application of ice along the back, on the same principle that it is used in cerebral inflammations. Counter-irritation can have but little effect except it be severe and applied over an extensive surface. For this purpose, a sinapism or blister extending the whole length of the spine, or the ointment of tartarized antimony, may be employed.

The chronic affections of the spinal meninges consist chiefly of new formations in or upon them. Such are the cartilaginous pieces found on the arachnoid, in various regions; bony incrustations, which however rarely occur, as well in the dura mater as in the arachnoid; chronic tumours of various kinds; hydatids; tubercles. The cartilaginous incrustations appear to be developed in the arachnoid. They are generally very small and numerous, nor does it appear that they are prone to be converted into bone. Several cases of one or more hydatids found in the spinal canal have been observed. Cancerous or fungoid tumours, originating externally, may send deep processes into the canal, and thus compress the marrow. Of this Ollivier gives a remarkable case. (Page 751, vol. ii.) The tumour originated externally in the neck, and a deep process from it was prolonged into the cervical portion of the spinal canal through the intervertebral foramina; the tissue external to the dura mater was for a considerable extent converted into a similar matter. There was paralysis of the arm of the same side.

The symptoms produced by these chronic growths are by no means uniform; they will vary according to the region of the spine they may be placed in, or according to the part of the spinal cord upon which they may directly press, whether anterior or posterior. Paralysis, as well of sensation as of motion, sometimes general; muscular spasm, pain in the course of certain nerves, sometimes a morbidly acute sensibility of the cutaneous surface to a considerable extent, constitute the principal phenomena resulting from their presence. It is proper to remember that a large aneurism, compressing and causing the absorption of the bodies of the vertebræ, may so find its way to the spinal cavity as to compress the marrow, and produce additional symptoms still more calculated to perplex the practitioner than those which are commonly attendant on those cases. The writer lately assisted in the examination of the body of a man who exhibited, some time before death, symptoms which seemed to depend on spinal compression. For a considerable period prior to his death, the integument of the thorax was so exquisitely tender that he could not bear the least touch; this continued till four days before death, when the integuments became perfectly insensible, except along the middle line, both anteriorly and posteriorly, where the former tenderness remained. This was a case of aneurism occupying nearly the whole thoracic aorta; the bodies of the corresponding dorsal vertebræ were completely destroyed from the pressure of the tumour. The spinal marrow in that region struck us as being peculiarly firm; and the fatty membrane, external to the dura mater, presented an unusual degree of density.

2. Spinal Effusions.—These effusions vary as to their locality, and as to the nature of the effused fluids. They may take place—1. between the bony wall of the spinal cavity and the dura mater; 2. in the arachnoid sac; 3. in the space between the visceral layer of the arachnoid and the pia mater, (the sub-arachnoid cavity,) which in the healthy state is filled by the cephalo-spinal fluid of Magendie. In those situations serum, blood, pus, or air, may be effused, and thus produce symptoms analogous and sometimes precisely similar to those caused by the development of chronic growths from the membranes. Such effusions, however, may appear from other causes than those which operate directly upon the spinal meninges; the free communication between both the arachnoid sacs and sub-arachnoid cavities of the head and spine allows the fluids of one to pass to the other, and if there be cerebral apoplexy, the spinal fluid may readily be deeply coloured with blood. Pus and blood may come from chronic abscesses or aneurisms which have caused the absorption of the bodies of the vertebræ.

Effusion external to the dura mater may, as Dr. Abercrombie observes, be regarded as unequivocal evidence of spinal irritation. We have already alluded to cases of this kind related by Ollivier, Lallemand, and Bergamaschi. In that by Ollivier, the principal symptoms were opisthotones, difficult deglutition, and coma; a red and very consistent fluid was found between the dura mater and the bony canal in the tissue situated there, with serous effusion within the membranes; and the arachnoid of the cord was covered with an albuminous layer for the extent of four inches. In Dr. Abercrombie's case, (that of a child aged two years,) the symptoms commenced with fever; after two days she was seized with violent convulsions, which lasted an hour, and were succeeded by coma; and about two hours after the first she had a second convulsive fit, which left her in a state of coma from which she never recovered. During the fits, and for some time after them, there were violent and irregular action of the heart, and a peculiar spasmodic action of the diaphragm. The eye was completely insensible, and the pulse very frequent. She had several slight attacks of convulsion, and one more severe, a short time before death, which happened thirty-three hours after the

first attack. The brain was healthy; on the outer surface of the dura mater there was a copious deposition of colourless fluid, most abundant in the cervical and upper part of the dorsal regions; there was a little effusion of bloody fluid into the arachnoid sac, and the substance of the cord seemed softer than natural at the upper part. (*Abercrombie*, loc. cit. p. 375.)

Serous effusions occur most frequently in the space between the arachnoid and pia mater, and in forming an opinion as to the morbid nature of them, we must be careful to make due allowance for the quantity of fluid which naturally exists between these two membranes. A case of unusual superabundance of this fluid is recorded in one of the numbers of the Journal Hebdomadaire for August, 1833, by M. Montault. The patient, ætat. 68, a porter, strong and athletic, after a fit of intoxication (not unusual), fell rapidly into general paralysis, for which he was bled largely by leeches applied behind the ears, at the anus, and on the left side of the chest; he became delirious, and then comatose, and died on the sixth day. The body was examined fifteen hours after death; an enormous quantity of fluid was accumulated between the arachnoid and pia mater of the brain and spine. It amounted to nearly thirteen ounces in quantity, and extended into the lateral ventricles. There was no alteration in the texture of the brain or spinal cord.

Venous congestion may produce an increase of this natural effusion; but we conceive that it will often be impossible to say with certainty that it was not formed after death by the separation of the serum of the blood, and its infiltration through the coats of vessels. Increased serous effusion may also arise from any irritation in the immediate vicinity, and is found in cases of spinal curvature, or in meningitis, especially when chronic. This effusion may also occur in the arachnoid sac; and here it is impossible to say that it has not transuded from the sub-arachnoid cavity through the layer of arachnoid. It takes plase under circumstances similar to those which produce that last mentioned. Both these forms of effusion are in general present, at least after death, in dropsy of the spine. We have already stated that a form of hydrorachis of a different kind from that which is connected with congenital deficiency of the bones, is frequently found in children with hydrocephalus, and in all probability is attributable to the same cause: it also frequently accompanies serous apoplexy in the adult. There is no external tumour in these cases, as may be reasonably supposed; the posterior wall of the spine being so resisting, except at its inferior extremity, where this wall is completed by a ligamentous expansion closing the sacral canal. Morgagni (Epist. 12, § 9, and Ollivier, loc. cit. vol. ii. p. 494,) relates a case from Genga, in which spinal dropsy of this kind manifested itself externally at the situation of this ligament. A child, aged four years, was attacked with hydrocephalus in consequence of a blow on the head. About a month afterwards a tumour appeared at the coccyx; it was opened, and the head appeared to diminish gradually in size as a large quantity of water was discharged from the puncture. Compression on the head increased considerably the impetus with which the fluid flowed from the opening; a circumstance which proved that this tumour communicated with the head, and resulted from the distension of the spinal membranes. It should be observed, however, that spinal effusion is not necessarily coexistent with hydrocephalus, for the exit of the fluid from the ventricles may be and often is prevented by the closure of the opening beneath the valve of Vieussens. Sometimes we find a viscid almost jelly-like matter effused round the cord, but this is most probably merely a post-mortem effect.

Effusion of blood into the spinal cavity, or between the membranes, constitutes the disease termed spinal apoplexy. The blood is generally found in a state of coagulum. This effusion may arise from concussion of the cord, occasioned by a fall from a great height—by a blow inflicted on the back; it is found also after death from cerebral apoplexy, hanging, tetanus, (Vide Reid on Tetanus and Hydrophobia,) hydrophobia, (*A. T. Thomson*, Med. Chirurg. Transactions, vol. xiii,) and in children whose death has been occasioned by difficult parturition. Sometimes a portion of the spinal marrow itself is so mixed up with the coagulum as not to be distinguished from it, in which case the hemorrhage would appear to have originated in the tissue of the marrow.

Convulsions, paralysis, sometimes a diminution and at others an increase, of sensibility, pain in the back, are the most usual symptoms which have been observed in such spinal lesions. In a case related by Dr. Abercrombie, of a child seven days old, the symptoms were repeated attacks of convulsions with trismus, and sometimes universal tonic spasm. Death took place on the fourth day. On dissection, a long and very firm coagulum of blood was found lying between the bones and membranes of the cord on the posterior part of the whole cervical region. A case of encysted spinal apoplexy is recorded by Dr. Stroud. The cyst was an inch in length, and about half an inch in diameter; it was external to the cord, and existed at the upper part of the dorsal region on the left side. The patient died universally paralysed; the disorder, however, set in with hemiplegia, to which succeeded paraplegia, and then the palsy spread.

Purulent effusions in the spinal canal are the surest indications of inflammation of one or more of the meninges, which likewise present other characters to particularize them.

Effusions of air, constituting *pneumatorachis*, have been described by Ollivier as occurring in the spinal canal. We are not acquainted with any writer who has fully confirmed his experience on this point. Otto has met with air in the spinal canal, but, he says, not under such unequivocal circumstances as would justify him in regarding it as a morbid product. Andral does not at all allude to its occurrence. M. Ollivier says, "It is not very rare to find the lumbar portion of the meningeal canal more or less swollen by a gaseous fluid, inodorous and colourless, which cannot be attributed to putrefaction, inasmuch as I have seen it in the spinal canal of subjects recently dead, and could not discover it in a great number of others which were dead some days. I have not remarked that this disengagement of gas took

place as a consequence of any particular disease." (Opus cit. vol. ii. p. 537.) The cases in which he has found air in the meningeal sheath did not present symptoms of spinal disease before death; in most of the cases the examination was made twenty-four hours after death. Billard met with a case in connection with ramollissement of the brain and spinal marrow.

In the treatment of spinal effusions it is obvious that the practitioner must have in view not only the removal of the effusion, but also that of its cause, when that cause may happen to continue. To effect the latter object, it is evident that he must vary his treatment according to what the symptoms would indicate as the most probable cause; but to remove the effusion various remedies may be had recourse to. Sometimes it fortunately happens that the effusion is absorbed as soon as its cause is removed, and thus the application of one remedy answers a double purpose. When after accidents of the spine there are numbness and pains in the limbs, symptoms in all probability denoting an increase in the natural spinal effusion, these symptoms are often removed with a remarkable rapidity after a free local depletion or a pretty extended counter-irritation. This latter object may be effected by the usual blister, by the moxa, by setons or issues, or by frictions along the spine with any irritating applications that will produce a discharge. Of these we decidedly prefer the last; they are often purely local in their action; whereas when blisters are used, some active principle of the cantharides seems to be absorbed into the system, which, though it may not be manifest from appearance of strangury, yet, we cannot help thinking, produces in a similar way that aggravation of symptoms which so constantly follows the injudicious application of blisters. Mercurials may be administered with benefit in these cases, either internally or through the medium of the skin. Perfect rest, the horizontal posture, and an exemption from such causes as may disturb the circulation or respiration, are obviously indispensable.

3. **Morbid conditions of the Spinal Marrow.**—These conditions may be thus enumerated:—Inflammation and its consequences; atrophy and hypertrophy; new formations in the substance of the marrow.

Inflammation of the spinal marrow, called by Harles (Ueber die Entzündung des Rückenmarks,) and Ollivier *myelitis*, is principally known by its terminations; the first stage, that of simple hyperæmia, being of rare occurrence, inasmuch as the derangement of function which it occasions is seldom sufficient to cause death. It is only in cases where death has occurred in consequence of severe injuries, that we can expect to find the early stage of myelitis. Mr. Stafford speaks with a confidence which would imply that he has seen this early lesion; he says,—"All that can be perceived is that it is redder than natural, and that when a section of it is made its vessels are found turgid, presenting bloody points in its substance; it is usually found in this state in injuries of the spine, opposite to where the blow was received." (Loc. cit.) From all that has hitherto been collected relative to inflammation of the spinal cord, it seems pretty well ascertained that it may present the following terminations:—1. Ramollissement; 2. induration; 3. suppuration.

1. **Ramollissement.**—As in the brain, anatomists are not agreed respecting the inflammatory nature of ramollissement in the spinal cord. But when the medullary substance surrounding a portion of marrow thus softened is in a vascular state, and that vascularity extends even into the softened portion; when, moreover, (as is not uncommon,) there is unequivocal evidence of meningitis, it appears to us that there are ample grounds for the opinion that the ramollissement is inflammatory; and as such cases as we have described are the most common, a great number of the cases of ramollissement may be regarded as the results of *myelitis*. The softened part is in general of a brownish colour, resembling that of the lees of wine; it is most frequently found in the lumbar region, and next in frequency in the cervical. According to Ollivier it commences in the grey substance; but that substance is itself so obscure, that we can hardly regard this opinion as fully substantiated. M. Dupuy has frequently found ramollissement of the cervical and lumbar portions of the spinal marrow in horses. So great is the softening in some cases, that the substance of the marrow has become a diffluent mass; and in raising the cord out of the vertebral canal, it gives way at that part, the upper and lower portions being only united by the pia mater. Sometimes the softening does not extend through the whole thickness of the spinal marrow, appearing in one or two cases to be accurately confined to the anterior or to the posterior columns.

Ramollissement of the spinal marrow is by no means uncommon with new-born infants; it is most frequently coexistent with a similar ramollissement of the brain. One remarkable feature in this ramollissement is that it exhales a marked odour of sulphuretted hydrogen, indicative of a rapid advance of putrefaction. Such an alteration, Billard says, is generally found in infants who had lived only a few days, respired with difficulty, and exhibited but few signs of sense and motion. Congestions of blood are in general found in the viscera of the other cavities, and there is extensive disorganization of the brain. (Maladies des Enfants, &c. pp. 614–15.)

It is a fact deserving of attention, that the substance of the spinal cord softens very rapidly after death: the lapse of half an hour, during which the nervous substance has been exposed to the air, often produces a manifest alteration. This we have verified on numerous occasions.

2. **Induration** may be likewise regarded as a consequence of the inflammatory action on the cord; but the inflammation appears to be of a more chronic character. The opinion is founded upon the occasional co-existence of meningitis with many cases of this alteration and increased vascularity of the cord in the neighbourhood. When the induration is considerable, Ollivier observes that the nervous substance is similar to the white of egg boiled hard. It is not vascular; and in such cases there are not, in general, obvious indications that the indurated portion had been the product of inflammation. Induration has been found by Esquirol and Pinel in the spinal marrow of epileptics; and Ollivier gives an instance of

induration in the whole length of the cord in an epileptic. Billard, also, found it so extensive in a new-born infant, that the cord, after being stripped of its membranes, was able to support nearly a pound weight; in this case the meninges were lined by false membranes. (*Andral*, Anat. Path. by Townsend, vol. ii. p. 750.)

3. **Suppuration.**—When pus is found in the spinal marrow, it is generally infiltrated through its substance. Abscess of the spinal cord is very rarely met with. Two cases of this lesion are now recorded; one by Velpeau, and the other by Mr. Hart of Dublin; a third, which was met with by Dr. Carswell, has been alluded to in the article Abscess.

The symptoms which result from inflammation of any portion of the spinal marrow, vary according to the region in which the inflamed part exists. In the early stages there will be increased sensibility, more or less pain in the back, muscular spasm, and sometimes convulsion; as disorganization proceeds, the sensibility becomes blunted, and paralysis of sense and motion ensues; sometimes there is no paralysis, but violent convulsions, and in such cases the fatal result ensues speedily. The progress of the symptoms is proportioned to the activity of the inflammation. Hence in some cases we have a train of obscure premonitory symptoms: pain in the course of particular nerves; formication; feebleness of muscles; sometimes a kind of subsultus; deficient action of some internal organs which may be connected with the spinal marrow. If the seat of irritation be in the cervical region, difficulty of deglutition is among these precursory symptoms, and sometimes slight dyspnœa, which may end in complete asphyxia; but there is a remarkable variety as to the extent of the paralysis which follows disease in this region. In some cases it has extended to the four extremities, but in others it was confined to the upper, and in a few instances the paralysis affected the lower extremities only, although the upper part of the cord was most extensively the seat of disease. This fact has been regarded by some physiologists as proving that the several segments of the spinal marrow are independent of each other; though it is obvious that, if we admit the justice of this inference, a difficulty, perhaps as hard to be surmounted, will arise to account for the occurrence of paralysis from a lesion precisely similar in locality, extent and nature. It is well known that the division of the spinal marrow in the neck of an animal leaves his four extremities powerless; and that the dislocated cervical vertebra which so compresses the marrow as, if we may so speak, to stop the nervous current downwards, paralyses every part below it. Have we not, then, as much reason to infer from these facts, that the inferior portions of the marrow are dependent on the superior, as to suppose them independent, merely from the occurrence of a few such cases as those we have alluded to? In the present state of our knowledge as to the connection of the brain and spinal marrow, and their influences on each other, and on the organs of motion and sensibility, we are not authorized to form conclusions from data which, to say the least, are not completely established.

Sometimes the symptoms of an acute affection of the heart have manifested themselves when the irritation was seated in the dorsal region. M. Serres relates a case of meningeal inflammation and ramollissement of the cord, in which the heart's action and impulse were of such a nature, that the disease was pronounced to be dilatation with hypertrophy of the left side of the heart, which notwithstanding proved to be perfectly sound.

The lumbar region of the spinal marrow is most frequently the seat of morbid irritation: this produces all the symptoms of paraplegia, more or less perfectly paralysed limbs; formication or insensibility; tendency to the formation of bullæ; gangrene from pressure; retention and incontinence of urine; paralysis of the sphincter ani, &c. We would remark as to the nature of the incontinence of urine in these cases, that it is of that description which, paradoxical as it may appear, can exist along with retention. In some of these cases the bladder seems to be reduced to the condition of an inert reservoir, alike insensible to stimuli from within, and incapable of obeying them. Although all anatomists are not agreed as to the existence of a sphincter to the bladder, yet all admit that the *detrusor urinæ* muscle is opposed by muscular fibres, which prevent the urine from transgressing at least the limits of the prostatic portion of the urethra: we allude particularly to the muscle of Wilson, which compresses the membranous portion, and so opposes the flow of urine through it. This muscle may be paralysed, and so the passage of the urine remain free; or the sensibility of the mucous surface may be destroyed; and thus, although the muscle may be in a state of integrity, it will not act because the insensible surface will not convey the necessary stimulus. Hence, the retention of urine is always a prominent symptom from paralysis of the detrusor; and the incontinence appears whenever a patient is placed in such a position as will cause the urine to flow by its natural gravity.

To determine, then, the precise situation of the spinal inflammation, the practitioner has recourse to the early symptoms—the parts paralysed—and a minute examination of the spine. For this last purpose he may have recourse to the method proposed by Mr. Copeland, viz. passing a sponge filled with hot water along the spine; the patient will shrink as the sponge passes over the affected part. Percussion may in some instances direct us to the inflamed spot.

We subjoin two interesting cases of encysted abscess of the spinal cord, with a view to illustrate the symptoms in that stage.

The first is from the pen of Mr. Hart, a distinguished anatomist of Dublin, and is extracted from the fifth volume of the Dublin Hospital Reports. (P. 523.) A child, aged nine months, had been for about a month suffering from irritation of the bowels, which the parents supposed to be owing to dentition, when a lateral curvature of the lumbar portion of the spine to the right side was observed, accompanied with spasmodic twitching of the right leg and thigh. Soon after this occurrence the child was affected with convulsions, which became more frequent, and were shortly accompanied with well-marked symptoms of hydrocephalus, which, notwithstanding active treatment, proved rapidly fatal. On examination of the

head, there were the usual appearances from hydrocephalus. When the spine was opened, the spinal cord appeared of unusual thickness: an incision was made into it, from which some *thick purulent matter* flowed out. It was found that this matter was contained in a cyst which occupied the very centre of the spinal cord. This cyst was of an oblong form, extending from the first to the twelfth dorsal vertebræ, and was terminated by an obtuse extremity both above and below. Its diameter was about four lines, its parietes were a line in thickness, and so solid as not to collapse when the contained fluid was discharged. So completely did it occupy the centre of the cord, that the medullary substance formed a tube of equal thickness on every side.

The second case is quoted by Dr. Abercrombie from Velpeau. A woman, æt. fifty-six, was affected with sudden loss of power of the limbs of the left side without loss of feeling; it soon amounted to perfect palsy; her voice became feeble and her speech embarrassed; the pulse was natural, but the respiration quick. The left arm became œdematous. After four days the speech could not be understood, the pulse became feeble, with increasing general debility and stertorous breathing, and she died in a week. In the centre of the right column of the spinal cord, in the middle of the cervical portion, there was a cavity three inches long and two or three inches in diameter. It was full of a soft matter like pus, which became more consistent towards the parietes of the cavity, which were firm and about a line and a half in thickness. In the left column there was a similar disease but less extensive, being about one inch long and one in diameter, and its contents were less purulent, rather resembling ramolissement of the substance of the cord. (Velpeau, Revue Médicale, 1826.)

As to the duration of inflammation of the spinal marrow, it may be said to vary considerably; some cases have terminated fatally in three days. It has been observed that the fatal termination is much more rapid when the dorsal region is the seat of the disease; a fact which is attributed by Mr. Earle to the greater narrowness of the spinal canal in that region. When the disease has become chronic or passed into any of the stages above mentioned, life may continue for even a very prolonged period, patients thus affected continuing to live from five to fifteen or twenty years; but the ordinary period of duration of the chronic disease is two, three, or four years.

Treatment.—There is no reason why inflammation of the spinal marrow should not be cured, but it is so very seldom met with in the first stage, that the practitioner has always to labour at a great disadvantage. In the treatment of inflammation of the spinal marrow, the antiphlogistic system must be rigidly observed; general and topical bleeding, with counter-irritation from blisters or stimulants of various kinds. Issues or setons are to be employed if the inflammation be of the chronic form. The tepid or the cold douche applied from a great height to the suspected region, has been known to be very serviceable.

In the chronic stage we may expect to confer some benefit by the application of remedies. Perfect rest in the horizontal posture is, perhaps, the most necessary and useful measure, to which we may add the adoption of means to keep up a continued counter-irritation. Close attention to the digestive organs, a continued course of purgatives, combined with a mercurial, tepid or cold bathing or the douche, will often be found useful. The strychnine, too, may be administered either internally or to a blistered surface through the medium of the skin.

The effects of concussion of the spinal marrow seem to depend very much upon chronic inflammation. Concussion sometimes proves immediately fatal; probably in consequence of the altered circulation about the spine and the general shock to the nervous system, but in general no morbid appearances can be detected. It is possible that acute inflammation may follow concussion, but more frequently there are all the signs and symptoms of chronic inflammation, which in some instances disappear without any bad consequences. At other times the concussion is followed by some permanently morbid state of the cord, which causes permanent paralysis. Sometimes these symptoms continue from the moment of the accident, but at others the patient is taken up powerless; he recovers, and in a short time gradually relapses into a worse state. General paralysis has not uncommonly succeeded to this accident.

Atrophy.—According to M. Chaussard, the spinal marrow is one of those organs in which the effects of old age become very conspicuous. This organ, he states, becomes much increased in density as age advances, and exhibits a proportionate diminution in volume as well as in length. These changes take place simultaneously with similar ones in the brain. Ollivier has confirmed these observations. The volume of the spinal roots he found in a direct ratio with that of the spinal marrow, and atrophy was appreciable in each of them. It has also been noticed by Cotunnius and Magendie that the quantity of fluid round the marrow is in these cases inversely as the size of the organ.

Prolonged inactivity will produce atrophy even to the whole extent of the spinal cord, as in two cases seen by Ollivier and Magendie; and in many cases of paraplegia the spinal cord is found in a state of atrophy at the original site of the disease which caused the palsy. The condition of the roots of the nerves in atrophy of the spinal marrow is worthy of notice. In one case the anterior roots exhibited little more than neurilemma, but the posterior did not exhibit any obvious change. In another case the roots of the lumbar nerves were reduced to threads.

Prolonged pressure, as from a displaced vertebra, or a tumour in the spinal canal, has been known to produce atrophy of the compressed part.

Hypertrophy.—This affection has been a few times noticed in the cord. It is characterized, to use the words of Andral, by the enlargement and increased firmness of the cord without the presence of hyperæmia. The cord then fills the whole cavity of the dura mater, and is closely applied to the parietes of the vertebral canal. Laennec and Hutin have observed this condition to exist in the whole length of the spinal cord. Andral found it in the cervical region of an epileptic girl.

In consequence of the induration which accompanies hypertrophy, Ollivier inclines to the opinion that it is the product of chronic inflammation.

We know of no symptoms which particularly indicate the existence of either this or the preceding affection.

New Formations in the Substance of the Spinal Marrow.—There appears to be a perfect identity as to the nature of the morbid conditions of the brain and spinal marrow. This is in nothing better exemplified than in those chronic formations which are met with in the substance of the latter organ. All of them tend to the production of similar affections of sensibility and the power of motion, varying, like all the other diseases of this organ, according to the portion of the marrow in which these products are developed. The access and progress, however, of these symptoms are uniformly insidious and slow, and at first often simulate diseases of other organs; so that until the sensitive and motive faculties begin to be impaired, either together or separately, the practitioner is at a loss to account for the train of symptoms, or attributes them to a cause very different from the true one. These morbid products are as follow:—1. tubercle: 2. encephaloid and other tumours similar in the slowness of their growth: 3. entozoa: 4. osseous or cartilaginous tumours; but these are of rare occurrence.

Tubercle occurs more frequently in children than adults, and is much more rarely found in the lower than in the upper parts of the cord. In general, and according to Gendrin and Leveillé always, these tumours are surrounded and separated from the nervous substance by a cyst. Very often the symptoms resulting from the presence of one of these bodies are localized to one extremity, or to a particular nerve or nerves of an extremity, but in general there is very great variety in them. Epileptics are frequently found to have had tubercles in the spinal marrow.

Encephaloid tumours exhibit the same characters here as in other parts. We often find other tumours of a cellular or cellulo-vascular nature producing similar effects and similar symptoms.

The entozoa found in the spinal cord are principally hydatids and cysticerci. They are likewise found exterior to the meninges, which sometimes have seemed to have entered from some external part through the intervertebral foramina.

Having thus examined the obvious and tangible morbid changes which the spinal cord or its meninges exhibit, we shall next inquire how far a disturbance of the functions of the spinal cord may take place without the occurrence of any change of the structure visible after death.

It is by no means uncommon for the practitioner to meet with cases in which pain referred to some particular region, generally about the thorax or the abdomen, seems to have a remarkable connection with the spine. If, in these cases, the finger be passed down along the spinous process, making slight pressure on each, the patient will shrink when it comes to one or two particular vertebræ, and will complain that the pain shoots forward from the point compressed by the finger to that where the pain was previously felt. A very slight degree of pressure is in general sufficient to produce this result; but an increase of the pressure always adds to the intensity of the pain. Sometimes there is so much tenderness that the least touch will cause pain, and when there is such extreme tenderness it is not generally confined to one spot, but extends over the whole or a greater portion of the spine; at first, one would be led to consider the integuments as the seat of this extreme sensibility, but it is difficult to account for the connection of this increased cutaneous sensibility with the pain which had previously existed; and, moreover, it is equally difficult to conjecture how pressure of the kind alluded to on an osseous ring, such as the vertebra, can be communicated to a part so well protected and so far separated from the surface of the vertebral canal as the spinal marrow. That these cases very frequently, more especially when the irritation is confined to a small space, recover rapidly after the local detraction of blood by leeches, or by some counter-irritant, is a fact now pretty generally known; nor can we say that this fact serves to throw much light upon the true cause of the symptoms we have mentioned. On the other hand, instances are by no means wanting where these remedies have totally failed in removing the symptoms in question. The difficulty of finding an adequate explanation is greatest when the phenomena are slightest and confined to a very limited extent; but when the tenderness occupies the whole spine —when not only pressure from without, but even the slightest motion, aggravates the pain—we are then forced to admit that the origin of the evil is in the vicinity of the spinal cord itself. It is not fair to deny the previous existence of a morbid compression or irritation of the spinal cord or of the spinal nerves at their origins, because the anatomist can detect no vestige of disease after death. It must be remembered that the spinal cord and the nerves which emerge from it are surrounded by a venous anastomosis of remarkable complexity; that these veins do not possess valves; that they communicate freely with the superficial veins and with the numerous muscular veins in the region of the back. That respiration exerts a considerable influence on the venous circulation, has been long since fully proved. Nowhere can we expect this effect to be more marked than in the venous plexus of the spine, where the respiratory movements are so constantly felt, and where muscular action is so prominent in all the efforts of the trunk. From these anatomical and physiological considerations we may with justice infer that such a degree of congestion or turgescence of this spinal venous plexus as will excite irritation at the origins of the spinal nerves, may easily occur; and it appears to us that it is equally fair to conclude that such a congestion may exist *ante mortem*, and no trace of it appear *post mortem;* for to set aside all other means of accounting for the absence of the appearances, the very sections which are made to get at the supposed seat of the disease are sufficient to dissipate the venous congestion: we have stated thus much to show that anatomy affords some support to the doctrine of **spinal irritation,** as a source of many obscure morbid phenomena, a doctrine which has been put forward with more enthusiasm than discretion, and which, for that very reason, has received more opposition and less dispassionate consideration

than it deserved. While we would express our fullest concurrence in the wise caution which Dr. Abercrombie gives, that we should take care that this doctrine be not a *gratuitous principle* assumed so as to answer phenomena rather than deduced from observation, we must likewise endeavour, on the other hand, to avoid setting too slight a value on observations which are supported by many respectable names, and thus falling into an error which might debar us from many an opportunity of relieving distressing and obstinate symptoms.

The most complete account of the phenomena resulting from what is called "spinal irritation" yet published, is to be found in a work by Messrs. Griffin, of Limerick, on what they term "Functional affections of the spinal cord and ganglionic system of nerves." These writers are entitled to the merit of having with great industry collected many interesting cases, in all of which anomalous symptoms prevailed, and had a more or less obvious connection with that irritable condition of the spine to which we have alluded. To enumerate these symptoms would be but to recount the numerous ills to which flesh is heir: it will suffice to state generally the result of their observations, which it is but just to say bear the internal evidence of truth and accuracy. The symptoms are in general localized to those regions of the body which receive their nervous supply from that segment of the spinal marrow that occupies the irritable portion of the spine. Thus, when the cervical region of the spine is the seat of irritation, there may be painful affections of the head, the neck, the upper extremities, the respiration may be affected, or there may be pain in the chest. Some of these symptoms are of so severe a nature as to give rise to the suspicion of acute or chronic organic disease, and indeed one of the greatest difficulties connected with this subject consists in being able to discern when organic disease and when a simple spinal irritation gives rise to these symptoms. In some of the cases there have been fits of insensibility, paralysis, numbness of the cutaneous integument, deafness, cough and oppression, amaurotic symptoms, hesitation and difficulty of speech; all of which would at a first view of the case excite apprehension as to the existence of organic disease. Again, when the dorsal region of the spine is the seat of tenderness, there are pains about the chest or in the side, weight and constriction in the chest, cough and fits of syncope, sense of sinking, loss of appetite, vomiting, gastrodynia, pain in the region of the liver, hiccup, and where the lumbar region is affected, pains in the abdomen, dysury, or ischuria, pains in the testes or lower extremities, with disposition to paralysis. In a few cases there are symptoms resembling those above enumerated, but without any spinal tenderness; these cases were however considered and treated as cases of spinal irritation.

Females of a nervous temperament, who have passed the age of puberty and are prone to hysteria, are commonly the subjects of spinal irritation. The duration of this complaint is variable, sometimes yielding readily to the simplest treatment, and at other times resisting every mode of practice that can be devised; sometimes it yields and returns again, and so continues alternately to vanish and re-appear. It is obviously highly important that the symptoms which arise from this condition should be distinguished from those which result from organic disease as well of the spinal cord itself as of the vertebræ. According to the Messrs. Griffin, from whom (pp. 214, 15) we take the liberty of quoting the following paragraph, the symptoms which more particularly indicate spinal irritation, are

1st. The pain or disorder of any particular organ being altogether out of proportion to the constitutional disturbance.

2d. The complaints, whatever they may be, usually relieved by the recumbent posture, always increased by lifting weights, bending, stooping, or twisting the spine, and among the poor classes often consequent to the labour of carrying heavy loads, as in drawing water, manure, &c.

3d. The existence of tenderness at that part of the spine which corresponds with the disordered organ, and, we would add, the increase of pain in the organ by pressure on the corresponding region of the spine.

4th. The disposition to a sudden transference of the diseased action from one organ or part to another, or the occurrence of hysterical symptoms in affections apparently acute.

5th. The occurrence of fits of yawning or sneezing, which, though not very common symptoms, yet as scarcely ever occurring in acute or organic diseases, may generally be considered as characteristic of nervous irritation.

The treatment in these cases is either local or constitutional: sometimes local treatment alone rapidly removes all symptoms; but in general it is necessary to combine with it a plan of constitutional treatment calculated to regulate the digestive organs and to tranquillize the nervous system generally. Bleeding by leeching and cupping, blistering or counter-irritation by other means, constitute the local treatment; the use of the cold or tepid shower-bath, the vapour bath, or the warm bath, may also be advisable. Change of air and scene, and indeed all remedies which tend to divert the patient's mind to other objects than himself and his sufferings, are peculiarly applicable in these cases.

Most of our readers will recollect that the coincidence of spinal tenderness with hysteria forms the subject of a small volume by Mr. Tate, in which he gives several instances of the successful employment of the friction of the back with tartar emetic ointment. (Tate on Hysteria.) This writer, like many other practitioners, considers that the frequency of the occurrence of spinal tenderness in hysterical cases may be accounted for by a supposed connection between the uterus and the spinal marrow. There can be no doubt that an anatomical connection does exist between these two parts, as well through the medium of those uterine nerves which are of spinal origin, as indirectly through the filaments derived from the sacral ganglia which inosculate with the anterior branches of the sacral nerves. Moreover it very frequently happens that symptoms of spinal irritation or more serious spinal disease rapidly make their appearance after the sudden stoppage of the menstrual flux from whatever cause. The generative system in the male seems

to have somewhat a similar connection with the condition of the spine, and we now and then read of and meet with cases in which the symptoms seemed to follow as a direct consequence upon an excessive abuse of sexual intercourse. The extreme pain and tenderness of the loins which precede a difficult menstruation or a hemorrhoidal flux, or which follow the stoppage of the latter, and which often accompany amenorrhœa, cannot be supposed to have their seat primarily in the lumbar muscles; but may, as it seems to us, be reasonably accounted for on the supposition of the existence of a vascular turgescence surrounding the branches of the lumbar and sacral nerves as they escape from the spinal foramina. This view may with equal probability be applied to account for the phenomena of spinal irritation generally, as it is obvious that a congestion affecting the nerves at their exit from the spine will be just as apt to produce the varied symptoms which we have detailed, as if the marrow itself were the congested part.

Mr. Teale adopted the doctrine of spinal irritation in explanation of many forms of neuralgia, and, as we think, with much justice. He records several cases of neuralgia of the scalp, upper extremities, the mamma, — lower extremities, the knee, in which there was an evident connection with spinal tenderness, and which were successfully treated by remedies applied to the spine. Mr. Teale's experience fully accords with that of the Messrs. Griffin, as well as that of Dr. Brown, who was among the first to call attention to spinal irritation in a paper which he published in the Glasgow Medical Journal for May 1828. Similar views were entertained by the late Dr. Darwall, whose opinions are recorded in a paper entitled "Observations on some Forms of Spinal and Central Irritation," and published in the Midland Medical and Surgical Reporter for May 1829.

We have thought it unnecessary in this article to enter into any statement of the views of many authors as to the degree in which the spinal marrow is engaged in many diseases of a convulsive or nervous character. Under the respective articles, Convulsions, Epilepsy, Hydrophobia, Tetanus, the reader will find this fully treated of.

R. B. Todd.

SPLEEN, DISEASES OF THE.—The internal structure of the spleen is very similar to the erectile tissue, being composed chiefly of arteries ramifying on the walls of cells formed by irregular perforations in the sides of the veins. It is connected in a remarkable manner to the stomach by the vasa brevia. Its artery is of great size and strength, and remarkable for its great tortuousness: the vein also is very large, and always forms a principal branch of the vena portæ; it is well supplied with nerves and lymphatics.

Diseases of the spleen are little studied, because they are not very obvious, and are supposed to be rare; but they are by no means of unusual occurrence. In moist countries, whether warm or temperate, they are endemic, as in Italy, Holland, South America, and some parts of India—in fact, wherever malaria exists.

Great diffidence seems to prevail in pronouncing on the existence of splenic diseases. It is most true that these affections are often rendered obscure by complication with other diseases, by the simplicity of the offices performed by the spleen, and by its being an organ of much endurance, occasionally suffering, with little apparent inconvenience, considerable derangement when produced slowly. Further difficulties are created by the situation of the spleen; placed, as it is, deep in the left hypochondrium, and surrounded by organs of great importance and easily disturbed. But it is by no means rare, as some seem to imagine, that diseases of this viscus are to be detected only when cure has become impossible.

The diseases of the spleen may be enumerated according to the various alterations in its structure: — 1. inflammation and its consequences— suppuration or abscess, and gangrene; 2. softening; 3. induration; 4. simple enlargement and hypertrophy; 5. atrophy; 6. hemorrhage or apoplexy of the spleen; 7. hydatids or cysts; 8. tubercles; 9. melanosis; 10. calcareous deposits.

Inflammation of the Spleen. — This may be either *acute* or *chronic*. The symptoms of *acute* splenitis, according to Grotannelli, are, after a sensation of cold and partial rigor, a feeling of weight, fulness, and pain in the left side extending to the left shoulder, increased on pressure and coughing; thirst, some degree of nausea, dry cough, with the usual symptoms of pyrexia. Hæmatemesis, faintings, or pain on respiration are occasionally observed, but not frequently in the simple form of this disorder. The same author states that a natural crisis is frequently observed after hemorrhage from the nose or stomach, after a copious deposit from the urine, after the disappearance of the headach; when the hemorrhoidal or menstrual flux supervenes, and also after a profuse discharge of the lochiæ. In violent examples of this disease, those which rapidly terminate in a general dissolution of the splenic tissue, incessant vomiting is a prominent symptom, which is often attended by discharge of grumous or clotted blood both from the stomach and intestines.

In the most satisfactory accounts of dissections of acute splenitis on record, we find it stated that the peritoneal coat is inflamed and adherent to the surrounding parts: the parenchyma is observed to be swollen, hardened, and variously discoloured. If the disease have been violent, the organ is more or less dissolved into a semi-fluid pulp of grumous or coagulated blood and sanies. There is often disseminated throughout this mass a creamy pus, either in innumerable drops, or in one or more large deposits — without being at all times contained in a distinct sac. Similar appearances were observed by M. Gendrin in the spleens of dogs, in which he had excited inflammation by the insertion of caustic into their substance. In these cases, when the inflammation was in its first degree, he found the splenic parenchyma of a brownish red colour, gorged with blood, denser than natural, though easily torn. At a more advanced stage, the spleen became of a greyish brown and still more friable, and when cut into, presented a close sponge-like tissue, filled with blackish blood. In the third degree of intensity, the spleen was resolved into a pulp, like the lees of red wine.

Dr. Ley has fully detailed a case of acute

splenitis, complicated with inflammation of the uterus, which terminated in nine days. (Trans. Coll. Ph. 1. v. 304.) On dissection, the spleen was found adherent to the contiguous peritoneum. Internally it seemed like a piece of extremely soft sponge. Its cells had been filled with an intimate mixture of pus and grumous blood. On placing it in water, innumerable vessels, as fine as the fibres of swan's-down, floated separately, rising from every point of the superficies of the organ. The contents of this spongy mass having been removed by repeated washings, something like an attempt at the formation of cavities, to contain the matter, manifested itself: no regular cyst, however, had been formed. All the other viscera, abdominal and thoracic, were healthy, except the uterus, whose inner surface was gangrenous.

The example of acute splenitis in a boy, aged three years and a half, related by M. Huguier, (Journ. Hebd. vii. 424,) is very curious. After the ordinary symptoms of the disease had existed for a week or ten days, occasional convulsions with insensibility came on and lasted a week. After the use of leeches and aperients, the boy became much better, but on the twentieth day of the illness, gangrene attacked successively the right foot, leg, and thigh, and some days afterwards passed to the left leg. The child died on the thirty-sixth day from the first seizure.

The external coat of the spleen adhered all around pretty generally, and in its substance two abscesses were found. All the other viscera of the body were sound. The most remarkable feature in the case, as connected with the sphacelus of the lower limbs, was that all, or very nearly all, the branches of the abdominal aorta below the second lumbar, were found plugged up with fibrinous clots. There was a dense clot in the aorta near its bifurcation, which seemed older than the rest.

If, after a certain period, the inflammation of the spleen do not yield, it assumes the chronic form. Dr. Grotanhelli thus enumerates its symptoms, as the disease occurs in Italy; and the description applies well generally. "There is a sensation of weight and pressure in the left hypochondrium, fulness and swelling in that situation; an obtuse pain or sensation of uneasiness, especially when turning in bed; indigestion; disturbed sleep and unpleasant dreams; sometimes dyspnœa, with a dry cough; defective nutrition; a sallow complexion, and sometimes scurvy. The enlarged spleen may occasionally be distinctly felt early, and always late in the disease."

Wandering pains in the limbs, sometimes ending in collections of pus under the integuments of the thigh, arm, &c. are not uncommon in chronic splenitis. In the latter periods of the disease, the debility and emaciation become very great; the complexion darkens and the appetite fails. Hectic, more or less violent, (sometimes very slight,) comes on, with diarrhœa or vomiting of unconquerable pertinacity, and blood is frequently discharged both upwards and downwards; the patient often complains of aching pains all over the body, accompanied with restlessness, anxiety, vertigo, or sleeplessness.

The variation in the severity and duration of the complaint is very great. If it have accompanied ague, the symptoms may possibly not have been urgent in the outset, but it is almost always a painful as well as formidable disease. It commonly continues for some months, and may last for years with remissions.

The spleen is so closely connected with several important organs, that it cannot well be inflamed without implicating one or other of them. When the diaphragm becomes inflamed, the breathing is hurried, laborious, and painful; there is frequent dry cough, with palpitation at times. Thus, in a case related by Cozè, (Ed. Med. and Surg. Journ. xx.) and in another by Cruveilhier, (M. C. Rev. xii. 63,) great anguish and an occasional sense of impending suffocation aggravated the sufferings of the patient; and dissection showed that the enlarged spleen, and the adjacent part of the diaphragm, were covered with false membrane. In an example described by Dr. Bree, the suffocative feeling came on in spasmodic attacks, attended with faintness and confusion of head. These paroxysms left the patient very weak, and were attended with intolerable pain in the side. In two cases, one reported by Mr. Howship, and the other by Mr. Cozè, (before quoted,) the spleen adhered closely to the stomach, and poured its contents into it by an opening. In that of Mr. Howship, the man, during life, passed blood constantly both by stool and by vomiting; and, on dissection, the stomach was found full of that fluid. M. Cozè found the spleen full of pus: the vomiting, during life, had consisted of pus and blood.

The liver, according to systematic writers, is usually diseased in this form of splenic inflammation, but we believe that this does not so often occur as is supposed. Out of fourteen severe cases ending in abscess, the liver was only in some degree deranged in two. In five other protracted and finally fatal cases, not ending in suppuration, this organ had only undergone slight alteration in four. If the complaint last very long, any of the surrounding viscera may become involved in inflammation; and the instances are not few. One of the most remarkable combinations takes place when the disease extends to the kidney, and proves rapidly fatal, with the usual symptoms of ischuria renalis. (Abercrombie.) Accumulation of serum in the peritoneal sac is not an uncommon effect of chronic inflammation of the spleen.

The terminations of chronic splenitis are resolution, hypertrophy, suppuration, softening, induration, ossification, and gangrene. Though there are cases on record of the termination of inflammation of the spleen in resolution, this does not take place often. Collections of pus in the spleen are on the whole rare, and the symptoms of their formation are obscure and unsatisfactory. When the pus is deposited in the parenchyma, the membranes being sound or nearly so, the pain in the part is small; but there is uneasiness, and both strength and flesh waste gradually until the patient dies. As soon as the investing membranes are affected, the sufferings become varied and acute; frequently with a peculiar sense of heat in the left hypochondrium. The pain often strikes to the spine, clavicle, or shoulder. The membranes are almost always affected sooner or later, and, together with the neighbouring viscera, are covered with coagulable lymph. The pus is of the ordinary

creamy kind, but is sometimes concrete. (Cruveilhier.) It varies in amount from a few ounces to many pounds. It is often found infiltrating the whole or part of the substance of the spleen, or in minute yellow dots intermixed with the blood in the cells. (Andral.) The filamentous tissue of the organ, though bathed in pus, is sometimes quite uninjured; but generally it is pulpy and diffluent. On most occasions the pus is collected in a distinct sac or sacs, within the parenchyma of the spleen, which is more or less softened, or even altogether destroyed. The pain and fever generally run high when there is an organized sac. The sac may be fibrous, cartilaginous, or even bony. It is often very large, and is occasionally easily torn, although perhaps half an inch thick. The matter may find its way into the stomach, colon, peritoneal cavity, the left side of the chest, or into the lungs, inducing symptoms of phthisis; or it may burst outwards through the abdominal walls. In Dr. Tweedie's case of splenic abscess during fever, it had nearly perforated the contiguous part of the diaphragm; and in two cases given by Drs. Grotannelli and Raikem, there was a purulent discharge through the abdominal parietes, the spleen having formed an adhesion to them.

Softening.—We have stated that there are many cases of chronic splenitis in which the only morbid changes observable in the viscus are, an inflamed and even ulcerated state of the membranes, and the dissolution of its substance into a bloody colluvies. Under such circumstances, the spleen is generally enlarged, and converted into a cyst with thickened and hardened coats, full of dark-coloured sanies, as in a case narrated by Dr. Heberden, (Comm.) and in one of Dr. Abercrombie's cases it was broken down like grumous blood, and full of a matter like the lees of red wine.

Besides the inflammatory softening there is another of a character quite peculiar, and not as yet well understood. The structure of the spleen is here more or less destroyed; and it is often reduced to a simple bag, containing a substance which varies from the state of clotted or grumous blood to that of tar. It is unattended by any of the characteristics of inflammation. Such, most probably, is the softening of this organ so constantly accompanying fever, if we take into consideration, with Louis, that the whole tissue of the organ is always affected, that in his forty-six cases, the peritoneal membrane was never inflamed, and that pus was never formed: it seems in some way connected with a febrile state of the body, and dependent on a change in the blood. Andral inclines to believe that the softening in intermittents is owing to the miasmatic poison altering the qualities of the blood. In forty-six dissections of typhoid fever, (Edin. Med. and Surg. Journ. xxxiii. 128,) Louis found the spleen natural only in four. In three-eighths of the cases, it was enlarged to more than thrice its usual volume; in three-fourths it was softened; in a fifth part of these to such a degree as to be reduced to a pulp with the greatest ease; and its colour was also generally changed. As this diseased state was universal in those who died at an early period, and was less and less frequent in the more advanced stages, it probably was never absent at the beginning. Softening of the spleen occurred much less frequently in other acute diseases, namely, in little more than a fourth part. Dr. Tweedie's (Illustrations of Fever,) experience is similar. Pearson Dawson, Vetch, Wardrop, and others, state that in the Walcheren fever, the spleen was usually found, after death, of great size, and generally a mere bag, filled with a liquid like tar, and weighing from three to five pounds. In the malignant fever of Italy, the dissolved or pulpy spleen, just described, is very common, in conjunction with acute inflammation of various organs, especially of the membranes of the brain, of the stomach, and intestines. Fatal rupture of the spleen, from extreme tenuity, is in these diseases an ordinary event.

Most chronic diseases, and especially those of the liver, and the dysentery of Arracan, are occasionally accompanied with this softening of the spleen, but the fact is often not known until after death.

Induration.—After symptoms of splenitis, we sometimes find the spleen much enlarged, with a compact structure like healthy liver. (*Hodgkin*, Med. Gaz. ix.) Dr. Abercrombie (Edin. Med. and Sur. Journal, xvii.) gives a case where the spleen was thus hard and enlarged, after all the symptoms of phthisis, for three years. The liver was also enlarged, but the lungs sound. The coats of the spleen in these instances are sometimes cartilaginous. Baillie states that cartilage usually shows itself on the convex surface. It is commonly smooth, and resembles the cartilages of the nose and ears rather than that of the ends of the bones. The substance of the spleen is sometimes so hard and brown as to have acquired for it the designation of scirrhus, but without any statement of particulars. Sauvages quotes a scirrhous spleen which weighed thirty-three pounds; but Dr. Baillie questions the existence of scirrhus in this organ.

Ossification, which is enumerated as another termination of chronic splenitis, is usually confined to the investing membranes, and is most frequently seen in elderly persons. Morgagni is probably correct in his opinion, that the ossifying process almost always commences on the dorsum of the spleen. He supports it by many examples. Morgagni describes the spleen of a day-labourer as "osseo-lapideum." The man had severe pain in the seat of the spleen. Andral once found this viscus transformed into a mere osseous shell, with a bony cancellated structure within. It contained a small quantity of reddish fluid like muddy wine. (Path. Anat. ii. 439.) Mr. Bampfied (Med. and Phys. Journ. xlv. 15) details the appearances on dissection, of a drunken wine-porter, who died of hydrothorax, with dilatation of the heart, in whose spleen a large bony tumour was imbedded and fixed to the parts about the spine. The man had for years had pain about the large end of the stomach, which left him after vomiting. He was also troubled with constipation, dyspnœa, cough, and pain in the left side of the thorax. Littre (Med. Essays, vol. i.) mentions an elderly gentleman of gay disposition, who, dying suddenly, was opened. He never complained during life. The spleen only weighed an ounce and a half; it was completely ossified.

Gangrene.—Ollivier (Dic. de Méd. xviii.) speaks of inflammation of the spleen proving mortal by gangrene; and Portal, in his Anatomie Médicale, says that this condition of the organ is often seen, and that it is more especially to be recognised by its fetid odour. There are, however, on record very few incontestable examples of gangrenous splenitis. Morgagni only gives two cases, and these not in detail.

In the treatment of *acute splenitis* we must be prompt and energetic; general bloodletting should be practised as long as the inflammatory pain is considerable, provided the patient's strength will admit of it. A moderate degree of catharsis should be kept up. A plentiful application of leeches to the seat of pain, followed by vesication, will sometimes complete the cure; but the disease is apt to remain latent: it may subside apparently, and then reappear with a violence sooner or later fatal.

In *chronic splenitis*, besides the removal of the cause and the restoration of the system to a healthy condition, we have to overcome subacute inflammation, to impart tone to the relaxed organ, and to stimulate its absorbents. This is a most obstinate disease under whatever shape it appear. The treatment indicated by Sauvages, (Nos. Meth. t. v. 493,) and even by earlier authorities, is that which, with some additions, is practised at present by most physicians in Europe. It consists chiefly of the combination of aperients with iron and sedatives. These had been laid aside, in Great Britain, in favour of mercury, until recently; but now almost all concur in testifying that the good effects of mercury as a deobstruent in chronic diseases of the spleen, are precarious, trivial, and temporary at best, while usually this remedy procures no mitigation of the complaint whatever. For this return to successful practice we are much indebted to Dr. Bree. He trusts principally to a combination of aloes with antimonials and neutral salts, given in small doses twice a day, with great perseverance; but he has latterly preferred the drastic purges to neutral salts. From three to six stools are procured daily with a decided increase of strength, and the gradual removal of the complaint; which, however, seems to require from three to six months to complete. The Hindoos for ages have cured this disease by administering vinegar and steel, and by procuring at the same time the above number of alvine evacuations daily by means of aloetics. Dr. Bree subdues increased irritability by conium and other sedatives; and if inflammatory exacerbations occur, he meets them in the ordinary way. This physician mentions that there is sometimes an apparent connection between epilepsy and chronic splenitis; at least, that there is a coincidence, and that by means of drastic purgatives he has cured both diseases. A similar remark is made by Hoffmann, in the chapter "De Vomitu cruento."

If the spleen seem to suffer from relaxation, more especially after iron, bitters, and acids have been used, iodine becomes worthy of trial: indeed it is strongly indicated here whether the strumous diathesis be present or not. Dr. Milligan (Med. Chir. Trans. ix.) and many others have furnished cases where cures have been effected by iodine, in chronic enlargement of the spleen, accompanied by a low degree of inflammation, occurring in children. We have ourselves seen this medicine of decided service.

Grotanelli recommends, as soon as the passive state is formed, those remedies which act chiefly by promoting absorption, and by operating through the kidneys, and which at the same time are both antiphlogistic and diluent. In conformity with this plan, he prescribes squills combined with digitalis and colchicum, the precipitated sulphuret of antimony joined to nitre and the supertartrate of potass.

In the chronic splenitis which terminates by softening, the stomach is peculiarly irritable: a blister should therefore be laid on the precordia occasionally, and an effervescing draught with a few drops of laudanum will be found beneficial. Smart purging was always productive of immediate relief in M. Cruveilhier's protracted case of chronic inflammatory softening. Issues and setons in the left side have been found particularly useful in this complaint, and especially in cases preceded by uterine disorder. Dr. Glionna, in Arch. de Méd. tom. xvii. gives a singular case of a cabinet-maker, aged twenty-nine, in whom an abscess of the spleen pointed externally, and was relieved of three pounds of pus by the insertion of a trochar. The wound closed after remaining open some days, and the man was restored to perfect health.

We think that the saline chalybeate springs of England, such as those of Leamington or Cheltenham, or the sulphureous waters of Harrogate, are entitled to a prolonged trial: the probability of their being serviceable is very great; they answer at once many indications of cure, and possess valuable collateral advantages.

In the temporary exacerbations of fever and pain in the side, which are but too common, general bleeding expends too much of the powers of the constitution to be used frequently in this protracted malady. Cupping, leeches, fomentations, or bran poultices, are productive of great benefit.

Simple Enlargement and Hypertrophy of the Spleen.—There is a simple enlargement of the spleen from mere temporary congestion, [*Splénohémie*, of Piorry,] as when brought on by sudden mental emotion, or by oscillations of the circulation from internal causes. Andral observed the spleen of the living dog to undergo remarkable changes of bulk during a painful experiment, (Dict. de Méd. art. *Erectile*); and Cruveilhier mentions the great frequency of rupture of the spleen in the draught-horse, after violent exertion. (Dict. de Méd. et Chir. i. 291.) Numerous observers (Stoker, Andral, &c.) state that, during the cold stage of the ague, the spleen has been perceived to be painfully tumefied, subsiding immediately after the fit. In temperate climates, the more permanent enlargement or hypertrophy of this organ not being accompanied by the same violence of constitutional disease as in the hotter, is usually of a passive character, and probably in a majority of instances is owing to relaxation of fibre. In Lincolnshire, individuals carry about with them very enlarged spleens for many years, and die eventually of other diseases. Lommius knew many who had tumid spleens all their lives. Lieutaud speaks of a woman who had for seventeen years a

spleen weighing thirty-two pounds. Haller abounds in such facts. The most frequent causes of enlarged spleen are ague and remittent fever; it is therefore chiefly to be found where these are endemial, but it is not very uncommon in any part of Great Britain.

Hypertrophy is liable to pass into inflammation, but it may remain stationary, or yield to the restorative powers of the constitution, with or without the use of medicine.

The most characteristic symptoms of hypertrophy are, a sense of weight in the left side, with or without evident swelling; inability to lie on the right side with ease; debility; disordered stomach; dry cough, and absence of fever. When obvious enlargements take place, we can almost always distinguish them from other tumours by their history, and by their usually increasing obliquely from above downwards, or from left to right. Percussion makes us sensible of a peculiar uniformity of consistence in them, and often enables us to trace their boundaries with great accuracy. It is true that there are here many sources of deception, as, for instance, tumours in the peritoneum, increased bulk in the left lobe of the liver or left kidney, thoracic disease, &c. But in such cases we shall be greatly assisted by the symptomatology.

The indications of treatment in this form of splenic disease are, first, to remove the cause; secondly, to restore the organ to its natural condition; and, thirdly, to improve the general health. If ague be the exciting cause, it must be combated by the appropriate remedies. Warm and brisk purgatives should be given once or twice a week, of the kind affecting the upper bowels. Mercury in all its forms should be avoided, from its having been found prejudicial on extensive trial.

The bowels being kept somewhat more open than ordinary, the nascent irritative stage having gone by, and the case being strictly passive, tonics are to be had recourse to, and especially the acids, with the preparations of iron. The quinine, which has been prescribed to cure the ague, will probably be serviceable to the hypertrophy.

[Of late, strong testimony has been brought forward in favour of very large doses of sulphate of quinia—from twelve to eighteen grains and more in the twenty-four hours; and the most obstinate cases are said to have yielded to a continuance, for a few days, of this treatment. (MM. Bally, Nonat, and Piorry, cited in *Med. Chir. Rev.* for July, 1840, and Dalmas, Art. *Rate* in *Dict. de Méd.* xxvii. 269, Paris, 1843.) The sulphate of quinia has likewise been used both endermically and iatraleptically; but this course appears to have had more effect upon the fever than upon the splenic enlargement. In most cases, the action of the sulphate of quinia is aided by the previous abstraction of blood, by cupping or leeches, from the left hypochondrium. Occasionally, the application of a mercurial plaster, with which six or eight scruples of sulphate of quinia have been incorporated, has relieved the enlargement effectually. The plaster must be renewed when the substances of which it is composed are exhausted, which requires from 40 to 50 days. This method, however, must necessarily be slow in its action.]

When the complaint is preceded or accompanied by suppression of the menses, in addition to the application of leeches to the left side, and moderate but sustained purging by aloetics, the sulphate of iron should be prescribed in such doses, and as soon, as the pulse will permit. Under the use of iron we may expect to see the morbid pulsation of the heart and arteries, the tumefaction of the spleen, and the chlorotic tint, depart as by a charm.

[In long protracted cases of every kind, no better preparations exist than the combination of iodine or bromine with iron: iodine ointment may also be rubbed on the region of the spleen night and morning; or the ointment may be composed of iodine and iodide of potassium; or of iodine and mercury.]

Repeated emetics have frequently dispersed simple enlargement; and cataplasms of tobacco-leaves have, according to Mr. Stedman, (Med. Essays, Edinburgh,) produced the happiest effects.

Kneading with the hand twice or thrice a day has been practised with benefit, and especially in the West Indies. Equable and moderate pressure by a broad elastic belt would probably create a beneficial excitement in the diseased organ.

The diet should be bland, nutritious, easily digested, and less liquid than usual.

[In certain highly malarious countries, splenic hypertrophy is attended with a series of symptoms, which have been termed, in the aggregate, **Splenic Cachexia**; and although this *vice* of the whole system of nutrition is more common in torrid climes, it is occasionally witnessed in the temperate. The patient is sallow, almost anæmic; liable to dropsical effusions, and to hemorrhages, which are checked with difficulty, owing to the irregularity in the circulation, which is partly produced by the modified transmission of blood through the spleen. (See Twining, *Clinical Illustrations of the more important Diseases of Bengal and Calcutta*, 1832.)]

Atrophy of the Spleen is by no means so common as hypertrophy. Haller, (Elem. Physiol. vi.) Bonetus, and modern writers relate instances, but their statements are so meagre and contradictory, that no use can be made of them. It is sometimes found exceedingly small and even shrivelled, when some other organ is much enlarged, where there have been great discharges of blood, in ascites, and in extensive chronic disease. This form of disease of the spleen obviously admits of no remedy.

[An interesting case of the kind fell under the care of the writer, and was exhibited by him to the clinical class of the Philadelphia Hospital, in the winter of 1842–43. The spleen was not larger than an almond. The patient died of dropsy, without any indication of splenic disease.]

Hemorrhage, or Apoplexy, of the Spleen.—We shall here introduce M. Cruveilhier's valuable observations on internal hemorrhage of the spleen, which he denominates "apoplexie." (Dict. de Méd. et Chir. Pratiques, i. 291.) "I have often," he says, "met with in the substance of the spleen, apoplectic deposits of various sizes, round in figure, and exhibiting all the changes which the blood undergoes in such circumstances in the brain and other organs. The spleens of persons affected with agues have often presented, at one or more points in their parenchyma, brownish blood in larger or smaller quantities. I have also seen

ochry-brown cicatrices and fibrous cysts of the same colour—indubitable traces of former hemorrhages, with breach of substance. I am persuaded that these appearances are very frequent in the spleen. This is very distinct from pulpy softening of this viscus. At every strong muscular effort, the blood rushes in abundance into the cells of the spleen, and distends them, and so rupture may be the consequence. What renders this opinion probable is the frequency of hemorrhage in the spleen of the horse. I showed at one of my lectures hemorrhagic deposits, in many stages, in the spleen of a horse. Bailly gives two cases of spontaneous rupture in remittent fever."

It is impossible to predicate this state of the spleen in the living subject; if it were ascertained, however, the treatment is the same as in hemorrhage from the lungs or any other organ.

Hydatids have the same origin in the spleen as in the liver and other organs in which they are found. They may be simply attached to its surface, be placed between the membranes, or within its substance. They are met with in males and females of relaxed and feeble stamina, but more frequently the latter sex. Their occasional causes are not known. The disease arises quite unconsciously to the patient, the first intimation of its existence being debility, dyspepsia, and the uneasiness created by a slowly increasing tumour, which, in its progress, causes further derangement by compression and displacement of other organs, and becomes itself but too perceptible externally. It is only when the containing membrane, or some organ, becomes inflamed, that fever, pain, and their fatal consequences ensue. The patient may die of another complaint during the indolent continuance of this; it may end in suppuration or ulceration of the containing sac, when the hydatids will probably destroy life by passing into the peritoneal cavity. The cysts may be burst by external violence. Hydatids may prove fatal without being inflamed themselves, by disturbing the circulation or by irritating other viscera. This is a very obscure disease, and admits of but little medical interference.

Full statements of two very interesting examples of hydatids in the spleen are inserted in the sixth and twelfth volumes of the Medical Repository. The symptoms during life in both were those of a general breaking-up of the constitution. In one there was hæmoptoe. The spleen in both cases was very large, quite disorganized, and divided by a membrane into two cavities, full of large and small hydatids containing serum.

Cysts of other descriptions are also seen in the spleen, which, although not discernible during life, should not be passed by in silence. "The simplest form," according to Andral (Anatom. ii. 438), is that "of small vesicles filled with serous fluid, which are sometimes found in great numbers, either singly or in clusters, not in a sac. These vesicles are not confined to the splenic cells: I have also found them in the interior of the splenic veins, some floating loose, others attached by peduncles to the sides of the veins, and others again lodged between their coats. Cysts of a more complicated structure are likewise found in the spleen. I have seen one with a fibro-serous tunic, which contained in its interior a substance resembling suet interspersed with hairs. In another spleen I found a cyst composed of serous membrane filled with a substance like honey, and of a bright yellow colour."

Dr. Abercrombie (Dis. of Abd. p. 389) describes an infiltration of the substance of this viscus with a gelatinous fluid, and deposition of fatty matter, throughout its structure. It is distinguished by no particular symptoms.

The formation of hydatids in the spleen is irremediable in the present state of medicine. We cannot with any degree of certainty detect them during life until they become very bulky, or until some have been discharged. Almost all that is in our power is, to keep the system as nearly as possible to the healthy standard. If the cyst point, it will be unwise to puncture it, although this has been done in a very few instances with success. If it be resolved to puncture, a trochar must be used, not thicker than a common needle, and then only when the sac evidently adheres to the abdominal parietes. In opening the cyst there is a momentous risk of the contents flowing into the abdomen; and a second risk, of the suppuration of its internal parietes, with the usual fatal consequences of such an event; and, moreover, who will assure the operator that his trochar shall not wound some large vascular trunk in the sac?

Tubercles.—We occasionally find tubercles disseminated in the splenic tissue. They are in masses or grains, few in number or in great quantities. They are of the same nature as the pulmonary tubercle. We rarely meet with tubercles in the spleen, except in cases where they also exist in other organs. They very commonly attack this organ in children, in whom they are often found in a state of softening. This tuberculated condition of the spleen, which is met with in children, is certainly much under the control of iodine, continued long, and in small doses. It should be applied at the same time to the side in the form of a liniment. Of course, the same attention to food, clothing, air, and exercise, which is observed in strumous disease, must be paid here; and the medicines most beneficial in such a diathesis should be employed, if it become necessary to omit the iodine for a time.

Melanosis.—The spleen is occasionally affected with melanosis, as is seen in the accounts of this affection published by Cullen, Halliday, Alison, Carswell, and others.

Calculous deposits are seldom observed in the spleen. Bonetus (Sep. l. ii. s. iv. obs. 48) states that a widow had fever, pain in the back, suppression of urine, and then died dropsical. After death the spleen was found doubled up, as it were, and full of calculi. There was a square calculus in the right kidney. Morgagni (Ep. 36 a. 14) mentions two cases of splenic calculus in a woman and a youth. He says that they are sometimes very white; that they may be many or few. He saw one which weighed twenty-one drachms, and which was formed in concentric layers.

The treatment of melanosis and calculi of the spleen must be obviously palliative, and does not call for particular remark.

Rupture.—Numerous cases are to be found in Bonetus, Van Swieten, and the periodical pub-

lications of the present day, of rupture of the spleen by blows or falls. While the organ is lacerated extensively, the parietes of the abdomen may be little or not at all injured. In the instances which prove fatal in a few hours, the symptoms are great shiverings, coldness of body, vomiting, and other signs of extreme collapse. When there is time and strength for reaction, there is considerable fever, with a remarkable heat of skin, and great pain in the left side, or all over the abdomen; the stools and urine are nearly natural, for a short time at least.

In a case related by Mr. Greene (Med. Gaz. iii. 591), where the man had fallen from the third story of a house, the peritoneum was not inflamed, although much blood had flowed into the sac which it forms. The man lived four days. In the Archives de Médecine, vol. vi., there is an uncommon case reported by M. Deguise, where the splenic vein was ruptured by a blow on the left side, a month before death. The splenic vein had poured its blood into the abdomen. A remarkable example of spontaneous rupture is well detailed by Mr. Ancill in the Med. Chir. Review, vol. xiii. It occurred in a drunken blacksmith. There was immediate and extreme prostration of vital power, together with great sense of weight at the epigastrium. He died in sixteen hours. On dissection, an extensive black coagulum was perceived to occupy the upper part of the belly, and concealed the spleen. The substance of the latter was torn into large triangular fragments of bloody pulp, cemented together by a dark coagulum of a firmer consistence. A small round hole was observed in the dorsum of the organ. It adhered to the surrounding parts much more largely than usual, and seemed increased in size from effusion of blood. Scoutteten and others have noticed very truly that the redness of the parts round the ruptured spleen is not inflammation, but a stain from imbibition.

In the majority of instances of ruptured spleen from external violence, the injury is so overwhelming that little is left for the medical attendant to do. Free venesection and perfect rest, however, have saved life.

J. J. Bigsby.

[**Dislocation** *of the spleen, Splenectopia*, or removal of the spleen from its place, must be an uncommon occurrence, and when it does occur must give rise to phenomena that are by no means easy of comprehension. Few such cases are on record. One, of a highly interesting character, fell under the writer's notice, and has been described by him elsewhere. (*General Therapeutics*, p. 305, and *Practice of Medicine*, 2d. edit. i. 554, Philad. 1844.) In this case the spleen was found after death to have broken loose from its attachments, and was resting with its convex surface on the brim of the pelvis; the lower extremity of the organ being turned up so as to reach the lumbar region of the right side. It was suspended by its peritoneal and vascular attachments, and could be moved freely in every direction.

It need scarcely be said, that if dislocation of the spleen should be detected during life, no skill on the part of the practitioner can restore it permanently to its situation. That position must of course be selected for the patient, which gives occasion to the least inconvenience; this will probably be on the left side; but it can rarely happen that the dislocated organ does not speedily give rise to fatal inflammation of the peritoneum.

Robley Dunglison.]

STATISTICS, MEDICAL. *Vital Statistics.*—The word statistics is of modern origin; it was first invented in 1749 by Achenwall, a professor of Göttingen. Applied to political subjects, this term expresses the investigation and exposition of the actual condition of states and countries. It principally includes those particulars in the condition of a nation which are capable of being reduced to numerical calculation; but its domain is not necessarily confined within such limits. Medical statistics may, perhaps, be defined to be the application of numbers to illustrate the natural history of men in health and disease.

[A recent writer (Raige-Delorme, art. *Statistique Médicale*, in *Dict. de Méd.* xxviii. 549, Paris 1844) considers it to be "synonymous with *numerical method, and calculation of probabilities* applied to the systemization of medical facts," and so treats of it.]

We know too well how enormous is the quantity of facts which has been accumulated in every department of medicine during the last two thousand years; the most pressing want which our science at present suffers, is the reduction of this vast mass into separate groups, and the establishment of certain definite principles. The performance of this important task has occupied the attention of many eminent men; but they do not appear, until lately, to have sufficiently appreciated and employed the valuable instrument of statistical calculation. By the aid of numbers we are enabled to classify the irregular, and many-coloured, and conflicting observations which have been bequeathed to us by our predecessors, and which are daily presented to us by our contemporaries: instead of losing ourselves in a continual reference to opposite authorities, we compute the amount of evidence on both sides of a question, and thus arrive at a positive conclusion. It is probably only by the assistance of the statistical test that we shall finally arrive at fixed conclusions respecting the efficacy of various modes of treating a disease, and the prognosis to be formed respecting the issue of various diseases. It is only by means of this auxiliary that we can estimate the comparative salubrity of different situations and of different modes of life, and that we can justly decide on the value of various modes of discipline and of diet.

As the principle of population is intimately connected with all inquiries of this nature, we shall commence our brief outline with a few observations on that long-contested point; believing that it cannot be indifferent to the physiologist, and that the best solution of its difficulties must always be sought in the stores of medical science.

The majority of writers at present agree with Malthus in maintaining the proposition that *cæteris paribus*, a population will uniformly increase with the powers of subsistence, and diminish with their decrease. To prevent the sufferings from want and disease which would attend the struggles

of a population against those limits on its increase which arise from the want of food, it is generally allowed that we must endeavour gently to check an excessive increase by moral restraint, and by the occasional exercise of a prudential abstinence from marriage. Such a prudential restraint is only that which a young man of education and reflection usually imposes on himself; however desirous of forming an union, he patiently awaits the moment when he can accomplish his wishes without degrading the object of his choice from her former standard of comfort, or without entailing poverty on his offspring; and we find, accordingly, that marriages occur at a later age amongst those classes or individuals who are distinguished for intelligence, sobriety, and self-denial, than among the uneducated and the careless. But, on the other hand, every endeavour should be used, by those who have the means of influencing the movements of nations, *to increase the supply of food*. From the wonderful activity of the principle of population, we are bound to deduce the expediency, not of multiplying checks, which already press but too heavily, but of removing that obstacle which is most opposed to the multiplication of the species and to its happiness and health, namely, the difficulty of obtaining nourishment. It has been justly observed that, until the world is already fully peopled, and until all its fertile soils are cultivated, the problem would appear to be not how to diminish but how to disperse; not how to lessen the number of consumers, but how to increase the means of subsistence; not to keep out of life, by anticipation, the multitudes ready to inherit it, but to place them in the situations most advantageous for their reception, and, in short, most hospitable to the new comer. Perhaps too much has been assumed, in treating of these subjects, respecting the *fixed limits* of every nation. Such limits, however, do not exist generally, and wherever they are found, they are also capable of being removed by enterprise, courage, and industry. Such limits, assuredly, are not the lot of our own country, which includes in the bosom of its various colonies a sufficiency of practicable and unoccupied land to supply bread, under suitable efforts, to inhabitants far more numerous than our present list. Independently of the benefit which colonization confers on the father-land, it promotes the general diffusion of knowledge, of civilization, and of religion in the most eminent degree, and in the only sure and permanent mode: pestilential regions thus become purified, barbarous practices are discouraged, the arts of life are made to travel, the rugged aspect of nature assumes a smile, and a new climate is created in the wilderness where vegetation was extinct, and where life had almost gone out. It is true that the able-bodied emigrant has not always the means of transporting himself from the old and closely-packed country to the comparatively empty land of his adoption; but selfish indeed must be the wealthy inhabitants of the parent state, blind or reckless must be its legislature, dull must be the prophetic spirit of all, if the funds which are ever at hand to gratify ostentation cannot also be supplied to remove the idle, the miserable, too often and too inevitably the criminal, from a theatre in which they are only sullen, ungratified, and unplaced spectators, to a new and ample stage, where they themselves will be enabled to act, and to reap the profits and the honour of their exertions.

Misery is one of the most powerful agents which operates in restraining the excessive growth of population. How far this scourge is capable of being permanently diminished by the wisdom of a legislature and the virtue of private citizens is a matter on which benevolence will always entertain a secret hope of better days, although we have no assurance that in *this* world the reign of great calamities is ever to be at an end. *Famine* is one branch of misery which is, perhaps, least under the control of human precautions; but *war*, the most terrible of all evils, is undoubtedly often induced by the vices of individuals. How frequently, to gratify selfish and grasping ambition, has this consuming fire been kindled to ravage whole districts, to extinguish villages, to destroy thousands of beings totally uninterested in the results, and to bring in its ghastly train both scarcity of food and epidemic diseases, scarcely less fatal than the sword? Unhappily in no age have such enemies of mankind been wanting; and too blindly have historians and poets offered their incense on the altar of blood. How often, if not to serve the views of an individual, at least to promote the designs of some political party, has a war taken its origin, and gradually extended itself over distant nations! War is the real parent of famine and of the most deadly diseases. The most severe epidemic fevers which have ever visited Europe have marched in the van of an invading army, or in the rear of a retreating one.

The price of *corn* has a most remarkable influence on the movements of population and of disease: we have not a sufficient number of data to enable us to estimate the exact amount of its influence, but we shall assuredly not be mistaken in classing it among the most energetic causes which press on the operations of life. This influence extends not only upon deaths but upon births; it affects also the number of marriages, of diseases, and even of crimes. Variations in the price of corn, then, form one of the most serious changes which can occur on the surface of a state; they may insensibly lead to the most unexpected, the most formidable results; and we may affirm with confidence, that one of the most important duties of a government is to temper and to diminish, as far as is possible, all the circumstances which promote these fluctuations in the price of the most necessary article of all which man can purchase.

The causes which tend to produce *longevity* have been repeatedly the subject of controversy; we shall present a few facts towards the illustration of this difficult subject.

The married live usually longer than the single, and it is amongst the married that the greatest instances of longevity have been found. The inhabitants of convents and of monasteries, in spite of the regularity of their habits, do not live longer than men of the world: De Parcieux and an old curate of St. Sulpice have produced tables which show that but few of these individuals attained the age of eighty, during the interval of years which elapsed between the years 1685 and 1745. But monks and nuns are not so long-lived as the

religious orders which are not immured within the gloom of the cloister; and, finally, we may observe, in order to point out the injurious tendency of that mode of life, that celibacy in the lay-classes enjoys a better chance of life than is the portion of the inhabitants of the monastery and the convent.

An abundant supply of the necessaries and even of the luxuries of life has a powerful agency in inducing longevity; and if we add to an easy condition of life the more rare gift of a tranquil mind, we shall have enumerated the two circumstances which are best calculated to ensure it.

Cultivation of the sciences and of literature is not a little favourable to longevity: we might produce many facts in support of this assertion. Such pursuits are well suited to compose, to calm, and to fortify the mind, and hence to form the quietude of soul which is a real elixir of long life.

The instances of *extreme* longevity are very rare, and form lonely exceptions to the established order of things; insomuch that an individual could scarcely be suspected to be in possession of common sense or information who should hope by any modes of diet, or any advantage of constitution, to exceed the age of 100. The most authentic examples of those who have far outstripped a century of years are afforded by the famous Parr, who married at the age of 120, retained his vigour till 140, and died at the age of 152, from a plethora, induced, it is stated, by a change of diet. Harvey, the illustrious discoverer of the circulation of the blood, who dissected him, could detect no signs of decay in any organ. Henry Jenkins, who died in Yorkshire in 1670, exceeded Parr, and attained 169 years. He is probably the oldest man on genuine record in modern times. The latest case is that of Joseph Sarrington, a Norwegian, who died at Bergen in 1797, at the age of 160.

Haller, whose accuracy and industry are well known, collected together the most authentic facts recorded in his time respecting the duration of the life of man, and found the following to be the relative proportions:—

Of men who have lived from 100 to 110 years, the instances have been	.....	1000
From 110 to 120	"	60
" 120 to 130	"	29
" 130 to 140	"	15
" 140 to 150	"	6
169	"	1

An American writer has lately expressed his belief that between 30,000 and 40,000 persons annually fall victims to the abuse of spirituous liquors throughout the United States. This belief is founded on the Bills of Mortality of the city of Boston, which, during the last two years, have reported an average of fifty deaths yearly, as proceeding from this source. Professor Hitchcock of Amherst College, in his Lectures on Dietetics, has lately estimated at from 30,000 to 50,000 the annual number of those who die prematurely, above twenty years of age, in consequence of such intemperance. These estimates are probably beyond the real amount of the mischief, extensive and revolting as it unquestionably is. On the amount of deaths produced by the *indirect* action of ardent spirits our evidence must always remain defective, because there is not a disease so induced which might not also admit of another cause, and here is an insurmountable perplexity.

[These observations are taken from an article by the writer in the *American Quarterly Review*, for Dec. 1830. The American writer, referred to above, affirms that the fifty deaths in the city of Boston, are "occasioned so directly by intemperance as to be entered under names of disease to which none but drunkards fall victims;" and supposing, he adds, "that on an average throughout our country, the deaths from intemperance bear about the same proportion to the whole number as they do in Boston, the *direct* victims to the use of ardent spirits in the United States may be estimated at 10,000 annually." (*American Almanac* for 1830.) The names of disease are not given; allusion is, however, doubtless made to mania a potû or delirium tremens; but it appears scarcely within the verge of possibility that 10,000 persons should die annually in the United States from delirium tremens, which is not a very fatal affection. Of 84 cases, treated during the years 1840–1841, in the women's lunatic asylum of the Philadelphia Hospital, which is under the writer's charge for six months of the year, but one died; and that one under particular circumstances. (*Human Health*, p. 306, Philad. 1844.)]

Mortality, or the calculation of the number of deaths which occur in a country or town, has become an object of important research; and tables are formed in almost every civilized state, by direction of the government, in order to ascertain this point. In some districts this amount is increased or diminished in a slight degree by direct and by local causes; but, on the whole, it appears that the good or bad condition of a people, the possession of the necessaries of life or their absence — the mildness or rigour of the mode of government—the advance or retrogression in knowledge — are the principal circumstances which influence the result. The following calculation of the annual number of deaths in the principal countries of Europe will give a sufficiently exact idea. Among all their inhabitants every year destroys, in

England and Wales, nearly	1 in 60
Pays de Vaud	1 " 49
Sweden	1 " 48
Holland	1 " 48
France	1 " 40
Kingdom of Naples	1 " 35
" " Wirtemberg	1 " 33
Prussia	1 " 33
Lombards—Venetian provinces	1 " 28*

This is the present proportion, but in several of these countries the number of deaths was formerly much more numerous. The mortality has diminished in nearly the same degree in which their prosperity has gradually increased. In England and Wales, for instance, the annual deaths were, in the census of 1780, so numerous as 1 in 40. In 1831 they were 1 in 47. So in France the annual mortality was, in the year 1781, 1 in 29, and in 1802 1 in 30. In Sweden, also, the annual deaths were 1 in 35, during the years between 1755 and 1785.

* In 1817, a year of scarcity, the number of deaths was so large as 1 in 14.

The mortality of large towns exceeds considerably that of small ones: the following table presents an approximation to the comparative mortality of great towns:—

In London, about	1 in	40 dies annually.
Birmingham	1 "	43
Nice	1 "	31
Naples	1 "	28
Leghorn	1 "	35
Paris	1 "	32
Lyons	1 "	32
Strasburg	1 "	32
Barcelona	1 "	32
Berlin	1 "	34
Madrid	1 "	29
Rome	1 "	25
Amsterdam	1 "	24
Vienna	1 "	22½

The late census of 1832 has not, as yet, been sufficiently examined to admit of any accurate inference, but we believe that it is rather less favourable to England than the preceding one.

[From the *Fourth Annual Report of the Registrar-General of Births, Deaths and Marriages, in England*, (London, 1842,) the mean mortality in four years is shown to have been 1 in 45.]

The deaths in a city are almost uniformly more numerous than those in a rural district. It is unnecessary in this place to inquire into the causes of this difference; they will readily occur to medical observers. Cities are the theatres on which the violent passions find their appropriate scene; in them the desperate struggles of life are decided; and they afford the most constant temptation to an excessive indulgence of every appetite. The atmosphere, the scanty exercise, the irregular hours, all add to the depressing influence of civic life; but still there are many individuals who habituate their constitutions with safety to a constant residence in towns, and attain a great age. These are beings cast in a happy mould, who are equally well placed in almost any situation, and flourish under every exposure. Children endure a town life less easily than adults; and, in general, those who are on the eve of sickness, or who have just recovered from it, begin to perceive the injurious effect of the confined air of cities, although they may have never been previously aware of it when in a state of health. As long as the patient remains in this situation, we often perceive that tonic remedies disappoint us of their expected results.

[The great attention which has been paid, of late years, to the influence of occupation and customs on human health, and more especially on the health of operatives, has thrown much light on this subject. (See ARTISANS, DISEASES OF.) The admirable Sanitary Reports presented to the British Parliament by Mr. Chadwick, and the inquiries of Messrs. Ure, Villerme, Noble and others, sufficiently show, that no peculiar evils to health and life attach necessarily to manufacturing pursuits; that, in so far as factories, and other corresponding places of labour, interfere with the right conditions of health, they lead, of course, to the production of disease, and to the shortening of life; but that these evils appertain rather to their *domestic* than to their *industrial* relations (*Brit. & For. Med. Rev.* April, 1843, p. 313.) A reference to the following table, from Mr. Chadwick, (*Sanitary Report*, p. 159, Lond. 1842,) of the mean annual mortality of females in twelve metropolitan districts, demonstrates, that difference of mortality is dependent rather upon locality, inasmuch as the greatest mortality prevails in certain places where no factories exist.

Districts.	Annual Deaths, 1 in
Hackney	57.87
St. George, Hanover Square	57.05
Camberwell	55.34
Islington	50.03
Rotherhithe	38.58
Clerkenwell	38.54
St. Luke	38.49
Greenwich	38.42
St. George, Southwark	33.77
East and West London	33.50
St. Giles and St. George	33.46
Whitechapel	28.15]

The number of deaths which occur at *hospitals* is very various, and yet admits of being explained on some general principles. The deaths in a large hospital are usually more numerous than in a small one; they are also more numerous in the hospital of a great city than in the hospital of a small town. The mortality of hospitals is always greater than that of the same number of cases taken from the same ranks of life in private dwellings, because the separation from the familiar scenes of home and from beloved faces is not compensated by the superior cleanliness and more abundant comforts of an hospital. It will be usually found that the number of deaths in hospitals bears a very near proportion to the state of prosperity and to the diffusion of knowledge in any given country or town. On sifting the reports of the hospitals of the continent, it will be usually found that their mortality is greater than that which is presented by the registers of British hospitals. Amongst other causes of this difference must be assigned the disinclination which has long prevailed on the continent towards the use of copious bloodletting in inflammations. Defective ventilation is one of the most common causes of an excess in the deaths of an hospital. The mortality in dispensaries is much less considerable than in hospitals.

A gratifying result, on the whole, presents itself to us in this section of medical statistics; the number of deaths in hospitals has greatly diminished throughout Europe during the last half century, and particularly in our own country.

It has been lately calculated that the number of the *deaf and dumb* is about 1 in every 1585 individuals. According to this computation, France has about 20,189 deaf and dumb; Austria has 16,684; and Russia in Europe has 27,834. Supposing, then, that Europe contains 214 millions of inhabitants, it will also probably contain 139,212 deaf and dumb individuals.

[According to the census of the United States for 1840, the proportion of deaf and dumb amongst the whites was 1 in 2123; amongst the coloured, 1 in 2933. (Prof. G. Tucker, *Progress of the United States in Population and Wealth in Fifty Years*. New York, 1843.)]

According to a computation recently made at

the Institution for the Deaf and Dumb at Paris, it would appear that only one in twenty-four of those unfortunate beings receives an education throughout the world at large: but that, in France, so many as one in four of them obtains a suitable course of instruction.

Suicide is a theme unfortunately very prolific of examples and of tables in almost all parts of Europe. But the number of its victims is very various in different places. England certainly no longer deserves the pre-eminent disposition to this crime which the conjectures of her neighbours formerly assigned to her. In France, Germany, and Denmark, suicide is extremely frequent; in England it is less common, but far from rare; in Sweden, in the Neapolitan dominions, in Russia, and, above all, in Spain, it occurs only in a scanty proportion. It is far more common in great towns than in small ones; far more frequent in towns than in rural districts; and its victims are more often single than married, more often males than females. It is impossible any longer to ascribe its prevalence to *climate*, or to the weather. We may trace it occasionally to two obscure causes, one of which is the principle of imitation; the other is an hereditary disposition. On the whole, it appears to occur more frequently among the lower classes of life than in the middle or higher stations.

According to the registers preserved in France, and recently analyzed by Mr. Guerry, about 1800 suicides take place in a year in all France; 6900 have been committed between the years 1827 and 1830. Mr. Guerry believes, however, that this number is considerably inferior to the total number of *attempts*; because the judicial authorities only take cognizance of those which terminate in death, or which furnish materials for a process. The nearer each department of France is to the capital, the more abundant are its suicides and its murders; the more distant each department is from the capital, the less frequent are both the one and the other. Thus, in the department of the Seine, which contains Paris, the annual proportion of suicides is one to every 3600 inhabitants; while in the province of the Haute Loire, the annual proportion is only 1 in 163,000 inhabitants. These two departments furnish the maximum and the minimum of suicide in France.

It would lead us too far, if we were here to enter into the interesting details which relate to the *increase* and *decrease* of particular diseases, and into the *comparative prevalence* of disease in different countries. We can only remark, generally, that the results of the inquiry are greatly in favour of our own time and country.

The statistics of the *sexes*, of *marriage*, of *pregnancy*, and of *infant life*, afford the most important information, alone sufficient to fill a volume. The proportion of males to females [born] throughout the world is about 21 of the former to 20 of the latter. The proportion of births to a marriage fluctuates in different countries: in England it is about 4 births to a marriage. At Paris the proportion is scarcely 2·44 births to a marriage, while in some villages of Scotland it is so high as 7. A most remarkable change has occurred gradually in the fate of lying-in women and of infants. In 1750, at the British Lying-in Hospital of London, 1 woman died out of 42, and 1 child out of 15; about the year 1800, in the same hospital, only 1 woman died out of 288, and only 1 child out of 77. In Prussia, 1 mother dies annually out of 112, taking hospitals and private life altogether. The deaths at lying-in hospitals are far more numerous than those which occur among the same class of women at their own dwellings. The deaths from parturition are far more numerous in great towns than in the country. [See, on all these subjects, the excellent work of Quetelet, *Sur l'Homme;* and especially the translation, Edinb. 1842: also, the writer's *Human Physiology*, 5th ed. p. 433, Philad. 1844.]

The subject of *life assurance* ought to be glanced at in this article, because it is almost entirely founded on the facts afforded by medical statistics. And as medical practitioners are very frequently applied to respecting the assurance of lives, it may perhaps be useful to supply the student with some elementary notions, or with an outline which may be easily filled up at leisure by a reference to the labours of Price, Milne, Quetelet, Babbage, and Finlayson.

Nothing is more subject to uncertainty than the duration of the life of a single individual; and a conviction of the frailty of this tenure has laid the foundations of institutions for the assurance of lives. One of the most encouraging signs which a nation can afford of the prudence, economy, and kind affections of its inhabitants, is the growth and popularity of such establishments, because they evince that the individual is content to sacrifice some present enjoyments in order to lay up a little store for some being or beings who are to survive him; and that selfishness is with him a secondary consideration to prospective benevolence. Annuities upon lives are an operation conducted in a spirit totally opposite; although often extremely eligible and suitable, they provide rather for the present than for the future, and it is a good feature in the times when the demands for life assurances are more numerous than for life annuities. It was remarked in France, shortly before its first revolution, that a prodigious number of citizens were eager to obtain life annuities, and thus to convert their capital into an increase of present indulgences for themselves, but to extinguish any benefits which might otherwise have streamed from it to fertilize some kindred soil.

Assurances on lives have no analogy whatever with the speculations of gamesters, since their object is to equalize chances, and not to disproportion the risk; they fix the monied relations of large bodies of society on a basis quite unconnected with the hazard of individuals. In order that this desirable object may be accomplished with advantage to all parties concerned, it becomes absolutely requisite to ascertain the average number, or proportion of persons, out of a numerous population, who die at the different periods of life; or, in other words, we must know the law of mortality (as it is called) which belongs to every age of existence. Nothing appears more difficult, at first sight, than the construction of such a law; but the progressive labours of mathematicians, political economists, and physicians, in different countries, have gradually produced an abundant collection of facts on which to ground

the principles of a science which is entirely the offspring of modern times, and more particularly of our own country.

We shall not enumerate here the various tables of the duration of life which have been founded on observations made in different places; nor shall we do more than allude to that remarkable improvement in the tenure of life which has rendered some of the older calculations obsolete.

But since medical men are universally consulted before assurances of this kind can be effected, it is perhaps not superfluous to explain the nature and process of the transaction. An assurance on life, then, is the assurance of a certain sum which is to be paid in the case that an individual named is alive at a particular time, or dies within a particular time; or which is to be paid within a particular time after the death of an individual named, at whatsoever time that death may occur. The *assurer* is the party who undertakes to pay this sum, and the *premium* of assurance is the sum which he obtains as a recompense for that which he is to pay. The *policy* of assurance is the document or instrument by which the party is obliged to the assured sum. This policy is called *absolute*, when the assured sum is to be paid on the death of an assured party; and it is said to be *contingent* when the payment of this sum is made to depend upon some other circumstance, as, for instance, the existence or the previous death of some other individual or individuals. The premium of assurance is in some cases a sum paid down all at once; but the more usual method is to pay down a certain sum on the day on which the engagement is completed, and to enter into an obligation to pay the same sum yearly, so long as the policy continues in force.

When a party wishes to accomplish an assurance, he receives, from the particular assurance-office to which he applies, a paper called a *declaration*, which he fills up with the name, the age, the time and the place of birth, the actual residence, and some details respecting the health of the individual to be assured. This declaration includes a notice to this very important effect,—namely, that any falsehood introduced into the declaration invalidates or vitiates the policy. The declaration is then properly signed; and in order to confirm the statement, references are afforded to two persons, who must be familiar with the habits of the party on whom the assurance is effected; one of these two is a medical practitioner, and in some instances more than two references are demanded. The individual who makes the assurance next appears in the presence of the directors of the company, who endeavour to ascertain his ordinary and actual condition of health, and introduce a memorandum of the result into their journals. The directors ultimately decide upon the case according to the answers which are obtained from the persons to whom reference has been made, and occasionally from other additional sources of information. If the individual on whose life the assurance is to be effected, is unable to make his appearance in the presence of the directors, or of any person delegated by the directors, an additional payment is demanded in lieu of personal appearance.

Life-assurance offices usually employ a stationary medical adviser, who assists the directors with his judgment respecting the health of the applicant, and with his advice on the evidence submitted.

The questions contained in the circulars which are transmitted by the life-assurance offices to the medical attendants of the applicant are various in form, but nearly similar in import, at all the various establishments. The spirit of these queries may be conveyed in a few words:—How long have you known ——? When did you last see ——? State of health at that time? General state of health? Have you had occasion to know, or to hear, that the applicant is subject to fits, diseases of the lungs, scrofula, insanity, gout, or to any hereditary disorder? Are his habits sober? Is there any circumstance connected with his health, within your knowledge, with which the directors ought to be acquainted?

The questions addressed to the medical friend of the party require, it will be seen, considerable caution in the answer; any suppression of facts, whether intentional or accidental, may in the end render the whole transaction nugatory, or, in other words, may vitiate the policy. These queries refer both to the past and present state of the health of the party, and to his predisposition to disease, either hereditary or acquired. A medical practitioner, placed in intimate relation with the party, may feel a desire to soften certain circumstances, through a natural impulse of friendship; but, in reality, this undue delicacy may prove an ultimate injury to the person whom he intends to serve, and is totally unjustifiable in every sense. His report will be confidential: the motives for rejecting an application will not transpire; and a debt is to be discharged not only to our own conscience, but equally to our friend and to the community at large, because a transaction so beneficial to all parties can only continue to be carried on through the medium of frankness and of good faith.

We might illustrate the practical bearings of this subject more clearly by selecting some of the most important trials which have occurred in consequence of errors in the statement of health; but we should trespass too largely on the space which is more necessarily allotted to practical medicine. It will be sufficient to have pointed out the necessity of caution and the sources of information.

We have been obliged to treat the whole of this article in a cursory manner, and entirely to omit the consideration of several topics belonging to it. There is one general principle, however, which unites together every branch of it, and which, if properly considered, will supply our omissions, and lead the reader to the collection of new materials for reflection and generalization. Life and death, then, mainly depend on the *prosperity* of the circumstances which surround us; physical prosperity and moral happiness, which often depend and re-act upon each other, present a safeguard at every crisis of existence both to individuals and to nations. We may often judge with tolerable accuracy of the mortality which is likely to exist in any given country, town, or hospital, from the degree in which poverty or wealth, knowledge or ignorance, misfortune or success, are seen to prevail. Whenever *want* and *misery* exist, there the mother is more likely to

die in labour, there still-births will be more frequent, there the deaths during infancy will be more numerous, there epidemics will rage more violently, there the recoveries from disease will be more tedious, and the fatal termination of it more probable, and there also will death usually approach at an earlier period of life than in happier situations.

This important conclusion deserves the highest attention, and a variety of considerations flow from it which we cannot here follow in their windings. It is a state of things highly instrumental towards the improvement of our social state. It encourages us to improve our physical and moral frame to the utmost of our power, in order that we may reap the harvest of life which only awaits those who can succeed, to a certain degree, in elevating themselves above want and ignorance. It is a distribution of health and disease, of life and of death, entirely analogous with the state of trial in which we are here placed.

It would be endless to enumerate the works which furnish the materials for this subject, or rather for the illustration of various parts of it. To those who are desirous of prosecuting it we may recommend—*Bérard*, Discours sur les Améliorations Progressives de la Santé Publique, *Paris*, 1826. *Blane*, Select Dissertations. *Tommasini*, della Necessita di sottopere ad una Statistica i Fatti piu importanti della Medicina Pratica, *Bologna*, 1821. *Casper*, Beiträge zur medicinischen Statistik, *Berlin*, 1825. Roberton, Observations on the Mortality and Physical Management of Children. *Quetelet*, Recherches sur la Population, les Naissances, &c. *Bruxelles*, [Sur l'Homme, &c.] *Malthus*, Essay on the Principle of Population: and last, but not least, we may direct the reader's attention to innumerable reviews and essays of great value, which Dr. Villermé of Paris has contributed to the *Geographical Section* of the *Bulletin Universel* (now extinct), and to the excellent *Annales d'Hygiène*.

BISSET HAWKINS.

[Highly valuable information has been afforded by recent medical statisticians, some of whose works have already been referred to,—for example, the various *Reports of the Registrar-General of Births, Deaths, and Marriages in England*, and the remarks of Mr. W. Farr contained therein; the Reports of Mr. Chadwick *On the Sanitary Condition of the Labouring Population of Great Britain;* the papers of Dr. Gouverneur Emerson in the *American Journal of the Medical Sciences;* and the *Journal of the Statistical Society of London;* the article on the vital statistics of Boston, in the *American Journal of the Medical Sciences*, for April 1844, by Mr. L. Shattuck, &c. &c.

The term *medical statistics*—as before remarked—is now often used synonymously with *numerical method* and the *calculation of probabilities*, applied to medicine. Originally statistics meant the science of states—from the German *staat;* but by an extension of signification, which is not uncommon, that which was originally applied to states, came to mean any collection of observed facts of the same order, and was subsequently extended to comprise, as at the present day, numerical methods or numbers employed for the elucidation of any of the sciences of observation; so that the term medical statistics is now as well understood as medical jurisprudence. The employment of numbers as a means of comparison is by no means new; yet in consequence of the word statistics being of modern origin, it has been supposed by many that numerical methods were unknown until recent periods. They have long been used in other branches of science; and as a late writer (*Brit. & For. Med. Rev.*, July 1841,) has remarked, "their non-employment in medicine until a recent period proves, that medicine has profited little by the example of the more perfect sciences, and gives us good ground to hope, that improved methods of investigation may do much to retrieve its character, confer upon it a greater degree of certainty, and enlarge the sphere of its practical usefulness."

Impressed with the imperfect modes of observation that had previously existed, and were existing, M. Louis proposed to introduce as far as possible, the same mode of exact estimation as had been practised in chemistry for example. "Doubtless" he observes, "this department of learning had many learned men among its votaries previous to the last forty years; nevertheless, it is only within this last period that chemistry has made rapid progress. What means has it employed of late, which were not used before? It has demanded exactness; it has weighed and counted always when it was able to do so; it has taken rigid notice of every thing which had any bearing upon a question; it has substituted a strict analysis for an imperfect and careless one; its methods have become daily more and more precise, and its progress is rapid and constant. The same cause which kept chemistry so long in its infancy—viz. the want of rigid method—has weighed upon the destiny of medicine, and prevented its growth." (in *Mémoires de la Société Med. d'Observation de Paris*, tom. i., art. i., Paris, 1837: or translation of the same by Dr. Bowditch, in Dunglison's *Amer. Med. Library* for 1838.)

Much has been written against the practicability of employing numbers or of *counting* in medicine, notwithstanding the valuable information that has been afforded for ages on the laws that govern the movement of the population; the calculation of probabilities in regard to the average duration of life, as a guide to the insurance of lives, &c. &c. The nearest approximation to the truth in regard to facts or observed phenomena must obviously be deduced in this manner. It is the only accurate mode in which averages can be taken. Every practitioner, in all periods of history, has endeavoured to carry in his recollection the precise difference which he notices from day to day in the condition of his patients; but this must be far inferior to the record which he daily makes approximately by numbers, from which he can deduce his averages. Averages and numerical methods can in no case, however, afford more than an approximation to the truth; yet the approximation is closer than can be attained in any other manner. The history of disease has, indeed, benefited materially from them; and many of the results arrived at may be regarded as certain as the subjects above mentioned, which have received much elucidation from statistical inquiries. "Averages," as a recent medical writer has observed,

"may in some sort be termed the mathematics of medical science. The principal is one singularly effectual in obviating the difficulties of evidence already noticed; and the success with which it has been employed of late by many eminent observers, affords assurance of the results that may hereafter be expected from this source. Through medical statistics lies the most secure path into the philosophy of medicine." (*H. Holland, Medical Notes and Reflections*, Amer. edit., Philad. 1839.)

It need scarcely be said, that facts must be accurately observed before they can be made the basis of calculations; imperfect observation must be regarded as one of the main causes of the imperfection of medical science; — another and a not less important cause being the mode of making analyses which are incomplete or dependent upon facts entrusted to the memory. (Louis, *op. cit.*) It is clear, too, that any average deduced from a small number of observations may lead us into error. The tables of insurance of lives formed upon the observation of one or two years would certainly be fallacious; whilst we know that those formed from the calculation of a long series of years lead to satisfactory results.

Observed phenomena in disease furnish more certain facts for the numerical method than the apparent and often perhaps real results of therapeutical agencies. Therapeutics is confessedly the most difficult of all the departments of medical science, because in it is concentred a knowledge of every other; and it requires not simply observation, but the constant exercise of reason to rectify the erroneous impressions which imperfect observation or the apparent evidence of the senses often engenders. A glance at the history of medicine shows, that it has suffered more from faulty observation—false facts—than from false theories; for, after all, most of the theories have been based upon fancied observation.

A just appreciation of the effects of therapeutical agents, and the determination of their action, whatever that may be, are properly regarded by M. Louis as the most important, and doubtless the most difficult part of the method of observing. So many circumstances have, indeed, to be borne in mind in the estimate, that the inquiry has appeared to some to transcend the powers of the human mind. "We must compare together," says M. Louis, (*op. cit.*) "a great number of cases of the same disease of equal severity, some relating to subjects in whom the disease was left to itself; others of individuals to whom certain medicines were given. After doing this, we must study the action of the same therapeutical agent on those in whom the disease was severe, and on those in whom it was slight,—on those in whom the remedy has been used in large or small doses, at a period near to, or remote from, the commencement of the disease. This last circumstance is very important. So likewise we must mention whether the medicine is used alone or in conjunction with other remedies. But not only does this method require much labour; it also supposes a considerable series of facts, the connection of which is difficult, especially when treating severe affections in which we are accustomed to frequently make new attempts, and which will not allow of our remaining a mere spectator of the progress of the disease. For it must be evident, that we do not seek to know by approximation what remedies have *appeared* to be more or less successful, but to demonstrate in a rigorous manner, that a certain remedy, or certain method is useful or hurtful, and in different degrees, according to the manner in which we employ it."

The necessity for such repeated observations for any accurate estimate of therapeutical agencies has been appreciated by every able medical statistician. Even M. Louis himself has been censured by M. Gavarret, (*Principes Généraux de Statistique Médicale, ou Développement des règles qui doivent présider à son emploi*, Paris, 1840,) for having pronounced as to the limited efficacy of bleeding in pneumonia, erysipelas of the face, and cynanche tonsillaris, on the strength of one hundred cases of the first disease, forty-four of the second, and twenty-three of the third; and he lays it down as an undoubted principle, that every statistical inquiry, in order to furnish admissible indications, ought to consist of many hundreds of observations. Were this indispensable, it is obvious that it would be impracticable to arrive at any satisfactory knowledge in regard to the effect of remedies; for amidst the numerous shades of difference in the manifestations of disease, (some of which only have been enumerated above,) it would be difficult, if not impossible, from hundreds of cases of the same malady, to find a dozen that are circumstanced exactly alike; and that would consequently admit of unquestioned therapeutical deductions. The observations of M. Gavarret apply to cases, in which the calculation of the influence of multitudes of extrinsic and intrinsic causes are associated in producing the result; not to phenomena in health and disease, which require merely that the observations, without being very numerous, shall be frequently repeated. Hence, in part, why diagnosis is so much more easy, and so much more attended to and more capable of being appreciated—counted,—than therapeutics, which, notwithstanding, is the final object of the science of medicine;—the goal of every practitioner. As a matter of scientific knowledge it might be well to understand disease, even if we did not attempt to cure it; but as practising physicians and philanthropists, the alleviation and cure of disease is the grand desideratum. Yet it has been lamentable to witness the almost exclusive attention which has been paid by many of late years to diagnosis. In hospitals especially, the main object of the attending physician has too often appeared to be to discover the precise disease; and the treatment has been left to the *élève interne* or resident physician; — the former priding himself on his skill and attention to the *science*, whilst he leaves to the latter what he considers the *art*. Hæmatology has been attended to in the same manner. Blood has been drawn in disease, in order to detect, by the nicest evaluation, the ratio of its main constituents; and after this has been determined, but little care, in too many cases, has been paid to treatment.

The difference between the results afforded by statistics as applied to the establishment of the history and of the treatment of disease is well shown by many of the monographs on individual diseases that have emanated from the medical statisticians, from

those who rank themselves amongst the disciples of the numerical school. Take, for instance, typhoid fever, so well analysed by M. Louis and others. For the history, medical statistics has furnished us with most valuable information; for the treatment, we have little more than a detail of the methods of observers—often most discordant—nay, at times, diametrically opposed to each other.

This difference between the results of the numerical investigation of histories of disease and of therapeutical agencies must, we apprehend, continue. It may be lessened, but never perhaps removed. An accurate appreciation of facts—of numerous well observed facts—is essential to both; but it can never, it is to be feared, be rendered extensively available for the latter. A knowledge of the healthy and diseased functions derived from careful observation, and of the ordinary effects of therapeutical agents on those functions, obtained by careful and repeated observation, must be the basis of that enlightened theory, which necessarily leads to enlightened practice; and much mischief would result to both were we to discard all rational therapeutics, and restrict ourselves to mere observation. The complex functions executed by man are so modified by multitudinous external and internal influences that are inappreciable; so much agency is perpetually exerted by the *moral* over the *physique*, that no comparable facts can be obtained in sufficient numbers to permit of any accurate numerical deduction; and, accordingly, we must either treat disease in accordance with principles suggested by conjoined observation and reason; experiment for ourselves *ab initio;* or resign our faith to the asserted observation and experience of others; and of these which of the *legion* shall we select as masters?

ROBLEY DUNGLISON.]

STERILITY. (See IMPOTENCE.)

STETHOSCOPE, from στῆθος, *pectus*, and σκοπέω, *exploro, contemplor*,) is the name of an instrument invented by the late M. Laennec, to assist the ear in examining the acoustic signs of various diseases, especially of those of the chest.

The use and indications of the stethoscope have been so fully explained in the article AUSCULTATION, that it remains for us here only to study the stethoscope as an instrument, and the physical principles of its adaptation to the object to which it is applied. When we bring to the aid of our senses artificial instruments, we can neither perfect their construction nor fully avail ourselves of their uses, without a knowledge of the laws by which they assist our organs. No one can satisfactorily use the microscope or telescope without understanding the laws of optics; and we hold that the easiest, the most agreeable, and the surest road to a knowledge of stethoscopic phenomena, is through a study of acoustics. It was by a happy application of a general law that Laennec was led to the discovery of this instrument, and he never could have enriched his description of its use with such a number of interesting and valuable facts, if his experience had not been guided by a familiar knowledge of natural philosophy.

The first instrument used by Laennec was formed of three quires of paper, compactly rolled into a cylinder, and kept in that shape by means of paste. He afterwards tried various other materials, and found a cylinder of wood, with certain modifications, answer better than any other. He found denser bodies, such as glass and metal, less effectual; and a cylinder of gold-beater's skin, inflated with air, proved inferior to all the others. It will be found that these facts are in perfect accordance with principles which we can only glance at here; and that the superiority of bodies of moderate density, such as light firm wood, although opposed by what Laennec considered to be an axiom in physics, is really an illustration of an acoustic law, which has never, as far as we know, been accurately exposed.

The power of bodies to conduct sound varies according to the density of the medium in which the sound is generated—those bodies being the best conductors which correspond in density with the body communicating the sound. Thus the sounds produced by the vibration of air are best conveyed by air; and those of solids, by a rigid solid of similar density. On the other hand, air with difficulty receives the sonorous vibrations of very dense bodies; and the latter, in great measure, intercept the sounds of air; but rigid bodies of intermediate density will greatly facilitate the transmission of sound between these dissimilar media. Two examples will suffice to illustrate this principle. The common pitch-bar or tuning-fork, when struck, yields very little sound as long as it is held in the fingers, or placed in contact with metal only; but as soon as it touches a table, or especially a sounding-board, its sound becomes distinct and clear.* Again, a metal or even a glass partition between two rooms, much more effectually prevents the transmission of sound from one to the other than a partition of wood, even of greater thickness.

In acoustic instruments, we avail ourselves of the conducting power of similar bodies, and the reflecting quality of dissimilar substances, to direct sound into any particular channel. It is with regard to these principles, in the first place, and with a certain respect to portability and convenience, that the best stethoscopes are constructed. As the sounds which they have to transmit to the ear are various in origin and intensity, so these instruments have modifications in their make, which, with a view to avoid the multiplication of apparatus, were contrived by Laennec in a single instrument of convenient portability. Thus to convey the sounds originating in the denser contents of the chest, such as the heart, a cylinder of light but rigid wood, as free as possible from knots and inequalities, answers perfectly. To transmit the sounds produced in the more aerial contents of the chest, this cylinder is perforated longitudinally, so as to contain a column of air, which being perfectly closed from external communication by the ear at one end, and the chest of the patient at the other, readily conducts the sounds of the voice, or of the respiration, produced in the spot which the aperture covers. To concentrate the diffused sound of respiration, and

* Many other illustrations might be adduced; and we believe that the long sought-for explanation of the principle of sounding-boards of musical instruments is to be found in the same law.

to expedite the examination by making the stethoscope take in as large an extent of surface at a time as possible, the cylinder is hollowed out at the pectoral end into a conical cavity, the apex of which terminates in the central canal; so that all the sounds that enter the excavated end are reflected through this canal into the ear. To reconvert this into a simply perforated cylinder for the uses before mentioned, a perforated plug or stopper is adapted, of size and form exactly filling the conical excavation. The instrument last recommended by Laennec was a cylinder of walnut, a foot long and an inch and a half in diameter, with the longitudinal perforation three lines in diameter, and the excavation and stopper of a parabolic form, with a metallic tube to fix the latter into the central bore. For the sake of portability, and to render it applicable in a shorter form, the instrument is divided in the middle, with an excavation into which the stopper can be fitted as at the other end. We have found reasons, in both principle and practice, to prefer a conical to a parabolic cavity; and we would recommend, as the best and most easily used stethoscope, a cylinder of cedar nine inches long, of the diameter and bore prescribed by Laennec, with a conical excavation tapering at least an inch and three quarters, so that its sides do not subtend an angle of more than twenty-five degrees. The stopper must be made to fill this cavity completely, and it may be held in it either by a flute-joint at the base of the cone, or by a thin ivory or horn tube projecting an inch from the apex of the stopper and fitting into the central bore. The flute-joint is in principle the best of these, but as it is with difficulty made accurately, and from its requiring ivory or ebony ferules, is liable to get out of repair, the tube may be preferred. The general excellence of this instrument will depend on the smoothness and true turning of the interior, and the perfect adaptation of the stopper to the cavity; but to be fully available to the auscultator, the auricular end should be made wide or narrow, flat or concave, to fit comfortably to his ear. Generally it will be found useful to make this end slightly concave, and somewhat wider, by a ferule of ivory or ebony, than the general diameter of the instrument, or this width may be formed in the wood itself. A beginner should not choose a stethoscope hastily, but when one is found exactly to fit the ear, a more perfect tact will be acquired by keeping to the same instrument than by using a variety.

[Almost any of the stethoscopes, offered for sale, will answer the purpose of the auscultator, provided, that the ear part can be easily adapted to the ear. It is proper, however, to observe, that the writer has found those which are wholly conical, or which, in other words, consist of the funnel part only, the least satisfactory, in consequence of the confusion of sounds, resembling, in some measure, those that are heard when a hollow shell is applied to the ear. The instrument should always have, in addition to the funnel-shaped portion, space enough for an inch or two of tube which is perfectly cylindrical, in order that, by the concentration of vibrations, this source of inconvenience may be obviated. The length of the original instrument of Laennec rendered it inconvenient of application in many cases; and it was by no means easy to place the end of the instrument entirely flat on the chest, whilst the other was in apposition with the ear. Hence, the writer has, for years, used an instrument, which, like that of Dr. Billing, (*Principles of Medicine*, Amer. edit. p. 15. Philad. 1842,) is merely Laënnec's abridged. It is about four inches long.

At the meeting of the British Association at Manchester, in 1842, Dr. Williams presented a communication on the construction and application of instruments used in auscultation. (*Lond. Med. Gazette*, Dec. 16, 1842: or Braithwaite's *Retrospect*, vol. ii. Lond. 1843.) In this he states, that finding the considerable share which the solid walls of stethoscopes have in communicating sounds, and from experiment, that their efficacy depends chiefly on the formation of the pectoral end, by which they receive the vibrations, he had devised a form of instrument which qualifies them better, he thinks, for this purpose than any now in use. This consists in a bugle or trumpet end, the edges of which being made very thin, and applied flat on the walls of the chest, are most readily affected by their vibrations. An instrument thus constructed of a light rigid wood, such as sycamore, and tried with a test sound, will be found, according to Dr. Williams, superior for most purposes to the stethoscope hitherto used.]

For further information on the construction of the stethoscope, assisted by diagrams, see the writer's "Rational Exposition of Physical Signs," &c. second edition, 1833, pp. 52 and 184. [Amer. edit. Philad. 1830.] After trying many artificers, we have at last succeeded in finding one who makes stethoscopes with nicety; and to those who want a good instrument, we can, therefore, recommend Grumbridge, turner, 42, Poland-street, Oxford-street. Our limits do not permit us to describe other forms of stethoscopes that are to be met with. In all those which we have seen, acoustic rules are sacrificed to portability or elegance. That of M. Piorry, which is commonly used, is faulty in having the conducting power of the wood impeded by screws and a thick cap of ivory; besides which, the excavated end is generally very ill fitted. Although, when unscrewed, more portable than the other instrument, the trouble of screwing and unscrewing the several parts is enough to counterbalance this advantage. Our friend Dr. Stroud uses a caoutchouc tube, with an ivory funnel attached, like the flexible hearing trumpet. The flexibility of this instrument is certainly an advantage, but it is obtained at a great sacrifice of intensity and distinctness of the sounds, in consequence of the imperfect and irregular reflecting power of the interior of the tube. This flexible stethoscope separates the sound from the impulse of the heart more completely than any other.

[The author has frequently used the flexible stethoscope, but he greatly prefers the ordinary instrument where the sounds require acuteness of hearing. Dr. Williams has lately affirmed, that when tried by a test sound he has found it much inferior in conducting power for all the more delicate sounds of the breath and heart. Louder

sounds, he adds, such as those of bronchial or cavernous breath, and voice sounds, it exaggerates by the addition of a conchal echo, which renders it very difficult to distinguish them from each other. This objection has not, however, impressed the writer.]

Although, for general purposes, the common stethoscope fulfils sufficiently well its triple office, it might be well for the attainment of greater accuracy in physical diagnosis, if auscultators in hospitals would use separate instruments for the three classes of signs. 1. A solid cylinder of wood for the auscultation of the heart. 2. A metallic tube, half an inch in diameter, furnished with a wooden or ivory ferule at the pectoral, and an ear-piece at the other end, for the investigation of the respiration and vocal resonance of small spots. 3. A metallic tube, like the last, but with its pectoral end expanded into a tapering cone, for the same purposes as the stethoscope without the stopper. After a little practice, we have little doubt that these instruments would be more powerful aids than the common stethoscope, but we do not pretend to recommend them for general adoption. [See, farther, on the construction and application of instruments, Dr. Williams in *op. cit.*]

Before we conclude this article, we would say a few words on the advantages of mediate auscultation, and on the necessity of the stethoscope to those who wish to avail themselves fully of physical diagnosis in general practice. After what has been said by Laennec and others on this point, we should have hardly deemed it necessary to mention it here, were it not that several writers, otherwise advocates of auscultation, have spoken slightingly of the stethoscope. Could the naked ear be in all cases applied to the chest of a patient, the utility of the stethoscope might be more reasonably questioned. But it cannot be denied that immediate auscultation is in many circumstances impracticable,—in some cases being indelicate, in others disgusting, and in infectious disorders unsafe,—while these objections are not applicable to the use of the stethoscope. Further, if it be said, restrict the use of the cylinder to these cases, we reply, that unless we have more practice with it than can be obtained in these only, the stethoscope would be comparatively useless in our hands; for its indications, although decidedly more accurate than those of the unaided ear, unquestionably require more practice to obtain them.

But there are other circumstances which give to mediate auscultation a claim to preference. The unaided ear, although capable of perceiving very delicately the sounds produced under the surface to which it is applied, cannot isolate any particular spot; and the sounds transmitted by the parts adjoining the ear, the temporal zygoma, the mastoid protuberances, &c., as well as the adventitious noises liable to be produced by the friction of the hair of the head and face, are frequently mixed with and confuse the signs from the spot under examination. On the other hand, with the stethoscope, we can isolate any particular point; and, by tracing the sounds to their real position in the organs within, we can accurately determine their value as signs. This faculty is, in some cases, of great importance. It is only by its means that we can discern the limits between a natural resonance of the voice under the clavicles, beneath the scapulæ and in the axillæ, and the morbid resonance which an induration of the tissue of the lung produces in parts immediately adjoining these regions. The stethoscope, with the stopper, not unfrequently discovers a sound to be merely a natural resonance, which, to the open instrument, or to the naked ear, has the character of morbid bronchophony; and the variations in the form of the instrument furnish a means of distinction between the degrees of pectoriloquy more accurate than can be obtained by the ear alone. (See Auscultation.) The capability of the stethoscope to separate the sound from the impulse of the heart, and the facility with which it can be applied to the infra-clavicular and axillary regions, and to the examination of the sounds in the carotid arteries and abdominal aorta, which are not within convenient reach of the unassisted ear, are further and important advantages of mediate auscultation. In conclusion, we would express our conviction that although, with a view to expedition and convenience, immediate auscultation may be occasionally substituted, no one who has once thoroughly trained his ear to the use of the stethoscope will ever so lightly esteem its aid as again to abandon it.

C. J. B. Williams.

STIMULANTS, (from *stimulare*, to prick, to goad,) *Excitants*, are medicines which augment the functions peculiar to the different organs of the body, by a primary impulse on the sensibility and irritability of the part to which they are applied, extended to the whole system of the nerves. Every medicine, indeed, which communicates mobility, or increased action, to any organ, may, in strict language, be regarded as a stimulant; consequently, expectorants, emetics, cathartics, diuretics, emmenagogues, diaphoretics, and epispastics, are all stimulants; but their influence is chiefly exerted on particular organs, whilst stimulants, exclusively so called, are substances which excite the entire system.

All substances that operate as stimulants produce some effects in common. When administered in small doses, their influence is scarcely perceptible; they cause no obvious change in the condition of the organ into which they are received; but, nevertheless, their impression on the nerves of the part is communicated to the brain and spinal cord, the nervous energy is exalted, and their excitant property becomes evident in the increased action of the pulse. When administered in larger doses, they first impart a sensation of warmth or acrimony to the organs of taste; this is extended to the stomach; and the particles of the substance being carried into the blood, the impression on the nervous system is not only greatly augmented, but, every organized tissue sharing the impression, all the functions are exalted, and the whole system becomes preternaturally excited. In still larger doses, their effects assume the characteristics of disease. Besides producing such impressions on the vital energies, almost all stimulants possess some sensible properties in common. These impart, as already stated, a warm and acrid impression to the organs of taste; awaken the sensation of smelling in the olfactory organ; and, when applied to the surface, augment the sensi-

bility and the temperature of the part, and cause a greater flow of blood into its vessels than is consonant with their natural condition. The qualities producing these effects are regarded by several writers on Materia Medica as constituting the essential properties of every stimulant; but they are those chiefly found in stimulants obtained from the organic kingdom of nature, and belonging to that class of vegetable bodies termed aromatics, in which it is probable that the exciting agent is *volatile* oil. It must nevertheless be admitted, that there are even vegetable stimulants in which no volatile oil can be detected; but these furnish a principle analogous in its effects to volatile oil There are stimulants which have neither taste nor odour; as, for instance, caloric and electricity, as well as those of a mental description, such as the exciting passions; but, whatever may be the nature of the stimulant, the impulse communicated to the system differs rather in degree than in kind. In one respect, however, inorganic are particularly distinguished from organic stimulants; they have no principle in common to which their excitant influence can be referred.

Four changes in the condition of the body are obvious, on the administration of stimulants: — 1. a greater than usual susceptibility of impression in the nerves; 2. an increase of action in the moving fibres; 3. an acceleration of the beat, and an augmentation of the force of the pulse; 4. an elevated degree of the temperature of the body. These effects are displayed chiefly on the cuticular organ, and in the organs of digestion, circulation, respiration, and secretion, as well as on the cerebro-spinal centres; and if we examine any of the organic tissues during the operation of stimulants, we find that they are redder, hotter, and more sensitive than in the ordinary state of the habit. These appearances do not always depend either on the nature of the stimulant, or on the extent of the dose, but very frequently on the state of the body of the patient. Something, also, is due to the manner in which the stimulant is administered, whether simple or uncombined, or in a state of combination.

Stimulants differ greatly in the rapidity with which their effects are produced, some acting almost instantaneously, others requiring time to display their influence; and this difference does not depend on the nature of the part to which they are applied. In general, the degree of power is in the ratio of the rapidity of their action; and the permanency of the impression is more or less connected with the same circumstance. The operation, also, of all stimulants is followed by symptoms of collapse; and this result, in an especial manner, distinguishes them from *tonics*, and at the same time renders it extremely difficult to separate them from narcotics, which at first increase action, but soon afterwards exhaust both sensibility and irritability. To illustrate this effect of stimulants, it is requisite to have a clear conception of the nature of *excitement* and *collapse*; terms that are evidently relative to some standard or point which, in the healthy system, can be considered as neither.

With respect to excitement, "if," says Dr. Cullen, "we take the lowest, every higher degree than that must be called a degree of excitement; and if we take the highest degree, and consider the lower degrees which may take place while life still subsists, every lower may be called a degree of collapse." (Materia Medica.) In the opinion of the author of this article, *excitement* implies every condition of the nervous system in which the energy of the brain is greater than that which, in the waking state of a healthy man, is exactly adequate for the performance of the ordinary functions of the system; *collapse*, that condition in which the cerebral energy is so much diminished as to suspend the exercise of the functions of sensation and volition,—a state of defective activity of the brain, similar to that which causes sleep, only in an augmented degree. The function of the brain cannot be carried on without a sufficient supply of blood, which is essential for its support and continuance: a greater increase of the momentum than usual produces excitement; a diminished afflux, within certain limits, or an exhaustion of energy from previous over-excitement, is productive of collapse. In some instances there is much difficulty in distinguishing these states.

Let us now examine the effects of excitement on the different organs on which this class of medicines chiefly displays its influence.

1. On the **digestive organs** stimulants exert a primary action: a sensation of heat is experienced which is immediately referred to the stomach. The liver, the pancreas, the brain, and the spinal cord sympathetically share this local excitement: but the chief effect is felt in the stomach, the mucous membrane of which, could it be seen, would be found redder than natural, and more sensitive; whilst the capacity of the organ is diminished, owing to the contraction of its muscular coat. If the stomach be empty, a sensation of hunger is experienced; if the excitant be mingled with the food, the process of chymification is hastened; and this also is the case, if food be taken soon after a stimulant has been swallowed. This excitement, commenced in the stomach, is extended through the whole alimentary canal.

The effect of a stimulant on the primæ viæ is always in the ratio of the dose; small doses merely augment the energy of the digestive faculty; large doses, on the contrary, impair this, awaken a sensation of heat, thirst, and uneasiness in the gastric region, and suspend or render inefficient the action of the stomach; causing nausea and sometimes vomiting. But although these effects are the result of a very large dose even of a salutary excitant, yet the impulse which it communicates to the rest of the system is not always commensurate to the impression thus made upon the stomach; and many substances that display scarcely any obvious influence on that viscus, operate powerfully on the general habit. But if they quickly pass the pylorus without acting on the stomach, then their influence on the general system is less than when their impression is previously made on that organ. We must search for the cause of this in the function of the intestinal canal, and the nature of the stimulants which thus operate. The natural effect of the action of a stimulant on the intestinal canal is to increase its peristaltic and vernicular motion; thence the stimulant is carried forward, and it continues its impulse in its progress; yet this is too transitory

to be very influential. With regard to the nature of the stimulants which thus operate, the active principle is often so sheathed in other matters, that the digestive process is not able to evolve it until it pass out of the stomach. Some stimulants, also, of an organic nature exert little influence on the general habit until they are taken into the circulation; they may, therefore, be said to communicate their impulse directly to the heart and arteries, independent of any primary impression on the stomach.

The primary influence of stimulants on the digestive organs is, also, greatly modified by the condition of the stomach. If this be relaxed and thin, excitants appear to exert little action upon it; but small as the impression may be, the effect is salutary, the appetite is improved, and chymification proceeds with more regularity. If the capacity of the organ be considerable, and its parietes thick, stimulants produce a powerful impression on it: hunger is more urgent, the appetite is rendered voracious, and chymification accelerated. When the stomach is in an irritable state, every impression produced by an excitant is increased; the patient suffers from anxiety, hot eructations, tightness across the epigastric region, and a general uneasiness, which is referred to the viscus. If ulceration or open cancer exist there, all these symptoms, accompanied by acute pain and a burning sensation at the epigastrium, are experienced in an augmented degree. If no organic lesions are present in the organ, but the gastric nerves are in an asthenic condition, owing to softening or some similar affection of the brain or the spinal cord, then the impression of the most active stimulants is scarcely felt in the stomach; but should the nervous centres be suffering from irritation, in that case the stomach shares in their morbid susceptibility, and even the slightest excitant produces a serious effect on it. Something, also, depends on the state of the neighbouring organs, the morbid condition of which is more or less extended to the stomach, and consequently modifies the operation of stimulants received into it. On the other hand, the neighbouring organs, being more or less affected by contiguity when any excitant is taken into the stomach, have their secerning functions increased; but, at the same time, in making this statement, we must admit that this effect is not confined to the action of excitants on the stomach; for in whatever manner or on whatever part the impulse is first impressed, it is rapidly communicated to the neighbouring organs, and progressively to the rest of the system.

2. The influence of stimulants on the **circulating and respiratory organ** is a secondary effect of their impression on the stomach; thus when a stimulant is swallowed, it renders the pulse both quicker and stronger than before; and this excitement is extended even to the capillaries. Red blood is propelled into vessels not accustomed to receive it, and the skin appears, as it were, suffused with a blush; its temperature is elevated, and either sweating is induced, or the action of the kidneys or that of the uterus is augmented; or, if the dose of the stimulant be considerable, the brain feels its impulse, and restlessness, watchfulness, and cephalalgia supervene. These effects are undoubtedly owing, in a considerable degree, to the absorption of the excitant, or rather of its active principle, and to the impulse which it directly communicates to the coats of the vessels: they are necessarily proportionate to the dose and the nature of the excitant; but other circumstances, in some degree, also modify them. Thus on persons of a sanguine temperament stimulants act with more energy, as far as concerns the circulating system, than on those of an opposite frame of body, in whom their influence upon the heart and arteries is often scarcely perceptible. Indeed, there is no doubt that the circulating organs are more or less susceptible in different individuals, and, consequently, the variety of effects produced by the same stimulant substances, administered in the same doses and in the same manner, to different persons, are readily explained. One set of excitants, namely, the mental, display their influence in a striking manner on the circulation; thus blushing, palpitation of the heart, and that sensation of a glow of warmth overspreading the chest which often attends highly agreeable and pleasurable feelings, are merely the effects of the stimulant influence of these mental affections on the circulation.

As in the case of the digestive organs, morbid conditions of the vascular system necessarily modify the action of stimulants on this part of the body. Thus, in hypertrophy of the heart, every impulse of an excitant, however slight, increases the movements of that organ; both the momentum and the frequency of the pulse are augmented, the surface is reddened, and hemorrhages not unfrequently follow. When the hypertrophy is chiefly confined to the left ventricle, the administration of excitants is often accompanied with singing in the ears, weight of the head, epistaxis, and other symptoms of congestion of the vessels of the encephalon; and thence apoplexy is not an unfrequent attendant of free living in persons labouring under this affection of the heart. On the contrary, if the right ventricle be the part affected, the influence of stimulants is chiefly displayed on the pulmonary circulation.

In febrile states of the habit, in which the circulation is rapid, and the animal temperature greatly elevated, stimulants precipitate still more this increased action, and exasperate every symptom which constitutes the disease.

3. That stimulants affect the **respiratory system** is evident; indeed, the natural consequence of an accelerated action of the heart and arteries is an increase in the movements of the thorax. The result of a greater number of inspirations and expirations, occurring in a given time, is a more rapid change than ordinary in the blood circulated through the pulmonary vessels; it is exposed more frequently to the action of the air, becomes more arterialized, and displays a more vivid redness when drawn from the arm than is customary. If stimulants be administered during febrile states, this condition of the pulmonary system is augmented; and the air expired from the lungs seems almost burning hot. If the mucous membrane of the bronchial tubes and cells be inflamed, stimulants oppress the breathing, and excite a dry cough; and if the inflammation extend either to the pulmonary tissue or affect the pleura, the consequences of their administration

are almost immediate; the cough becomes hard, excites violent pain, and the expectoration ceases. This influence of stimulants on the pulmonary organ points out the advantages to be derived from their employment in those states of the chest in which the bronchial tubes are choked with mucus, and the debilitated state of the frame renders it impossible to clear them by the effort of coughing: in truth, expectoration is merely the effect of the influence of an excitant on the lungs in a state of disease.

4. With respect to the influence of stimulants on **the secerning system**, we have already stated that an excitant taken into the stomach increases the action of the capillaries, and rouses the activity of both the secreting and the exhalant organs. This, however, never occurs until the excitant is carried into the circulation, and is immediately applied to the glands. It is difficult to trace the causes of the apparent selection which occurs: one set of excitants, for instance, augmenting the secretion of the kidneys, another that of the salivary glands; a third the elaboration of bile in the liver, and a fourth the cutaneous exhalation; but every day's experience demonstrates the fact. The skin, in particular, is highly susceptible of the impression of stimulants taken into the blood; the capillaries act with redoubled vigour; and diaphoresis quickly follows. It is only, however, within a certain limit of excitement, one considerably short of inflammatory action, that these effects follow; when the stimulant is too powerful, secretion is impeded; thence we find that some volatile oils, when taken in a large dose, if they do not immediately operate as purgatives, cause most distressing effects on the urinary organs. As it is also unquestionable that to a certain extent the natural conformation of an organ modifies the action of stimulants upon it, so if the skin be thick, firm, and well nourished, a sudorific effect is readily obtained; whereas this is slowly induced, and the secretion itself is imperfect, when it is thin, soft, and pallid. The condition of organs also, when altered by disease, modifies greatly the action of this class of medicines; and this is particularly true with respect to the skin and the kidneys. In febrile affections attended with cutaneous eruptions, exciting medicines, instead of producing diaphoresis, augment the tension and the heat of the surface; and, in the same state of the habit, the kidneys become morbidly irritable, and their secreting function is suspended; if stimulants be now administered, the irritation is augmented, and the organs are occasionally attacked with inflammation. On the contrary, when the kidneys are in a state of atony or paralysis from affections of the brain or spinal cord, and their secreting powers languish, then stimulants tend to re-establish the function of the organs, and the flow of the urine is more or less abundant, according to the supply of fluid received into the stomach.

5. In reference to the **Nervous System**, it is well known that no exciting substance, in a sufficient dose, can be taken into the stomach without primarily exciting the nerves of the viscus, after which the impulses thus received are rapidly transmitted to the rest of the frame, developing vital energy in the various organic centres to which the nerves relate. It is true that we cannot explain this power of transmitting impressions inherent in the nerves; and we must acknowledge that an acquaintance, however intimate, with the structure of the nervous tissue affords us no information.

On the brain itself the influence of stimulants is obviously manifested by the perceptions becoming more vivid, the imagination more prolific with ideas, and those of a more brilliant and exalted character than usual. Indeed it cannot be denied that the employment of stimulating substances, within a moderate limit, is often followed by the happiest inspirations, and the most delightful sensations; but it is, also, well known that this excitation of the mental faculties, when stimulants are taken in the evening, is productive of agitated and sleepless nights; thence the medicines belonging to this class were denominated exhilarants by the ancients; and, even in the present day, powders, electuaries, and aromatic spirits composed of stimulating ingredients, are administered to dissipate melancholy and renovate the spirits. Another proof of the influence of excitants on the cerebral functions, is the awakening of memory: many events and circumstances effaced from recollection; verses, anecdotes, and facts long forgotten, again present themselves to the mind when under the operation of excitants. Even circumstances which occurred in a state of high excitation, and which were completely forgotten in the interval, are again remembered on the recurrence of the same state. A curious illustration of this fact is recorded by Mr. Combe. A porter, who when drunk left a parcel at a wrong door, on becoming sober could not recollect at what house he had left it; but the next time he got drunk, he at once called to mind the house, and went and recovered the parcel. In the state of inebriety, however, the influence of stimulants on the brain is more generally manifested by vertigo, temporary delirium, and a change of perception, than by a restoration of memory.

Whether the cerebellum be affected by excitants in the same manner as the brain, is uncertain; but there is no doubt that many stimulants affect, in a special manner, the medulla spinalis: the susceptibility of the sensitive nerves of the skin is increased, the respiration is quickened, and the muscular system displays an unusual aptitude for action. It is necessary here to remark that, although this power of augmenting the general sensibility of the body is common to all excitants, yet it is possessed in a higher degree by some than by others. Upon the whole, however, we may conclude that the influence of stimulants is more or less evidenced on every part of the nervous system, by the greater susceptibility than usual to impressions on every part of the body, and by a higher degree of intellectual energy, displayed not only in the acuteness of perception, but in the facility of comparing, separating, and arranging our ideas. These phenomena, it must be admitted, are not always sequences of the administration of the same stimulants, neither in intensity, nor at different epochs, in the same individuals,—results which can only be referred to altered conditions of the organs receiving and transmitting the impressions; and thence we are authorized in asserting the influence of the condition of the

nervous system in modifying the action of stimulants,—a fact of great practical importance. It is difficult to trace the alterations in the nervous tissue which produce these modifications; and we even hesitate in according with the opinion that a less natural susceptibility of impression is to be attributed to a defective development of the volume of the nervous centres; neither can we admit that an unusual bulk of brain and enlargement of the nervous fibrils are likely to produce a higher degree of excitement on the administration of stimulants. It must, however, be admitted that the changes on the nervous system produced by disease modify, in the most striking manner, the action of stimulants.

In an irritable state of the brain, manifested by general morbid susceptibility, tremours, and agitations, with irregular muscular contractions, delirium, and maniacal hallucinations, or great mental exaltation, the administration of stimulants either exasperates these symptoms, or, producing sanguinous congestions, causes a new train of symptoms equally unfavourable. If one portion only of the cerebral pulp or of the meninges be affected, the perturbation is confined to one or a few only of the senses; or if convulsions occur, they are limited to some particular muscles. Stimulants in such cases often induce epilepsy, or, if the patient be already subject to its attacks, augment the violence of the paroxysms; and the same occurs when the spinal cord or its theca is the subject of irritation.

If the excess of stimulus be always hurtful, in a moderate degree it is salutary; and, consequently, we are in the daily habit of employing excitants mixed with our food, and rely on their salutary influence, under certain circumstances, as remedial agents. With regard to the state of the body in which they are useful as remedies, we may advance the following as a general principle,—namely, that it is that state in which powerful and sudden impressions on the system are required; in which the functions of the brain and the nervous energy are diminished, and in which the impulse of the blood on the brain, necessary for its healthful action, is defective—in truth, one of direct debility of the brain. That this condition of the brain depends on a deficient impetus of blood to that organ, may be inferred from the fact that a state closely resembling it is induced by pressure on the carotids; but, when this impetus is excessive, so as to produce convulsions, these are subdued by whatever diminishes the action of the heart — for instance, bloodletting. They have also been stopped by compression on one or both carotids. The renewal of impulse, when it is absent or defective, is to be obtained by increasing the general momentum of the blood; an effect most rapidly induced by the application of stimulants either to the nerves of the stomach, or those of the Schneiderian membrane, or of other parts in which their influence can be directly impressed. Some objections may be raised against the explanation of the mode in which the increased momentum is produced, by those who contend that the brain exerts very little power over the action of the heart and arteries; but when we reflect upon the influence which passions exert over the heart during perfect health—when we consider the magnitude of the cardiac nerves, and the sympathy that exists between the heart and other organs in relation to its momentum, we shall not hesitate to admit that excitants, operating on the blood-vessels, produce their effects chiefly through the medium of the nervous system.

With respect to the nature of the substances operating as stimulants, it is necessary to remark that their distinction from tonics is not solely in degree, but also in the character of their effects. Thus stimulants augment the mobility of the system, tonics the strength of the muscles; stimulants exhaust the excitability, tonics, within a certain limit, maintain it; the action of stimulants is immediate, powerful, and transitory, that of tonics slow, almost imperceptible, progressive, and permanent. The necessity, therefore, for separating these two classes of medicines must be obvious.

Stimulants may be arranged under three distinct heads: *organic products*, *inorganic substances*, and *mental affections*.

1. The most important of the organic products employed as stimulants is undoubtedly volatile oil, whether in its uncombined state, or as separated from the plants containing it, or as it exists in combination with other principles in the roots, wood, barks, flowers, fruits, and seeds of many vegetables.

The **uncombined volatile oils** are chiefly obtained from plants belonging to the natural orders Umbelliferæ, Myrtaceæ, Aurantiaceæ, Rutaceæ, and Labiatæ. Those procured from the umbelliferous plants, namely, the oils of caraway, anise, dill, fennel, and carrot, are secreted in the seeds of the plants, and deposited in small cells or *vittæ* in these organs. The melaleuca cajuputi, one of the Myrtaceæ, which yields the cajuputi oil, contains it in the leaves; whilst in those well-known members of the natural order Aurantiaceæ, the citrus *aurantium* and citrus *medica*, the uncombined oil which they yield is found in the cells of the rind of their fruits. It is the product of the flowers of lavandula *spica*, and rosmarinus *officinalis*; and of the whole plant of ruta *graveolens*, and the following Labiatæ, namely, mentha *piperita*, mentha *viridis*, mentha *pulegium*, and origanum *vulgare*. From all of these plants it is procured by distillation with water, the oil and the watery vapour passing over together and afterwards separating, and the oil either collecting on the surface or settling at the bottom, according as its density is less than or exceeds that of the water. This is not the place to enter into the consideration of the chemical properties of these oils; it is only necessary to remark that, although they are all insoluble in water, yet they are readily rendered soluble by combining them with sugar, or as an *oleo-saccharum*, and they may thus be prescribed in conjunction with aqueous fluids.

All these uncombined volatile oils operate at first as direct stimulants on the tissue with which they are in contact, whether introduced into the stomach or applied to the surface of the body; but their influence is soon extended over the body, both by nervous sympathy and by absorption into the circulation, and they can be generally detected in one or more of the secretions. When the dose of the oil is moderate, and its acrimony sheathed

with mucilage or other demulcents before being swallowed, the stimulus proves salutary; the digestive function is promoted, the action of the heart and arteries is moderately augmented, and the secreting faculty both of the skin and the kidneys favoured. Although they are all more or less general excitants, yet the volatile oils are individually determined to particular parts of the system, and display their influence specially upon distinct organs: thus, whilst the oil of anise operates as a sudorific, that of dill produces an antispasmodic effect. But in whatever manner they operate, the volatile oils are too violent in their action to be administered in the simple form, or uncombined with some material which can obtund or sheath their acrimony. The best form for internal administration is that of an oleo-saccharum dissolved in any aqueous infusion or decoction. Externally, volatile oils operate as counter-irritants, and relieve deep-seated inflammation; whilst in cases, such as tooth-ach, in which they can be directly applied to the part, they exhaust the nervous excitability and thus allay pain.

Many vegetable stimulants owe their efficacy to volatile oil, although it cannot be readily separated from their other components. Thus we find it in the roots of the Asistolochia *serpentaria*, in combination with a bitter principle, gum and resin; in the rhizomes of the Acorus *calamus*, ginger and turmeric, Curcuma *longa* with fecula; in the wood of sassafras, and the barks of Drymis Winteri and cinnamon, with tannin and gallic acid; and in that of Canella *alba* with fecula; in saffron, the stigmata of Crocus *sativus*, with a peculiar colouring matter which chemists have named polychroite; in the clove, allspice, laurel-berries, the cardamom and the nutmeg, chiefly with fecula, tannin, and gum; and in the cubeb, the fruit of Piper *cubeba*, with resin, gum, and extractive. In all these the volatile oil is the efficient principle. It is separated by the digestive function of the stomach when these medicines are given in substance, and is afterwards taken into the circulation: thence its primary influence is exerted on the coats of the stomach and intestinal canal to which it is applied, its secondary on the capillary system, and the cerebral and rachidien centres. When the action is intended to be confined to the digestive organs, either uncombined volatile oil, as an oleo-saccharum, or those substances containing it in combination with tannin and the bitter principle,—namely, the roots and barks above enumerated,—should be selected. When the stomach is suffering under that chronic debility which is characterized by sickness and occasional vomiting, and in all cases of deficient action of that organ, particularly when it is accompanied with cardialgia and flatulence, these aromatic stimulants are indicated. It is, however, important to discriminate that pain which is the result of spasm, and that arising from inflammatory action, in dyspeptic affections; and even when the disease is grafted upon a hypochondriacal condition of the habit, the uncombined volatile oils should not be employed. In affections, also, of the intestinal canal, when no inflammation is suspected, as, for example, flatulent colic and cholera and atonic gout attacking the stomach, the warmest of the uncombined volatile oils may be prescribed, even during the utmost violence of the pain. In Asiatic cholera these oils have been strongly recommended, but the pathology of the disease is still too obscure to enable us to decide on the propriety of their employment, although in general atony of the bowels, producing either obstinate constipation or passive diarrhœa, the addition of aromatics, more especially the uncombined oils, in conjunction with purgatives in the one case and astringents in the other, by rousing the nervous energy, is productive of the best effects. In the administration, however, of these agents in gastric and intestinal disease, it is of importance to ascertain the exact condition of the abdominal viscera, and most particularly that of the whole mucous membrane of the alimentary canal. We should be satisfied that no ulcerations, nor scirrhous or cancerous tendency exist in any portion of the canal; and if vomiting or gripings be present, that these are not symptomatic of cerebral congestion or irritations of the encephalon or of the spinal cord; and at the same time the state of the liver, the pancreas, and the spleen must be carefully investigated. Much caution is also requisite, in prescribing any of the aromatics, when the tongue displays that red and glazed state which denotes subacute inflammation of the mucous membrane of the stomach,—a not unfrequent cause of dyspepsia.

In looking at the peculiar determination to distinct organs produced by some of the combined oils, we are enabled to select the substances containing them for the relief of particular symptoms, when the general state of the habit does not contra-indicate the employment of stimulants. Thus, in those dyspeptic affections in which the circulation is languid with a dry harsh skin; or in cases of remittent and malignant fever, when the powers of life sink and the skin is hot and dry; or in pustular eruptive fevers, when the eruption suddenly recedes; or in protracted intermittents, especially when these are combined with cough; the serpentaria root is better calculated to fulfil the intentions of the physician than any other of this class of stimulants. If the surface be kept warm, it rarely fails to excite the action of the cutaneous capillaries; and while it promotes diaphoresis, it supports and supplies energy to the general system. In such cases the best form of administering the medicine is tincture, as proof spirit takes up both its volatile oil and bitter extractive. On the same principle the volatile oil of cubebs is determined to the kidneys, and probably produces its beneficial influence in gonorrhœa both by stimulating the kidneys and augmenting its secretion, and acting directly on the urethra during the excretion of the urine; thus overcoming the disease by setting up a new action in the affected part. When this action on the urinary organs does not take place, cubebs excite great irritation and fever, and paralysis is sometimes the result. In a case which fell under the care of the writer of this article, in which the extent of the dose was ʒi, so much febrile irritation was excited that the life of the patient was in danger.

All of the aromatic stimulants are admirable additions to tonics when judiciously prescribed, and some of the most important of the class owe their excellence to a natural combination of this

description; as, for example, Winter's bark and Calamus aromaticus, the latter of which is one of the best additions to cinchona bark and sulphate of quina in intermittents. Several of the aromatics, nevertheless, cannot be combined with cinchona or the salts of quinia, as, for instance, cinnamon, cloves, and pimento, on account of the precipitates which they throw down, — a disadvantage from which the uncombined oils are free.

As external stimulants, all the uncombined volatile oils may be employed, the extent of their rubefacient effect being easily regulated by the quantity of bland oil used for diluting them.

Such are the stimulant properties of volatile oil, both in its uncombined and combined state; the list of substances yielding it, contained in the British pharmacopœias, might be greatly abridged, and yet ample means afforded for fulfilling every indication for which vegetable aromatics can be required in the treatment of diseases.

Many vegetables owe their stimulant influence to **acrid fixed oil,** which exists in the plants in a state not in all cases quite evident, although in some it seems to be deposited in distinct cells. This acrid principle is apparently mixed with fixed oil if the parts of the plants containing it be submitted to the operation of expression, but it is perhaps in every instance separate from it during its existence in the plant: it is usually more or less volatile. All the peppers, mustard, and pellitory, derive their stimulant property from an acrid principle of this description. In black pepper it is combined with fecula, uric and malic acids, and piperina; and its stimulant powers, whether internally administered or externally employed as a suppurative, are solely due to this acrid principle. When separated, this oil is too pungent to be tasted with impunity; it reddens and inflames the skin, and thence we can readily trace the cause of the long-continued insupportable burning sensation which it excites when taken into the stomach. It rapidly increases vascular action, and powerfully excites the sexual organs. The effect of pepper as an antiperiodic has been attributed solely to the piperina; but the writer of this article accords with Magendie in thinking, that something is due to this stimulant principle, as alone it has cured intermittents. It has not generally been employed as a therapeutical agent; but pepper in substance is given in the form of powder, in doses of six, eight, or ten grains.

The same remarks apply to mustard and pellitory root; both of which, however, are employed almost exclusively as local stimulants. The chief advantage of the mustard cataplasm is in the promptness of its action, and the facility of regulating it. The use of pellitory is confined almost exclusively to cases of paralysis of the tongue and the internal organs of deglutition, arising from circumstances affecting partially the nerves of these organs. A small portion, more or less bruised according to the power of mastication enjoyed by the patient, is chewed as constantly as the sensibility of the mouth will admit, and the saliva ejected.

There can be no doubt that *camphor* is properly placed in this class of remedies; but much difference of opinion exists regarding the mode in which its stimulant influence is exerted. Its first effect, in a full dose, is undoubtedly derived from its stimulant power; this might, indeed, be assumed from its reddening and causing heat and increased action in the part when it is applied to the skin; and it is rendered evident, also, by the warmth which is felt in the throat and at the epigastrium in swallowing it. Its influence on the gastric nerves is propagated to the brain, the spinal cord, and the whole ganglionic system; and, during this time, the heat of the surface is diminished, rigors sometimes occur, and vertigo with perverted vision supervenes. Were our observations to proceed no further, camphor might be regarded as a simple narcotic, not affecting the heart and arteries; but a secondary effect—one, undoubtedly, of increased action—soon displays itself: the pulse becomes strong, frequent, and vibrating; the temperature of the body is elevated; the eyes glisten, and cephalagia occurs. From these effects we may conclude that camphor operates, at first, solely on the nervous system; and that it is not until it is taken into the circulation, that it stimulates the vascular organs. Its influence as a stimulant is much less permanent than that of aromatics, as it passes rapidly out of the habit by the cutaneous exhalants, producing its excitant effects in transitu. The action of camphor is also greatly modified by the dose of the medicine. In moderate doses, namely, from five to twelve grains, it softens and fills the pulse, and promotes diaphoresis, mitigates pain, dissolves spasm, and seems to rouse the nervous energy without quickening the pulse; thence, in combination with antimonials it may be administered even in diseases of excitement: but when its stimulant property is required, the dose should not be less than a scruple; and it may be combined with aromatics, opium, or tonics, as the indications direct. In such combinations, its influence in checking the progress of gangrene, and in supporting the powers of the habit, in confluent small-pox, measles, and other eruptive fevers, when they assume a typhoid character and the eruptions recede, has been amply demonstrated. Professor Hallé informs us that it acts as an antiperiodic when it is administered in combination with nitrate of potassa, in the intervals of intermittent fever. As an external local stimulant or rubefacient, camphor is in very general use when dissolved in oil or soap liniment; nevertheless, when dissolved in proof spirit and applied to a hot and inflamed surface, instead of stimulating it causes an agreeable sensation of coolness,—a circumstance depending on the great volatility of the camphor; whereas, when dissolved in fixed oil, its volatility is restrained, and its stimulant effect secured. Another method of employing camphor as an external stimulant is as a fumigation. The patient is covered with a blanket pinned close round the neck, and from half an ounce to an ounce of camphor is thrown on a hot iron plate placed within the blanket. The effect is copious perspiration.

Owing to the insolubility of camphor in water, aqueous fluids are unfit vehicles for its exhibition, unless means are adopted to keep it suspended in them. The best method of effecting this is by dissolving the camphor in fixed oil, then forming this solution into an emulsion by triturating it with gum and water, or the almond emulsion. It has also been formed into a soap by means of

liquor potassæ, or triturated with soap, and thus rendered miscible with water; or it may be dissolved in milk in the proportion of ℥ss of the camphor to f.℥iv of milk and f.℥viiss of distilled water, as recommended by Dr. Cassils, of Kendal. (Edinburgh Med. and Surg. Journal, vol. viii. p. 124.)

One of the most powerful of the vegetable stimulants is **strychnia**, an alkaloid,* the active principle of Strychnos *nux vomica*, the seeds of which contain in it combination with igasuric acid, as an igasuriate. Its first obvious effect when taken into the stomach in a moderate dose, namely, one-tenth of a grain, is an augmented energy of the digestive function, without much change on the pulse; the vigour of the cutaneous function is also increased, and perspiration flows freely. By degrees, however, as it accumulates in the system, the respiration becomes oppressed, and the respiratory muscles suffer a clonic contraction. This extends to the rest of the system, and violent twitchings and tetanic contractions supervene. In addition to these symptoms, the surface of the body becomes morbidly sensitive to the slightest impressions, even the motion of the air, as in hydrophobia; whilst a sensation of heat, prickings, formications, and other uncomfortable feelings, are experienced in the limbs. These symptoms increase at one moment and subside in the next, keeping pace, as it were, with the changes which supervene in the power of the irritations impressed on the medullary matter of the spinal cord. From these symptoms, as well as the fact ascertained by experiment, that strychnia produces no effect on the system when the spinal cord has been previously destroyed, it is evident that it acts directly on the motor tract of the spinal marrow;† and when the dose is sufficient to destroy the animal, death soon follows the clonic spasm of the respiratory muscles, and the deficient decarbonization of the blood in the lungs.

The employment of the extract of nux vomica, and of the powder of the seeds, was formerly common in pyrosis, and its influence in changing morbid into healthy action in the digestive organs was well ascertained; but the introduction of the administration of strychnia in paraplegia is due to Dr. Fouquier, of the Hospital de la Pitié, in Paris; and the expectations of its powers raised by the result of his practice have been fully verified: strychnia is now, therefore, generally regarded as a most valuable stimulant in paralytic affections, especially those of the lower extremities. With respect to the mode of prescribing it, on account of its great insolubility in water and the variation of activity according to the greater or less ascescency of the stomach during its employment, the author of this article has proposed to administer it always in the form of an acetate, which is readily produced by dissolving one grain of the alkaloid in a fluidrachm of distilled vinegar. Six minims of this solution, containing one-tenth of a grain of strychnia, is the dose of the medicine to be given at first. It must be gradually increased until the tetanic twitchings appear, which generally occur before the dose amounts to thirty minims, equivalent to half a grain of strychnia. When the powder of nux vomica is given, the dose may be gradually increased from five grains, until fifty be taken in the course of a day; or if the extract be preferred, two grains may be first prescribed to be taken at night and in the morning, and one grain added every day or every second day, until the specific effects of the remedy display themselves with sufficient intensity to lead to a salutary result. If strychnia be employed in cases where there is much irritability of stomach, instead of being swallowed, it may be sprinkled on a denuded surface in double the dose requisite when internally administered.

Besides the use of strychnia or its acetate, or the extract of nux vomica, in paralysis, it has been found useful in several other diseases. M. Frisch, a German physician, affirms that he has cured ague in robust persons, when sulphate of quinia failed, by adding to this salt the powder of nux vomica in doses of four or five grains; and Dr. Bardsley has found strychnia equally serviceable in amenorrhœa and chronic diarrhœa. (Hospital Facts and Observations, &c., by James Lomax Bardsley, M. D. p. 57.) When overdosed, the fatal effect which has followed seems to proceed chiefly from the poison exhausting the irritability of the heart. The first symptom characterizing an overdose, or the result of its poisoning influence, is tremour; this is followed by stupor, which is quickly succeeded by tetanus, stiffness of the muscles of the neck, trismus, severe pain under the ensiform cartilage, opisthotonos, laborious respiration, and fatal asphyxia. M. Donné has proposed iodine as an antidote in such cases; and the results of his experiments on dogs afford strong reasons for trying it on man.‡ [See Tetanus.]

The stimulant influence of **alcohol** in all its modifications and combinations has been known almost from time immemorial. When alcohol, diluted and uncombined, is applied to the living system, it acts upon the nervous energy, augmenting the tone of the part, diminishing the capacity

* Strychnia, according to the analysis of Liebig, consists of

Carbon,	76.43	or 30	equiv.	183
Hydrogen,	6.70	" 16	"	16
Nitrogen,	5.61	" 1	"	14
Oxygen,	11.06	" 3	"	24
	100.00			237

It is procured by precipitating a concentrated decoction of the seeds of nux vomica, or St. Ignatius bean, with acetate of lead; decomposing the acetate thus formed with magnesia, and treating the precipitate, well washed and dried, with strong alcohol. By repeated solution and crystallization it is procured in the form of minute, white, elongated, tetrahedral prisms, terminated by a pyramid, permanent in the air, and inodorous, but so intensely bitter as to impart a sensible bitterness to 506.400 parts of water.

† Fodéré found, that on exposing the spinal cord in the loins of an animal to which strychnia had been administered, he could arrest the tetanic convulsions by making pressure on the anterior segment of the spinal cord.

‡ As the advantage, however, arises from a chemical change effected on the strychnia by the iodine, it cannot prove useful if the poison be absorbed; but it is more probable that it operates solely through the intestinal nerves. Post-mortem examinations display the venous system of vessels gorged with blood, whilst the arterial is nearly empty, and the arteries contracted to nearly one-half their usual diameter. Scarcely any traces of inflammatory action have been detected even in the stomach.

of the blood-vessels, and adding to their power of carrying forward the blood which they contain. But this effect is modified both by the strength of the alcohol and the susceptibility of the part to which it is applied: if the sensibility be considerable, and the alcohol strong, the state of augmented tone, and the contraction which renders the surface pale, are of short continuance; the vital energy is rapidly exhausted, and inflammation is the consequence. The stimulant property of alcohol thus becomes obvious to our senses. When taken into the stomach in large quantity and pure, its primary influence is experienced on the organ itself; its mucous membrane is inflamed and its vitality destroyed: this shock is communicated through the nerves to the brain; and the person often dies before there is time for absorption to have taken place. In animals killed by injecting alcohol into the stomach, Mr. Brodie found on dissection every appearance that indicates strong inflammatory action, and blood extravasated between the tunics; but, except a gorged state of the vessels, no appearances of any injury to the brain were observed; thence dissection strengthens the opinion that the impression is wholly on the nerves. When the alcohol is somewhat diluted, it acts with less energy, and merely causes ebriety. The first impression, in this case, is one of augmented energy; the mental function acts with unwonted power; fancy is awakened, and creates, from uninterrupted associations, new and often brilliant combinations; and at this moment, imagination luxuriating unrestrained, the poet pours forth his most harmonious and sublimest strains. By degrees, however, this blissful sensation vanishes; all control of the will as well as reason is suspended; and, instead of agreeable conceptions, ideas crowd into the mind in the most incongruous order; vertigo supervenes, and delirium precedes a state of exhaustion, which at length terminates in collapse and sleep resembling that of apoplexy, and not unfrequently proves the prelude to death. In general, however, nature adopts this method of restoring exhausted excitability; but, after the repose, the shock given to the nervous system is rendered obvious in the tremulous hand, the unsteady limb, the rigors, the nauseated stomach, the irascible temper, and the completely overpowered state of the system which the individual experiences on awaking. That all these symptoms depend more on the impression made on the nerves of the mouth, the gullet, and the stomach, and its transmission to the brain by nervous sympathy, than by absorption, is evident from the influence of a small portion of wine or of alcohol in causing intoxication, if it be allowed to pass slowly over the sensitive extremes of the nerves of the tongue and fauces in its progress to the stomach; and, also, by the sudden sobriety which often follows the act of vomiting. The repetition of such impressions, however, affects seriously the powers of life; cancer of the pylorus, abscess of the liver, delirium tremens, palsy, dropsy, epilepsy, mania, and a long train of evils, attack and soon subdue the strongest constitution. It is true that some habitual drunkards have lived to a good old age; but this is an exception to a general rule—

> "Perhaps some doctor, of tremendous paunch,
> Awful and deep, a black abyss of drink,
> Outlives them all; and from his buried flock
> Retiring, full of rumination sad,
> Laments the weakness of this latter time."
>
> THOMSON'S SEASONS—*Autumn*.

But notwithstanding these frightful results of the dietetical abuse of alcohol, it is, when temperately indulged and discriminately prescribed as a medicine, a most salutary stimulant.

As a medicinal excitant, alcohol in some respects resembles a narcotic in its operation; its use is more or less followed by sedative effects; but its stimulant influence is too great to allow it to be employed as a narcotic. In its diluted state it is serviceable in those fevers, and those periods of fever, which indicate much depression. Great attention is necessary in determining the degree of dilution which is always requisite: as a general rule, one part of ardent spirits to five of water, and the mixture acidulated with lemon-juice and sweetened, is a mixture of a proper strength, and forms an excellent substitute for wine. In this degree of strength, it may even be prescribed in some diseases of excitement, if no vital organ be affected, and the powers of life are sinking.

In dyspeptic states of the stomach, although often recommended, alcohol is often pernicious. The symptoms of dyspepsia sometimes depend on a state of subacute inflammation instead of debility of the organ; thence only one opinion can be formed respecting the propriety of prescribing stimulants. If alcohol, simply diluted with water, produce these effects, we may also look for them from its combination in wine, beer, and cider.

In regarding the therapeutical influence of wine, we must consider both the chemical properties of the kind of wine to be prescribed, and the condition of the habit of the patient. With respect to the former, sweet wines, such as mountain, constantia, tent, lisbon, &c. although they do not intoxicate so quickly as some other wines, yet, owing to their imperfect fermentation, promote acidity, and therefore they should not be prescribed in any case when the stomach is in a low state of vitality. The brisk and sparkling wines, the produce of Champagne and Burgundy, intoxicate sooner than dry or still wines, owing to the carbonic acid which they contain; but their effect is more transitory, and the subsequent exhaustion less than that caused by other wines; thence they are salutary stimulants in those diseases which are termed nervous, when taken in moderation; and no opinion is worse founded than that which regards them as injurious to gouty habits. The light wines of the Rhine and the Moselle are less likely than any of the others to influence injuriously the nervous system: they are less inebriating and possess diuretic properties, and although acidulous, yet they do not disorder the stomach so readily as the stronger wines, both because the acid which they contain is the tartaric, the least fermentable of the vegetable acids, and also because their alcohol is intimately combined with the other principles of the wine. The strong wines, as port, sherry, madeira, and the aromatic spirituous wines of Burgundy, are the least wholesome, owing chiefly to the uncombined brandy which is

mixed with them for the purpose of securing their exportation, and their powerful intoxicating properties. All of them, also, contain volatile oil, which displays narcotic properties in the nervous system, and induces a tendency to apoplexy.

With respect to the second object of consideration,—the state of the habit in diseases which require the stimulus of wine,—we may venture to affirm that wine, under proper management, is well adapted for the advanced stages of continued fevers, and every disease in which the powers of the constitution fail. Its exciting powers are of primary importance, and it is grateful to the palates of most patients; but various circumstances are requisite to be attended to in its administration.

1. It is more necessary and safe if during health the patient has been accustomed to take wine, than if his habits have been abstemious.

2. It is indicated when, in the advanced stage of fever, the pulse is frequent, small, and compressible; if there is low muttering delirium, and subsultus tendinum.

3. It is also indicated when there is a strong instinctive desire for it; on the contrary, its use should not be urged when there is no such desire.

4. Its effects should be watched: if it do not disorder the stomach, or augment the heat of the skin, but fill the pulse and lessen its frequency, mitigate delirium, and remove restlessness, it is not only proper but absolutely requisite.

5. In contagious fevers, with a languid pulse and oppressed spirits, wine may be administered in an early stage. It should be given in small quantities, frequently repeated, as long as it seems to answer the intention of its exhibition; nor should it be rapidly withdrawn, but gradually diminished as the febrile symptoms abate, and the system displays more susceptibility of its impression.

6. Claret and Rhine wines are more proper than the stronger wines in the earlier, but not in the later or sinking stages of fever. The lighter wines generally tend to open the bowels, the stronger to check diarrhœa; but sometimes the opposite is the case.

7. With respect to the form of administering wine, it is generally most grateful to the sick when warmed, sweetened, and slightly acidulated; but to many patients it is most grateful when diluted with cold water.

Wine proves hurtful in neuralgic and rheumatic affections, and, like every remedial agent, is beneficial or injurious, according to the degree of skill, discrimination, and judgment which directs its administration.

These remarks are applicable to **ether** and its preparations, which differ from wine in their operation chiefly by the rapidity with which their effects are propagated over the system. It is probable that ether is absorbed in its state of vapour, and applied directly to the nervous centres. When taken into the stomach in moderate doses, twenty or thirty minims in a glass of water, it stimulates the gastric nerves, and has a powerful influence in checking vomiting. In malignant fevers it aids in allaying subsultus tendinum and hiccough; and when prescribed in larger doses, on the approach of the intermittent paroxysm, it often succeeds in preventing its accession.

In treating of **electricity** as a stimulant, it would be out of place here to enter into any investigation of the causes of its phenomena; its influence as a therapeutical agent in the removal of disease is our object. In whatever form it be employed, whether as voltaic or common electricity, when it is applied to the animal system in a moderate degree it increases excitement; in a large quantity, it destroys life. It operates equally on the sensibility and the irritability of the system, is quickly propagated, and excites the action of the most distant parts. It differs from other powerful stimulants in not being followed by those secondary effects which are the result of the excitant influence of almost every other stimulant. It is indicated only in diseases of debility, and it requires to be continued for many weeks in order to secure beneficial effects from its use. Much, also, depends on the mode of applying it. In all cases the isolation of the patient and the *accumulation* of the electrical fluid on his body should be first tried; then the *aura* used; after which *sparks* may be taken; and, lastly, when the system has accommodated itself to the stimulus, *shocks* may be given. The necessity of proceeding in this cautious manner is obvious: in delicate and nervous habits a strong shock may not only induce syncope, pain, and vomiting of blood, but it may further so exhaust the strength as to accelerate and even cause death. (Percival's Essays, vol. i. p. 393.)

Electricity has been found a useful stimulant in glandular affections. In recent cases it operates by exciting the capillary action and reducing the swelling; in the more advanced, by promoting suppuration. On the same principle much confidence is placed on it in amenorrhœa; it produces a current of blood to the uterus, and stimulates the secreting powers of that organ. It is especially indicated when atony of the uterus accompanies a pale leucophlegmatic condition of the habit. The shocks should be passed directly through the part. When, on the other hand, there is plethora, with rigidity of fibre and a high sanguine complexion, electricity is hazardous in amenorrhœa, unless preceded by bleeding, purging, and other antiphlogistic measures. In every case, before determining on the employment of electricity on the female habit, it should be ascertained that pregnancy is not present, as either miscarriage or premature labour, according to circumstances, and the death of the fœtus, may follow its use. In passing shocks through the uterus under any state of the organ, much caution is requisite in regulating its force: if the shocks are too powerful, danger may result; if too weak, no benefit will accrue from their use.

The beneficial influence of electricity has often been observed in paralysis in all its forms, if it be not complicated with determinations to the head. Thence it is more useful in old than in recent cases, in partial than in general paralysis, and in paraplegia arising from the poison of carbonate of lead, than hemiplegia following apoplexy. In the most favourable cases for its employment it must still be cautiously applied, and the remark of Dr. Percival should always be kept in recollection,

"that few cases which resist the power of small and repeated shocks, yield to great and terrifying ones." Rubefacients aid considerably the beneficial power of electricity. In asphyxia, gentle shocks may be passed through the region of the heart. In deafness from atony of the auditory nerve, sparks should be taken from the internal part of the meatus by means of a metallic conductor passed through a glass tube: the effect is swelling of the part, with an increase of ceruminous matter, which is followed by an improvement in the faculty of the organ. In amaurosis from mere defective sensibility of the optic nerve, much benefit may result from taking sparks from the eye, directed through the back part of the head, following the course of the optic nerve; but if the cause be a tumour pressing on the nerve, either at its origin or in its course, no benefit will follow the use of electricity. In some cases galvanism may be substituted for common electricity, but in general electricity has succeeded where galvanism has failed. See ELECTRICITY and GALVANISM.

We have already treated of the stimulant influence of caloric. See BATHING.

Iodine is a powerful stimulant, whether it be employed in its simple or uncombined stage, or as it exists in many preparations. Its great utility depends on its entering the circulation and exciting the capillary system. Its primary influence, however, is exerted upon the stomach, a fact which has been fully ascertained by the appearance observed on that organ in persons who have been poisoned by it: indeed, the powerful manner in which it attacks the skin might have enabled us to prognosticate a similar effect when it is introduced into the stomach. Like some other medicines, it accumulates in the system; and, therefore, the continued employment of it, even in small doses, has occasionally proved hurtful. Its absorption is demonstrated by the facility with which it is detected in the blood, the urine, the perspiration, and other secretions; thence its stimulant influence is extended to every part of the frame; the absorbents are urged to unusual activity, and not only diseased but healthy parts are carried off by its means; the mammæ in women and the testicles in men waste: in truth, no gland is exempt from the influence of iodine. There is a remarkable discrepancy, however, in its action, which was first observed by M. Lugol,—namely, that women labouring under scrofula, instead of becoming emaciated, gain flesh. In overdoses it operates as a poison, causing heat and a sensation of weight at the epigastrium, pain at the lower part of the sternum increased on pressure, cardialgia, burning heat of the skin, excessive thirst, and frequent purging of dark bilious matter; the pulse is weak and tremulous; great restlessness and palpitations supervene; with frequent syncope and extreme exhaustion.

The principal diseases for which iodine has been advantageously administered are bronchocele, scrofula, amenorrhœa, chlorosis, dropsy, and every form of disease arising from or connected with diminished capillary action. The activity of the medicine is modified by its combination with other substances; as in the hydriodate of potassa, the iodurets of mercury and of lead, and ioduret and hydriodate of iron. The first is the least active of these preparations, and is chiefly employed as a vehicle for augmenting the solubility of iodine in aqueous fluids: the iodurets of mercury and of lead are more powerful stimulants than the iodine alone, and require to be cautiously administered in doses at first not exceeding the sixth of a grain; on the other hand, the combination with iron, which was introduced to the notice of the profession by the writer of this article, diminishes the irritative action of the iodine, whilst the iron being rendered soluble, and in a state to be readily converted into the protoxide, is carried into the habit with the iodine, and aids its deobstruent influence by giving tone and support to the system.* It is admirably adapted for chlorotic affections, and cases of glandular obstructions, connected with diminished power and a leucophlegmatic state of the habit. On account of its deliquescent property it cannot be administered in substance; and when dissolved it is converted into a hydriodate, in which form it may be administered in doses of from two to six grains three times a day. The influence of both its components is rapidly visible on the habit, by the improved colour of the skin, the increase of appetite, exhilarated spirits, and invigorated strength of the patient; and so quickly does it get into the system, that in twenty-four hours after the first dose has been taken, both the iron and the iodine can be detected in the secretions. It is incompatible in prescriptions with alkalies and their carbonates; the metallic salts; all vegetable infusions and decoctions containing tannin and gallic acid; the preparations of opium, henbane, and conium; the alkaloids and their salts, and chlorine. It has one advantage over all the other preparations of iodine,—it does not produce emaciation, or that wasting of glandular bodies, which renders the closest watchfulness requisite in their administration.—[See EUTROPHIC.]

The stimulant influence of all the preparations of **mercury** has been long known and acknowledged. In whatever manner they are introduced into the body, whether they be taken into the stomach or applied by friction to the skin, they excite powerfully, and set up a febrile condition of the system, evidenced both by the state of the pulse and the nerves, and by an augmented energy in the whole secerning organs. This action, like that of every other energetic stimulant, when carried beyond a certain point, or when long continued, debilitates, and, consequently, emaciation is a constant attendant of a mercurial course. In producing their effects, mercurial preparations,

* The ioduret of iron is prepared by placing one part of soft tempered iron-wire in a hollow porcelain vessel with a considerable quantity of distilled water, and adding five parts, by weight, of pure iodine, and then subjecting the mixture to heat, constantly stirring until the solution is accomplished and the liquid is nearly clear. The solution is then to be filtered and immediately evaporated to dryness in a flask, which must be broken as soon as the ioduret has crystallized, and the preparation directly put into a well-stopped phial. It is a protoioduret, containing one equivalent of each of its components. When well made, and well preserved from the air, it dissolves entirely, and affords a pale greenish-yellow solution; but when not well preserved from the air, a portion of the iron is converted into the peroxide of the metal, and a sesqui-ioduret is formed, so that when it is rubbed up with water the peroxide remains insoluble. [For one of the best modes of preparing it, see *Pharmacopœia of the United States*, Philad. 1842.]

whether oxides, chlorides, cyanides, or iodides, are decomposed, and the mercury, in a metallic form, is either thrown out of the body by the skin and lungs, or, under certain circumstances, is deposited in the glands and the bones. The first of these facts is demonstrated by the amalgam formed between the exhaled mercury and gold and silver coins worn in the pocket of a person under a course of mercury: the second has been confirmed by the discovery of metallic mercury in various parts of the body, in *post-mortem* examinations. Amongst other well-authenticated proofs of the latter, there is a pelvis of a young woman who died of syphilis, preserved in the Lubben cabinet of midwifery, which is infiltrated with metallic mercury.

The stimulant influence of mercurials is much modified by the manner and the doses in which they are administered, and to a certain extent by the nature of the preparation employed. In large doses, given at distant intervals, mercurials operate as local stimulants, first on the liver and pancreas, by exciting the orifices of their excretory ducts, through which the impression is conveyed to these glands; and, secondly, on the exhalants of the alimentary canal, thereby unloading the vascular system and giving a new impulse to the circulating powers. In this case no primary excitement is communicated to the capillary system. When smaller doses, repeated at short intervals, are administered, the mercurial is absorbed, and being directly applied to the capillaries, the whole glandular system is excited; and the salivary glands being more susceptible of impressions than those of the rest of the body, salivation is the consequence. When this high degree of irritation is carried to excess or long-continued, it is apt to be followed by a state of exhaustion which sometimes proceeds rapidly to a fatal termination; or when that condition of the nervous system which has been denominated hysterical, exists, particularly if the patient be exposed to sudden alternations of heat and cold, the ordinary febrile symptoms resulting from mercurial action are attended by dry cough and tightness across the præcordia; and an eruption closely resembling eczema appears. At first a redness is diffused over considerable portions of the surface; this is followed by crowded minute vesications, accompanied by a stinging sensation, and this continues after the vesications; dry and extensive exfoliations of large flakes of the skin occur; the eyes and palpebræ are completely denuded of their hairs; the head swells; the whole body exhales a fetid odour; and a degree of exhaustion, which tends to the fatal termination, generally supervenes. (See article Eczema.) This affection was first noticed, as a result of the action of mercury, by Mr. Alley of Dublin, (Essay on a peculiar eruptive disease, arising from the exhibitions of mercury, by George Alley, Dub. 1804,) and afterwards ably investigated by Dr. Moriarty, (Description of Mercurial Lepra, by D. Moriarty, Dub. 1804,) Dr. Spens, (Cases, &c. by Thomas Spens, M.D. Edin. Med. and Surg. Journ. vol. i. p. 7,) and others. All temperaments, it is stated by those who have written on the disease, are liable to this species of eczema, but the experience of the author of this article is at variance with that opinion; and he believes that it is peculiar to that state of habit which is termed *hysterical*, occurring in a sanguine temperament.

In no circumstances, not even in the treatment of syphilis, is the introduction of mercurials into the habit required to be carried so far as to risk the appearance of these effects. Salivation is not essential, and can be regarded as a mere proof that the system is fully under the influence of the mercurial action; to throw in more is merely raising a higher degree of irritation, which is not only unnecessary but hurtful. Too profuse salivation has induced epilepsy, and occasionally led to that fatal erethismus which sometimes occurs when mercurials appear to act as poisons on the system, in which the use of the stimulant must be discontinued, and the patients exposed freely to a cool atmosphere, whilst the strength is sustained by a liberal allowance of mild but nutritive diet. On this account, mercurials should be introduced into the system gradually, and the mildest forms of the preparations first employed. The efficacy of the remedy undoubtedly depends on its exciting power, but this should be maintained only in a moderate degree; and it is of importance that the excitement should not be disturbed by that of any other stimulus, dietetical or medicinal; thence the necessity of dieting patients during a mercurial course. If wine or other stimulants be allowed, the peculiar action set up by the mercury may be so modified as to prevent it from overcoming that induced by the virus of syphilis; a rule which is applicable, perhaps, in regulating the employment of all other stimulants. It is proper to remark here, that the degree of the febrile action induced by mercurials does not always depend on either the extent of the dose or the nature of the preparation; two grains of calomel will cause salivation in some persons, whilst in others no effects can be produced by the largest doses, long continued, until fumigations are resorted to; and even these have been resisted. A knowledge of the circumstances on which these anomalies depend is important: they may be arranged under those which refer to the body,—temperament, idiosyncrasy, and sex; and those extraneous to it,—climate, and the nature of the preparations employed.

1. With respect to temperament, the sanguine and choleric are more susceptible of the mercurial action than other individuals: if the remedy be given for the cure of syphilis, great caution is necessary not to bring the habit suddenly under the full influence of the medicine.

2. Some idiosyncrasies are occasionally met with which prevent the free use of mercurials; and as this may occur in reference to some preparations and not to others, it is proper, when syphilis is the disease, that a person who seems to suffer in this manner should try other preparations before his system is pronounced incapable of bearing mercury, and he is thereby deprived of the only chance of being cured.

3. With regard to sex, women are more easily brought under the mercurial influence than men; and as it promotes the uterine secretion, the use of mercurials should be suspended during the continuance of the catamenia. In pregnancy, also, their employment requires the utmost caution.

They do not, however, materially interfere with lactation; and therefore, when infants are affected with congenital syphilis, the mercurial influence is readily communicated to the system of the child by the milk of the mother.

4. As climate renders the human habit highly susceptible of the impression of all medicinal agents, a smaller quantity of mercury and a shorter period for its application will suffice to cure syphilis in a warm than a cold climate; and, for the same reason, this stimulant is more beneficial when employed in summer than in winter. Sydenham sent his syphilitic patients to the south of France.

5. In reviewing the comparative merit of the various preparations of mercury, it would be out of place here to enter into pharmaceutical details. Among the *protoxides* the *blue pill*, when properly prepared, is the mildest of those which certainly mercurialize the habit. It seldom incommodes either the stomach or the bowels, unless much acid be present, in which case it is apt to gripe and purge. From the mildness of its operation, it is admirably adapted for the naturally delicate and those debilitated by previous disease. But in some persons, however, it proves too active, and requires the addition of opium, or the administration of a few grains of rhubarb, in the morning, to communicate tone and prevent griping. It gradually displays its influence by affecting the gums, when given in doses of five or six grains night and morning.

The *hydrargyrum cum cretâ*, in doses of a scruple to half a drachm, is sometimes substituted for the blue pill when much acid is present on the stomach, but its action is slow and uncertain.

The *grey oxides*, although precipitated from active salts, yet are mild preparations. They incommode the stomach and bowels less than the blue pill, and, being more oxidized, they act with more certainty; but they are not much employed, except for fumigations.

The *peroxides*, constituting the red precipitate *per se* and the precipitate with nitric acid, operate with too much acrimony to be used internally, inducing griping, diarrhœa, and tenesmus. They are, consequently, used only as topical excitants.

The *chlorides*, *calomel* and *corrosive sublimate*, are also most active stimulants. The protochloride, calomel, in doses of four or five grains, frequently operates topically, stimulating the orifices of the gall-ducts, and, by thus throwing much bile into the intestinal canal, causing purging. In smaller doses, it brings the habit under the mercurial influence more rapidly than the blue pill, and it is even more manageable. Its stimulant influence on the capillaries greatly aids the action of other remedies; as, for instance, the diaphoretic powers of antimonials, and the diuretic of squill and foxglove; it aids, also, the force of the milder purgatives, whilst it moderates the acrimony of the more drastic. The best form of administering it is that of pill combined with opium.

The *perchloride*, *corrosive sublimate*, is the most active of all the mercurial salts, but it frequently gripes, even when administered in very small doses, and is supposed to have the power of causing cough, hemoptysis, and phthisis. It is, nevertheless, one of those preparations on which experience has taught us to rely in cases of syphilitic eruptions, especially those which assume the characters of psoriasis or of lepra; and from the rapidity with which it brings the habit under the mercurial influence, it proves, as Mr. Pearson has remarked, often beneficial at the commencement of a course of mercury. The dose of the perchloride should not exceed, at first, one-tenth of a grain; but, if it be guarded by opium, it may be gradually increased to half a grain, twice a day. A good vehicle for administering it is nitric acid, in which the salt dissolves without undergoing any chemical change; and in this form it may be given in conjunction with decoction of sarsaparilla or of elm-bark, in cases of syphilitic eruptions. In such case that attention to diet, which has been already noticed, is most essential, little benefit following the use of the perchloride if the patient is permitted to indulge in his usual diet, and to use, even moderately, either wine or spirits, or any fermented liquor; he should be restricted to milk and farinaceous matters.

These remarks are applicable to the remaining mercurial preparations, the iodides and cyanides, which are gradually coming into general use; the iodides in particular, as they are equal in stimulant power to the most active of the old preparations, and possess, besides, other advantages. From the influence of the iodine which they contain, they are likely to supersede the perchloride as an internal remedy. [See EUTROPHIC.]

The only other material stimulants which require to be noticed are **ammonia** and its **carbonates.** In the state in which the former is medicinally employed, it excites powerfully the living solid, inflaming and causing vesication or suppuration, according to the nature of the surface or tissue to which it is applied. When very largely diluted, and taken into the stomach, its primary stimulant impression is made on the nerves of that organ, and the impulse is rapidly propagated over the system; but its effects are transitory; thence it is, like ether, regarded as a diffusible stimulus. It is indicated in those diseases and stages of the habit in which there is an evident deficiency of nervous power, and where it is important to rouse the nervous energy without affecting, in an equal ratio, the sanguiferous system. In prescribing it, the only object to be kept in view is not to administer it in doses sufficient to exhaust the excitability. The carbonates operate in a similar manner, but with less energy. The dose of the liquor ammoniæ is from ten minims to half a drachm; that of the subcarbonate from five to fifteen grains; both should be involved in some bland mucilaginous emulsion. The ammonia possesses one advantage over the carbonates—it may be prescribed in conjunction with muriate of lime and the salts of baryta, which are precipitated by the carbonates.*

Some consideration is due to **mental stimulants,** which are too much overlooked by the physician. The effects of all the exciting passions closely resemble those that follow the impression of a powerful material stimulant; the action of the heart and arteries is suddenly augmented; the animal temperature is elevated; per-

* Nothing is more likely to prove injurious than applying a bottle of liquor ammoniæ to the nostrils of persons who are in a state of syncope. The life of a medical man was nearly sacrificed to a rash act of this kind.

spiration flows freely, demonstrating the direct influence on the capillaries; the face glows, the eyes sparkle, and the respiration becomes quicker and fuller. The mental functions of the brain are not less excited than those of the body: the imagination takes a more excursive range; the pleasurable scenes of former life are again presented to the memory; the future teems with gay and delightful anticipations; every task seems easy, every labour light; whilst the most difficult and momentous schemes appear already accomplished, and crowned with the most brilliant success. But, besides these effects, the excitement of some passions, especially *joy*, quickens the corporeal sensibility; every object makes a stronger impression on the organs of sense; the eye sees more distinctly, the ear is more acutely alive to sounds, the taste and the touch are delicately sensitive, and every bodily movement is more prompt and energetic. It is unnecessary here to enter into any metaphysical conjectures respecting this influence of the intellectual essence, connected with our existence, on the material part of our frame; the effects of its excitant power are sufficient to enable us to trace its importance as a therapeutical agent.

The condition of the habit in which the exciting passions, particularly joy, may be employed as a remedy, is that which is characterized by languor and debility, in such diseases as melancholia, hypochondriasis, dyspepsia, and chlorosis; and many cases might be detailed to display their beneficial influence on those afflicted with these diseases. (Lory de Melancholia, tom. i. p. 57.—Trellianus, lib. ix. p. 17.) The application, however, of such agents requires the utmost judgment and discrimination: a sudden impulse of joy has made so powerful an impression on the nervous and irritable frame of delicate persons, as to produce epilepsy, and even death. The influence of mental excitants in such cases, like the stroke of a flash of lightning, whilst it illuminates, destroys its victim. (Haller's Physiology, vol. v. p. 501.)

The knowledge of this stimulant influence of mind on body is also important in pointing out, to the student and the inexperienced practitioner, the necessity of guarding those weakened by disease from indulging in impetuosity of feeling, whether during the progress of the malady, or in convalescence. The fatal consequence of such a state of excited feeling was once witnessed by the writer of this article. A gentleman in the advanced stage of phthisis was visited by an old friend, whom he had not seen for many years; the conversation turned upon an event in which the poor invalid felt deeply interested; in relating it he became greatly excited, rose from his seat, and displayed an unusual impetuosity of manner; but he had scarcely concluded the narrative ere he sank into his chair and instantly expired. It is easy to conceive that in such a state of excitement the effects would be felt chiefly upon the thoracic viscera; for, even in a state of health, impetuosity causes an unusual glow of warmth in the præcordia, the pulse beats quickly, and a peculiar sensation is experienced, which is referred, and not without reason, to the heart.

Such is the nature of those stimulants which are so manageable as to be fitted for therapeutical purposes; their importance as remedies is undoubted; but the very nature of the substances belonging to this class renders them more liable to be abused than those in any of the other classes; we shall conclude this article, therefore, with a few remarks upon the cautions requisite to be kept in view during their administration.

It is scarcely necessary to caution against the general employment of stimulants in febrile affections marked by a quick and full pulse, with much heat of body: in truth, it is only in the latter stage of fevers, when the diminished action of the heart is manifested by a fluttering pulse and a cold clamminess on the skin, that stimulants are advisable: they rouse again, not only the nervous energy, but also that action of the capillary system without which the powers of life cannot be sustained. Great discrimination, also, is requisite in determining the exact period when they are demanded, even in this stage of fever; and there is, perhaps, less risk in permitting the prostration of strength to proceed for a short time, than to hazard their administration on the first indications of the approach of collapse: even when the circumstances which demand the employment of wine in typhus are fully developed, much caution is requisite. When the debility seems to yield to the free administration of wine, the observing physician will often find sufficient reasons for suspecting that the temporary vigour that it apparently bestows is succeeded by a greater degree of debility, and, consequently, that the utmost danger may result from persevering in the use of stimulants. When petechiæ appear, or when there is protracted diarrhœa followed by sudden collapse, wine and other stimulants are not only admissible, but are remedies upon which we must rely for the safety of the patient; and this is also true when the tongue is coated with a brown fur, the teeth and gums are covered with sordes, the skin is hot and dry, and when subsultus tendinum and low delirium are present, with a rapid, small, compressible pulse.

Stimulants have been found beneficial in those affections of the chest which are accompanied with spasm, as, for example, the latter stage of hooping-cough. In bronchitis and similar affections, although, during the continuance of the inflammatory action, when the cough is dry and the expectoration difficult, stimulants would be productive of the greatest mischief, yet in the advanced stages, particularly in peripneumony, their administration is demanded, not only to aid expectoration, but to excite the capillaries so as to relieve the engorged state of the pulmonary tissues. On the same principles, also, camphor and sulphuric ether prove successful in relieving the urgent symptoms in some varieties of dyspnœa, whilst they are as injurious in others. It is in those cases in which effusions into the air-tubes take place, consisting of either a redundancy of the natural secretion, or frothy mucus the result of previous inflammation, that we may most confidently anticipate advantage from the administration of stimulants. In softening of the muscular tissue of the heart, they prove serviceable in renewing the vigour of the ventricular action, and rendering the contractions more steady and regular. Stimulants, however, are not only contra-

indicated, but are directly injurious, wherever there is reason for suspecting hypertrophy of one or both ventricles of the heart. When the hypertrophy is confined to the left ventricle, their administration is followed by vertigo, dimness of sight, singing in the ears, weight in the head, and epistaxis; or, if this do not occur, by congestion of the encephalon and apoplexy.

In hysteria, epilepsy, chorea, catalepsy, tetanus, neuralgia, and, under some circumstances, in hypochondriacal and maniacal affections, stimulants are clearly indicated. In these cases, however, the state of the brain and the spinal marrow must be clearly ascertained; morbid dissections having demonstrated that many affections which are frequently regarded as altogether nervous, are connected with and dependent upon abscess, ulcerations, tumours, or depositions of blood in the substance of the brain, or collections of fluid in the ventricles; sometimes on a similar affection of the spinal cord or its tunics. Wherever these are suspected, there can be only one opinion respecting the impropriety of the administration of stimulants.

In many instances of paralysis, especially in that of the lower extremities, constituting paraplegia, experience has fully demonstrated the utility of strychnia and other stimulants; but, at the same time, circumstances may exist which contraindicate their employment, and nothing is more necessary than a sound judgment and a cautious diagnosis in such cases. The employment of external stimulants is less hazardous; but the result of their employment, not excepting electricity, has been disappointment.

From the state of the nervous centres closely resembling that which produces paralysis, the skin often loses its natural qualities, becomes pale or discoloured, soft and scaly, or covered with crusts. In this condition stimulants prove serviceable, by throwing the blood upon the surface and exciting generally the cutaneous capillaries. It is essential, however, to distinguish between this state and that in which inflammatory pustules and tubercles appear upon the skin, the disposition to which is undoubtedly increased by exciting medicines.

In many painful affections, in which it is necessary to exhaust the sensibility of nerves, the topical application of stimulants has been found beneficial; as, for example, toothach from caries, whitlow, and paronychia; the various species of erythema, and in some of those of herpes. In malignant sore throat, capsicum and some other stimulants form the bases of the most useful gargles.

Many stimulants are employed as condiments; some of them are our daily beverage; and the general predilection of all nations for diffusible stimulants, particularly wine and ardent spirits, is sufficient to demonstrate the caution requisite in their employment as remedial agents. It is of the utmost importance, also, that the student should clearly understand the distinction between stimulants and tonics, or those medicines which simply increase action and those which are capable of producing a permanent augmentation of power. It is true that the excitement which stimulants afford to the nervous system, in a debilitated state of the body, gives a temporary impulse to the power of the digestive organs and consequent increase of strength to every part of the frame; but this effect is merely temporary: and the continued employment of the stimulant, instead of maintaining this condition of the habit, is followed by the directly opposite state, that of exhaustion; indubitably proving that action is not strength. The combination, however, of stimulants and tonics aids greatly the power of the latter; the former calling forth, as it were, the tone which the latter renders permanent.

A. T. Thomson.

STOMACH, ORGANIC DISEASES OF.—The term organic disease, as it is used in this article, comprehends alone the morbid affections which involve *profound* alterations of structure in the stomach, as distinct from those pathological states in which structural changes are imperceptible, or are only slight and transitory. The important affections which fall under the latter description are treated of in this work in the several articles, Gastritis, Indigestion, &c.

In this acceptation the term organic disease has been employed for a long period, and is generally received at the present day. Its strict limitation, however, is not without ambiguity, on account of the great advancement which pathological anatomy has made in modern times, and in particular because the doctrines of some influential writers have asserted for it a position in medicine which it is not likely to retain. When we consider the comparatively short period within which it has become a branch of science, and the copious fruit it has yielded, it seems indeed only difficult to imagine the bounds of its application. Previous to the time when Bichat's researches gave a new direction to physiological study, the lesions of structure were not at all investigated. Descriptions of morbid appearances were occasionally recorded, but they refer almost exclusively to the surface of organs, and notice merely their alteration in volume, form, and colour. But the analysis of the tissues soon made it apparent that a rich mine of pathological discovery remained unworked in their morbid anatomy, and the attention of most of those who pursued medicine with scientific views was soon directed to this subject. To their labours is to be ascribed the unprecedented progress which medicine has made within the last half century, and the partial remodelling which has taken place in its principles and practice. The effects of disease have been investigated not only in the interior of organs, but in every variety of tissue which contributes to their formation; morbid products have been discovered and classified, and the minutest alterations have been observed, insomuch that it would seem that the researches of anatomy have approached the verge of what is cognizable by the senses, in tracing the organic changes caused by diseased action. But notwithstanding this, the fundamental dogma of the school of Bichat and Reil (viz. that vital actions are ultimately referable to the organization of matter) is warmly maintained, and applied to pathology by some who are desirous of basing the latter altogether upon anatomy. They assert that every morbid action is primarily caused by an organic change, and they consequently admit no definite distinction between diseases which exhibit lesions of structure, and those in which none can

be discovered, every disease having thus in their doctrine, the nature of an organic disease. (*Rostan*, Cours de Médecine Clinique, tom. ii. p. 6, et passim.) This appears to us to be an abuse of pathological anatomy. We shall not, however, discuss this matter further here, as our object in alluding to it is mainly to fix the value of the term, which, as we have said, has been somewhat embarrassed by being mixed up with those theoretical subtilties. But these have not attached any uncertainty to its meaning (particularly when applied to the stomach) in practical medicine, in which it unequivocally signifies the diseases of that organ which are obviously connected with structural lesions.

Organic diseases of the stomach may, for the sake of description, be conveniently divided into the diseases in which the parietes, or the separate tunics which enter into their composition, become altered in structure, and those in which the entire viscus suffers a pathological change. To the first class belong cancer or scirrhus of the stomach, ulceration, hypertrophy, and atrophy of the tunics, and softening. The second comprises the alterations in volume of the whole organ; viz., its enlargement and contraction. This division is as precise as the present state of the subject will admit of, and seems to be founded on natural distinctions. The lesions comprised in it possess different degrees of importance, and we now proceed to notice them separately, in the order in which they are enumerated. We shall treat of them in as practical a manner as possible, and shall observe brevity on many of the subjects, to avoid the repetition of matters which are amply discussed in this work, in articles specially devoted to them, viz. Atrophy, Hypertrophy, Scirrhus, Softening, Ulceration, &c.

I. **Cancer or Scirrhus of the Stomach.**—This formidable malady has for its essential character the growth of a morbid product, usually called scirrhus, upon some part of the parieties of the stomach, which, being once developed, advances until this viscus becomes disorganized, and in its course produces a slow succession of distressing symptoms, and eventually a fatal termination. Its history had been traced with considerable accuracy long before anatomy had given any light to pathology, and it seems to have been among the first internal organic diseases which attracted notice. Some have asserted, not unreasonably, that it was described by Hippocrates under the name of μελαινα; and although this, from want of anatomical evidence, cannot be proved with certainty, it will appear, on reference to the brief but graphic description which he has left us of the disease represented by this term, (De Morbis, lib. ii. sect. v. *Chardel*,) that it corresponds closely with that of cancer of the stomach. Galen also must have had this disease before him, when he observed that the growth of certain tumours in the stomach sometimes obstructed or even interrupted the passage of food, inasmuch as organic obstructions of this viscus are almost invariably of a cancerous nature. And, as before necroscopic inspection had revealed its nature, its formidable symptoms had given it a place in medical writings, so at the earliest period at which this was practised, we find an account of it. Antonio Benevieni, who is cited by Lobstein as the first author that was specially occupied with pathological anatomy, makes particular mention of scirrhus of the stomach. (De abditis nonnullis ac mirandis morborum et sanationum causis. Florent. 1507.) Afterwards Hildanus, Morgagni, Lieutaud, and Haller, noticed its external anatomical characters with reference chiefly to its obstruction of the alimentary canal. At the commencement of the last century the subject of scirrhus and cancer was much discussed in the schools. Then only the identity of this morbid structure as invading the stomach, with that which produces the long known cancer of external parts, became fully recognised, and from this period it formed an ordinary topic in every collection of medical observations. Some interesting facts are recorded in these, but the history and pathology of the disease were advanced but little by them, as the theory of medicine was still fettered by narrow speculations, and the only method which was employed to investigate cancer was to reduce it to the dogmas of the humoral pathology. At the beginning of the present century this had given place, and amongst the first benefits which accrued to medicine from the enlightened spirit of observation which succeeded, is to be reckoned the ascertaining of the physical properties of the anormal tissues, inclusive of scirrhus and cancer. This, the result of the researches of Bayle and Laennec, was the chief step in our knowledge of the pathology of cancer of the stomach, as it at present stands. It is also to be acknowledged that in this as well as all other diseases of this organ, the science is greatly indebted to the labours of Broussais. His writings and the agitation of his doctrines challenged for the stomach an importance in pathology which has directed to it the attention of the distinguished men whose labours constitute the richest materials of modern medicine.

History.—Cancer of the stomach is a disease very insidious in its commencement, and chronic in its course. Few cases come to a termination in a period shorter than six months from the time at which the organ first exhibits signs of being affected, but for the most part it entails upon the patient a protracted train of suffering not unfrequently of several years' duration. On comparing the numbers of males and females affected by it, the former greatly predominates. The stomach of the latter comparatively enjoys an immunity from cancer, which observation has been confirmed by the rare occurrence of the disease at the great hospital Salpêtrière at Paris, which is tenanted by old females. This difference as to the sexes seems to depend on the greater exposure of men to some of its causes, such as the habitual use of ardent spirits, and still more to the greater frequency in them of deep moral emotions of a gloomy character, which are observed to exert a peculiarly injurious influence upon the digestive organs. In the female these are less prevalent; besides, in this sex the genital system suffers those physical effects of moral emotion which in man bear upon the digestive system; and, in agreement with this, it is found that cancers of the mamma and the uterus fully compensate for the lesser number of cancers of the stomach in the female than the male sex. It is a disease of mature age, and seldom manifests

itself before thirty or after seventy. We believe there is no authenticated case on record in which it occurred before puberty, which observation, it may be remarked, is an additional indication of the influence which moral causes exert in its production. Some authors affirm that the temperaments have a different predisposing influence with respect to it, and that the lymphatic and sanguine are more liable to its invasion than the bilious and nervous. If this be on the whole founded in fact, the preponderance is not very great. As far as our own observation extends, individuals of dark hair and eyes possess a greater immunity neither from this disease nor from pulmonary tubercles (with respect to which the same difference in the temperaments has been asserted), than those whose complexion is of an opposite character.

In detailing the symptoms of cancer of the stomach, it is convenient to consider its progress as having separate periods or stages. Chardel (Monographie des Dégénerations Skirrheuses de l'Estomac, Paris, 1808) conceived this plan, and in his description marked three periods. Succeeding authors have observed it likewise, but as we think, with greater insight into the pathology of the disease, they have recognised but two. The latter division will be followed in this account of the symptoms which we shall give very succinctly, as we shall notice some of them separately in adverting to the diagnosis afterwards.

First period. — There is but little perceptible difference between the earliest features of this disease and those of common nervous dyspepsia. As in the latter, flatus, acid eructations, and weight at the epigastric region are commonly its first symptoms, accompanied, however, by a greater degree of general languor than that which attends on any form of dyspepsia. No uncommon attention may be paid to these, until considerable pain begins to be felt in the region of the stomach, especially after meals, and pressure in the epigastrium detects soreness. On some occasions it has commenced by a sensation quite the reverse of pain, which consisted of an indescribable tickling of an agreeable nature, occurring when the stomach is empty. But sooner or later pain at length arrives; at first it is confined to its own seat, and disturbs the patient only at intervals, but in a little time it becomes very oppressive, and shoots from the stomach into the back and loins down the thighs. The animal spirits sink more or less, and often the individual is known to express his consciousness that he is the victim of some profound disease. Nausea sets in, and the food is rejected, mixed with quantities of ropy mucus, by which the pain and oppression are relieved, so that in the beginning the patient rather desires vomiting, and sometimes uses artificial means to provoke it. When the process of digestion is past, much mitigation of all the symptoms ensues, during which a comparative calm and even cheerfulness prevails in the mind of the patient. He learns to pay the greatest attention to his diet, from the peculiar distress experienced after eating any substance which causes flatulency. On this account he avoids feculent vegetables, highly seasoned puddings and other dishes, and prefers small quantities of solid meat. Yet the appetite is sometimes but little impaired, but it cannot be indulged to satisfaction from the aggravation of the symptoms which full meals induce. Feverish excitement rarely occurs at this period, neither is any remarkable thirst present, but occasionally spirituous drinks are taken with avidity for the purpose of helping the torpid digestion, and by this means mitigating the pains, which are more severe when this process is slowly and laboriously performed. A sensation of dryness and of constriction in the throat (more permanent than what is called globus hystericus) is not uncommonly an additional source of distress and alarm. The bowels are habitually costive, and the use of laxatives becomes indispensable. These are followed by temporary relief, for the same reason as the vomiting, viz., by the evacuation of the fæcal and gaseous accumulations which oppress the stomach by their distention. While the disturbance of the digestive organs is manifested in this manner, the tongue varies little from its natural appearance; it rarely presents any saburral coating or redness, as in inflammatory affections of the digestive tube. Occasionally it is chopped, and lies flat and flabby in the mouth, and sometimes an excessive development has been observed in the fungiform papillæ which are situated at its base.

So far the absence of some of these symptoms may cause variety in this account of the disease. But an observation of still more practical importance is presented in the fact, that in this first period the whole suite of phenomena has been known, under the influence of some cause, evident or undiscovered, rapidly to vanish, and continue suspended for a term of several weeks or months. This inconstancy may appear incompatible with the nature of an organic disease, and thus lead the patient, and even the physician, to form prognostics more favourable than are destined to be realized. The occurrence of this respite is the more usual event, but whether it takes place, or that the symptoms proceed without remission, a time arrives, the term of which it is impossible to assign, at which the malady takes firm possession; and its phenomena, although they may be still ambiguous as diagnostics, are no longer inconstant in their progress. They all at this period take on an increased activity, and henceforth the patient is never left entirely without suffering. The unfavourable change is now and then connected with some imprudence of the patient, but for the most part it supervenes without any evident exciting cause. Its phenomena constitute the second stage.

Second period.—Before the confirmation of the symptoms which marks the commencement of this stage, the nutrition is seldom remarkably affected; but now a visible wasting sets in, and as the malady advances, increases to a frightful degree of emaciation. The pain and weight in the epigastrium in a certain degree become constant; they are aggravated, however, at a particular period after meals, and spontaneous pains of a lancinating character are added. It occasionally happens that the appetite still remains, yet the wretched patient fears to satisfy it, and even prefers to suffer hunger rather than the pain produced by the entrance of food, or by the rejection of it, which he knows will ensue; for the vomiting no longer affords relief as at the beginning, but now much increases the distress.

At length a tumour appears in the epigastric region, which may be detected by accurate touch a considerable period before its external progress produces a visible elevation of the abdominal parietes. Pressure on the tumour does not aggravate the pain immediately, but often it causes great distress to the patient to recline upon the side which is most remote from it. This is evidently owing to the stretching of the irritated viscera by the weight of the tumour, as may be inferred from observing that the patient usually lies upon that side on which the latter least depends.

To the foregoing causes of distress are added sleepless nights. Suffering now becomes habitual, and leaves its impress strongly marked upon the countenance by a peculiar contraction of the features—(the French call this painful expression "*face grippée*")—which is often rendered more ghastly by a dun discoloration of the skin. Nothing is more harassing than the vomiting, which is almost inevitably brought on by the smallest quantity of food. It has been observed that a remarkable anomaly sometimes occurs in the action of the stomach: amongst different articles introduced into it at the same time, it retains some and rejects others, exhibiting thus a kind of election as to the vomited matters. A stronger instance still of this is related, in that the food of the preceding day was vomited, whilst that latest swallowed was retained and digested. But besides the food, various other matters are thrown up from the stomach. Of these the most common are fluids, containing a dark substance like coffee-grounds, uncoagulated blood, a thick porraceous matter, or finally, a dark green serum.

The breath exhales a foul odour, which is disgusting to the patient himself. Towards the latter periods, aphthæ appear in the pharynx. Dropsical effusions occur in the peritoneum and general cellular tissue, which may conceal the extreme marasmus which would be otherwise visible. The constipated state of the bowels gives place to a diarrhœa, which hastens the close. When this symptom is present, a weak febrile action occurs; but independent of it, the disease runs its course without any exaltation of the pulse, loading of the tongue, or feverish heat. At the last, so much debility seizes upon all the functions, that the pains and vomiting cease, and death arrives without any struggle. In some cases it is preceded by delirium.

Pathology and Causes.—As the essential element of this disease lies in the organic lesions to which it gives rise, a description of these is the first consideration in its pathology. Their situation and extent are various. At one time the stomach is found lying in its natural position, unaltered in its size and external appearance; while in others these relations undergo the most important changes: its volume may be uncommonly enlarged, or it may be shrivelled up into a small compass. Instances are on record in which the parietes of the entire viscus were engaged in the cancerous development, but these are exceedingly rare. For the most part its seat is circumscribed, and it occupies in preference,—1st, the pylorus; 2d, the cardia; 3d, the body of the stomach.

1. When it is situated at the *pyloric extremity* of the stomach, this part is changed in a greater or less degree. On inspecting it from without inwards, the peritoneal coat is generally seen in its normal state of smoothness and transparency, and through it appears a dull white mass, forming a tumour of considerable magnitude. It extends from the pyloric orifice, where it is thickest, for some distance towards the body of the stomach, but it is seldom found to encroach upon the duodenum. The cellular tunics are so confounded in the foreign tissue which forms the tumour, that they cannot be distinguished in the midst of it; they form the original nidus of it, and are incorporated in its growth. The muscular tunic is also embedded in the mass, but is generally transformed into mere fibrous bands, or so atrophied as to be difficult of recognition. Cases, however, are recorded in which this coat has not only been spared, but found hypertrophied to a considerable degree. (*Laennec, Louis, Prus.*) The appearance of the mucous membrane varies according to many contingent circumstances; but the state of that part of it which bounds the cancerous tumour internally depends much upon the extent to which the latter is developed. If it has produced no lesion of continuity by its internal growth, the mucous membrane is generally united firmly to it as far as it extends, and in the most central part of the area occupied by the tumour a depression is often found, which has been compared to the round mark left by the blow of a hammer on a piece of lead. In many instances, however, the mucous membrane is found to have yielded by ulceration before the advance of the cancerous mass, which then presents itself at the internal surface of the stomach, with the appearances peculiar to itself.

The intimate structure of the cancerous deposit possesses considerable variety in this as in other situations of the body. Its incision by the scalpel most usually shows it to consist of a firm homogeneous substance of a white colour, resembling the section of a potato, from which this variety was called by Recamier *solanoïd*. In other instances fibres in a concentric arrangement are observed to pass through the mass, which the same pathologist, under these circumstances, would propose to call *napiform*, from its resemblance to the fibrous texture of a cut turnip. Not unfrequently the denser cartilaginous variety which has been more especially known under the name of scirrhous, is found to constitute the mass wholly or in part. Again, it is found in a softer condition, formed by a pulpy substance, having a lobular disposition, and traversed copiously by dark veins, by the rupture of some of which the softest portions of the mass are occasionally found infiltrated with blood. This is the description of cancerous formation to which Laennec gave the well-known name of encephaloid or cerebriform matter. In other cases a viscous jelly has been observed to form some part of the tumour, and this has been found situated in cells, occurring for the most part in the cartilaginous variety; whence it has been considered by some pathologists to be the latter in a state of diffluent softening. All these varieties occur in cancerous masses; and it is to be remarked that they may be combined in the same pyloric tumour, forming separate portions of it, or it may be mingled together so as to lose their distinct

character. They are all referable to some of the varieties of carcinoma, which Dr. Carswell has classed under the two species, which he has denominated *cephaloma* and *scirrhoma* in the Article Scirrhus. We refer to this for the anatomical and physiological history of these heterologous tissues.

2. *The cardia* is the situation in which, next in frequency to the pylorus, the disease occurs. The structural changes differ from those of the pylorus only with respect to their conformation and their relation to the neighbouring viscera. The cancerous mass is seldom voluminous in this situation, but the disorganization extends generally for some space along the lesser curvature and into the œsophagus. Instead of the loose tumour which the pyloric extremity presents when it is the seat of the disease, rarely any morbid appearance is to be seen until by opening the stomach it can be inspected from within. It is then perceived that a greater or less narrowing has taken place in the cardiac orifice by the deposit of the foreign substance. The latter is disposed in various ways; at one time it forms an annular circumscribed stricture, occupying precisely the orifice; at another it projects internally, having burst through the mucous membrane, and presents a cauliflower fungus. Such a vegetation has been known to hang loosely from the edge of the orifice into the stomach, like a valve, so as to prevent the rejection of its contents by the act of vomiting.

3. *The body of the stomach* is, in comparison with the other situations, rarely the primitive seat of cancer. It is, however, by no means uncommon for the affections of the cardiac and pyloric orifices to spread for some space, and involve the adjoining portions of the organ; especially the lesser curvature, which is sometimes found disorganized through its whole extent. In this case the gastro-hepatic epiploon with the lymphatic glands and the vessels contained in it often partake in the disease; as, in like manner, if the greater curvature be much engaged, the greater omentum may be found in a state of scirrhous degeneration.

Independently, however, of disease of either the cardia or pylorus, the cancerous structures in the various conditions above recounted are occasionally observed in the body of the stomach. It is here more especially that a variety which is properly called primitive cancerous ulcer (to distinguish it from those ulcerations which occur in previously existing cancerous deposits) is found. This form of disease commences and runs its course without any antecedent deposit of cancerous structure which can be discerned; yet, as it spreads, its edges are distinguished by a scirrhous hardness, and upon its surface grow fungus vegetations which partake of this character. There is, moreover, another form which is in a measure peculiar to the body of the stomach, being rarely met with at the pylorus or cardia. We allude to a hard circumscribed condition of the parietes, caused by what is called *atrophic* cancerous degeneration. The area which this occupies appears contracted, and the mucous membrane involved is condensed and puckered into hard ridges or star-like streaks. The scirrhous substance does not undergo softening as the other varieties; the alteration which time induces is rather to contract it, and give to its texture a more gritty hardness. It seems to be a laminar deposit of the cartilaginous structure, properly called scirrhus, and it is said to be accompanied with lancinating pains of a more intense description than any other variety of morbid product.

The lesions thus detailed are those which are immediately connected with the pathology of cancer of the stomach: we have now to advert to some variations of these which are of minor interest in this regard, but yet are worthy of attention as connected with some striking phenomena which occasionally complicate the disease towards its termination.

The usual course which the cancerous mass takes in its progressive development, as above remarked, is towards the interior of the stomach. Exceptions to this rule sometimes occur, in which a contrary direction is chosen, and then this morbid product exhibits its well-known characteristic of propagating itself from one surface to another, which is unconnected with it, either by continuity of tissue or analogy of organization. From this it results that other organs are involved in the morbid appearances by a process which is sufficiently evident from an examination of the lesion. In its outward progress adhesions are contracted between the peritoneal coat of the stomach and that of the adjacent organ, and the cancerous matter is deposited in the latter, while its proper tissue is absorbed, apparently by its advancing pressure. This is most frequently observed in the liver, the middle lobe of which is often found firmly united to the pyloric end of the stomach by a cancerous mass, which had originally spread from the latter. A similar propagation of it takes place to the other neighbouring organs, the spleen, pancreas, colon, &c.

Many of the morbid phenomena depend upon the degree in which softening has proceeded in the cancerous formation. This process is for the most part slow in its arrival, and partial. Instances, however, are known in which it pervaded the entire thickness of the mass, and induced rapidly fatal peritonitis by its perforation. (See Perforation.) But this is rendered a rare occurrence by the adhesive union, which is usually established between the stomach and adjacent viscera before perforation can ensue. The same provision, however, which prevents this accident, gives occasion for the softening cancerous mass to pursue its course into the adherent organ: in this way the liver has been found deeply corroded, and forming a cavity continuous with the stomach, the parietes of which were in this place destroyed, and their edges adherent to the liver. In an instance which is on record, a cancerous mass above the cardia propagated itself into the right lung, and excavated it into a profound cavern, in which food was found lodged. Still more striking consequences are exhibited in some rare cases in which the softening cancer proceeds to a perforation, while the stomach is united by adhesion to the anterior wall of the abdomen, or to some of the intestines. In the former instance an external fistula is formed, and the food having free egress escapes in the abdomen. In the latter, the contents of the stomach and of the intestine pass reciprocally into each other by the perforation: on

the one hand, fæcal vomiting occurs as a consequence; and vice versâ, the aliment passes from the stomach through the opening, directly into the intestine, and is voided without having undergone the action of its natural passage.

These are the organic lesions directly connected with this disease which post-mortem examination discovers. Besides these, it is to be remarked that other organs are found simultaneously with the stomach to be the original seat of cancerous deposits, of which the most frequent are the liver and pancreas. Finally, we must not omit to observe that the morbid appearances of several other diseases, which are known occasionally to complicate its course and termination, are revealed by dissection. Amongst these may be enumerated inflammation of the lower portion of the small intestines, peritonitis, bronchitis, tubercular disease of the lungs, and of other organs.

In pursuing the pathology of the disease, it will be useful to subjoin to this account of the anatomical lesions some remarks with reference to the influence of these in the production of the symptoms as above detailed, and to notice here some variations in the latter, which are more or less explicable by the former. The connection between some of the phenomena and the organic lesions is direct and obvious, in others obscure. In adverting to some instances in which it may be recognised, we shall consider in what manner the stomach is affected by the morbid product as to its functional and physical relations, and then notice that constitutional depravation which it gives rise to, called cancerous cachexy.

a. Doubtless the organic lesion produces a prejudicial effect upon the functions of digestion and general nutrition, and must in this manner contribute materially to the cachectic emaciation. This would be anticipated, on considering the malignant character of the disease, and the primary position which the stomach holds in the digestive apparatus: and it seems proved by the fact that the emaciation is a more prominent feature of cancer when seated in the stomach or intestines, than in any other organ of the body. Some cases, however, are occasionally met with, which show that its influences in this respect are not so great, or at least so general, as would be suggested by these considerations; for such must be the inference drawn from cases on record, in which little diminution of the appetite and no emaciation took place, while the stomach was profoundly disorganized by cancerous deposit. In these instances the disease was situated at the pylorus and the lesser curvature, leaving the larger end of the stomach untouched. (See *Chardel*, p. 39; and *Abercrombie*, Diseases of the Stomach and Intestinal Canal, p. 61.) This is an interesting remark, inasmuch as the latter is the part of the stomach in which the functions of chymification and absorption are mainly performed; and it permits the conclusion, that unless cancer either invades these parts, or becomes a focus of irritation for the entire organ, these functions remain comparatively uninjured. *b.* In its physical relations the chief pathological considerations are the mechanical obstacles which the cancerous products afford to the passage of the aliment. These exist when the disease is situated at either of the orifices, and they become the source of some of the phenomena which are most pathognomonic of the malady. When they occur at the cardia, the food being hindered in its entrance into the stomach, is rejected shortly after deglutition. But if the pylorus be the seat of the obstruction, the alimentary mass is retained in the stomach for a period of two or three hours during the process of chymification; at the end of this, in its progress towards the intestine, it meets the pyloric obstruction, and then vomiting is set up. The amount of obstruction which is presented varies from the smallest contraction of the dimensions of the orifice to a total occlusion. It appears self-evident as a general rule, that the constancy of vomiting is in proportion to the obstruction; but exceptions to this occur of such a nature as make it manifest that the mechanical obstacle is but a part of the conditions on which this symptom depends. The most obstinate vomiting has been observed in cases where a pyloric tumour was so situated as to produce little or no contraction of this orifice: and, on the other hand, its calibre has been found greatly diminished in instances in which vomiting rarely happened during the course of the disease. These different facts demonstrate that other conditions conspire with the mechanical obstruction, and modify its effect in producing vomiting; the most obvious of which is a state of congestive irritation in the organ. Cardiac obstruction gives rise rather to a regurgitation of the food than the proper act of vomiting; but notwithstanding this, it is the cause of deeper distress than that of the pylorus, as, on account of the food not reaching the stomach, the pangs of hunger may be added to the other sufferings of the disease, and the slow progress of the latter may be anticipated by a deplorable death from inanition. *c.* Its propagation to other organs, and the pathological complications which their affections furnish, constitute another class of phenomena entering into this malady. To this may be referred the jaundice, which is not an uncommon occurrence, particularly in the advanced periods of the disease: it owes its origin for the most part to direct disease of the liver, but it may be also produced by the pressure of a cancerous tumour of the stomach upon the bile-duct. The anasarcous infiltrations have been simply referred to the debility of the last periods of the disease, which undoubtedly contributes in many cases to their production; but they have been observed in others where the strength was as yet little broken, and the vigour of the circulation undiminished. On this account we must look to other sources in order to give a sufficient explanation of them; and these are presented to us in the obstructions of the venous circulation, which are caused alike by morbid states of the liver, and by the direct pressure of a pyloric tumour upon the trunks of the venæ portæ and cavæ. These vessels themselves may also be the seat of cancerous deposits, as in the remarkable case detailed by Reynaud, in which obliteration of the right branch of the vena porta and the inferior vena cava was produced by a foreign substance (apparently encephaloïd) deposited within their cavity. (Journal Hebdomadaire, 31 Oct. 1829.) *d.* Cancerous *cachexy* is the term which designates the special alteration

of the whole system sooner or later consequent upon the disease in whatsoever part of the body it is situated. It comprises all the effects of the morbific influence which it exerts on the general constitution, distinct from its local ravages, or the sympathetic derangement which these give rise to in other organs. When fully developed, it is characterized by a peculiar livid colour of the skin and the mucous membranes, emaciation, friability of the solids, and diminution of density in the liquids, but more particularly of the blood. To the change which it produces in this fluid is to be ascribed the facility with which hemorrhage occurs in advanced cancerous deposits, and the liquid uncoagulable character of that which is occasionally vomited during the latter stage of cancer of the stomach. It is to be observed that the full manifestation of the constitutional cachexy is less frequently met with in cancer of the stomach than elsewhere; because, as it would seem, the lesions of this organ are more injurious to the vital economy, and so anticipate the time in which the general system becomes fully subjected to the malignant influence of the cancerous disease. Finally, we would remark that this constitutional condition receives additional interest, if we may contemplate it as having any connection with the facts mentioned by Dr. Carswell relative to the presence of carcinomatous substance in the blood. (See Scirrhus.)

The essential nature and the origin of cancer of the stomach are points to which all other matters in pathology are secondary. As the elementary morbid product of which it consists is identical in this and in other organs, the question of its origin here involves that of cancer in general. Many doctrines have been from time to time promulgated on this mysterious subject, but have successively fallen into merited neglect, being founded on crude and insufficient observation. In the present day it is studied in a manner which promises more fruit; but it must be confessed that modern researches, while they have exposed false views, have done little more: the origin of cancer still lies covered by the veil which keeps from our penetration the secret operations of nutrition and special secretion. The reader is referred to the article Scirrhus for an account of the subject, which is carried as far as the actual state of knowledge permits. We only desire to express here our full accordance with the author in renouncing two modern theories on the subject; one of which assumes it to be a degeneration of a pre-existing tissue, and the other (chiefly supported by Andral), which maintains, that in its essence it differs nothing from hypertrophy and induration of the submucous cellular tissue.

It is a generally admitted fact, irrespective of any theory concerning its essential nature and origin, that the deposit of cancer in the parietes of the stomach is preceded by an irritation in this organ. Much diversity of opinion exists concerning the nature of this irritation, and it is well known to be the doctrine of Broussais that it is of an inflammatory nature; he has in fact maintained that cancer is a direct product of inflammation. It is a question of very difficult solution to decide in what manner this irritation differs from inflammation; but that it does so is not doubted by any pathologists who confine the latter term to its ordinary signification. Without offering any opinion on this subject, we merely notice it in this place for the purpose of adverting to a practical point connected with it, which is deserving of notice; namely, whether the irritation which precedes it (whatever be its kind or degree) originates in the mucous membrane, or has its primary seat in the subjacent cellular tissue, where the foreign substance is found deposited. To determine this directly, the stomach should be inspected in its first stage, while it yet retains the earliest appearances of the disease. But opportunities of post-mortem examination are rarely presented until a long continuance of the disease has produced great alteration, so that immediate proof is wanting of the relative condition of the tunics at its commencement. The mucous membrane has, however, been found in its physiological state at a time when the subjacent texture was filled with the cancerous product. Recamier has observed the latter developed to several lines, or even an inch in thickness, while both the mucous and peritoneal coats were in a healthy state and glided without any adhesion over the engorgement. (Recherches sur le Traitement du Cancer, t. ii. p. 44. Paris, 1829.) This proves, according to him, that the latter was not of an inflammatory nature in these cases; and he infers, à fortiori, that as the tunics were not in a pathological state at an advanced period of the subjacent deposit, they had not been so at an earlier. M. Andral has examined this question with his usual sagacity, and has fully shown that such negative facts are not to be received in evidence. In adducing his arguments we should state, that although we have not adopted the opinion with which this eminent pathologist has connected them, (namely, that scirrhus and cancer is a mode of induration of the cellular tissue,) yet, as we recognise the fact that such a condition is frequently a *nidus* for its deposit, and moreover agree with him that it is preceded by irritation, they are equally applicable to the notion we entertain as to its origin. He first illustrates the fact, that in irritations of the intestinal, bronchial, urethral, and conjunctival mucous membranes, and of the skin, the subjacent cellular tissue is frequently involved. He then passes in review some instances in which these mucous surfaces became free of the inflammation, while the subjacent tissue still remained the seat of organic changes which had occurred during its subsistence. Of this a familiar example presents itself to us in stricture of the urethra; this is a circumscribed hypertrophy of the submucous cellular tissue, which for the most part supervenes at a period when the inflammation of the lining membrane of this canal is receding. Finally, M. Andral deduces arguments of a still closer analogical application from observation of certain conditions of the gastric mucous membrane itself: he has been able to follow the different degrees by which it returns to a healthy aspect after inflammation, and he has observed in many instances that the submucous tissue still remained morbidly affected. His observations and reasoning appear to us satisfactory as to the general principle: while, therefore, we draw a broad line of distinction between scirrhus and hypertrophied cellular

tissue, which he identifies, we are enabled to enter fully into his conclusion, viz. that cancer may arise in the submucous cellular tissue of the stomach, subsequent to irritation originally seated in the mucous membrane. We add, that Chardel arrived at a similar conclusion from the study of the anatomical lesions, (Op. cit. avant propos. p. 11); and his opinion is so much the more entitled to regard, as it was expressed before it became a subject of doctrinal emulation in the schools.

We shall, lastly, advert to that branch of the etiology of the disease which includes its *occasional* causes. The concurrence of all observers places as the foremost amongst these, the operation of depressing moral emotions; and it may be indeed stated, that the influence of the mind upon the animal economy is not so prominently displayed by any other chronic malady. Corroding cares, caused by reverses of worldly circumstances and disappointment, concealed grief, and protracted terror, are the conditions of mind which are more particularly connected with its origin: so commonly does it partake of their influence, that few cases occur in which some of them could not be discovered, were it always possible to fathom the moral history of its subjects. With reference to this, it is worthy of remark that during and subsequent to the French revolution the disease was common in France, and it seems probable that many of the numerous cases, which Chardel's monograph contains, were caused by "the reign of terror." This was the malady of Napoleon: when he arrived at St. Helena he was in the possession of perfect health, and it was two years afterwards that the first indications appeared of this disease, which slowly consumed his life in a period of three years and a half. We allude to his case as an example of these conditions acting probably at a maximum; yet we have seen the same causes produce similar effects in individuals who occupied the other end of the scale of moral power. The mode of action of this class of causes it is very difficult to explain, and according to the present strict method of investigating medical doctrines, it seems rather to be drawing more than is warranted by the actual data, to offer any decisive opinion with respect to it. It cannot, however, be reasonably doubted that their direct action is on the nervous system, and we feel much inclined to assent to the opinion which Lobstein has ventured to put forth concerning their remote effect. He affirms that moral emotions give rise, first to a defective innervation; secondarily, to a perverted nutrition, in which consists the elementary change which produces organic products of an anomalous nature. (Anat. Pathol. tome i. p. 557.)

There are various phenomena connected with the healthy action of the economy, *the cessation* of which may become occasional causes. Some of those are of a physiological nature, as the menses; others are pathological, but are so habitual or periodic that they become, as it were, grafted on the constitution; to these belong hæmorrhoids, sweats in different parts, as the feet and axillæ, headachs, periodic gout, &c. The suppression of these has been known to originate cancer in the stomach as well as in other parts of the body, and with these may be classed the existence of a syphilitic taint in the system, under the influence of which, if not this, a disease in almost all respects similar has been known to arise. It has also been clearly traced, in some instances, springing up as a consequence of hereditary predisposition.

Other causes are to be enumerated of a more definite and local character; amongst which is to be first mentioned the long-continued use of ardent spirits. It is incontrovertibly established by a collection of many facts that this disease is frequently brought on in those who become addicted to the inordinate use of spirituous liquors; it is not, however, so clear that the entire effect of these is owing to their local action as a stimulant to the stomach, which some are ready to maintain. Several considerations with respect to individuals of this class seem to oppose this, and we are disposed to think that this cause acts, in part at least, upon the nutritive function in a manner analogous to the first set of causes, either by a prejudicial effect upon the nervous system or directly upon the blood. But whether its action be general, or merely local, or that it partake of both, it is certain that this effect of habitual drinking is much promoted by the depressing passions. These act in the relation of a predisposing cause to determine this effect from the former; and unhappily amongst the poor, the influence of both is too frequently found in concert, from the prevalence of ignorance, and of the desperate delusion which tempts the wretch blindly to have recourse for solace to the ruinous habit of drinking.

Continued pressure on the epigastrium, or mechanical injury of this part by any means, are also to be reckoned amongst the causes of this disease. Chardel relates two cases, which exemplify the effect of such causes: the one of a hatter, whose particular province obliged him to press the abdomen against a board; a cancerous tumour formed in this man's stomach, which ultimately broke through the abdominal parietes by the formation of a gangrenous slough at the epigastrium: the other case was that of a coachman, in whom the disease occurred consequent upon the kick of a horse received at the lower part of the chest. (Op. citat.) Haller has recorded one of similar import in the instance of a young man, who in a drinking revel received a kick in the belly from his drunken companion, and afterwards became affected with a lingering and ultimately fatal illness, which was proved on dissection to be caused by an extensive cancerous disorganization of the stomach and omentum. (Opuscula Patholog. Lausan. 1755, p. 49.) These cases are illustrative of the effect of mechanical injuries of the epigastrium in giving rise to cancer of the stomach, a result, besides, which ample evidence has established. While, therefore, it is fully acknowledged as an occasional cause, the explanation of its action is not so easy as may at first appear, inasmuch as, for several reasons, it seems evident that its influence is not to be directly referred to its immediate irritation of the parietes of the stomach. First, because, as Chardel observes, the cancerous product resulting is not found to occupy the part of the stomach which receives the direct mechanical impression, namely, the anterior wall which lies against the epigastrium, but manifests the same election as to situation (the pyloric or cardiac ex-

tremities) as when it arises from other causes. Moreover we remark that mechanical irritants acting, though with considerable force and permanency, *merely on the walls of the stomach*, do not produce cancer. Thus we find, in a case noted by Baillie, in which five halfpence were lodged in the stomach for some time, and had formed a pouch by their pressure, "the coats of the stomach were thinner at that part, but were not inflamed or ulcerated," (Morbid Anatomy, 1793, p. 92); and in another recorded in the Medical Commentaries, two pistol-bullets were lodged in the organ, previously the seat of cancer, for two months, apparently without any effect. (Vol. iv. p. 154.) A third, more curious than either, is the singular case narrated by Tonnelier, and witnessed by Laennec, of a girl, who, with the purpose of poisoning herself, swallowed an ounce of arsenic, but unexpectedly recovered. Again, a year afterwards she took poison, and this time died. On post-mortem examination, beside the effects of the recent poison, a cyst was discovered of the size of a goose-egg, which had been obviously just detached from the parietes of the stomach near the pylorus: on being opened, it was found to contain an ounce of arsenic. (Auscult. Médiate, vol. ii. p. 634.) These cases afford examples of the action of powerful mechanical and chemical irritants *immediately* upon the stomach; yet by none of them was displayed any disposition to the formation of cancer. The question then recurs undecided—in what manner do pressure and contusion in the epigastric region act, in occasioning cancer of the stomach? Chardel thinks that their injurious operation can only be accounted for by their mechanical disturbance of the process of digestion. It is an inquiry of much interest; and while we abstain from expressing a decided opinion, we beg to suggest it as an important consideration, how far it is to be referred to a lesion of innervation, caused by a *mechanical shock* on the solar plexus. If such an explanation should be accepted, it would place epigastric contusions and moral emotions in the same class of causes, and permit us to express their mode of action similarly.*

The abuse of certain therapeutic agents must not be omitted amongst the occasional causes of this disease. Those medicines are to be reckoned as such, which while they are exhibited for the sake of their specific effect, depress the animal system, and at the same time act locally on the organ. Preparations of mercury and arsenic are especially alluded to; and it must be confessed that the effects of the former in inducing that condition of the system which is favourable to the development of anomalous products, have not been hitherto sufficiently regarded; they begin, however, to excite general attention. The fear of this disease forms also one of the chief reasons for vigilance in using arsenical medicines in minute doses. Their exhibition should be strictly watched, that the constitution be not kept too long under the influence of this mineral; which, as would appear from the case cited by Laennec, has not the power of originating the disease by its local effects, unless the economy be previously deteriorated by its general influence. Finally, with respect to inflammation, (without reverting to the question as to whether it may be an occasional cause of cancer of the stomach,) it is of the utmost importance to be aware that it frequently accompanies its commencement, complicates its course, and hastens its termination.

Diagnosis.—Accuracy of diagnosis is the foundation of good practice in all diseases, but if it be required in the practitioner on one occasion more than another, it is when engaged about the diseases which are deemed incurable, because upon it so much depends. On the one hand, the mistaking of a disease beyond the resources of medicine for one in which these might be applied with success, subjects the patient to illusory hopes, and treatment that might have been spared, or that may even hasten the unlooked-for termination. On the other, the pronouncing a disease to be incurable, which in reality may not be so, is a still more grievous error; for this cuts off from the patient resources which had been available, were they not interdicted by ignorance of the nature of the disease; not to speak of the loss of reputation which accrues to the practitioner, if the course of nature or the application of another's skill discover his error, by restoring to health the patient whom he had doomed to the grave. These remarks are worth attention in connection with the disease before us, to which they are obviously applicable with reference to its incurable nature; but they are so equally with respect to its diagnosis, concerning which we should greatly miscalculate, were we to estimate its facility by merely regarding the profound organic changes and the prominent features of its history, as we have endeavoured to trace them. No general description could comprehend all the diversity which its symptoms may present; more particularly, however, we wish to direct attention to this fact, that its most striking phenomena may be simulated in the course of some diseases which have a totally different origin and issue. For the purpose of elucidating its diagnosis, we shall now compare it with the affections which present similar phenomena: this can be effected most conveniently by noticing these affections in connection with the symptoms of cancer of the stomach which constitute the resemblance between them. This method also affords us the opportunity of noticing some diversities of these symptoms, which were reserved for consideration in this place, as they are chiefly important with reference to the diagnosis.

a, Vomiting.—It may be in general stated, that

* The above was written before we met with M. Recamier's opinion on this subject, and we are gratified at finding that it is expressly similar to that which we have proposed. He brings forward several arguments of a positive as well as negative import, against the notion of cancer being developed in the stomach by the mere irritation of the viscus from local violence, and proving that the operation of the latter is to be referred to "*nervous commotion.*" He cites two facts which seem decisive. One person received a blow in the pit of the stomach, which was followed by violent pain and anxiety in this region, yet the individual stated that he had been scarcely touched by the blow. Another was only frightened by a gesture imitating a blow, which however was productive of the same anxiety and "malaise." In both individuals *an organic affection of the stomach was consecutively developed.* "Such examples at the same time manifest this," adds this experienced and judicious author, "that general commotions of the system exhibit their *local* power in proportion to the *local* predominance of nervous susceptibility."—Op. citat. tome ii. p. 45.

when vomiting occurs immediately after deglutition, the disease is situated at the cardia, and that when a period of two or three hours elapses, its seat is at the pyloric extremity. No relation which can be with certainty relied on, appears to exist between the intensity of this symptom and the extent of the cancerous deposit which causes the obstruction; for besides the latter, the state of general irritability of the organ influences it in a degree little inferior; and this is often observed to be greater at the first period of the disease than later, when much disorganization exists. Much diversity is to be remarked in the different stages of the disease with respect to the character of the vomited matters. In the beginning they consist of large quantities of ropy mucus, and of this mingled with the aliment in different stages of digestion. Afterwards they become mixed with secretions of dark-coloured fluid, in which a sediment forms like the grounds of coffee. These, with a muddy liquid of the colour of chocolate, and occasionally blood, are the fluids thrown up from the stomach, which are regarded as characteristic of the confirmed and later periods of the disease.

Nevertheless, it is to be remembered that this symptom may occur under every variety as a phenomenon of other diseases; so that neither its constancy or periodic recurrence, nor even the quality of the matters vomited, can with certainty assign it to cancer of the stomach. Added to this, other semblances of the disease may coexist with it, which tend to heighten probability to its highest pitch, and yet it may be unconnected with it. This is strikingly illustrated by two cases related by Louyer Villermay. One, a man aged forty, whilst a prey to profound grief, became affected with nausea, weight and shooting pain in the epigastrium; to these were added, while his strength declined daily, vomitings after every meal. After a month's treatment this man recovered. The other case was a youth aged twenty-one, who had many of the preceding symptoms, and in addition to these, the vomiting continued for nine months, and the matter rejected was of a blackish colour. The application of blisters and other remedies completely restored his health. Chronic gastritis, affections of the liver and gall-ducts, are some of the other various sources whence it arises. Certain forms of hysterical disease exist, also, in which a constant vomiting often prevails as the principal symptom for months; in one instance of this kind within our observation, it continued unappeasable night and day upwards of two years. An infinite variety of cases are also on record of nervous or spasmodic vomiting which for obstinacy might be compared with that caused by the most profound organic lesion. A most remarkable instance of this is related by Morgagni in the case of a lady of Padua, who was affected with this symptom from her birth. It came on two hours after dinner daily, and during pregnancy at the age of thirty-four it became much aggravated; and thence it continued unremitted until her death, which happened twenty-four years afterwards. No organic disease was found in the stomach, but it was small and contracted near the pylorus, so as to appear divided into two parts. Vomiting, with a long succession of symptoms which were mistaken for the effects of organic disease, were caused, in a singular case recorded in the Mémoires de l'Académie Royale de Chirurgie, (Tom. i. p. 702,) by hernia of the stomach between the recti muscles. The patient, a young surgeon, underwent the most severe sufferings, chiefly from the unconquerable obstinacy of the vomiting, and found no relief from a great diversity of treatment, until at length, hearing a description of this rare affection from Garengeo, he thought that he recognised the source of his own disease, whereupon he applied a proper truss, and from that hour was cured.

Finally, with regard to bloody vomiting, and especially the fluids resembling chocolate, if these coincide with other prominent features of the disease, it cannot but be considered a symptom of ominous import. Yet in proportion as it merits this character in its true connection, caution should be exercised not to assign it a false value in cases where it is not really indicative of this disease. The other conditions under which blood may be vomited are its metastasis from hæmorrhoids, retention of the menses, or any suppressed discharges. Falls and contusions not unfrequently give rise to hæmatemesis which continues long after all their other effects have subsided. It may be caused by hemorrhage from the posterior nares, which has been found to pour its blood into the stomach, and to be rejected from thence at intervals of a melænic appearance.*

b. Tumour.—On referring to the anatomical relations of the two orifices, it is scarcely necessary to remark, that when a tumour, externally perceptible, is developed by the disease, the pylorus is its probable seat. We say probable, because, although a rare case, a cancerous growth situated in the body of the stomach may attain to such a form and size as to be felt through the parietes of the abdomen; and it is conceivable that even a cardiac tumour might be detected by the touch, under the ensiform cartilage, in an individual with a short breast-bone. The characters belonging to a pyloric tumour are more or less distinctive. It is felt, for the most part, rather on the right of the median line, lying obliquely from right to left, with its most prominent part two inches below the lowest rib. It is movable by the hand, so as to allow of being pushed considerably out of the position it occupies; and it possesses, moreover, a spontaneous motion, which affords a diagnostic mark with respect to it of peculiar value; under the influence of this, it may be placed one day in a different situation from that of the preceding, and it sometimes even retires so deep, as to be no longer distinguishable by the touch, which circumstance has been known to create some embarrassment.

The presence of the tumour is the least equivocal sign of the disease; but yet the diagnosis can by no means be reposed upon it with an unreserved confidence; for, in the first place, extensive cancerous disorganization has been found at the pylorus as well as in other situations of the stomach, after death, which had previously escaped the most accurate investigation. Its thickness may be

* See this origin indicated, case by Manchart Misc. Acad. Nat. Cur. dec. iii. and iv. (*Archiv. Générales*, Oct. 1833;) also by Dr. Graves, Dub. Med. Journal, vol. i. p. 297.

too small, or take an internal development, or its situation may be entirely confined to the posterior part of the pylorus. Any of these conditions may prevent it from being recognised; moreover, other abdominal tumours frequently present themselves, from which it requires not a little discrimination to distinguish it. It is unnecessary here to do more than indicate that these may be constituted by any of the following, namely, tumours situated in the liver, the pancreas, the omentum, the mesentery, the colon, the abdominal parietes, and by aneurisms of the aorta. Two cases are before us which illustrate this double source of fallibility here referred to, that is, with regard to the presence and the nature of the tumour. The one was that of a man who died of pulmonary inflammation of five weeks' standing. He was under the observation of Dr. Graves for seventeen days preceding his death, and during that time no phenomenon was remarked, capable of exciting the suspicion of organic disease of the stomach. This organ, on dissection, externally presented the appearance of an hourglass contraction, but on opening into its cavity, a morbid growth of a medullary structure, equal in size to a large mushroom, was found projecting internally from the greater curvature, about midway between the two orifices. (Dublin Medical Journal, vol. ii. p. 175.) The other case, occurring under the same physician, in the Meath Hospital, was one in which a fistulous opening permitted the food to pass out from the stomach through the abdominal parietes; and no doubt was entertained but that this remarkable phenomenon depended upon the softening or ulceration of a cancerous mass, its ordinary source. On dissection, however, it was shown to be caused by the bursting of an encysted abscess of the peritoneum at once into the stomach and externally through the walls of the abdomen.

Cancerous growths of the cardiac orifice become also frequently objects of exploration; and as obstructions in this situation are in the majority of instances caused by tumours of this nature, their diagnosis is of fearful interest, both on account of their ominous character, and of the dysphagia resulting from them, which occasionally proceeds to such a degree as to occasion death from inanition. As the various abdominal tumours complicate the diagnosis of disease of the pylorus, in like manner cardiac cancer may be simulated by morbid products within the thorax of a very different origin. Innumerable instances are on record in which enlargements of the bronchial, œsophageal, and the other lymphatic glands of the mediastinum have caused dysphagia, and ultimately, as its consequence, death. (De Glandulis Thoracis Lymphaticis atque Thymo, Specimen Pathologicum. *F. W. Becker*. Berol. 1826, p. 56.) The same results may be derived from abscess situated behind the œsophagus, and from aneurism of the thoracic aorta. In these doubtful cases the principal method in use for exploring the state of the cardia is the introduction of the probang, but when this is called for, it is commonly as much for the purpose of endeavouring to overcome the obstruction as to establish its diagnosis. Under such circumstances, however, this means of examination requires to be employed with great caution, and this more especially with reference to the possibility of interfering with an aneurismal tumour. The utility of this admonition is testified by a case published by Mr. Porter, of a man, who, amongst other distressing symptoms, had nearly complete inability of passing any food into the stomach, and frequent vomiting; for these a probang was introduced, without meeting any decided obstacle, but without relief. Death suddenly occurred six days afterwards, and *post-mortem* examination disclosed a large aneurism of the aorta, which had burst into the œsophagus. (Dub. Med. Journal, vol. iv. p. 206.)

c. Emaciation, pain, &c.—Cachectic emaciation is common to this with many other chronic diseases; it is, however, to be noted, that as far as this symptom depends upon cancerous development it is unaccompanied by febrile action. This observation serves to distinguish it more especially from that which attends upon tubercular phthisis, as hectic fever is more or less prevalent from the time that emaciation sets in in the latter disease. But notwithstanding this, in individual cases of cancer of the stomach which are complicated by a catarrhal affection, so much resemblance may exist in many of their features to phthisis as to embarrass the diagnosis at the first examination; at the present day, however, in which the resources of auscultation and percussion are becoming fully recognised, this difficulty cannot exist long.

The pain belonging to this disease is peculiar, and a difference has been even remarked with respect to it as occurring at the two orifices. When the cancer is seated at the cardia, the pain is described as a tensive circumscribed sensation about the pit of the stomach, striking through to the back, and exciting a feeling of incipient suffocation, which is aggravated on taking food, and relieved by vomiting. (*Pemberton*, Practical Treatise on various Diseases of the Abdominal Viscera, fourth edit. 1820, p. 128.) The pyloric affection gives rise to pain less confined to one spot, but rather producing a dragging sensation (as the patient sometimes expresses it) over the upper part of the abdomen. But, besides these local peculiarities, the lancinating pains which are common to cancer in all situations must not be omitted, nor yet a characteristic circumstance which is still more properly diagnostic of this terrible disease, namely, that the pain does not immediately respond to pressure upon the morbid product, as does the pain of inflammation, but allows a sensible after-period to elapse, when it occurs, as it were, by a spontaneous reaction. It is here, however, important to observe, that on collating the history of several cases of *simple* ulceration of the stomach, with reference to this symptom, no difference sufficiently distinctive could be established between it and that of cancer.

The dark colouring of the skin is one of the most characteristic signs of the cancerous cachexy, yet it is so often absent in this disease that it cannot be depended on as a symptom of negative import.

Terminations.—When it once becomes established that the stomach is the seat of cancer, the only question which the prognosis admits regards the duration of the malady, for no other hope grounded on experience can be entertained but that it must inevitably terminate, sooner or later,

in death. We are aware that some, in contemplating the cicatrices of ulcers of the stomach, which have been found in a few rare cases, have been led to express a less rigorous conclusion; we cannot find, however, that this is countenanced by the healing in any instance of ulceration of the stomach which could be demonstrated to be connected with a cancerous deposit.

We have referred to the intermission which occasionally takes place in the early periods of the disease, and to the progressive manner in which its course proceeds, when these being passed away, its symptoms are all established; but with respect to the disease in general, it is not possible to assign any period of time as the term of its duration. This is obvious, when we reflect upon the diversities in the power of resistance to morbid action which the various constitutions exhibit, and the other contingent affections which modify this malady. To the slow exhaustion of the vital powers produced by the disease itself, the weakening effect of the constant vomiting is added, and not unfrequently the deficiency of actual nutrition. The fatal period is at one time brought on suddenly by the softening and breaking up of the cancerous mass, and the consequent hemorrhage; at another, it is hastened by the occurrence of perforation and communication with the peritoneum, which is, however, rare, from the protective causes before explained. Moreover, the affections above indicated, as complicating its latter stages, the diarrhœa, inflammations of the peritoneum, lungs, and the liver, are all influential in its termination. Finally, observation confirms that the disease of the pylorus lasts a considerably longer time than that of the cardia.

Treatment.—It is obvious that since this disease, when decidedly formed, is one which does not yield to the resources of medicine, the most practical considerations which it presents to the mind of the physician are those attempted to be illustrated in the foregoing part of this notice of it, which conduct to correct notions of its nature and its diagnosis. These, in the first place, suggest the responsible part which he performs towards the patient in pronouncing positively upon its existence; and, secondly, when it is recognised beyond doubt, they should dissuade from the employment of untried experiment in its treatment, which must necessarily fail, and not only disappoint hope, but tend to hasten the unavoidable period. This remark would much misrepresent our meaning, were it conceived that it contains any pretext for omitting the assiduous application of means: the first part of it is intended especially to convey a warning against a too hasty conclusion in any given instance that we have to do with an incurable disease; while the second is directed against an abuse of therapeutic agents, which might bring them into unmerited neglect were not the period in which they are unavailing plainly pointed out. In the confirmed disease, medicine, with its present resources, can only be applied with a palliative view. In the early period, however, while there is yet ground for hope that the malady has not become irreversibly fixed, or when some doubt exists in the diagnosis between it and other organic affections, the treatment should be directed with perseverance to combat it radically. But the line of demarcation must be very obvious before we give up the latter, hopelessly to resign the treatment to the former; and on this subject there may exist some danger of reposing too much reliance upon the minutiæ of diagnosis. The following remark of a modern writer expresses appropriately our meaning, coupled also with a statement which may not be altogether unwarranted. "Our predecessors, who were less acquainted than we with the fatal progress of organic lesions, succeeded perhaps oftener than we do in palliating the symptoms and prolonging the life of the patients, by applying themselves incessantly to oppose the most obvious symptoms. Their attention was not entirely preoccupied, like that of the anatomist-physicians of the present day, with the incurability of the local lesion which is the source of the disease." (*Gibert*, Revue Médicale, Juin, 1833, p. 375.

The first care which should engage the physician in entering upon its treatment, is to investigate its occasional cause, and, if this be possible, to have it set aside. Moral causes are at once the most frequent and the most difficult to remove; but until this be, in some part at least, accomplished, little success need be expected from any remedial measure; while, on the other hand, a decided improvement has been often observed to follow upon a change of circumstances which has alleviated mental depression. If the malady be observed to spring up simultaneously with the cessation of the menses, or of any other discharge or pathological condition which had become habitual, in case it be not possible to restore these, it would be a most advisable step to effect a substitute for them by the employment of some derivative plan, as issues, blisters, or local bleedings. Pains should be taken to examine into the probability of a syphilitic taint having got entrance by any means into the system: it is a fact of a most interesting nature, that some cases presenting the characters of an advanced stage of this disease have been known to yield to a mercurial treatment, which had been undertaken as a last resource, on discovering that the patient had been either mediately or personally exposed to venereal contamination. Hereditary predisposition should also be inquired into,* and idiosyncrasies dependent upon temperament, or other conditions; and if any source of this nature be detected, appropriate attempts to obviate its influence by a total change of circumstances should form a consideration in the treatment of primary importance.

The main principle to be observed is the abstraction of every condition which tends to cause or maintain a state of irritation in the stomach. It will be readily seen that, in pursuit of this, the regulation of the diet is to be chiefly relied on, and this, in fact, demands, from the earliest suspicion of the disease, the attention of the practitioner even more decidedly than medical agents. At this period he should impress the patient's mind with the necessity of submitting himself to a peculiar regimen, from which the latter ought not to suffer himself to be tempted on any occasion to depart. The object of this is to regulate

* See *Recamier*, op. cit. tome ii. p. 48, for some remarkable instances of the influence of this, and the attempts proper to counteract it.

in such a manner both the quantity and quality of the food, as that every thing of an exciting nature should be steadily renounced. It seems certain that this disease owes its chief progress to the physiological congestions which occur during digestion, in accordance with the law, that the functional action of an organ becomes a source of irritation to it when in a morbid state; all the symptoms are aggravated during the continuance of this process. This is the explanation of Chardel's remark — "La digestion finie, ordinairement *le calme renait*." Our aim should be to preserve a state of as great quiescence in the organ as is possible, consistently with affording sufficient nutriment to the system. With this view the patient should deny himself the use of solid meat; and, in cases where excessive irritability of the stomach prevails, animal food should be altogether dispensed with. However, as the object is to spare the organ, not to reduce the system, this is not in all cases advisable; and in individuals of a lymphatic constitution, in whom the more animalised materials of the blood are deficient, it is contra-indicated. Nutritious broths, made without spice or vegetables, answer well for such; they should be taken rather in small proportions, oftener repeated, than much at one time. All the varieties of boiled vegetables should be inflexibly refused. Where animal food in other forms is judged inexpedient, jelly may still be used, and this will be advantageously interchanged with the bland gelatinous substances, arrow-root, sago, tapioca, &c., which, being at once nutritious and unexciting, are valuable adjuncts to the patient's diet-list. With respect to the choice of these, experience must decide, as that which is adapted to the stomach of one does not agree with a second, and too frequently it will be impossible to find in any of them articles which fulfil our end. Few cases occur in which milk does not serve, and, when it agrees, it should constitute a large portion of the aliment. If, as sometimes happens, it sours upon the stomach, this may be obviated by the addition of lime-water, in the proportion of one-third. (Dict. de Sc. Méd. t. iii. p. 631.) Asses' milk has been endured on the stomach in cases where all other substances have been vomited. The patient must be inhibited the use of wine and spirits; it is sometimes, however, deemed necessary to allow some stimulant potion of this nature on account of painful digestion; and in such a case light table-beer should be preferred to alcoholic liquors, which, whatever impression they make for the time, invariably promote the progress of the malady. The meals should be taken at a fixed hour; irregularity in this matter increases irritability in the stomach; nor is it unworthy of being noted, that slowness in mastication has the effect of making substances, otherwise difficult, pass through the digestive process with much less irritation. We would remark, finally, that the beneficial effect of a rigorous regimen, in this first doubtful period, will mainly depend upon the constancy with which it is persevered in. We have seen a decided improvement which had followed upon its adoption speedily lost, because the patient permitted himself to indulge in a slight relaxation upon some incidental occasion. On the other hand, the example of the eminent anatomist Beclard affords much encouragement (if not in cancer, yet in simple ulceration) to a steady perseverance. Having become affected with an organic disease of the stomach, manifested by unequivocal symptoms, he determined on treating it by a rigorous diet, little short of abstinence, from which he did not suffer himself to swerve until, after a considerable period, the symptoms disappeared. He recovered perfectly, and afterwards his death took place from an acute disease of the brain, consequent upon erysipelas; post-mortem examination displayed the cicatrix of a large ulceration in the stomach.

The use of local bleeding by leeches is found beneficial when there exists evidence of more than ordinary gastric irritation, and for the relief of excessive weight and pain in the epigastric region. It may be sometimes preferable to apply them beside the spinal column, about the first lumbar vertebra, in which situation acute shooting pains often occur. General depletion can never be requisite in this disease, and care should be taken in the use of leeches that they be not applied in number sufficient to give rise to a very prejudicial debility. Small blisters on the epigastrium repeated at intervals, or kept open by an irritant ointment, may be in some cases attended with benefit, in others setons applied in this situation, or at the back, merit the trial more. Not unfrequently, however, the weakness and irritation consequent upon the derivative means will be found to interdict their use. The state of the bowels will demand the continued attention of the physician: they are seldom free from constipation, and the accumulation and distension of flatus, together with the weight of the alvine contents consequent upon this condition, give rise to considerable distress. Aperient medicines can seldom be endured by the stomach, and drastic purgatives of every kind, especially such as contain mercurial preparations, should never be exhibited. The daily use of emollient injections, on the whole, fulfils this indication better than the habitual use of any laxatives; but as those lose their efficacy in time, it will be expedient at occasional intervals to assist them by a purgative or turpentine injection. In certain cases, however, gentle laxatives, composed of senna, manna, rhubarb and magnesia, or castor oil, do not disagree with the stomach, and then their use may be conveniently alternated with the enemata. Emetics are to be deprecated as injurious in any stage of the disease. The antispasmodics, as castor oil, ether, valerian, ammonia, assafœtida, &c., which afford relief to the flatulence and pain in nervous dyspepsia, should never be exhibited for the same purpose here; their use, it is to be remembered, is invariably followed by irritation, which by no means compensates for their temporary effects of this kind; and besides the object is better fulfilled by the seasonable application of narcotics.

The administration of narcotics should not be left over to that latter period, when they are indeed indispensable, but when their alleviation of the worst symptoms is in proportion to their oppression of the sensibility of the brain. It will be very advantageous to procure their sedative action for the stomach from the first suspicion of organic disease, and they may be properly used at

the same time as the rigorous regimen and derivative treatment. Recamier's plan of exhibiting the extract of cicuta, while the patient observes a severe diet (Callisen's *cura famis*), seems to be more appropriate in this disease than in the scirrhous engorgements, where he employed this combined treatment with decided advantage. (Op. cit. tome i. p. 476.) (See Scirrhus.) Opium, the extracts of cicuta, hyoscyamus, aconite, belladonna, and stramonium, have been each lauded at different times; a variety of circumstances may incline the physician to the choice of one of them rather than another, but it seems that the general suffrage of modern practice remains only with the three first. The salts of morphia are preferred by several before any other narcotic, as producing the sedative effect with the least local and general excitation. The acetate may be given in the dose of a quarter, third, or half a grain. The solution of the muriate, in the proportion of five grains to an ounce of distilled water, is considered to be equal in strength to the common tincture of opium. In some instances where a tendency to acescence in the stomach exists, alkalies and absorbents may be advantageously given in combination with narcotics; for this end we have used the following formula:

℞ Extracti conii maculati
——— hyoscyami nigri ãã. gr. i.
Oxydi bismuthi, gr. ii. M. ft. pilula quotidie bis terve sumenda.

The sedative effects of the prussic acid in gastrodynia may also commend its trial: it is conveniently conjoined with a light tonic infusion as a vehicle, as that of chamomile, calomba, rhubarb, or cascarilla.

Finally, we would repeat our former observation, that the treatment here detailed is applicable to the cases where, the symptoms plainly indicating an organic disease, we are compelled to apprehend the coming on of cancer, rather than to those in which its presence is too obvious to be mistaken. Where the constitution is sinking under this disease fully developed, the medical art can do nothing more than attempt the palliation of its appalling symptoms, and it affords for this object scarcely any resource but a free use of anodynes. An opium plaster, or one composed of extracts of belladonna and cicuta, with a little camphor, applied to the epigastrium, may procure temporary relief. If diarrhœa supervene, it should be opposed by astringent opiate injections. In the case of impending inanition from the rejection of all kinds of food by the stomach, some support may be derived from the use of nutritive injections, and the application to the abdomen of large poultices of bread and milk. The anodynes fail at length in procuring rest, and towards the close the disease triumphs wholly without control.

II. **Ulceration.**—In noticing this and the remaining organic diseases, we shall not pursue the systematic method which we observed in cancer of the stomach. These affections are of great interest and have been much studied of late, but to the present time they have been handled by writers rather in the form of essay than of regular treatise; and this appears to us to be still the best adapted to the measure of our knowledge of them. Besides, much information with reference to them is contained elsewhere in this work, as their consideration belongs in many respects as much to other articles as to this.

Ulcerations of the stomach are less diversified in their anatomical characters than those situated in other parts of the alimentary canal; all the varieties which it is of any pathological interest to remark, may be comprised under three heads, as follows:

1. The form which is more especially called the simple ulcer. This is a solution of continuity which extends more in breadth than in depth, being seldom found to engage any of the tunics beneath the mucous membrane. Its shape and extent are various, but it is more usually found to affect a roundish form than any other. The edges are formed by the mucous membrane smoothly eroded, and are not elevated above the rest of its surface; the base or ground is uneven, and often studded with minute vascular eminences, or small patches of the mucous coat which had been isolated in the midst of the ulceration. Over the parts of the stomach which are not engaged in the latter, more or less vascularity prevails, and according as this is the case, the ulcer presents different shades of colour. This is a form which is either acute or subacute, and it corresponds to the ulcerations which occur in the lower third of the ileum, and in the colon, but does not embrace the patches of agminated glands, which are so conspicuous in it, when it occupies those situations. It may be present in any part of the organ; more commonly, however, it is found on the greater curvature and the cul-de-sac. The slight erosions which are occasionally found on the surface of the mucous coat in fevers and other acute diseases are reckoned by some pathologists to be a variety of it, while others with equal reason consider those as not produced by true ulceration, but rather as connected with the diseased condition which gives rise to the softening of the tunics. We have placed this variety first because it presents the simplest form of ulceration, not with reference to its frequency: it is, in fact, comparatively seldom met with, inasmuch as, however frequent in the intestines, ulceration is not a common consequence of acute inflammatory action in the stomach.

2. Ulcers of a small extent, with a defined circular area, and edges somewhat raised above the level of the rest of the internal surface. The base may be formed by the cellular tissue, or it may have eroded through this and the muscular layer, so as to lie upon the peritoneal covering. Its size varies from that of a split pea to a shilling, and it more frequently occurs singly than in number, although occasionally a succession of them seems to take place, in which case they may be presented in different degrees of development, some showing a tendency to form cicatrices. This form of ulceration is for the most part primarily seated in the glands of Brunner, which occur singly in different parts of the stomach, but chiefly along its curvatures and towards the duodenal end. It arises at one time on their surface by their direct irritation and ulcerative absorption, while at others it seems to succeed upon their internal swelling from obstruction to their follicular orifices.

3. Circumscribed ulceration of a decidedly

chronic character, with much thickening over its base and edges. It varies in extent from the size of a shilling to that of a crown-piece or larger; it may occur in any part of the stomach, and involve the different tunics to a greater or less degree; yet for the most part, as it proceeds, in depth, its ground becomes overlaid with a thickened cellular substance which also occasions the elevation of its circumference. Its origin does not differ obviously from the last form, but its course is more chronic, and although generally solitary, it is more extensive in its disorganization. Some pathologists are not disposed to admit the separation of this from ulcers of a cancerous nature, regarding the thickened and indurated cellular tissue as a mode of scirrhous formation. It appears, however, manifest to us, that an ulceration with these chronic features is not unfrequently met with, which is entirely devoid of the cancerous character; and with regard to the thickened condition of the tunics which it originates, it seems that it is strictly analogous to the callous edges and base which are found upon certain old ulcers of the leg. We see the latter every day removed by stimulants, escharotics, or pressure; and cicatrizations have been found to ensue upon the former. This at once affords a strong argument, and is an important practical reason for not generalizing them under the same head as the intractable scirrhus. Yet it is to be observed that by this distinction we do not deny that this form of ulceration of the stomach may degenerate into a cancerous disease by the deposit of foreign tissue, as happens in like manner occasionally to some ulcers of the skin. For the purpose of distinction, then, it would be advantageous to designate all the forms which are free from any foreign complication by the term *simple* ulceration, although this is in a peculiar manner applied to that first described, because it is generally confined to the mucous membrane.

The inflammatory origin of ulceration of the stomach appears to be undeniably established. Accurate investigation has evinced that the ulcerative solution of continuity is preceded on all occasions by more or less hypertrophy and hardening of the mucous membrane in which it arises. In those ulcers which are consequent upon an acute inflammation, this is less obvious than in chronic cases; and on the other hand also, in some of the most chronic forms occasionally little alteration is found in the parts surrounding the ulcer. Yet these appearances are so commonly found, that it gives room for the inference that ulceration is a change which has a secondary relation to foregoing inflammatory alterations in the stomach. The mucous coat, or the glands connected with it, are invariably the primary seat of the ulceration, which is a distinguishing circumstance between the simple ulceration and those forms depending upon the development of foreign structures. In the latter, which have their seat generally in the cellular tissue subjacent, the ulceration is for the most part propagated from this to the other tunics; but although these may suffer in simple ulceration, their destruction is secondary to that of the mucous membrane, in which it always commences. It is obvious likewise, that as it commences by inflammatory action, its extension, whether in breadth or depth, is to be ascribed to the occurrence of the same condition, which is from time to time kindled in the part.

The inflammation which attends ulceration is of an extremely low character; on some occasions it is not indicated either by its symptoms during life or by the appearances after death, and the high free inflammation of acute gastritis never terminates in ulceration. It is true that it occurs in certain forms of fever, which, with reference to the general system, is an acute disease. This, however, does not form an exception to the remark, as it has been proved by the investigations of Krimer and Schrœder van der Kolk, and is sufficiently evident from daily experience, that in fevers of this kind in which the general nervous influence is weakened, the inflammations which arise are of a very imperfect character. (Die Darmgeschwüre dargestellt von Dr. J. Fr. H. Albers, Leipzig, 1839, s. 68.) It is also a remark of great interest, that if the nervous influence of the part becomes prejudicially affected during the subsistence of this low and chronic form of inflammatory action, the ulceration may lose its simple nature, and assume a cancerous character.

The symptoms attending upon the early stages of ulceration are rarely of a more alarming nature than those which are characteristic of functional derangement of the stomach. Flatulence, acidity, anorexy, oppression of the stomach after eating, and pain, are the ordinary indications which it presents in the commencement, and these are common to it and the dyspepsia which takes its origin from a different source. It is when the pain becomes the prominent symptom that a more serious affection is indicated, its character also being different from that of gastrodynia. In its degree and duration it varies considerably, but it is usually of a dull oppressive description, yet occasionally sharp and rather approaching to soreness. In many cases it is complained of only after eating, and continuing with much severity while digestion is going on, subsides when that process is completed. A frequent expression of such patients, says Dr. Abercrombie, is, "I should be quite well if I could do without eating."- (Op. cit. p. 17.) It affects others more permanently, but in all it is aggravated on taking food, on which account the patient acquires a dread of his necessary meals, sometimes rendered the more distressing by the circumstance that the appetite remains nearly unimpaired. Occasional nausea is apt to occur from the commencement, but vomiting is not usual until the decided establishment of the disease. Great uncertainty, however, prevails with regard to this symptom; in some it occurs from the beginning, but without constancy, and may yield to a regulation of the diet; in others it is more permanent, and entirely uncontrollable; while cases are not wanting in which the disease ran its course to the last period with little or none at all. A similar diversity exists in the substances rejected by vomiting; these consist at one time of ropy mucus or various secretions, at others of a brownish fluid; and on some occasions blood in considerable quantity is thrown up. Dr. Abercrombie illustrates the variety which occurs in this and the other symptoms by several in-

teresting cases, which serve to exhibit the insidious nature of the disease, and the impossibility of finding limits which would exactly define the features of its history. But their general outline is sufficiently distinct, and permits us to perceive the similarity which it bears to the phenomena of cancer of the stomach. The important practical question contained in the latter remark has received the attention of M. Andral; and his consideration of it leads him to the conclusion, that neither simple ulceration nor the other lesions resulting from chronic gastritis are to be distinguished from cancer of the stomach, except where abdominal tumour, the least ambiguous sign of the latter, is present. (Clinique Médicale, t. iv. p. 432.)

It is, however, needless to state that the issue of simple ulceration of the stomach is not to be regarded in so hopeless a light as that of those which are connected with foreign degeneration; but although this is so, it must be added that a favourable termination is rather to be counted an exception. Four modes of termination have been observed, in the consideration of which we are led to some interesting points of its pathological history.

1. Like other chronic diseases, it may terminate by the gradual exhaustion of the powers of life. In such instances it gives rise to a protracted train of suffering, and is generally complicated at an earlier or later period by other affections, as dropsy of the abdomen, or anasarca, disease of the liver, intestines, pancreas, or spleen.

2. It may prove fatal by a hemorrhage proceeding from the ulcer. The hæmatemesis resulting is sometimes at first inconsiderable, yet by its uncontrollable continuance or frequent recurrence it wears out the patient; in other instances it comes on suddenly and extinguishes life rapidly by an overwhelming effusion. This termination has been observed to occur most frequently in the large chronic ulcers with much thickening. It is ascribed either to erosion of vessels by the ulcerative process, or to exhalation of blood from the surface without any lesion of continuity in these. The latter has been very seldom directly observed in simple ulceration, and analogy seems to teach us that the pouring out of blood from the superficial capillaries is the more usual mode of its occurrence.*

3. It may produce perforation of the stomach, and give rise to peritonitis, which proves rapidly fatal. (See Perforation, Peritonitis.) Some modifications have been noted with respect to the manner in which this occurs. At one time the disease proceeds to the gradual erosion of all the tunics in succession, and the forming of a direct opening between the stomach and the peritoneal cavity. This is infinitely more rare in the stomach than in the small intestines, in which situation the observations of modern pathologists have shown it to be by no means an unfrequent accident, especially at the close of certain forms of enteric fever. For the most part when the stomach is thus directly perforated, the ulcer is of a small extent, and belonging to the second variety we have above described. Several observations are recorded by ancient and modern authors which rendered the opinion more or less prevalent that such perforations were produced by the eroding action of intestinal worms. In some instances lumbrici have been found lying near the perforation in the stomach; in others, as in the case related by Dr. Crampton, (Irish Med. Trans. vol. i. p. 29, New Series,) they had apparently passed through the opening into the peritoneal cavity. Gaultier de Claubry has described an appearance in which this origin was more strongly suggested than by their situation in either of the other localities. He has seen the stomach and intestines perforated in several places by lumbrici, which were so impacted in the openings as to require force for the purpose of withdrawing them. (Guersent, Dict. de Méd. art. *Vers.*) At the present day, however, this opinion seems entirely discarded, and the presence of worms at or near the perforation is regarded as a mere coincidence. In some instances the ulceration has not penetrated the entire parietes of the viscus, but resting upon the serous or muscular tunic, perforation suddenly occurs by the rupture of its deepest part during efforts of vomiting, coughing, or other forcible exertions of the muscles of the abdomen. A modification of this happens where the ulcer, having eroded the stomach and united it by its edges to a neighbouring organ, this union is torn by a similar shock. Cruikshank relates a remarkable example of this in the case of a lady in whom an illness, fatal in two or three days, ensued upon a fit of vomiting, which, as it was afterwards found, had separated the adhesions of a large ulcer from the left lobe of the liver. (Anatomy of the Absorbing Vessels of the Human Body. London, 1786. p. 113.)

4. Finally, simple ulceration may terminate by cicatrization. The occurrence of this condition has been a matter much debated by pathologists. Some assert that cicatrized ulcers are seldom if ever met with in any part of the digestive canal, (*Louis, Albers, Lesser*); others affirm that their anatomical researches have demonstrated that their occurrence is not exceedingly rare. (*Cruveilhier, Scouttetten, Prost, Trousseau.*) Albers supposes that these opposite statements concerning a matter of observation are explicable by the fact, that different conditions of the digestive tube were contemplated by the observers on either side, (Op. cit. p. 120); that the attention of one party was particularly directed to the ulcers connected with foreign degeneration; while that of the others was engaged about the simple forms of ulceration. In whatsoever manner this may be reconciled, too many cases amply authenticated are on record, to leave any doubt that ulceration of the stomach may heal by undergoing cicatrization. The importance of this conclusion in its pathology is manifest: a practical distinction arises out of it between the simple ulceration and that connected with foreign structure; and it affords a ground for hope in undertaking the treatment of these affections, which its absence should entirely take away. The cicatrix which was found in the stomach of

* We were much confirmed in this opinion by once observing the sudden effusion of blood which took place from the whole surface of a large ulcer at the nape of the neck, (which had been artificially produced by an escharotic application,) on the use of a douche over the head and back. The form and aspect of the ulcer was like the third variety above described.

Beclard has been already referred to; it was situated at the lesser curvature, near the cardia, and was about an inch in diameter; its surface was depressed, and traversed by a few cellular bands, one of which passing through its centre divided it into two lacunæ, whose base rested upon the peritoneal tunic. This example of cicatrization is cited by authors as a proof of the efficacy of a resolute adherence to a severe regimen in its treatment. Recamier has recorded a case which equally deserves attention on another account. A woman, twenty-six years of age, presented symptoms of a profound organic disease of the stomach, viz. pain, vomiting some hours after meals, and progressive emaciation. From inquiry into her husband's health, this physician was led to suspect the possibility of the disease being connected with a syphilitic taint, and accordingly recommended a mercurial treatment by frictions, and a milk diet; under this she gradually improved, and in four months entirely recovered her health. Six years afterwards she was attacked by pulmonary phthisis, and died. Examination of the body displayed, besides tubercular cavities in the lungs, a cicatrix in the stomach, of the size of a crown piece, resting upon the pancreas, to which it adhered; and the stomach immediately around it was formed into folds, like those of the mesentery. We recite this case, not only on account of the extensive cicatrization of which it affords an example, but more especially for the sake of the instructive lesson which it contains in the consideration of the occasional cause of the disease and of the success of the appropriate treatment. It evidently shows, says Recamier in his comment upon it, that even in an extreme instance of such a disease, we may have a hope of obtaining a cure, provided a cause be recognised which can be advantageously combated, such as the syphilitic taint. (Op. supra cit. t. ii. p. 55.) This important remark is illustrated with equal force by the history of a case related by Andral, in which a train of the most profound symptoms, in every respect characterizing this disease, had brought a lady, after four months' illness, to the verge of the grave; when at this point the detection of an ulcer in the throat, possessing a venereal aspect, together with the account of former suspicious circumstances, suggested to the physician (M. Andral's father) the possibility of the disease of the stomach having a syphilitic origin; whereupon, as every mode of treatment had entirely failed to arrest the progress of the disease, he acted upon this, as a last resource, and exhibited mercury gradually, both internally and by inunction. Some amendment was perceptible even from the commencement of this treatment; and ultimately, from its continuance, the patient, who had been to all appearance in the last stage of this disease, was perfectly restored to health. (Clinique Médicale, t. iv. p. 470.)

The ordinary treatment of simple ulceration of the stomach consists in regulation of regimen, local depletion, and counter-irritation, together with the conservation of as great a state of calm with respect to the function of the stomach and the general system, as possible. It is unnecessary to enter into the detail of the means by which these ends are to be procured, as this would be but a repetition of those which are described under cancer of the stomach. The treatment exposed in that place is, in fact, given more with the aim of combating the disease here described than cancer; and any success which it promises is almost entirely grounded upon the similarity of the phenomena presented by the two affections, which in many cases permits us to encourage a hope that we have to deal with the least formidable.

III. **Hypertrophy and Atrophy of the Tunics.**—An organic change, consisting in a mere increase or diminution of nutrition, is occasionally met with in the stomach, which may involve its tunics either separately or entirely. Its most frequent seat is the mucous membrane, but it has also been observed to occur in the subjacent textures; with the exception of the peritoneal covering, which is not affected with any structural alteration, properly limitable to the gastric portion of this serous membrane.

1. *Hypertrophy* invades the mucous membrane of the stomach either partially or generally, and may induce various modifications of form and colour. For the most part this membrane preserves its smooth and uniform aspect, but receives an increase in its density, as well as in thickness, so as to admit of being raised upon the scalpel in flakes from the subjacent tissues. Occasionally it is found developed in round eminences of various sizes, from that of a split pea to a large filbert, which appearance has been called mamillated (Fr. *mamellonnée*). The colour of the hypertrophied part is at one time that which is proper to the rest of the membrane; but this is not common, as it usually presents different shades of brown, slate-colour, or even black; and in some rare instances it is disposed in circumscribed patches of a milk-white colour, similar in appearance to those lymphy exudations which are occasionally found incorporated in serous membranes; but on examination by incision, according to M. Andral, they prove to be nothing but the mucous membrane in a state of hypertrophy, and altered in colour.

To this condition are to be referred the polypous growths and vegetations of different sizes and shapes which are met with from time to time in examinations of the stomach. Considerable variety exists in the instances of excrescences of this nature, which are recorded by authors; at one time they are attached by a pedicle, and represent pyriform polypi; at others they resemble mushrooms, or present a foliated appearance like the *book* portion of the ruminating stomach; but whatsoever diversity of conformation such productions exhibit, they are constituted by the mucous membrane in a state of hypertrophy, and differ from its ordinary form chiefly by taking a projecting development in isolated points. Their internal texture occasionally is contrasted with the remainder of the villous coat by a different degree of firmness or of softness, and also by a greater development of the blood-vessels, which are sometimes varicose, and so abundant as to give them the appearance of erectile tissue. In respect to the difference of texture in these productions, observers have denominated them vegetations, excrescences, polypi, fungus, &c. We cannot, however, follow M. Andral in comprehending under the same class any tumours which partake of a

scirrhous nature, as those seem to us to depart entirely in their pathological characters from the others here detailed, which are, according to him, simple developments of the hypertrophied mucous membrane. (Précis d'Anatomie Pathol. t. ii. p. 49.)

The muscular tunic also undergoes the change of hypertrophy, which may be confined to a portion of its fibres, or extend over the whole. But little notice has been taken of the occurrence of partial hypertrophy, although it is probable that it is more common than the silence of pathologists would account for. This remark appears to be warranted by the fact that the fibres of this tunic, altered in thickness and colour, are not unfrequently distributed through a scirrhous degeneration of the cellular membrane, but have generally been mistaken hitherto for fibrous productions of the substance in which they were found imbedded. (Clinique Médicale, t. iv. p. 411.) General hypertrophy has been observed to pervade the muscular tunic of the stomach by M. Louis, who has furnished an accurate description of it, as well as of the lesion with which it was connected in the cases in which it occcurred. It gave to the parietes of the viscus a double thickness and considerable increase of density, both of which conditions varied in the different parts of the stomach, but were greatest towards the pyloric extremity, in which the muscular fibres become interlaced in a cancerous degeneration. In the midst of this, however, they preserved their state of hypertrophy, but assumed a bluish, semi-transparent appearance.

This condition of the muscular tunic has been almost invariably found to occur in cancerous disease of the organ, and for the most part in cases where a contraction of the pyloric orifice existed. On this account M. Louis suggests that it may depend in the relation of effect upon the latter in the same manner as hypertrophy of the muscular parietes of the heart is caused by a contraction of the orifices of this organ. But he affirms this rather from analogical reasoning than on direct evidence, as a sufficient number of cases have not yet been collated with reference to it, to prove that it stands always in connection with a contracted state of the pylorus. The same observation applies to the conjecture of M. Prus, that it owes its origin to the constant vomiting attending upon organic disease, which, by increasing the muscular efforts of the stomach, causes this tunic to assume an excessive development. It appears, however, very probable that both conditions more or less contribute to produce this effect.

The cellular tissue which separates the tunics from each other is also not unfrequently the seat of hypertrophy. It then becomes condensed and deprived of its areolar structure, and may give so much firmness to the parietes of the stomach as to prevent them collapsing upon each other, as happens in the natural state of the organ. For the most part it occurs in the tissue subjacent to the mucous membrane, but it may involve that also which separates the peritoneal from the muscular coat, and penetrate between the fibres of the latter.

We have before adverted to the opinion of some pathologists, which has attached in modern works considerable importance to the hypertrophied condition of the cellular tissue; namely, that scirrhous and cancerous products are constituted by it, in a certain stage of development. It is certain that some varieties of these foreign structures bear much resemblance to it, and it even appears to us a tenable opinion that there is a gradation connecting them together, of which the tissue called *lardaceous* is an example. When perfectly developed, however, there does exist a distinction between the external characters of those products; and setting this aside, the difference in their history, their respective effects on the general economy, and subjection to therapeutic means, afford weighty grounds for considering them as different organic textures. These counterbalance in our judgment any arguments for their identity derived from their original deposit or molecular analysis; the latter considerations scarcely afford to the science any basis for the division of morbid tissues, which can be placed in competition with such palpable marks of pathological distinction as are supplied by the former. It is certainly often a matter of observation that the foreign deposits are found in the midst of the hypertrophied cellular tissue, nor is it possible to define the gradation by which the change takes place; but we would only remark that the same may be predicted of the conversion of cartilage into bone. Finally, we rather recognise that the hypertrophy of the cellular membrane of the stomach is frequently a nidus for the deposition of cancerous tissues, than agree with those who regard them as identical, and we publish this here only with the confidence derived from its being the opinion of some eminent British pathologists.

2. *Atrophy* of the gastric parietes is a change which is not unfrequently brought under observation by necroscopic examination. It may be local or general, and involve the tunics separately, or embrace them altogether. At one time the villi of the stomach have disappeared under its influence, partially or entirely; at another, the substance of the mucous membrane is so diminished as to be scarcely capable of being discerned separately from the subjacent tunics. These in their turn suffer the same diminution of nutrition; and lastly, it is found in different degrees to invade the whole parietes, which are occasionally reduced to such a thinness as to be transparent, and to seem to be constituted almost wholly by the peritoneal tunic. When the atrophy is local, it is ordinarily seated in the fundus of the stomach, and this situation manifests more obviously its effects, being naturally the thinnest portion of the organ.

Every form of these organic lesions is referable to some variety of chronic irritation in the stomach. The hypertrophy of the mucous membrane appears to be the only one of them which is contemplated by pathologists in the light of a primitive disease; this is a direct result of chronic gastritis. We have stated before that the hypertrophy of the subjacent cellular membrane is a secondary result of the latter, and that of the muscular tunic is found generally to attend upon cancerous disease. The atrophy of the stomach acknowledges an organ still more indirect, as proved by the researches of M. Louis, with respect to its occurrence in the mucous membrane; in the

great majority of instances it occurs as a secondary lesion in the course of chronic diseases of other organs, such as phthisis and disease of the liver and of the brain. These organic changes will have to be referred to again in considering the dilatation of the stomach.

IV. **Softening of the Stomach.**—This lesion constitutes the post-mortem appearances of a disease, which is in a great degree peculiar to infants, but which occurs also in adults, and is found in them generally to accompany the last stages of some profound affections of other organs. Although it has proved to be not a very rare occurrence, it escaped being fully identified until a recent period; but upon the recognition of its fatal character, and its importance as a pathological phenomenon, it received attentive investigation. It has been described by Jaeger, Cruveilhier, Guersent, Gairdner, and others, and experiments have been instituted by Camerer and Carswell, which have furnished satisfactory evidence with regard to its true nature. It would be superfluous to present its description in this place, as it has already been amply treated of in other articles. Under DENTITION and GASTRITIS is to be found an account of its history and symptoms; and for that of its pathology, which seems to be now fully established by the experimental researches of its author, we refer to SOFTENING OF ORGANS. Nothing remains for us but to indicate it here amongst the organic lesions of the stomach.

V. **Enlargement of the Stomach, and Contraction.**—1. *Enlargement* of the stomach is an organic change, which involves in its causes and many of its phenomena considerations of great interest. On account of it being almost always a secondary lesion, and one which is not of common occurrence, it has seldom been formally noticed in medical works; extraordinary cases of it have, however, been recorded by Mauchart, Riverius, Lieutaud, Bonet, Valsalva, Morgagni, and others among the moderns; but it deserves more special attention than it has received in any systematic work, if it were only because it forms one of the several causes of abdominal tumours, which are known to be a frequent source of diagnostic embarrassment in the practice of medicine. Amongst the descriptions of it which have been given by recent authors, none have occurred to us which contain so much information as that by M. Duplay, and we desire to acknowledge the obligations which we lie under here to his well-digested memoir.*

When the functional and mechanical relations belonging to the stomach are considered apart, its morbid dilatation has a strict analogy with that of the other hollow viscera which are endued with muscular parietes, as the heart and the bladder. The organic lesions with which it is connected are at one time obvious, and at another are not demonstrable to the senses; but like the corresponding affection of the latter organs, they are referable to two distinct classes; namely, to lesions producing mechanical obstruction to the contents of the stomach; or to others, which deprive the organ of its power of propelling the alimentary mass. In both orders of causes retention of the latter is the invariable accompaniment of the dilatation, in like manner as the urine is retained and becomes a secondary cause of distension, as well from obstruction in the urethra as from any condition which diminishes the expulsive power of the bladder. As far as has been already observed, the following pathological conditions of the stomach may be recounted as standing in the *relation of cause* to this affection.

1. Contraction of the pyloric orifice. This is by far the most frequent source of dilatation of the stomach, and is ordinarily produced, as we have seen, by cancerous disease. Its mode of action is obvious: the alimentary matters not finding a free outlet by the pylorus, accumulate in the stomach, and distend it to a greater or less degree, which is determined chiefly by the extent of the obstruction, and in part by the quantity of the accumulation which may be rejected by vomiting. When depending upon this cause, the parietes of the viscus may be found in a state of simple dilatation, or along with this they may have suffered thinning and softening to such a degree as to give occasion to rupture; or, on the contrary, hypertrophy of all the tunics, especially the muscular, may coincide with its increased capacity; which lesions, it may be remarked, preserve an analogy between this alteration of the stomach and diseases of the heart connected with valvular obstruction.

It is, however, to be observed that dilatation does not occur in every instance of pyloric contraction, nor even invariably where total obliteration of the orifice is found. Moreover, it happens in cases in which this orifice has continued perfectly patent, or still wider than in the natural state; all which circumstances conspire to prove that other conditions co-operate with the mechanical obstruction to produce the dilatation, even when they appear most obviously in connection. M. Andral has made it apparent from researches on the action of the pyloric end of the stomach, in propelling the chyme from this viscus into the duodenum, that the integrity of its muscular action is necessary for the performance of this movement. But it will be observed that it always happens in cancerous disease of the pylorus, that the muscular tunic, to a greater or less distance from the orifice, is surrounded by the scirrhous induration, which must impede its contraction, and thus deprive the stomach of its action. This sufficiently explains the cases of dilatation with patency of the pyloric valve, for in all the instances of organic disease in which these conditions coincided, the muscular fibres in its neighbourhood have been observed to suffer either by surrounding induration or by their direct lesion. Another circumstance which frequently co-operates in cancerous disease to impede the muscular action, is the occurrence of adhesions between the stomach and the neighbouring organs, which, in the same manner as the former conditions, contributes to effect the dilatation of the organ by causing the retention of the alimentary mass.

2. Organic alterations in the muscular tunic. With reference to their effect in originating dila-

* De l'ampliation morbide de l'estomac considérée surtout sous le rapport de ses causes et de son diagnostic; par A. Duplay, chef de Clinique interne à l'hôpital de la Pitié. Archives Générales de Médecine, Octobre 1833, et Décembre, même année.

tation of the stomach, these may be partial or general. Observation has established that the destruction of the muscular fibres which are situated near the pylorus is an occasional cause of this morbid condition, and not less certainly that it originates under an atrophied state of the whole of this tunic. On account of the special office which the pyloric end performs, of propelling the gastric contents into the duodenum, the partial injury of the muscular tunic, when seated here, is as effectual in causing retention and the consequent dilatation, as the general atrophy of this tunic, but it is easily conceived that the action of both is similar.

3. Paralysis of the stomach. — The dilatation has been occasionally observed to occur where none of the foregoing causes existed, the stomach being entirely free from any organic disease. This organ in fact may be affected with a paralytic loss of its contractility in the same manner as the bladder; and as the urine, under such a condition of this viscus, accumulates without the power of being voided, so the stomach, in like circumstances, yields, as a flaccid bag, and becomes dilated gradually by the accumulation of the food. This source is worthy of particular attention, as it affords a hope with reference to the employment of therapeutic means, which the affection connected with organic lesions leaves scarcely any room for entertaining.

4. Finally, it may be produced by tumours of various kind, polypi, fibrous growths, or hydatids, situated either internally and involving obstruction of the orifices, or by their weight giving rise to a relaxation of the viscus, which may occur when they have an external attachment, or are even situated in the omentum.

History and diagnosis.—With this enumeration of its causes prefixed, the phenomena of enlargement of the stomach present themselves with freedom to the mind, and we are prepared to meet the diversity which they offer, the result of the various morbid states connected with this lesion: in proceeding to detail its symptoms, we shall first notice the manner in which it progresses.

When the contents of the stomach become accumulated, either, as we have seen, from the obstruction of its orifice or loss of its contractile power, distension takes place. In the commencement this may not be immoderate, and only temporary, as it can be relieved by vomiting; which action, however, if the viscus be already somewhat weakened, is only partial, permitting much of the ingesta to remain still lying in its cavity. This, by its continual weight, diminishes the power of resistance, and by a reacting influence the alimentary matters are allowed to augment, so that at length the most depending part of the stomach begins considerably to yield under the downward pressure. As the dilatation advances, the oblique position of the viscus disappears, and the two orifices take the same level, and approach each other, so closely in some extreme cases as to be found in actual contact. The vomiting becomes more infrequent as the capacity is increased, and in the same proportion it becomes more difficult to unload the stomach completely, so that all the circumstances contribute to the accumulation. The dilatation augments in this manner to an enormous measure; in some cases it invades the entire abdominal cavity and pelvis, stretching downwards to the pubis, and covering the intestines which lie compressed behind it; in others, its pressure extends upwards and produces great distress by interference with the thoracic organs, and sometimes even dangerous effects by obstructing their functions.

With respect to the appearances which are found post-mortem, as far as they depend simply upon the enlargement of the stomach, they correspond of course with this description of its progress; but it is easily conceived that almost the entire pathological interest of those is absorbed in the investigation of the primary lesion with which they are connected. Concerning the latter we add nothing here; it may be mentioned, however, that besides the displacement of the various viscera which is occasionally found to have been effected by the dilated stomach, not unfrequently every trace of the epiploon disappears; the gradually expanding organ having glided between its separate folds, those overlay it, and become united to its parietes.

The symptoms belonging to the diseases of the stomach, which originates the dilatation, form an important part of its general features; but we shall consider them here only so far as they are characteristic of the lesion itself. Amongst the causes above enumerated, those which involve organic disease, such as cancer of the pylorus, afford signs which have been more or less adverted to; but it is necessary to notice the conditions which have been observed in connection with the atonic relaxation or paralysis of the stomach. This morbid state has been found most frequently to occur in those who have contracted extreme habits of gluttony, and more especially in those extraordinary instances of perverted appetite in which the individuals have been accustomed to swallow foreign substances. In a man at Brest whose stomach was found to contain a quantity of fragments of glass, pieces of wood, iron, and tin, with an entire knife and handle, this organ was found enormously dilated. In the case of a lunatic which latterly occurred in Dublin, the enlargement was connected with his swallowing buttons, half-pence, pins, &c. which were found after death in considerable number, and even during life betrayed themselves by a jingling sound on the succussion of the abdomen.* M. Percy has collected the histories of several cases of individuals addicted to gluttonous excess in eating and drinking, in whom enormous dilatation occurred; and it has happened in others in which the gluttony was not carried to the immoderate excess which distinguished the latter, as in an interesting observation related by M. Pezerat, where an evident paralytic relaxation of the stomach ensued in an individual who was unable to refrain from the indulgence of a habit contracted from his infancy, namely, taking copious drinks of weak wine and water. (Journal compl. des Dict. des Sciences Méd. t. xxxv. p. 162.) It has been known also to occur in females liable to recurrent attacks of hysteria, in whom the meteorismus of the stomach prevails, which is a common accompaniment of the nervous dyspepsia attending upon this disease. Other in-

* The particulars of this case, which are, as we learn, interesting in many respects, we hope to see shortly published by Mr. Adams, in whose practice it occurred.

stances are not wanting where no connection could be traced between it and any of those exciting causes; in such the stomach seems to undergo a true paralytic relaxation, which was regarded by Lieutaud, who described it, as similar to that which is observed in the bladder in advanced age: the same condition is noticed by Chaussier, and compared by him to the relaxation of the scrotum, which occurs in certain individuals.

Pain, oppression in the epigastric region, and general tension of the abdomen, repeated, uncontrollable eructations of sour air, and profound digestive derangement, are symptoms which are to a greater or less degree invariably present in this morbid condition. They cannot, however, be relied on as special characteristics; nor is any single sign entitled to be esteemed as such, as none taken alone is sufficient to establish the diagnosis. Yet for this object much assistance is furnished by the examination of a particular symptom, the vomiting, and more especially by the exploration of the abdomen.

The vomiting consists at one time of the mucus of the stomach in great quantity, and at others of the alimentary matters which had been swallowed, more usually of a mixture of both, or, if cancerous disease exists, of its peculiar secretions. Its action is remarkable, being rather a regurgitation of the gastric contents than the forcible muscular expulsion which characterizes ordinary vomiting. In the beginning of the affection it occurs more frequently than when the dilatation has already made some progress, and at the more advanced period it is apt to observe distant periodic intervals of two, three, or four days in its return, and then brings a much-desired relief, by unloading the organ partially or entirely of its enormous accumulation. To procure this artificially, the patient sometimes has recourse to tickling the fauces, or the use of emetics; in other cases he finds the relief, still more effectual, which the operation of drastic purgatives produces. Unhappily, instances occur in which the vomiting ceases totally, the stomach seems insensible to any stimulant, the consequence of which is, that the feeling of oppression is not to be relieved by any means, and the accumulation continually increases.

The exploration of the abdomen, the most palpable sign, in every respect furnishes the most valuable data towards recognising this morbid state. On this subject we quote from the memoir of M. Duplay, in which the information derivable from this source is lucidly set forth. The patient should be subjected to a double examination; the first to be conducted some time previous to the coming on of the vomiting, the second after the vomiting.

"*Before vomiting*, the examination of an individual with enlargement of the stomach, whatever be the nature and cause of it, presents to the touch *a tumour* more or less indistinctly circumscribed, which extends from the left hypochondrium to the right iliac fossa. This tumour extends also to the hypogastrium, and ascends towards the right side; in some instances, its outline along this track is easily distinguished. When the patient is placed in a vertical position, the epigastrium projects less than the lower part of the abdomen; on the contrary, when he lies in a horizontal position, this region participates in the general tumefaction of the belly, which in every part gives the sensation of an obscure fluctuation and absence of elasticity (*empâtement*).

"On practising percussion, the abdomen gives a clear sound in the epigastric region, which becomes more dull as we descend towards the hypogastrium; a difference which naturally depends upon the respective gravitation of the fluids and the air contained in the viscus. This consideration also evidently suggests that the difference is much influenced by position; the dulness in the inferior part of the abdomen augments in the vertical position and becomes diffused, and appears to ascend towards the epigastrium in proportion as the patient changes to the horizontal.

"On tapping for fluctuation (*ballottement*), by the hands being placed on either side of the abdomen, a particular sound is perceived, similar to that which is produced by striking on a bladder half filled with air and liquid.

"Succussion has not yet been employed in its diagnosis, or at least its application has not been described in any of the cases which the author has consulted. Smart shocks upon the trunk, with the ear applied to the epigastrium, would, however, produce the sound of fluctuation more distinctly than the *ballottement*, especially in individuals who have still preserved their fulness of flesh. This is evident from the fact that some individuals have the power of producing a gurgling sound by alternately contracting and relaxing the diaphragm and the abdominal parietes.

"The ingestion of liquids or of aliments may also contribute towards establishing the diagnosis of this morbid condition. In some cases, the patient will be able himself to perceive the substances which he receives into his stomach descending to the lowest part of the abdomen.

"*After vomiting*, all the signs above stated disappear in part, or become less evident. The projection which the distended stomach forms is less easily to be traced through the abdominal walls, even when these are emaciated. The dulness on percussion disappears more or less completely; the lateral pressure and the succussion no longer produce the fluctuation, nor the gurgling, or only in an obscure degree. Again, the signs are reproduced upon the re-introduction of food or liquid into the stomach." (Archives Générales de Médecine, Décembre, 1833, p. 549.)

It is scarcely necessary to add that those means of exploration furnish their data, both positive and negative, in proportion to the extent to which the dilatation of the stomach has proceeded. If it be supposed that this lesion is of such a palpable nature that it would not be difficult to recognise it, this is not accordant with the histories of it which the annals of medicine contain; in the great majority of these, it has never been discovered until after death. But, besides this fact, cases are recorded in which it had been mistaken for other abdominal tumours, such as ascites, encysted dropsy, or pregnancy. A case, extraordinary for the enormous quantity of fluid which was contained in the stomach, amounting to ninety pounds, is related in the works of Riverius, in which the disease of the female was first supposed to be pregnancy; when the period passed which dis-

closed this error it was taken for ascites, and after death a puncture was made in the abdomen to give exit to the fluid which was thought to exist in this cavity, the distension being so great as to exceed the size of the coffin: and finally the same case has been recited in several authors as an example of the disease which they named "dropsy of the stomach." A fact of similar import is related by Bonet, namely, that a woman, the volume of whose abdomen had caused her to be regarded as pregnant, died, and being opened, it was discovered that the swelling was produced by the stomach enormously enlarged. In these cases the puncture of the abdomen was not made until after death; but in an instance related by Chaussier, (Essai sur les fonctions du grand épiploon; Mém. de l'Acad, Dijon 1784,) and in another by Vacca, (Arch. Gén., Déc. 1823, p. 528,) this error was committed during life, and death was the speedy consequence. All those cases, but particularly those last mentioned, are worthy of consideration with regard to the diagnosis of this disease; it is not likely that at the present day any practitioner who is in possession of the resources of diagnosis would be so far deceived as to proceed to such an operation; but still much ambiguity may be found in certain cases, and it may be said that in none should we be so confident as to dispense with the diligent application of all the means which can be devised.

For the purpose of distinguishing it from ascites, the following will serve as valuable marks of difference. The form of the abdomen varies in the two affections; in ascites no approach to a definite contour is visible, as occurs where the tumefaction of the belly is referable to enlargement of the stomach. The progressive growth of the tumour in both diseases proceeds in contrary directions; in the stomach the fundus supporting the liquid and solid contents, gravitates from the epigastrium downwards; while in the dropsy of the peritoneum the gradually increasing fluid ascends from the hypogastric region into the superior parts of the abdomen, and corresponding to this opposite progress the dulness of sound on percussion also moves. Together with these the comparative states of the tumour before and subsequent to the emptying of the stomach afford a characteristic which is quite peculiar to enlargement of this organ, and distinguishes it with much certainty from ascites, pregnancy, or tumours in any other of the viscera of the abdomen.

Many of the same differential signs are applicable to prevent it being confounded with pregnancy. The latter condition, however, possesses in auscultation and its other means of exploration signs of such positive value, that an attentive investigation can at the present day scarcely fail to decide correctly between them.

Treatment. — It will appear manifest from the consideration of the ætiology of morbid enlargement of the stomach that the resources of medicine are of little avail for its counteraction. The connection in which it stands in the majority of instances with the most profound organic lesions leaves room for it only to be regarded as a distressing complication of a disease in itself hopeless. We have already seen the fatal character of cancerous disease of the stomach, and how impotent the medical art remains against ulceration, atrophy, or hypertrophy of this organ. In the variety of it which depends upon atonic relaxation, more room is left for the trial of curative means; but they can rarely afford any prospect of success in an affection which is the accompaniment either of old age or of some serious lesion of the nervous system. Where the dilatation exists in individuals addicted to gluttony, at first view it would seem more amenable to treatment, as it has rarely in such to contend with primary structural lesions, or with loss of the organic nervous power. But are the perversions of our spiritual nature less untractable than the diseases of the body?

Some relief may be obtained from the evacuation of the intestinal tube by means of gentle laxatives. Strong purgatives are not recommendable, as the irritation and weakness consequent upon their action tend to aggravate the evil. In the paralytic dilatation an attempt should be made to excite the action of the stomach by the use of light tonic bitters, such as the sulphate of quinine, gentian, calomba, or others of this class; a fair indication seems also to be afforded for the exhibition of strychnine. In a case in which M. Rayer employed it, the tetanic twitches seemed to be produced in the region of the stomach which have been sometimes observed to precede its successful operation in other parts affected with paralytic disease; but these were not attended by any sensible amelioration. The application of moxa to the epigastric region has been tried with the same object; it might be applied with as much suitableness to the dorsal region of the spinal column. It seems probable that in some cases the oppressive distension might be mitigated by the use of a bandage surrounding the stomach in such a manner as to give support to the depending viscera. Finally, the regulation of the diet demands close attention; it should consist of the materials which agree most with the stomach, and this at one time is answered by animal food, while at another this is improper. It is obvious that in the case of voracious eaters the overcoming of the vicious habit is the only hope of success; but the accomplishment of this is extremely difficult. It should be attempted by the limitation of their meals to a restricted quantity, and making them consist of that which is of the most nutritive quality, in the smallest compass. The internal use of ice may be employed for the purpose of allaying the hypersthenic state of the stomach, at once the effect and the reacting cause of the craving appetite of such individuals. On their part this treatment will meet probably with resistance, but it should be enforced, if possible, by persuasion, if not, by this combined with firm restrictive measures; and it will be happy for the victims of such a tendency who shall be placed in circumstances of life which admit of the employment of coercion.

2. *Contraction of the stomach.*—This lesion has been already adverted to as a consequence of cancerous disease of this organ, which is by far the most usual pathological state with which it is found connected. It is frequently met, however, quite independent of this; in almost every collection of anatomical observations promiscuous cases of it are related, and to many of those much inte-

rest attaches; yet there is wanting (as far as we are aware) a digest of the materials which illustrate the subject. When it receives an enlarged investigation of this nature, including facts which contain the light of modern research, little doubt remains but that this lesion will be found to possess much practical importance; at present we are obliged to be content merely to mention it with reference to the circumstances in connection with which it has been observed.

The diminution of volume is sometimes to be ascribed to direct pressure upon the organ, by collections of fluid in the abdomen or by enlargement of the different viscera of this cavity adjoining the stomach, as the spleen, the liver, and the pancreas. The same cause operates also acting from without; it has been proved to originate under the influence of tight lacing of the stays in females, and also in individuals whose daily employments necessitated them to lean the abdomen upon the edge of a table, as in the case of hatters and writing clerks.

It has been also observed to arise from the violent action of purgative medicines and emetics, which in such cases are to be placed in the rank of poisons, as it is one of the most common appearances which are found in those who have died from poisoning, especially from having taken the metallic poisons or the strong acids. Hysteria seems to be another cause of this lesion, as it has been also occasionally found in individuals who had been subject to this disease. Portal affirms, that in several persons who died from the abuse of magnetism, which had caused a disease manifesting languor, marasmus, and vomiting, the stomach and intestines were exceedingly contracted. (Cours d'Anatomie Médicale, t. v. p. 179.) According to the same author, venereal excesses are also to be reckoned amongst the causes of it, which have been proved by post-mortem inspection; and in individuals who have died after prolonged abstinence or chronic diseases during which little food could be taken, the stomach is often seen to have its capacity so much diminished as to present its cavity nearly obliterated.

Much diversity exists with respect to the forms which the contracted stomach under different circumstances may assume; in some cases longitudinally disposed, it appears like the remainder of the intestinal tube, in others it takes a globular shape, while in others it is found divided into two or more cavities; a condition which depends upon the irregular and spasmodic contraction of the muscular fibres, and seems to have originated a mistaken idea amongst some of the old authors, who describe the occurrence of two or three stomachs as a variety which the human subject occasionally presents.

J. Houghton.

[STOMATITIS, *Inflammation of the Mouth.*

The mucous membrane of the mouth is liable to various forms of inflammation, which may be simple or erythematous, accompanied by a pseudomembranous or diphtheritic exudation, or by an eruption; or the follicles of the mouth may become ulcerated, or the stomatitis may end in gangrene. All these pathological conditions deserve a separate inquiry.

1. Simple Stomatitis.

Diagnosis.—The mucous membrane is unusually red, hot, and dry, and extremely sensible to the contact of foreign bodies, even of the tongue. The redness is commonly in patches, and the affection rarely gives rise to general symptoms. It usually passes off in a few days by resolution, but occasionally terminates in ulceration or gangrene. The latter is not, however, to be anticipated; but induration of the submucous tissue is at times left by it. Ptyalism is not an unfrequent concomitant.

Causes.—The most frequent cause is the ingestion of hot or acrid substances; injuries done to the mouth by bruises, or the operations of the dentist, or by the accumulation of tartar around the teeth. During the age of the first dentition, stomatitis may arise from this source, when it may be accompanied by signs of general pyrexia. Occasionally, too, erythematous stomatitis would seem to be induced by disorder of the tube lower down.

Treatment.—This form of stomatitis generally yields readily. If induced by acrid or hot substances, it passes off spontaneously in a short time. Milk diet and mucilaginous gargles, as of flaxseed tea, or infusion of slippery elm, or a lotion of the white of egg mixed with water, are all that can be demanded. If the stomatitis be dependent upon gastric derangement, it disappears as soon as the derangement ceases. Small doses of magnesia, combined or not with charcoal, may generally be prescribed in such cases with marked benefit.

2. Diphtheritic Stomatitis.

This is the stomatitis with altered secretion of some, and ought to include both the thrush or *muguet* of the French writers, and the pseudomembranous stomatitis, *stomatite couenneuse* ou *diphthérite buccale*. Both are varieties of the same kind of inflammation of the mucous membrane, but it may be convenient to examine them separately.

a. *Pultaceous Stomatitis.* (See Aphthæ of Children.)

b. *Pseudomembranous Stomatitis, Diphthérite Buccale.*—This can be regarded as only a severe variety of the last, affecting the same parts; the exudation being detached in large flakes, having the ordinary appearance of false membranes. These are soon renewed, but in favourable cases, the inflammation, that gave rise to them, gradually disappears; in other cases, signs of gangrene supervene; this termination, however, and indeed the variety of the disease itself, is rare, except in large foundling establishments, where the mortality from it is at times frightful: of 193 cases, observed by M. Valleix, (*Clinique des Maladies des Enfants*, Paris, 1838,) 153 terminated fatally. In such cases a disagreeable sense of heat is experienced by the little sufferer, with pain augmented by the contact of foreign bodies; the breath is fetid, and the submaxillary glands enlarge and become painful. Later on, the lips and gums are tumid and bloody; a sanious saliva flows copiously from the open mouth; the breath becomes more and more fetid; and the face flushed and swollen. The fever is more or less intense, with headache, restlessness and want of sleep.

Treatment.—Where an impure air is connected with the origin of the disease, it is, of course, important that the patient should be removed from its influence. In the early period, the mucilaginous collutories, recommended in the last variety, may be used, with gentle laxatives of magnesia or castor oil. Afterwards, a mixture of muriatic acid and honey may be employed to touch the pseudo-membranous patches: this may be done by means of lint rolled around, or of sponge attached to, a small stick. Collutories of chlorine water, chlorinated lime, creasote, and vinegar and alcohol, have likewise been recommended.

The application of muriatic acid, as well as of the other collutories, must be made once or twice, or oftener, in the twenty-four hours, as the case may require.

Alum, nitrate of silver, and sulphate of zinc, have all been used as collutories, but they are not possessed of any advantages over the articles already mentioned.

3. Follicular Stomatitis, (See Aphthæ of Adults.)

STOMATITIS OF NURSES, (See Aphthæ.)

STOMATITIS, GANGRENOUS, (See Mortification, and Throat, Diseases of the.)

Robley Dunglison.]

[STROPHULUS, *Tooth Rash, Gum* or *Gown, Milk Spots*, has by some been described as a variety of Lichen,—*Lichen Strophulus*. It is very common in infants, and is characterized by an eruption of greater or less extent, or papulæ either more white or more red than the rest of the skin; which are seated generally on the face, and are accompanied by more or less itching (A. Cazenave, *Dict. de Méd.* xxviii. 659, Paris, 1844). It presents great diversity in its appearance, and all the forms are seen at times on the same child. When the papulæ are red, inflamed and prominent, scattered here and there, and intermixed with erythematous patches, it is the *strophulus intertinctus* of dermatologists, *Red gum* or *Red gown*. In some cases they are smaller or of different sizes, crowding in clusters, and in more extensive crops—*strophulus confertus* or *rank Red gum*; and in others, the eruption appears in little circular clusters, somewhat solitary, and generally on each arm or cheek; more commonly, however, flying from part to part—*strophulus volatilis*. Sometimes the papulæ are minute, hard, and of a whitish colour, surrounded occasionally by a reddish halo—*strophulus albidus* or *white gum*,—or the pimples are large, glabrous, shining, of a lighter hue than the skin, and without a halo or blush—*strophulus candidus*.

In the majority of cases, strophulus seems to be connected with the process of the first dentition. It generally requires and receives but little attention. It is commonly sufficient to administer an occasional dose of rhubarb and magnesia. The cause is generally transient; and as it yields, the disease yields likewise.

Robley Dunglison.]

SUCCESSION OF INHERITANCE.—LEGITIMACY.—It would be more than superfluous to dwell, even for a moment, on the immense importance of the interests which are involved in the determination of the question of *legitimacy*. It is sufficient only to remember that the honour and purity of virtue, and the succession to rank, titles, and property, not unfrequently depend solely for their invalidation or establishment on the settlement of this question; while the fact to be established is unfortunately one which does not always admit of being tested by any fixed criterion either in law or physiology, but on every new occasion of doubt or difficulty depends for its elucidation on the contradictory evidence of witnesses, and the opinion that may, in the particular instance discussed, be formed by judges or committees, of the connection between facts stated and admitted, and their relations with other circumstances, in general not admitting of any certain or satisfactory method of proof.

Our ancestors of the olden time were satisfied with a very simple rule on the subject of legitimacy:—*the husband of the woman was the father of her children*, unless he happened to be impotent or "beyond the four seas" during a period exceeding that of gestation; so that, in fact, the wife might with impunity, so far as the law was concerned, have twenty children by as many paramours, and the law would father them all on the husband. Absolute proof of paternity being nearly impossible, recourse was had to presumptions, and of these the most natural, reasonable, and satisfactory is that founded on marriage; and hence the rule of the civil law, *pater est quem nuptiæ demonstrant*, was very early adopted, and could not be impeached, except in the two cases already mentioned—impotence of the husband, or his absence from the realm. No rule of law was ever more strictly adhered to than this for a period of nearly five centuries, the judges with singular pertinacity resisting every effort that was made to infringe it.

The old English law, as laid down by Bracton, and copied from him in *Fleetwood*, differed considerably from this, and recognised three valid objections to legitimacy,—impotence, non-access, and all conclusive presumptions deduced from physical and moral causes; and so far did they carry the latter, that a refusal by the husband to recognise the child was held sufficient, so that it was in the power of any unnatural father to disinherit his offspring, and avoid the trouble and expense of rearing it. In all Bracton's cases this arbitrary recognition appears to have been a *sine-qua-non*, but the rejection of a once acknowledged child was at no time evidence.

These statements are confirmed by Britton; but no sooner had the common law struggled into respectability and thrown off the bondage of canonists and civilians, than a system entirely different grew up; and from the time of Edward III. until that of Lord Hale, one simple and inviolable rule prevailed, viz. that every child born in wedlock was legitimate, unless the husband was impotent or beyond the four seas (*extra quatuor maria*) at the epoch of conception.*

* For cases on the dictum of Hale, see Pendrill v. Pendrill, Strange, 925; Rex v. Reading, Case, Temp. Lord Hardwicke, 82; Rex v. Luffe, 8 East, 208. See, also, Rex v. Rook, Jay. Rep. 61, and Rex v. Inhab. of Bedell, Andr. 8.

That great judge resolved to purify the law from its manifest absurdity, and was the first to admit evidence of the non-access on the part of the husband without the foolish condition of *ultramarine* absence. This occurred in the case of Dickens v. Collins, of which unfortunately no report exists; but this was the whole amount of innovation. It was, however, regarded as of the greatest consequence, and immediately followed by the judges; and in a very important case in the beginning of the eighteenth century it was laid down by Lord Chief Justice Raymond, that the old doctrine was not to be held, but that the jury were at liberty to consider the point of access. This was the case Pendrill v. Pendrill:—the husband, after cohabiting with his wife for some months, went to Staffordshire, the wife remaining in London. At the end of three years the wife had a son, who rested his claim upon the presumption of law in favour of legitimacy, he being born in wedlock and his father *within the four seas*. Strong evidence was admitted that the husband had never left his house in Staffordshire; and so upon the ground of non-access the jury found the son a bastard. (2 Strange, 924; see, also, Paris and Fonblanque, vol. i. p. 216.)

Neither Lord Hale nor his successors ever thought of admitting evidence that did not demonstrate the absolute *impossibility* of access, as where the husband was in a different country, or entirely disabled by disease during the period of conception. Thus in Lomax v. Holmden and another, 2 Strange, 490, which was a trial in ejectment, where the question was whether the lessor of the plaintiff was son and heir of Caleb Lomax, deceased, the defendants gave in evidence the inability of the ancestor from a bad habit of body; but their proofs going only to *improbability* and not *impossibility*, there was a verdict against them. The disavowal of the offspring by the husband was of no avail, nor was the wife allowed to prove his non-access, although she might the access of another man.

As late as 1807, Lord Ellenborough said, "If we may resort to all impediments arising from natural causes, we may adopt other causes equally conclusive to show the *absolute physical impossibility* of the husband being the father, I will not say the *improbability* of his being such; for upon the ground of improbability, *however strong*, I will not venture to proceed."

How strictly such a rule was acted upon by one of our most acute judges, the following case, decided in 1792 by Sir William Wynne, will show. It was a cause in the Prerogative Court of Canterbury, for the administration of the effects of John Newport, Esq. The intestate was the only son of Ann the wife of Ralph Smyth, and was born when his mother had left her husband for some years to live with Lord Bradford as his mistress. He was educated by that nobleman as his son, inherited from him a splendid fortune, and assumed his family name by act of parliament.

The separation between Mr. and Mrs. Smyth was of an amicable nature; he appeared rather to promote her intercourse with Lord Bradford, and allowed her a small annuity. For the payment of this they had occasionally brief interviews, but there was no proof of any such having taken place for some time previous to the birth of her child.

Mr. Newport, on his return from abroad, became insane, (the disease was hereditary in Lord Bradford's family,) and he was placed under the care of some members of it. Suits in chancery were instituted respecting his property, and Mr. Smyth as his mother's husband was made party to them; but although the latter gentleman would have derived great pecuniary advantages from claiming the lunatic as his son, he studiously avoided all declarations to that effect; and both acted himself, and allowed the court to act, as if no doubt could be entertained of Mr. Newport's illegitimacy.

The lunatic survived his mother and her husband, and died possessed of property which had accumulated to an immense amount, which property was claimed by the grand-nephew of the deceased, Mr. Smyth; whereupon Sir William Wynne decided that the legitimacy of Mr. Newport was established, and consequently in favour of the claimant. His reasons were, that the circumstance of the husband and wife both residing in London for some time previous to the birth of the child was proved in evidence. It was also proved that they occasionally met; that she visited him at his lodgings in Holborn to receive her annuity, and on those occcasions remained alone with him in his room, which was a bed-room, for half an hour at a time. It seemed probable that he occasionally dined with her at a house of Lord Bradford's, at Hammersmith. Thus possibility of access was established, and the learned judge delivered his opinion as to the legal question in these words:—"The law of England on this subject, as now settled, I take to be this: that if such proof can be given, of whatever kind, as shall satisfy legally the mind of the court that the husband had no access to the wife at the time when the child must have been begotten, the child is a bastard, though born of a married woman in the lifetime of her husband; but if the husband and wife were so circumstanced that access must be presumed between them (as if they lived in the same town or place, and cannot be proved by persons who have watched them never to have come together); or if by direct evidence it can be proved that they had access to each other, in such a case I take it the son is legitimate, *notwithstanding any circumstantial evidence that may be given to the contrary*."

Such appears to have been the law on this subject until the year 1813, when it was first disturbed and altered by a judgment of the House of Lords in the Banbury peerage case, in which, although constant access was admitted and impotence not proved, the offspring was declared illegitimate *from circumstantial evidence*. On this occasion Lord Ellenborough proposed that "it was desirable to have the opinion of the judges, whether any circumstances could rebut the presumption of access," and "whether there existed in this case any such circumstances." Accordingly, several important queries were submitted to them; and amongst the most material of their answers were the following:—"That the presumption of legitimacy arising from the birth of a child during wedlock, the husband and wife not being proved to be impotent, and having opportunities

of access to each other during the period in which a child could be begotten and born in the course of nature, may be rebutted by circumstances indicating a contrary presumption.

"That in every case where a child is born in lawful wedlock, the husband not being separated from the wife by a sentence of divorce, sexual intercourse is presumed to have taken place between the husband and wife, until that presumption is encountered by such evidence as proves, to the satisfaction of those who are to decide the question, that such sexual intercourse did not take place at any time, when by such intercourse the husband could, *according to the laws of nature*, be the father of such child.

"That the presumption of the legitimacy of a child born in lawful wedlock, the husband not being separated from his wife by a sentence of divorce, can only be legally resisted by evidence of such facts or circumstances as are sufficient to prove to the satisfaction of those who are to decide the question, that no sexual intercourse did take place between the husband and wife at any time, when by such intercourse the husband could by the laws of nature be the father of such child."*

Lords Ellenborough, Eldon, and Redesdale concurred in their opinions on this case; and their arguments may be thus briefly stated. "This is a question of presumption: the presumption of legitimacy arising from the fact of marriage may be rebutted by circumstances inducing a contrary presumption. Impotence is such a circumstance; so, also, is any other cause or combination of circumstances, proving that the husband could not be the father of the child. It is agreed that neither impotence nor want of access is proved in the present instance; there is, therefore, no *physical* impossibility of Lord Banbury's being the father. But in the absence of such evidence the question may be decided on the ground of a *moral* impossibility, which the conduct of the parties in this case establishes."

Lord Erskine made great exertions on the opposite side and in favour of the legitimacy, but he was unsuccessful; and on the 18th of June, 1813, the house resolved that the petitioner had no claim to the title, dignity, and honour of Earl of Banbury. (See Lords' Journals, vol. xlix. 178.)

It appears, then, that the law formerly stood thus:—

Presumption of legitimacy may be rebutted by *physical* evidence *proving* the contrary; and that, since the Banbury peerage case, it stands thus:—

Presumption of legitimacy may be rebutted by *physical* evidence *proving*, or by *moral* evidence *rendering probable*, the contrary.

Accordingly, Mr. Phillips lays it down as a doctrine to be extracted from this case, "that the jury may not only take into consideration proofs tending to show the *physical impossibility* of the child in wedlock being legitimate; but they may decide the question of paternity by attending to the relative situation of the parties, their habits of life, the evidence of conduct, and of declarations connected with conduct, and to every induction which reason suggests for determining upon the probabilities of the case." (Treatise on the Law of Evidence, vol. ii. p. 288. Edit. 1829.)

Blackstone lays down the law on some of the most material points connected with this subject, thus: (Commentaries, vol. i. p. 454 et seq. Edit. 1832.)—"A bastard, by our English laws, is one that is not only begotten but born out of lawful matrimony. The civil and canon laws do not allow a child to remain a bastard, if the parents afterwards intermarry; and herein they differ most materially from our law; which, though not so strict as to require that the child shall be *begotten*, yet makes it an indispensable condition, to make it legitimate, that it shall be *born* after lawful wedlock.

"As bastards may be born before the coverture or marriage-state is begun, or after it is determined, so also children born during wedlock may, in some circumstances, be bastards. As, if the husband be out of the kingdom of England, or, as the law somewhat loosely phrases it, *extra quatuor maria*, for above nine months, so that no access to his wife can be presumed, her issue during that period shall be bastards. But generally, during the coverture, access of the husband shall be presumed, unless the contrary can be shown, which is such a negative as can only be proved by showing him to be elsewhere; for the general rule is *præsumitur pro legitimatione*. In a divorce *a mensâ et thoro*, if the wife breeds children they are bastards; for the law will presume the husband and wife conformable to the sentence of separation, unless access can be proved; but in a voluntary separation by agreement, the law will suppose access unless the negative be shown. So, also, if there is an apparent impossibility of procreation on the part of the husband, as if he be only eight years old, or the like,† then the issue of the wife shall be bastards. Likewise, in case of divorce in the spiritual court *a vinculo matrimonii*, all the issue born during the coverture are bastards, because such divorce is always upon some cause that rendered the marriage unlawful and null from the beginning.

"From what has been said it appears that all children born before matrimony are bastards by our law; and so it is of all children born so long after the death of the husband, that by the *usual*

* In the celebrated case of Morris v. Davis, Mr. Justice Gaselee, who presided at the third trial of that cause in 1828, in summing up his charge to the jury, made the following observations on the subject of *access* and *intercourse:*—"The Banbury peerage is now the law. There is proof that the husband was in the wife's neighbourhood, and this is *primâ facie* evidence of intercourse: but it is competent in the defendants to rebut the presumption thus raised, by anything that amounts to satisfactory evidence that no intercourse took place. The question then will be, first, whether you are satisfied there was that access between the husband and wife, that sexual intercourse *might* take place: secondly, whether the evidence satisfies you that no such intercourse did take place? If it might take place, the law presumes it did, unless the contrary is proved. Many witnesses proved opportunities. If you are satisfied there were opportunities, the law says the child is the child of the husband."

† It would be very difficult to assign the opposite limit of advanced age which would preclude the possibility of procreation. "There is," says Lord Erskine, "no statute of limitations on the powers and faculties of man. Instances of robust longevity might be cited still more extraordinary than that of Lord Banbury. Sir Stephen Fox married at the age of seventy-seven, and had four children. The first child was born when the father was seventy-eight: the second and third were twins in the following year; and the fourth was born when the father was eighty-one. The Earl of Ilchester and Lord Holland can vouch for the accuracy of this statement, and I believe their genealogy has stood hitherto unquestioned."—*Speech on the Banbury Case.*

course of gestation they could not be begotten by him. But this being a matter of some uncertainty, the law is not exact as to a few days." (Comm. vol. i. p. 456.)

In the foregoing statements of the law connected with this subject, there is frequent reference to "the usual period of gestation," "the course of nature," "the laws of nature," &c. a conformity to which, in the birth of any individual whose legitimacy may happen to be questioned, constitutes one of the requisites essentially necessary to satisfy the law; "but this being," to use the words of Blackstone, "a matter of some uncertainty, the law is not exact as to a few days." Unfortunately the law is not exact as to any time, however unusual, and affixes no limit; and whenever a question of legitimacy is brought before the judges involving the determination of the usual period of gestation in women, and the variations to which it may be liable, the matter is made on every new occasion of the kind a subject of discussion, to be decided by the evidence of witnesses examined at the time: and the facts proposed to be investigated in reference to such questions generally are:—1. the natural period of gestation in women; 2. premature births; 3. the possibility of protracted gestation; each of which we shall now proceed to consider.

1. *Natural period of gestation in women.*—With regard to this point it must be confessed that our knowledge is by no means so precise as might be at first sight expected in a matter apparently capable of being made the subject of daily observation; but the fact is, that we are very rarely able to ascertain with anything like certainty the exact time of conception, and consequently having in general only one end of the chain, we can have no certain mode of counting the number of links of which it consists. Still, however, it appears to us that we are in possession of facts sufficient to warrant our belief that the natural period of gestation is ten lunar months, or forty weeks, amounting to 280 days, which is also the period acknowledged in law. (See Coke upon Littleton, 123, b.) A good deal of the confusion on this point seems to have arisen from considering forty weeks and *nine calendar months* as one and the same quantity of time, whereas, in fact, they differ by from five to eight days. Nine calendar months make 275 days, or, if February be included, only 272 or 273 days, that is, thirty-nine weeks only instead of forty. Yet we constantly find in books on law and on medical jurisprudence, the expression, "nine months or forty weeks."* Another source of confusion has evidently had its origin in the indiscriminate use of lunar and solar months as the basis of computation in certain writings of authority. This appears to have occurred in the Roman laws on this very subject. Hippocrates, in his book "De Septimestri et Octomestri partu," calculates by lunar months, while in several others of his works solar months are uniformly those referred to, and the Roman laws were founded on his authority. In like manner we find in the book of Esdras, (2 Esdras, iv. 40), "nine months" spoken of as the fixed time of gestation; and in the Wisdom of Solomon, (Chap. vii. 2.), "ten months" is the period assigned for the perfection of the child in the womb; a discrepancy which could only have arisen from the writers using different divisions of time.

An opportunity was lately afforded us of observing the natural term of gestation under circumstances in which the day of conception was known with certainty. A lady who had been for some time under our care in consequence of irritable uterus, went to the sea-side at Wexford in the month of June, 1831, leaving her husband in Dublin, a temporary separation being considered essential to the recovery of her health. They did not meet until the 10th of November, on which day he went down to see her; and being engaged in a public office, he returned to town next day. The result of this visit was conception: before the end of the month she began to experience some of the symptoms of pregnancy; and when she came to town on the 22d of February she was large with child, and had quickened on the 29th of the month preceding. Her last menstruation had occurred on the 18th of October. She went on well through her pregnancy; and the writer was called on to attend her in labour on the 17th of August, when she gave birth to a healthy child after a labour of a few hours' duration. Here the gestation exceeded nine calendar months by just one week, making exactly 280 days from the time of conception. It may be observed that this was the earliest instance of quickening which has presented itself to the writer, occurring as it did before the completion of the twelfth week.

2. *Premature births.*—The premature birth of children not unfrequently gives rise to discussions of a very delicate and important nature, involving on the one hand the legitimacy of the child, and on the other the honour and fair fame of the mother, and consequently the happiness of families, when suspicions are entertained that the development of the fœtus does not correspond to the period which ought to have been that of gestation, dating from the time of marriage, or the return of the husband, and so forth. It is, therefore, essentially necessary that all who are likely to be consulted on such matters should possess themselves with as accurate a knowledge as possible of the progressive development of the embryo, and the marks or characters which belong to each successive period of intra-uterine existence, even in the earlier months. The full details of this subject do not properly belong to the discussion of the question of legitimacy, the investigation of which can only become of interest or importance when the foetus has acquired such a degree of maturity as is likely to render it viable or capable of sustaining its functions independently of the mother. There will then be two distinct points of view under which we must consider this part of the subject. We must inquire, first, what is the earliest period of gestation at which the condition of viability† may be expected to exist; and,

* Vide Coke upon Litt., loc. cit., and Paris and Fonblanque, vol. i. p. 241. Smith's Principles of Forensic Medicine, p. 491. Dewees' Compendium of Midwifery, p. 164. Mr. Burns more accurately says, "nine calendar months and a week." Principles of Midwifery, p. 168.

† Viability is thus defined by Capuron:—"La viabilité pour un enfant qui vient au monde n'est autre chose que la possibilité de vivre complètement et aussi long tems que le commun des hommes; c'est à dire de devenir un adulte, un homme fait, un véritable membre société."—Médecine Légale, p. 152.

secondly, can we admit that a child may in six or seven months acquire that degree of maturity which we observe to belong to those which have continued in the womb the whole natural period of gestation?

With regard to the first of these questions, we think experience warrants us in adopting as correct the opinion of Wm. Hunter, given in answer to an interrogatory put to him on this subject:—"A child may be born alive at any time after three months; *but we see none born with powers of living to manhood*, or of being reared before seven calendar months, or near that time.* At six months it cannot be."† We do not take into consideration, or attach any value to such rare and wonderful histories as those of Fortunio Liceti, the Italian physician, who was said to have been born at four months and a half, and to have attained the age of manhood; nor to that of Cardinal Richelieu, in whose case the parliament of Paris decreed that the infant at five months possessed that capability of living to the ordinary period of human existence which the law of France required for establishing its title to inheritance.

In the consideration of the second point, we have to contend with a very formidable difficulty, intrinsic to and inseparable from the subject,—namely, the great variety constantly observed in the size, weight, strength, and appearance of children at the full time. Some of these, for instance, do not exceed seven pounds in weight, while occasionally we meet with instances where they are of double that weight. This should at least make us extremely delicate in forming, and cautious in pronouncing our opinion, particularly when the period of gestation may have advanced to within a month of its expected termination, in which case it might be impossible for us, with all our care and all our knowledge, to draw the distinction between a child of eight months and one of nine.

But in such case as occurs from time to time, where a woman six or seven months after marriage, or the return of her husband, produces a healthy well-formed child of the *full size* and *development*, we need hardly hesitate about its illegitimacy; at least we never saw an instance where a child, avowedly of six or seven months' growth, presented an appearance even remotely resembling that of a full-grown and matured fœtus. Even though the size alone may not enable us to distinguish the one from the other satisfactorily, there are several characters of imperfect development which mark the really premature fœtus whatever may be its size; while, on the other hand, there are others which accompany the fully matured child, although deficient in bulk.

Of the latter kind are the colour and firmness of the skin; the perfect condition of the hair and nails; the full development of the lower extremities; the solidity of the bones of the cranium, and their close approximation along the sutures. If along with these we find that the child is vigorous and active, crying strongly soon after birth, and taking the nipple readily or even eagerly, and sucking it effectually; that its length measures from 19 to 21 inches,‡ and that the *middle point* of that length *falls at the umbilicus*; we have an assemblage of characters which ought to leave but little doubt of maturity having been attained. The situation of this middle point was first proposed as a test of the age of the fœtus by Chaussier, and his observations have been since confirmed by several others.§ From the trial we have made of this test, we are disposed to attach considerable value to it. [Yet it is far from being decisive; as has been shown elsewhere.] (See the article INFANTICIDE, [in vol. ii. p. 679.])

It should be recollected, also, that there are certain women to whom it is peculiar always to have the time of delivery anticipated by two or three weeks, so that they never go beyond the end of the thirty-seventh or thirty-eighth week for several pregnancies in succession.‖ La Motte (Liv. i. chap. 28,) mentions two women who always brought forth at the end of seven months; and the same thing happened to the daughters of one of them. Van Swieten (Comment. vol. xiv. p. 6, 7,) takes notice of a similar circumstance; as does also Fodéré. (Méd. Lég. vol. ii. p. 28.) A member of the writer's family never passed the end of eight months in three successive pregnancies; but such cases cannot be looked on as instances of gestation *completed*, but of premature labour from some infirmity of the system, or indisposition in the uterus to enlarge beyond a certain size; nor is it contended or asserted by these writers that the children had acquired their full growth: in the instances occurring under our own observation they certainly had not.

[In 1835, an investigation took place before one of the Presbyteries of Scotland, in regard to certain reports which had been circulated to the prejudice of a minister of the district. The marriage of this gentleman took place on the 3d of March, and his wife gave birth to a female child on the 24th of August, that is 174 days after the marriage, and the child continued to live until the 20th of March 1836. When born it was very weak, and did not weigh more than three pounds. The birth of a living child, together with its surviving for so long a period, led to the report, that there must have been intercourse between the parties before marriage. The case went through several appeals, and was not fully settled until May 1839, when the libel was found not proven, and the defendant was absolved from censure. Many medical witnesses in Scotland, and others from France, Italy, and Germany gave evidence,

* The earliest instance we have met with were the following:—A fœtus which at the utmost could only have completed the fifth month, and which lived for a few minutes; and another of five months and a half, which lived for four hours.

† "Ante septimum mensem fœtus non potest supervesse."—*Haller*, Elem. Phys. vol. viii. p. 423. The French civil code, however, regards as legitimate and viable all children born after 180 days, or six months.—*Capuron*, Cours d'Accouchement, p. 69.

‡ Rœderer concludes from his examinations, that the average length of a male at the full time is twenty inches and a third: while that of a female is nineteen inches and seventeen-eighteenths.

§ *Capuron*, p. 172. *Hutchinson*, pp. 6–14. *Fodéré*, vol. ii. p. 149. *Burns*, pp. 114, 118. *Metzger*, by Ballard, 168. *Beck*, p. 112 et seq.

‖ While writing these observations we met with an instance of this. The writer was engaged to attend a lady in her fifth confinement, who told him a month beforehand that from particular circumstances she knew her time would be up about the 23d of the month, but that she expected her labour to occur about the 9th, as she had on the two former occasions anticipated by two weeks; she became in labour on the night of the 10th, and was delivered on the 11th.

the majority of them being in favour of this having been a legitimate and premature birth. (*Lond. Med. Gaz.* xvii. 92. *Med. Chir. Rev.* xxxi. 424. A. S. Taylor, *Manual of Medical Jurisprudence*, p 610, Lond. 1844; and Guy, *Principles of Forensic Medicine*, p. 173, Lond. 1843.)]

3. *Protracted gestation.*—The possibility or otherwise of an extension of the ordinary period of gestation has been for a very long time, and still continues, a question of very warm debate; some maintaining that the time is fixed and admits of no variation; while others, who agree as to there being a certain period most frequently observed, believe that it is not exempt from variety, and may be prolonged. In this view of the subject we entirely coincide; but at the same time we are ready to confess that many of the arguments brought forward in support of it have been vague and nugatory in the extreme, and several of the cases adduced totally unworthy of belief.

We cannot imagine why gestation should be the only process connected with reproduction for which a total exemption from any variation in its period should be claimed. The periods of menstruation are in general very regular; but who is there who does not know, that as there are on the one hand women in whom the return of that discharge is anticipated by several days, so there are also many in whom the return is postponed an equal length of time without the slightest appreciable derangement of their health! (For a case in which the regular menstrual period was five weeks, see Burn's Principles of Midwifery, Edit. 7, p. 168.) Again, menstruation and the power of reproduction in the female very generally, indeed almost universally, cease in these countries about the forty-fifth year; yet occasionally instances are met with in which both are prolonged ten or fifteen years beyond that time of life; and a similar variety is observable in the period of the first establishment of that function in the system.* If we turn our attention to brutes, the conditions of whose gestation so closely coincide with those of the human female, and are less exposed to have it disturbed, we cannot for a moment doubt the fact that there is a great inequality in the term of gestation in different individuals of the same species. The experiments and observations of Tessier, which were continued through a period of forty years, contain facts and information more than sufficient, as appears to us, to satisfy any one on this point with regard to the lower animals. (Magazin Encyclopédique, quatrième année, t. vi. p. 7; or Beck's Medical Jurisprudence, p. 194. Edit. 1829. See, also, *Capuron*, Cours d'Accouchement, p. 71. Edit. 1833.)

[Similar results were obtained by Lord Spencer from observations made on 764 cows. (*Journal of the English Agricultural Society*, part ii. 1839. See also on this subject the writer's *Human Physiology*, 5th edit. ii. 426, Philad. 1844.)]

There is a very curious fact mentioned by the late Sir Everard Home, which, if strictly correct, would go a great length in strengthening the argument from analogy. He says that "where the female of one species of animals breeds from the male of another, the utero-gestation of whose species is different in its period, there appears to be no approximation in the time in which the hybrid is brought forth; but the longest term of the two is the time of such utero-gestation. Thus the mare covered by the ass goes eleven months, her usual period; and the ass covered by the horse goes *eleven months*, although *ten is her usual period*."—Philos. Trans. 1822.

The circumstances of incubation are by no means without some weight, when we observe that of a clutch of eggs laid by the same hen and covered alike during the hatching time, some will produce the chick twenty-four, thirty-six, or even forty-eight hours later than the rest,—an excess in the period amounting to one-tenth of the whole, and as great as that which facts appear to show may be *reasonably* contended for as affecting the period of human gestation.

But if we relinquish the less certain support of analogy, and resort to facts alone, as observed by ourselves, or others worthy of belief, we are quite satisfied that we are in possession of more than enough to prove the point; and let it not be forgotten that the combined testimony of all who have maintained the unvarying fixedness of the natural term, merely because they had known no instance to the contrary, (and they could have no other grounds for their belief,) is, after all, only negative evidence, and must fall before a single well-established instance in which that term was exceeded.

The weight of authority is altogether on the side of those who believe in the occasional protraction of gestation, in favour of which we find the following have recorded their opinions:—Antoine Petit (Recueil des pièces relatives à la Question des Naissances tardives, 1766), Lebas (in a Memoir in answer to Louis), Haller (Elementa Physiologiæ, vol. viii., pp. 421–425), Roussel (Systême de la Femme, p. 174 et seq.), Zacchias (Questiones Medico-Legales, lib. i. tit. 2, quæst. 1), Buffon-Levret (Art des Accouchemens), W. Hunter (Hargrave's Notes on Coke upon Littleton), Fodéré (Médecine Légale, vol. ii. chap. 8, sect. 4), Gardien (Traité des Accouchemens, tom. i. p. 162), Velpeau (Traité de l'Art des Accouchemens, tom. i. p. 388), Capuron (Médecine relative à la Grossesse, pp. 217–224; and, also, Cours d'Accouchement, p. 62, edit. 1833), Desormeaux (Dictionnaire de Médecine, t. x. pp. 374 and 462), Richerand (Physiology, p. 499, edit. 1824), Dewees (Compendium of Midwifery, p. 166), Hamilton (Letter to Dr. Granville, Lond. Med. Gazette, Dec. 12, 1829, p. 344), Burns (Principles of Midwifery, p. 168, edit. 7), Denman,† with a host of others, of less though by no means inconsiderable authority. Many of these have, in confirmation of their opinions, related the cases on

* It is a law of nature very constantly observed, that dentition should commence a few hours after birth, and that some of the teeth of children should show themselves within the first year at farthest, and instances where the cutting of the first teeth is deferred to the end of a year are unusual; yet in the case of one of the writer's children, the first tooth did not appear until the child had reached the twenty-first month of her age, she being at the time and previously in perfect health.

† We think ourselves justified in adding the name of Denman on the strength of the following passage in his Introduction to Midwifery, p. 254, Edit. 5. "At the expiration of forty weeks the process of labour commenceth, unless it be hastened or *retarded* by some particular circumstance."

which their conviction was grounded, and which, of course, had fully satisfied their minds; and we cannot believe it possible that all of these writers could have been mistaken in a mere matter of fact or observation, and that none of the cases which they have put on record were really instances of gestation prolonged beyond forty weeks. At the same time, we must add that the cases which appear to us to carry with them the fullest demonstration of their truth, are those in which the ordinary term was not exceeded by more than three or four weeks. Some of those which appear the most satisfactory, we shall now notice as briefly as possible.

Dr. Blundell, in his evidence before the House of Lords on the Gardner peerage case, declared that he knew positively one case in which conception must have taken place on the 9th of November, and delivery did not occur till the 23d of August following, making an interval of 287 days, or one week beyond the usual time. On the same occasion, Dr. Merriman deposed that he had known cases to be extended to 285 days; in two or three instances, to 296; in one, to 303; and in one to 309 days. (See, also, Med. Chir. Trans. vol. xiii.)

Wm. Hunter, in answer to a query on this subject (vide Hargrave's Notes on Coke upon Littleton), said, "The usual period is nine calendar months; but there is very commonly *a difference of one, two, or three weeks.* I have *known* a woman bear a living child in a perfectly natural way, *fourteen days* later than nine calendar months, and *believe* two women to have been delivered of a child alive, in a natural way, above ten calendar months from the hour of conception."

The late celebrated Professor Desormeaux says, "Observations well attested prove that the term may be prolonged beyond the usual period;" and he adduces the following case, occurring within his own observation, in a patient whom he attended:—"A lady, the mother of three children, became deranged after a severe fever. Her physician thought that pregnancy might have a beneficial effect on her mental disease, and permitted her husband to visit her, but with this restriction, that there should be an interval of *three months between each visit*, in order that, if conception took place, the risk of abortion from further intercourse might be avoided. The physician and attendants made an exact note of the time when the husband's visit took place. As soon as symptoms of pregnancy began to appear, the visits were discontinued. The lady was closely watched all the time by her female attendants. She was delivered at the end of nine calendar months and a fortnight, and Desormeaux attended her." Concerning this case, Raige-Delorme, who is rather sceptical about retarded gestation, declares that it is a fact possessing "the elements of a perfect demonstration," in favour of a protraction so far." (Dict. de Médecine, vol. x. p. 462.)

Dr. Dewees, the professor of midwifery at Philadelphia, relates "that the husband of a lady, who was obliged to absent himself for many months in consequence of the embarrassment of his affairs, returned, however, one night, clandestinely; and his visit was only known to his wife, her mother, and Dr. D. The consequence of this visit was the impregnation of his wife; and she was delivered of a healthy child in nine months and thirteen days after this nocturnal visit."*

Dr. Hamilton, the present distinguished professor of midwifery in Edinburgh, says, "But the result of my experience has been different; in one case, many years ago, the lady exceeded the tenth revolution (of the menstrual period) by twelve days; another lady exceeded it by sixteen days, and another by twenty-four days. This latter patient menstruated on the 1st of August, and was not delivered till the 28th of June. Another lady, the mother of a large family, exceeded her period by above a fortnight on the 4th of March, when her husband went to England, where he resided for some months; but she was not delivered till the 6th of December." (See Extracts from his Lectures, in a letter from him in Lond. Med. Gazette, Dec. 13, 1829.)

Mr. Burns says, "On the other hand it is equally certain that some causes which we cannot explain or discover, *have the power of retarding the process*, the woman carrying the child longer than nine months; and the child when born being not larger than the average size. How long it is possible for labour to be delayed beyond the usual time cannot be easily ascertained." "The longest term I have met with is ten calendar months and ten days, dated from the last menstruation. In the case of one lady who went this length, her regular menstrual period was five weeks, and in her other pregnancies she was confined exactly two days before the expiration of ten calendar months after menstruation." (Principles of Midwifery, p. 168. Edit. 7.)

In the case of Anderton against Whitaker, tried at Lancaster a few years since, intercourse between the parties was sworn to have occurred on the 8th of January, and never at any other time, and labour did not take place until the 18th of October, being the 284th day from the time of conception.

A case which occurred in the writer's practice, closely coinciding with those described by Mr. Burns, appears to be also an instance of gestation prolonged to a like degree. The circumstances were these:—A lady who had suffered from puerperal mania after her previous confinement in 1830, from which however she perfectly recovered, conceived again in the month of July, 1831, and miscarried in October, being then in the third month of pregnancy. She menstruated regularly in November and December, and for the last time in the first week of January, 1832. The writer did not see her again till the 24th of March, at which time she considered herself as in the third month of pregnancy; and as she was suffering pains, was fearful lest abortion was about to happen at the same period as before. It did not, however, occur, and she went on safely. At this date the symptoms of pregnancy were well marked; the areolæ were very distinct on the breasts, and the increased size of the abdomen was obvious to the eye, and corresponded to the supposed period of pregnancy. Quickening occurred on the 10th of

* An interesting fact connected with this case was, that at the time of conception the lady was within a week of her menstrual period, which was not interrupted; but the interruption of the next period gave rise to suspicion in her mind, which was realized by the birth of the child.

May, and all parties looked forward to the occurrence of labour about the middle of October, which, however, did not happen until the 14th of November.

Now in this case, if we suppose conception to have taken place very soon after the last menstrual discharge, as it most frequently does, we have an interval of exactly forty-four weeks, or 308 days, a period of time exceeding the usual one by four weeks, or twenty-eight days, one whole lunar month. And on the other hand, if we suppose conception to have taken place on the very last day of the interval between the two menstrual periods, we should still have an instance of gestation occupying forty-one weeks and two or three days. And lastly, if we assume the middle period of the interval as the time of conception, we should have an interval of forty-two weeks and a half; and certainly, when we saw her in March, she had all the appearance of a woman in the third month of pregnancy. It is also to be recollected that quickening occurred on the 10th of May, just sixteen weeks after the probable period of conception, or eighteen weeks from the time of the last menstrual period, and nearly twenty-seven weeks before labour. We may add that this was the third instance of the same kind which has come under our own observation.

We cannot close this part of the subject without directing the reader's attention to the cases related by Dulignac (in the Causes Célèbres,) Fodéré, (Médecine Légale, vol. ii. ch. 8, p. 195,) and Dr. Granville, (in his evidence before the House of Lords); which, occurring as they did in their own wives, and under circumstances where there could be no possible motive to deceive, and where every successive period of the gestation was carefully observed by persons so eminently qualified to form a correct opinion, are entitled to great attention.

It appears to us that several of the foregoing cases ought to carry conviction to any unprejudiced mind; and it is to be recollected, that if any one of them be true, it establishes the fact in defiance of all objections made by those who deny it because they have not met with any case of it themselves, or because they conceive it to be inconsistent with the usual or established order of nature.* "We ought to admit it," says Fodéré, "not merely because it is possible, but because we have abundant proof that it has happened."

[Cases of single intercourse, if well attested, would be sufficient to settle the question; but it is difficult to obtain them in any considerable number. The following cases are recorded: (Guy's *Principles of Forensic Medicine*, p. 167, Lond. 1843.)

	Duration.
A case by Dr, Nixon,	273 or 276 days.
Dr. Montgomery, before referred to	280 "
Dr. Forster of New York,	283 " 285 "
Seduction case (Lancaster assizes,)	284 "
Dewees,	286 " 288 "
Desormeaux,	290 "
Dr. Reid,	292 " 293 "

The results of these cases are as follows:

Average of the 7 cases,	284 or 285 days.
Minimum,	273 " 276 "
Maximum,	292 " 293 "
Range,	16, 17, 19 " 20 "
Excess above 280 days,	12 " 13 "
Excess above 9 calendar months,	16 or 17 to 19 " 20 "

On a trial for seduction in this country, the female swore to a single connection on the 16th of October, 1840. The child was born on the 10th of August, 1841, being forty-one weeks and four days, or 291 days. (Dr. T. R. Beck, *Amer. Journal of the Med. Sciences*, April 1842, p. 291.)]

In the next place we find that the laws of different countries have been framed from a persuasion on the part of the legislators that a protraction of the ordinary term of gestation might occur. Thus the law of France, the Code Napoleon, provides that the legitimacy of a child born 300 days after the death or departure of the husband shall not be questioned; and the child born after more than 300 days is not declared a bastard, but its legitimacy may be contested. The Prussian civil code declares that an infant born 302 days after the death of the husband shall be considered legitimate. The Scotch law is very precise:—"To fix bastardy on a child, the husband's absence must continue till within six months of the birth; and a child born after the tenth month is accounted a bastard." Our English law fixes no precise limit,† but the decisions that have been made from time to time are in favour of the possibility of protracted gestation.

The first satisfactory precedent of which we are aware is that *M.* 17 *Jac. B. R. Alsop and Stacey.* Andrews dies of the plague; his wife, who was a lewd woman, is delivered of a child *forty weeks* and *ten days* after the death of the husband; yet the child was adjudged legitimate, and heir to Andrews; for *partus potest protrahi* ten days *ex accidente.*

In the case of Forster and Cooke, (Brown's Chancery Cases, v. iii. 349,) a legatee filed a bill to have his legacy, and in order to define the person on whom he had claims, it was necessary to establish a will. But as it is requisite in chancery, for establishing a will, to have the heir-at-law before the court, it was a question to whom that title properly belonged, and so the period of gestation came to be considered. An issue was directed to try whether a child born forty-three weeks after the husband's death was legitimate; and it appears that the jury found this posthumous child to be the heir-at-law.

With the exception of the last-mentioned case, the question of protracted gestation seems to have escaped legal inquiry for more than two hundred years before the contest for the Gardner peerage, which recently excited so much interest in England, and gave rise to a very lengthened investigation.

The following were the facts of this remarkable case. In the year 1796, Captain Gardner (who afterwards became Lord Gardner) married Miss Adderley. They lived together as man and wife until the 30th of January, 1802, on which day Mrs. Gardner took leave of her husband on board-ship, and shortly afterwards he sailed to the West Indies; from whence he returned to England on the 11th of July following. For some time before, and also during the whole time of Captain Gardner's absence, Mrs. Gardner carried

* Ignorat naturæ potentiam qui illi non putat licere, aliquando, nisi quod sæpius facit.—*Seneca*, Nat. Quæst. lib. vii. cap. xxvii.

† "And so it is of all children born so long after the death of the husband that by the *usual course of gestation* they could not be begotten by him; but this being *a matter of some uncertainty*, the law is not exact as to a few days."—*Blackstone.*

on an adulterous intercourse. Upon Captain Gardner's return to England he found his wife with child; and she, hoping to be delivered within the proper time, made no secret of her pregnancy. When, however, she ascertained that the child could not be brought forth in time to be supposed to be Captain Gardner's, she declared that she had a dropsy, and informed his family that such was the case; and not only Captain Gardner, but the whole of his family, considered her as labouring under that complaint. On the 8th of December Mrs. Gardner was delivered in secret, in the presence of three persons only. The child was immediately removed to a lodging, and was afterwards christened by the name of the paramour, who brought it up, and in all respects treated it as his son. The birth of this child was carefully and successfully *concealed* from Captain Gardner, who did not even discover his wife's adultery till the year 1803. He subsequently obtained a divorce, and married again. He succeeded to the title in 1808, and died in 1815, leaving a son by his second marriage, who in the year 1824 presented his petition to the king praying to be entered on the parliament-roll as a minor peer. This was opposed by the young man, Henry Fenton Jadis, alias Gardner, who claimed to be eldest son of Lord Gardner, being born 311 days, or ten calendar months and nine days after Captain Gardner's departure from the country.

The petitions were referred to the committee of privileges, who called before them seventeen of the most eminent practitioners in midwifery in London and elsewhere, and examined them as to the possibility of such a protraction of the term of gestation as was here contended for. *Five* of these gentlemen maintained that the limits of gestation were fixed, and consequently denied the possibility of such a protraction. The other *twelve* supported the affirmative side of the question, and some of them adduced cases very strongly in favour of their views, particularly Drs. Granville, Conquest, and Blundell. Without wishing to enter into any criticism of the medical evidence, we cannot help remarking that two or three of the gentlemen who asserted forty weeks to be the ultimatum, admitted that it might be *exceeded* by a *few* days; and we would ask, if the principle of extension be admitted, how or by whom can the limits be assigned?

The House of Lords decided in favour of the petitioner and against the counter-claimant, Henry Fenton Jadis, *but not because of the time of his birth;* for Lord Eldon, who was their Chancellor, in giving his judgment, says, "It is not by any means my intention to do more than express my conviction that the petitioner has made out his claim,—that there are a great many more questions which arise in a case of this nature, almost the whole of which were considered in the Banbury peerage, but without entering into a detail of these questions, and *without entering into a discussion as to the ultimum tempus pariendi*, I am perfectly satisfied upon the whole evidence that the case has been made out." (Le Marchant's Report of the Proceedings, &c. p. 335.)

It was the *adultery* of the mother, and the *concealment of the birth from the husband*, which justified the house in refusing the petition of the counter-claimant. If the only point in the case had been that he was not the son of Lord Gardner because it was *impossible* his mother could have gone forty-four weeks with him, the House of Lords could not have declared him illegitimate; and when Lord Eldon said he should give his opinion "*without entering into the question of the ultimum tempus*," it is perfectly clear he did so for the purpose of guarding against the decision being ever taken as a precedent that a gestation protracted four weeks beyond the usual time should be a ground for bastardizing a child.

W. F. Montgomery.

SUCCUSSION. (See Chest, Exploration of the.)

SUDORIFICS. (See Diaphoretics.)

SUPPURATION. This term is employed to denote the process whereby a certain fluid, called *pus*, is formed or deposited on the surface or in the substance of any tissue. It seems to be strictly analogous to the words εμπυησις, εκπυησις, or απο-πυησις, which Hippocrates appears to have applied indiscriminately to the deposition of pus, without any reference to the precise nature of the process by which it is produced. The propriety of regarding this process only as a sequel of inflammation will be considered in the course of this article; but it is obvious, that where there may exist a doubt upon this head, it is much more consonant with the most approved method of scientific definitions to omit all mention of a questionable connection. We prefer to denote by *suppuration* that which it so clearly expressed by a term used by some French writers, *pyogénie*, which we believe originated with Brugmans. (Brugmans de Puogenia, sive Mediis quibus Natura utitur in creando Pure.—Groningæ, 1785. Dict. des Sc. Médicales, Art. *Pyogénie*.)

Having first treated of the properties of the fluid which characterizes the suppurative process, we shall, in the second place, proceed to the consideration of the precise nature of that process, and, lastly, to the various phenomena which accompany it.

Pus is obtained in its greatest purity from the surfaces of external ulcers which are in a perfectly healthy state, and show a disposition to heal, or from acute and healthy abscesses. As the qualities of this fluid are apt to vary considerably under the influence of even trivial causes, it is desirable to be particular in procuring that which is destined for examination, from a healthy source. Pus thus obtained, and absurdly denominated "*laudable*," is a homogeneous fluid, of the consistence of cream, of a white colour tinged with yellow, slightly tenacious, of a mild taste, and sometimes a mawkish smell, but at times also inodorous.

It is important, in a practical point of view, to ascertain what are the fixed and constant characters of pus. Most observers have stated that it consists of globules, which they consider its essential part; these globules float in a fluid possessing some resemblance to the serum of the blood, but from which it especially differs in being coagulable by muriate of ammonia. Hunter, (on the Blood, Inflammation, &c.) Home, (on Ulcers,) and Pearson, (Phil. Transact. an. 1810,) have considered

these globules as very similar to those of the blood; and Gendrin, who regards pus as blood in a transformed condition, and whose microscopic observations fully confirm those of MM. Prevost and Dumas, thinks that the only difference between them is, that the globules of pus are somewhat larger and of an opaque yellow colour. (Histoire Anat. des Infl. tom. ii.) Mr. Lister and Dr. Hodgkin, however, have expressed a different opinion; and they state, as the result of their observations, that the globules of pus are extremely irregular in size and figure, and "bear no resemblance to those of the blood." (Appendix to Hodgkin's Translation of Edwards on the Influence of physical Agents on Life, p. 441.) The following concise statement is from Kaltenbrunner, an exact and cautious observer. "In hominis pure meraco, quod ab aëris injuriâ bene erat munitum, granula æqualia, spherica, pellucida, nucleo penitus carentia, conspiciuntur nec aliud quidpiam. Aëri vero exposita, granula mox inter se conglutinantia et decomposita, floccos inæquales exhibent, qui sero quodam cincti sunt." (Experimenta circa Statum sanguinis et vasorum in Inflammatione, § 86.) In fine, Raspail, the latest systematic writer on organic chemistry, considers the existence of globules in pus entirely dependent on the presence of albumen in it, and observes that they so easily alter their shape that it is but lost time to devote any attention to microscopic observations upon it, with the hope of ascertaining any determinate form in them. (Nouveau Système de Chimie Organique, p. 508.)

The great importance which was formerly attached to the discovery of some criterion for distinguishing between pus and mucus, led physicians to subject the former fluid very extensively to the action of chemical re-agents; nor does it appear that any very useful results have been obtained from their numerous trials. The well-known essay of Darwin, entitled "Experiments establishing a criterion between mucilaginous and purulent matter," was composed in consequence of this question having been appointed the subject for the medal offered by the Æsculapian Society of Edinburgh, in 1778. From this essay we learn that he treated pus with pure water, with sulphuric and nitrous acids, and with caustic alkali and corrosive sublimate; he found that it was diffused through water, forming a white, milky, opaque fluid; in dilute sulphuric acid it formed a uniform turbid white mixture, from which, when allowed to stand, a white sediment was deposited; nitrous acid dissolved a considerable quantity with great effervescence, "the mixture became green and retained its froth," but the addition of water rendered it very turbid and milky; with caustic alkali it mixed intimately, "the pus seemed dissolved, but when water was added a separation took place:" however, in six subsequent experiments, in which pus from an abscess of the mamma was used, the alkali would not dissolve it, for it remained viscid at the bottom of a glass of lixivium, and nearly separable for the space of twenty-four hours; on adding water to this, a semi-pellucid matter fell to the bottom, which was more tough and viscid, and readily drawing into strings than the pus before the addition, and could not be separated into parts nor in the least diffused through the water.

It apppears that, prior to the period at which Darwin instituted the experiments which we have just alluded to, Mr. Hunter had been examining into the true nature of pus. His most important conclusions respecting it are thus summed up in one paragraph of his chapter on this fluid. "True pus," he says, "has certain properties which, when taken singly, may belong to other secretions, but when all joined form the peculiar character of pus, viz. globules swimming in a fluid, which is coagulable by a solution of muriate of ammonia, which no other animal secretion that I know of is," and, at the same time, a consequence of inflammation; these circumstances taken together may be said to "constitute pus." (On Inflammation, &c. p. 421.) His experiments with chemical agents were of a more general kind, and were tried upon organic and inorganic substances; the former being muscle, tendon, cartilage, liver, and brain; the latter pus and the white of egg. He dissolved each in sulphuric acid, and then precipitated the solution with vegetable alkali; the precipitates, when examined with the microscope, all appeared to be of the same nature, viz. "fleaky substances." Similar results were obtained with the volatile alkali, and when he dissolved the same substances in the vegetable caustic alkali and precipitated the solution with the muriatic acid.

The experiments of Dr. Pearson, published in 1810 in the Philosophical Transactions for that year, were attended with similar results to those we have detailed. This physician appears to have examined pus on a more extended scale than his predecessors. He applied his tests to that fluid under all its principal modifications. He differs from Hunter in ascribing the effects of muriate of ammonia on pus to inspissation, not to coagulation. He conceives that pus consists essentially of three parts: 1. a fibrinous matter, to which he gives the name animal oxide; 2. a limpid fluid resembling the serum of the blood; and 3. innumerable spherical particles visible only by the microscope; and that the varieties of this fluid, which are so constantly met with, relate to the differences of proportions of the essential substances and of adventitious parts; these latter are curdy masses, which he considers to consist chiefly of lymph, colouring particles of the blood, small sloughs from neighbouring parts, some fluid in a putrefied state, specific infectious particles, such as characterize the purulent matter of small-pox, syphilis, &c.

Beaumes and Andral, in repeating Darwin's experiments, have not met with results similar to his. Andral's experiments were upon various kinds of purulent matter, softened tubercular matter, creamy pus collected from cavities in the lungs of patients dead of phthisis, pus furnished by a pleuritic effusion, the sputa of persons in the last stage of consumption, the sputa of patients labouring under chronic pulmonary catarrh, mucus from the pharynx and nasal fossæ: "All these different fluids were alike dissolved by the sulphuric acid, which in every instance turned at first red and afterwards black, this latter change being accompanied with a considerable elevation of temperature. When a small quantity of water was poured into these solutions, they assumed a greyish white colour, and, if a little more were added,

a grumous curdy deposit was observed gradually forming in large quantities, and when after some hours it had completely subsided, the rest of the fluid became transparent and colourless." (Anat. Pathol. by Townsend. vol. i. p. 487–8.—*Beaumes*, Traité de la Phthisie Pulmonaire, tom. i.) Andral did not find that nitric acid dissolved pus, as stated by Darwin, but on the contrary it acquired a greater degree of consistence, and remained suspended in the form of yellow grumous masses without depriving the medium of its transparency.

Pus does not appear to be either alkaline or acid: that from scrofulous individuals has been said to be in general alkaline, and, as Gendrin remarks, contains a large proportion of soda and muriate of soda. It is said by several writers, Pearson in particular, that pus resists the putrefactive process for a considerable time, except when it happens to be mixed with adventitious particles which are prone to it. Shwilgué has given us the following chemical analysis of pus: albumen in a state of concretion; extractive matter; a substance bearing a considerable resemblance to adipocire; soda; muriate of soda; phosphate of lime, and other salts. (Vid. *Pinel*, Nosographie Philos. vol. ii. p. 10.) According to this analysis, Andral remarks, the only difference between the serum of blood and pus consists in the presence, in the latter fluid, of extractive matter, and in the particular state of the albumen. The nature of the extractive matter has been successively regarded as a peculiar animal substance, *sui generis*; as a combination of albumen and fibrine; as a peculiar modification of fibrine, incapable of coagulating spontaneously or of being organized; an animal oxide, (*Pearson*); in fine, it has been supposed to present a considerable analogy to the caseum of milk. (*Andral*, vol. i. p. 485.)

Pus was supposed to possess certain acrid qualities by which it exerted a solvent or corroding power on parts in its vicinity; this supposition, though abundantly contradicted by facts of every day's occurrence, was more decisively overthrown by a series of comparative trials instituted by Sir E. Home, in which he exposed a piece of muscle to the action of pus in an abscess, of pus from the same abscess removed from the body, and of animal jelly. By these experiments he ascertained that the pieces of muscle placed in the last two lost weight much more rapidly than that immersed in the pus of the abscess. That pus varies considerably in its qualities, and that it changes under the operation of even the most trivial causes, and in an incredibly short time, are facts well known to those who have had any experience in the treatment of external ulcers. An increase or diminution of the local irritation, a sudden mental emotion, the occurrence of a fresh disease, change of temperature, indigestion, the action of some medicines, have been severally known to produce these alterations; and there are some persons whose constitutions or idiosyncrasies are such that the purulent fluid secreted from them is always of a peculiar character, as a sero-purulent fluid, a grumous fluid with fragments of cheesy matter floating in it. (*Andral*, loc. cit.) Pearson and Hunter account for this alteration by the addition of adventitious substances in variable proportions, and the former author has founded upon it the following varieties of pus:—1. creamy homogeneous pus; 2. curdy pus; 3. serous pus, or sero-purulent fluid; 4. glairy muciform pus, or puriform mucus; 5. concrete or lardaceous pus; which last has been added by Andral.

Of the distinctive characters of pus and mucus we have little to add to that already mentioned in the article Expectoration. The test proposed by Dr. Young does not seem to have obtained very general attention; it is founded upon the opinion that globules constitute an essential part of pus, and their presence is necessary in order to the production of the phenomena which characterize the test. If we put a small quantity of the substance to be examined between two pieces of plate-glass, and holding it near the eye, look through it at a distant candle, we shall observe the appearance, even in the day-time, of a bright circular corona of colours, of which the candle is the centre; a red area, surrounded by a circle of green, and this again by another of red, the colours being so much the brighter as the globules are more numerous and more equable. If the substance be simply mucus, there will be no rings of colours, although sometimes there is a sufficient mixture of heterogeneous particles, even in mucus, to cause the appearance of a reddish area only about the candle. (Young on Consumption, and Cooper's First Lines; also Young's Med. Literature, p. 574.)

Suppuration is commonly considered as a sequel of inflammation, and is by far most frequently met with in practice as such. Whether it be connected with inflammation as an effect to its cause has been doubted; but it is certain that the greatest number of suppurations met with in the body externally or internally would not have existed had not inflammatory action been previously excited. It was Mr. Hunter's opinion that pus could not be formed without inflammation; and this is the opinion of many moderns; among whom we may mention the distinguished Dupuytren, who observes, "les tumeurs purulentes ont toutes la même origine—l'inflammation." (Dict. de Méd. et Chir. art. *Abcès*.)

It may be truly said, with Thomson, that there are perhaps few subjects in pathology concerning which more numerous or contradictory opinions have been entertained than concerning the formation of pus. Boerhave and many of his followers attribute it to the breaking-down of the solids, and to the changes induced in the extravasated blood. Sir J. Pringle and Gaber conceived that the serum, when stagnant, underwent a particular alteration, by which the gluten present in it was changed into a white opaque fluid called pus. Gorter and Quesnai ascribed it to changes induced upon the coagulable lymph; Hoffmann and Grasius to the melting down of the fat; and Dr. Stewart to the putrefaction of chyle. But these hypotheses, adds Dr. Thomson, have deservedly become obsolete, and may be allowed to remain so, for they throw no light whatever on the process by which pus is produced. That pus is a new secretion, or formed in an analogous way, is a doctrine sanctioned by high names; it was first suggested by Simpson of St. Andrews, from observing the effect produced by keeping up irritation of a wound, and the changes in the characters of the effused fluid cor-

responding to the variation in the degree of irritation. De Haen formed a similar opinion some years afterwards. He considered that pus was secreted immediately from the blood; "that although the blood appears to be homogeneous, nevertheless it is obvious that there is something in it which when collected appears to be tenacious, whitish, or yellowish, and which ought to be called the matter of pus." And again, he expresses himself as authorized to conclude that a certain disposition is set up in the blood, ("in sanguine nostro dispositionem dari,") by which the matter, called purulent or phlogistic, is separated from the remaining principles of the blood and expelled from the body in various ways. (Rat. Medendi, cap. xi. tom. i. Edit. Lugd. Bat.)

Mr. Hunter was an advocate for the opinion that pus is a secreted fluid. "The cellular membrane," says he, "or circumscribed cavities have their vessels but little changed from the adhesive state at the commencemont of the suppurative disposition, so that they still retain much of the form they had acquired by the first state, the discharge being at the beginning little more than coagulating lymph mixed with serum. This is scarcely different from the adhesive stage of the inflammation; but as the inflammatory disposition subsides, the new disposition is every instant of time altering these vessels to their suppurative state; the discharge is also varying and changing from a species of extravasation to a new-formed matter peculiar to suppuration. *This matter is a remove further from the nature of the blood, and becomes more and more of the nature of the pus;* it becomes whiter and whiter, losing more and more of the yellow and green which it is apt to give the linen that is stained with it in its first stages, and in consistence more and more viscid or creamy." — "By the formation of this new substance, the coagulating lymph which was extravasated in the adhesive state of the inflammation and adhered to the sides of the cells either in cut surfaces, as in wounds, in abscesses, or circumscribed cavities, is pushed off from these surfaces, and if it is the inner surface of a cavity it is pushed into it, so that the cavity contains both coagulating lymph and pus; or, if it is a cut surface, the coagulating lymph is separated from it by the suppuration taking place, and is thrown off; but as such surfaces are dressed immediately after the operation while the wound is bleeding, this blood unites the dressings to the sore, which is assisted afterwards by the coagulating lymph thrown out in the adhesive stage: the whole, viz. dressings, blood, and coagulating lymph, are generally thrown off together when suppuration commences on these surfaces. This is the process that takes place on the first formation of an abscess, and the first process towards suppuration in a fresh wound."

"Pus is not to be found in the blood similar to that which was produced in the first stage, but is formed from some change, decomposition, or separation of the blood, which it undergoes in its passage out of the vessels, and for effecting which the vessels of the parts have been formed, which produces a subsiding of the inflammation from which it took its disposition; hence it must appear that the formation of pus consists of something more than a straining of juices from the blood. Many substances, indeed, which appear to be considered as extraneous bodies in the blood, being only mixed with, and not making an essential part of that fluid, and perhaps even necessary to it, may pass off with the pus as with every other secretion; yet the pus is not to be considered on that account as simply parts of the blood unchanged, but we must look upon it as a new combination of the blood itself, and must be convinced that, in order to carry on the decompositions and combinations necessary for producing this effect, either a new or peculiar structure of vessels must be formed, or a new disposition, and of course a new mode of action, of the old must take place. This new structure or disposition of vessels I shall call glandular, and the effect, or pus, a secretion." (Hunter on the Blood, &c., 4to. ed. pp. 415–17.)

Gendrin, to whose writings we have had occasion to refer so extensively when treating of the properties of pus, has with great care examined the mode of formation of this fluid, and with no less clearness and precision detailed the results.

One of the earliest effects of inflammation upon a tissue is the effusion or infiltration of a fluid into its substance; after the inflammation has reached a certain height, this fluid alters in its characters, becomes gelatiniform and coagulated, and is deposited between the fibres of the part to the extent of the inflammation; and, if the inflammation be extremely violent, this coagulated matter becomes red, sanguinolent, with all the characters of blood itself; a transverse section of the inflamed organ exhibits this infiltration in all its degrees. The gelatinous infiltration is formed of a reddish matter, half serous, half gelatinous, in which the blood appears in scattered striæ. At a distance from the centre of the inflammation, the proportion of serum is greatest, and the colour of the infiltrated matter is yellowish; and at the extreme limits the infiltrated fluid is serous and colourless. There is a direct relation between these degradations of the infiltrated matter and the degrees of vascular injection and of inflammatory alteration of the substance of the inflamed organ. (*Gendrin*, p. 406 et seq.)

On inspecting a tissue some time in the state of inflammation, and which has passed into suppuration, this coagulated gelatiniform matter is still seen at the limits of the inflammation, and even in the centre amid many other alterations. It becomes of a yellowish-grey colour in other points, more numerous as we approach the true purulent infiltration, which becomes evident from the deposition between the fibres of a yellowish-white fluid, which seems less adherent and less identified with the tissue than that which is found in the earlier stages. When this fluid is examined with the microscope, pus is recognised by its characteristic globules; and in some points, where the infiltrated matter is about to become purulent, we find the true purulent globules mixed with small globules which retain a little of the rosy-greyish colour of the globules of the blood, deprived of the colouring matter by rest after their escape from the vessels; so that it would appear that the infiltrated pus is only a modification of the spontaneously coagulated matter, the infiltration of which preceded its presence. This fluid may be collected, and on examination will be

found to differ in nothing from the pus of abscesses, excepting that, not being as yet completely elaborated, it is still more or less gelatiniform in consistence.

When an artery is obliterated by means of a coagulum, if a ligature be placed round it above the obliteration, and a seton passed through the coagulum in the direction of the tube of the artery, suppuration takes place; the coagulum is then seen to soften, and to be progressively converted into pus, in the same manner as in the inflated tissues. A similar effect is produced by the introduction of any foreign body into the interior of an artery, after stopping the course of the blood in that portion of it, and removing the blood which it contained. The artery becomes closed by the formation of coagulable matter by adhesive inflammation; this effused matter becomes softened, and converted into pus immediately around the foreign body. From these facts Gendrin justly concludes, "*Il n'y a donc entre le fluide purulent des tissus enflammés et le fluide coagulable organisable qu'un degré de plus;*" and the reader will not fail to recognise the correspondence of these facts with the opinion already quoted from Mr. Hunter, in which he states *that the new-formed matter peculiar to suppuration is a remove further from the nature of the blood than the matter formed by adhesive inflammation.*

From the preceding observations, it would appear that pus is formed from the blood in the same manner as the fibrino-albuminous deposits which are consequent on inflammation. Whatever be the mechanism by which some of the healthy secretions are formed, it must be admitted that pus is produced from an inflamed surface in a similar or analogous manner. When so produced, it sometimes is collected into a separate cavity lined by a distinct membrane, which is formed, doubtless, by the condensation of the surrounding cellular tissue from pressure, combined with more or less of the adhesive inflammation. This membrane appears to have the power of secreting pus, as is indicated by the rapidity with which that fluid is reproduced in cavities which have been opened and evacuated. Pus is produced in an analogous manner from the surfaces of inflamed membranes which have not suffered any solution of continuity. Delpech is of opinion that wherever pus is formed, whether with or without solution of continuity, a pseudo-membrane precedes its formation, and is the immediate secreting tissue (*membrane pyogénique*).

[Of late, under the revival of microscopic inquiries, the subject of pyogeny has been closely investigated. The common belief is, that the process takes place both within and without the vessels; and the process is conceived to consist in the conversion of the globules of the blood and lymph, from which the colouring matter has been separated, into an opaque fluid nearly of the colour and consistence of cream. Magendie considers the essential difference between the terminations by resolution and suppuration to consist in the fact that, in the former, the molecules of blood reenter the circulation after having been softened; whilst, in the latter, they undergo further modification, and are expelled from the system. In the opinion of Gerber (*Elements of the General and Minute Anatomy of Man*, &c., by Mr. Gulliver, Lond. 1842), which has been embraced by many observers, those exudation corpuscles that lie beyond the vivifying influence of the suppurating surface, and are exposed to external agencies, cannot be expected to retain their vitality for any length of time: they begin to degenerate in their organization, and to suffer changes in their chemical constitution, whilst those that continue in immediate contact with the living structures advance in their organization. The globules that are cast loose then die. In ill-conditioned sores, the surface of which is not giving origin to new structure, the discharge is not found to contain the true pus globule; but in place of it are found what are called ichor globules, which have been considered to be evidently altered blood corpuscles. These points of microscopic anatomy require, however, renewed observation.

That pus may be formed from blood, apparently without any action on the part of the capillary vessels, is shown by the fact that distinctly purulent matter, according to M. Andral, has been found within coagula in the large vessels and in the heart, where there has been no suppurating surface—the result, it has been supposed by M. Piorry (*Traité de Méd. Pratique*), of hæmitis or inflammation of the blood; and that the vessels are in other cases implicated, is equally demonstrated by the circumstance that, when inflammation has continued for some time in any important organ, globules of pus are said by Mr. Gulliver (Gerber, *op. cit.*) to have been recognised in the blood. This, however, has been combated by M. Mandl (*Anatomie Microscopique*, 2e série, livr. 2), who maintains that the white globules, considered to be pus globules, originate in the fibrin as it coagulates on the object-glass of the microscope. They do not exist, he affirms, whilst the blood is circulating, and form either on the object-glass, or in the vessels after death. M. Mandl maintains that microscopic examination cannot determine whether the blood be pure or mixed with pus, as the purest blood contains globules in every respect like those of pus. The size of the pus globules varies between the $\frac{1}{80}$th, $\frac{1}{100}$th, and $\frac{1}{110}$th of a millimètre; a circumstance which he considers to decide the question of purulent absorption, since globules of this size could not pass through the parietes of the vessels.

When pus is effused from large membranous surfaces, as from the pleura, the membranes are often found thickened instead of extenuated; and this has been adduced as a reason for the belief that pus is not formed at the expense of the tissues. The phenomena of *ulceration*, on the other hand, seem to show that there may be solution of the solids; but the loss of parts is probably owing mainly to absorption. Why this absorption takes place under such circumstances, it is not easy to say. The remark of Dr. Alison (*Tweedie's Library of Practical Medicine*, 2d Amer. edit. ii. 76, Philad. 1842), that "the commencement of ulceration, as an effect of inflammation, implies merely that the attraction by which extra-vascular matters are constantly taken into the small veins, preponderates over that by which portions of the

blood pass out of the capillaries," is a mere expression of what is conceived to be a fact. It throws no light on the subject.

It would appear that the globules of various species of pus may be recognised by certain physical characters, which vary, however, according to the organs or tissues in which it is formed. It is thin and greyish in the bones; opaque and caseiform in the cellular membrane; flocculent in the serous, and greenish and thready in the mucous membranes; reddish in the liver, and yellowish-grey in the muscles. Magendie asserts, that one of the gentlemen present at his lecture, M. Kluge, was able to distinguish the different species of pus from each other, by simple inspection of the globules. He was subjected to a variety of tests, and in every instance was successful. Magendie took pus from the hospital, which had been collected in the lung, the pleura, the peritoneum, and the cellular tissue, and M. Kluge invariably announced its source with perfect accuracy. On one occasion, Magendie endeavoured to entrap him by presenting him with some artificial pus of his own making, as if it had been taken from one of his patients, but M. Kluge was not to be deceived. "This important fact," adds Magendie, "is another to be added to the list of experimental discoveries."]

The process of suppuration is essentially the same in all tissues; some, however, appear more prone to it than others. Referring to that section of the article Inflammation, headed, *Varieties of inflammation according to texture*, for details respecting suppuration in them, we shall merely observe that as to relative proneness to suppurations the several tissues rank as follow:—1. Cellular tissue; 2. skin and mucous membrane; 3. serous membranes; 4. vascular tissue. In bone, cartilage, or fibrous tissue, purulent deposits are of rare occurrence. In muscle they, in all probability, originate from the large quantity of cellular membrane found in that tissue. In the brain and nervous tissue they are occasionally met with. In glands and parenchymatous organs suppuration is proportionally more frequent, as those parts contain a larger quantity of cellular membrane.

Suppuration, as the sequel of inflammation, is generally attended with similar symptoms, and a fever of the same characters. The occurrence of rigors in the progress of the inflammatory fever, followed by a hot fit, is very frequently indicative of the formation of pus. In inflammation succeeding to injuries of the head, Dr. Thomson observes, these rigors are often the first constitutional symptoms which give alarm to the well-informed practitioner, for they are generally, though perhaps not always, an indication that inflammation has already made a dangerous, if not fatal progress. These rigors, also, accompany the formation of pus in the viscera contained within the cavities of the chest and belly, and are often the first symptoms which inform the practitioner that his endeavours to procure resolution have not been successful.

The practitioner must be on his guard to distinguish these rigors from those of intermittent fever, those which precede continued fever, or such as may depend on some local irritation, as that which arises so frequently from irritation in the urinary passages, and which forms one of the most remarkable features of urinary fever.

When the suppuration has become chronic, that train of constitutional symptoms which constitute hectic fever is present; nor does it subside till the suppuration has ceased, or is greatly diminished. (See Fever, Hectic.)

Treatment.—The treatment of the suppuration of internal parts will depend very much on the nature or character of the constitutional symptoms, and must be directed to the alleviation of the violence of fever, or the support of drooping vital powers, for such opposite conditions are met with in company, in cases of internal suppurations. No plan of treatment that we know of can expedite the process of suppuration, bring it more speedily to issue, or completely arrest it when once it has set in. As the natural tendency of pus is to make its way towards the surface, it is an obvious indication to give exit to it by artificial means where and when that can be done with due regard to the patient's safety. For further details respecting the treatment of suppuration, we refer to the practical remarks at the close of the article Inflammation, especially at page 798 of the second volume.

It sometimes happens that purulent formations occur with great suddenness in the body under different circumstances. When a part is undergoing a profuse suppuration, pus may be formed in an organ remote from it: after injuries of the head, or severe or trifling injuries to other parts, whether from accident or operation; in the course of tedious fevers, and after parturition. From the fact that these abscesses appear when parts are in the state of suppuration, they have been supposed to be metastatic in their nature; or in other words, that the pus was absorbed from the suppurating surface and carried into the substance of the organs. They do not appear unattended with constitutional disturbances, although they sometimes come on insidiously, frequently at a period when there is every reason to hope for a favourable issue to the case. The constitutional symptoms that precede these purulent depositions with variable severity are, shiverings, sometimes resembling in the periodicity of their return the cold fits of intermittent fever; delirium; prostration of strength; sometimes insensibility. They have the constant property of being developed with extraordinary rapidity, especially when we compare the time they take for their completion with that commonly necessary for the formation of pus after inflammation. At times, moreover, they come on without heat, pain, or redness of the part affected; and the first indication of their presence is afforded by the prominence made externally. (Dict. de Médecine, art. *Abcès Metastat.*) The abscesses are generally found in internal organs, parenchymatous viscera, sometimes in joints, and sometimes even in the external cellular tissue.

Recent researches in morbid anatomy have traced a connection between these abscesses and inflammation of veins in their vicinity in a large proportion of cases. "There exists," says M. Dance, "in a great majority of cases, where we observe these metastatic abscesses, a venous inflammation which takes its origin round the wound or original injury; and this inflammation

is the true means by which the pus is produced and introduced into the circulation, and mixed with the blood, the composition of which it injures. The blood thus contaminated, finds its way into the parenchymata, and then excites new inflammations, which attack in preference those structures in which blood-vessels are most abundant." On this subject the reader will find much interesting information in M. Dance's Memoirs on Phlebitis, in the Archives Générales de Médecine, tomes xviii. xix.; and in the papers of Rose, Arnott, and Lee, in the Transactions of the Medico-Chirurgical Society of London.

R. B. Todd.

SURVIVORSHIP.—To determine which of a number of persons overwhelmed by the same accident, as shipwreck, fire, falling of buildings, &c. has perished first, or survived the last, is a question of as great difficulty as its solution is often important. Thus, in the case of a father and son, brother and sister, husband and wife, who have died together, without any positive evidence of the event, it is frequently necessary to decide which of them outlived the other, for the survivor having succeeded, although but for an instant, to the property of the other, gives to his or her heirs a claim to the inheritance. If a man be seized in fee of land and tenements, though but for a moment, his wife is entitled to dower; therefore, if both father and son perish by a common accident, and the son survive, however short the period, his wife shall have dower, for the lands descended the instant the father died. This doctrine was extended very far by a jury in Wales, where the father and son were both hanged in one cart, but the son was supposed to have survived the father by appearing to struggle longest; whereby he became seised of an estate in fee by survivorship, he and his father being joint-tenants, in consequence of which seising his widow had a verdict for her dower. So also of joint-tenants, (as partners,) where the interest of the first deceased passes to the survivor, and not to the heir-at-law or next of kin of the deceased; but the heir-at-law or next of kin of the last survivor is entitled. Also between testator and legatee, if the legatee die first, it is a lapsed legacy and falls into the residue; but if the legatee survive, his executor or administrator shall take it. (See Park on Dower. Cro. Eliz. 502. Paris and Fonblanque, 390.)

Always occupied by war, and dying more frequently in battle than in bed, the Romans had need of laws to regulate the order of succession when the father and son, the brother, uncle, and nephew, &c. had perished in the same action. It was accordingly decreed, that when two persons of different ages perished at the same time in an engagement, it should be considered that he who had not yet arrived at puberty had died first; that on the contrary, when the father and son already of adult age, had lost their lives together, the son should be esteemed the survivor. This law, which at first had reference only to the events of war, was subsequently extended to all other cases, and to it was added that which enacted, that if a man and woman died together, the woman should be considered as having died the first. These statutes were founded on the consideration of the relative state of strength and weakness of the respective ages and sexes. On these grounds judgment was given in a case mentioned by Zacchias, (Quæst. Med. Leg. lib. v. quæst. 13,) in which many persons were destroyed by the fall of a building. Among them was a father with his daughter aged thirteen years; and it was ruled that the girl, in consequence of her age and temperament, had perished first, while the father being in the vigour of health had survived her. This principle continued to form the foundation of decisions in the French tribunals up to a late period, of which a remarkable instance is related by Ricard, (Traité des Dispositions Conditionelles, chap. 5, sect. 5,) a celebrated advocate of the seventeenth century. In 1658 two persons perished in the famous battle of Dunes, one, the father, serving in the Spanish army, the other, the son, serving in the French. On the same day at noon the daughter of this gentleman, and consequently the sister of his son, took the veil as a nun, at the very hour in which the battle commenced. The nun being dead in law, it was inquired which of the three should be presumed to have outlived the two others. It was decided that the girl had died first, for her death being voluntary was instantaneous; while the death of the father and son having been violent, might have been protracted for some time after the receipt of their wounds. It remained, then, to determine which—the father or son—had died first, and this gave rise to a lengthened discussion, which terminated in the adoption of the ancient law; and it was ruled that the two having died in the same engagement, without any evidence to fix the precise moment of their death, the son should be presumed to have outlived the father, because he had passed the age of puberty. Many other cases are given by Fodéré (Méd. Légale, t. ii. p. 220, et seq.) as illustrations of the application of the old Roman law. A modification of this has been adopted in the construction of the present French law, (Code Napoléon, art. 720–1–2,) by which it is enacted, that if several persons, naturally heirs of each other, perish by the same event, without the possibility of knowing which died first, the presumption as to survivorship shall be determined by the circumstances of the case, and in default thereof, by strength of age and sex. If those who perished together were under fifteen years, the oldest shall be presumed the survivor. If they were all above sixty years, the youngest shall be presumed the survivor. If some were under fifteen and others above sixty, the former shall be presumed the survivor. If those who had perished together had completed the age of fifteen, and were under sixty, the male shall be presumed the survivor, when ages are equal, or the difference does not exceed one year. If they were of the same sex, that presumption shall be admitted which opens the succession in the order of nature; of course the younger shall be considered to have survived the elder.

According to the civil law of England, which generally regulates the administration of personality, it is held that when parent, whether father or mother, and child perish together, as in shipwreck, if the child be of the age of puberty, he shall be

presumed to have survived; but on the contrary, that he died first if he were under that age; regard being also had to the relation of the party who is to benefit by the decision. Indeed, the order of nature appears to afford the best general rule, and, therefore, in the absence of all evidence to the contrary, it is to be wished that it were established that the natural succession had taken place as if no accident had occurred; that the child survived the parent; the nephew, the uncle; descendants, ascendants; legatees, testators; and generally, that the younger had outlived the elder. (*Paris and Fonblanque*, Med. Jur. v. i. p. 391.) But since there is no enactment in force, it is well to inquire if medical science affords any assistance in the solution of this question.

For this purpose we may arrange our researches under two heads: — 1. the consideration of the state and condition of the persons who have perished by the same accident: 2. the examination of their dead bodies, and the observation of the lesions presented by them. Under the former we shall consider the age, sex, temperament, habit of body, diseases, bodily power, and mental affections to which the individuals had been subject during their lives.

Age.—It is true that in early youth we are endowed with much vivacity; that the vital powers, still new, often surmount serious diseases under which a more advanced age would probably have sunk; but the instruments are feeble, and have not yet attained that development and tone requisite for great trials: moreover, still unprovided with that experience which strengthens men in danger, and suggests numerous resources, young persons are easily frightened, lose self-possession, and often accelerate their destruction, and this the more in proportion to their youth. In old age, on the contrary, the solids have too much consistence in proportion to the enfeebled vital power. Such persons are aware of the manner in which to avoid danger; but their instruments no longer obey the will, and they die with a full consciousness of their state. It would appear, then, that in general very young persons, and those far advanced in age, sink more readily in a common danger than adults and those in the middle stage of life. Some exceptions, however, to this rule are occasionally observed. Thus Fodéré (Méd. Lég. t. ii. p. 236,) remarks that in the revolutionary war he observed very young drummers, and even infants, conduct themselves with the greatest courage and presence of mind in dangerous situations, such as crossing rivers, and during sudden surprises of the enemy.

Sex.—With respect to sex it appears reasonable to assume that, all things being equal, the female yields first in an accident common to both sexes. It is certain that man, in virtue of the superiority of his strength, courage, and energy, is in a condition to struggle against danger, and resist causes of destruction more effectually than woman. Feeble, timid, and without experience, she is naturally placed, with respect to man, in the order of mortality from a common accident, as infants are in relation to adults, the weak to the strong. There are, however, some circumstances capable of modifying this statement, which it is necessary to consider. Female life may be said to be divided into two stages; the first of which continues until the cessation of her characteristic function—menstruation; a stage devoted to the propagation of the race, and accompanied with all the attributes necessary to its fulfilment. The second is marked by an interruption of this important periodical discharge, a loss of many of the peculiarities of the female sex, and an approach towards the conformation of the male. In this latter condition, the timidity, sensibility, and excitability so remarkable in the former, are gradually enfeebled; and thus the grounds of distinction in the order of mortality in the two sexes is removed. It has been remarked that women suffer less from obstruction to respiration than men, and that it is more common to observe them continue a long time without pulse or manifest breathing; from which cause they have sometimes been restored to life, when men overwhelmed by the same accident have been found irrecoverably dead. Females are, moreover, liable to sudden loss of sensation or fainting from the least fright, and thus becoming unconscious of surrounding objects, they avoid a great part of the horrors of their danger, and hence are not unfrequently rescued alive from calamities, which those to whom they have been fully apparent have not been able to withstand. From which it would appear that, however specious the doctrine that the weak should be considered to have died before the strong, it is very possible that this very weakness may be oftentimes a means of the preservation of life.

Temperament.—Galen said that persons of a cold temperament were more readily oppressed by any violent cause than those of an opposite; and the assertion of this great master is generally true, except in the case of death by simple suffocation. By temperament we mean the greater or less degree of energy and irritability of the instruments of the vital power, the chief of which is the heart, along with which may be considered the arteries and veins, for they are but ramifications of a great trunk the root of which is the heart. Upon the force of this latter organ depends, in a great measure, the temperament. When it is great, it accelerates the circulation and respiration, increases the secretions, and produces heat. When it is feeble, it constitutes the cold, humid, and phlegmatic temperament, opposed to the former. Between these two extremes there are a number of varieties, which it is not necessary to allude to more particularly in this place. The bodily force depends materially on the nature of the temperament. We do not speak of the power of carrying great weights, for we often see persons possessed of the greatest strength in this respect endowed with very little vitality. A phlegmatic temperament is often observed combined with great muscular development, as in the Alps and some parts of Hungary; and the athletæ of Greece were neither the most courageous nor vivacious. It is a circumstance frequently observed that persons of such a description sink more quickly under diseases than those of an opposite character, and when called on to make great and continued exertion, they always fail the first. The temperament termed bilious, or those temperaments that approach it, in which the flesh is not exuberant, and which unite a facility of conception to a promptitude of action, are those

which appear endowed with the greatest sum of vital power, equally disseminated, and capable of concentration to struggle against a common danger. We may say then that, relatively to temperaments, in the order of presumption of survivorship, the phlegmatic died first, then the melancholic, then the sanguineous, and last of all the bilious.

Habit and variety of constitution.—Under this head we comprehend the relative proportions of the principal organs of the body, and its conditions of obesity or leanness. There can be no doubt that a just proportion of the dimensions of the head and chest, with that of the other parts of the body, is a necessary condition for the exercise of health. It is well known that a large head and short neck are circumstances which dispose to apoplexy and other cephalic maladies; and that a narrow chest, whether it be by original formation, or the result of spinal disease, produces difficulty of breathing and other pulmonary affections. Thus, according to the kind of accident that may have caused death, and the organ, whether it be the brain or lungs, that is first affected by it, we can judge, with some appearance of certainty, that he whose head or chest was disproportioned died before those who were furnished with these organs in just proportion. With respect to obesity, it has been always considered as accompanied with less vigour than the opposite state. Hippocrates laid it down that fat persons die sooner than lean, and when we consider that they are more disposed to apoplexy, and more quickly oppressed in their breathing by any great exertion or by very warm temperature, there appears to be some foundation for the assertion. A great deposit of fat is an effect of venous plethora, and usually accompanies a deficiency of vital force and energy, commencing when the venous system excels the arterial. There is a difference, however, between persons fat by nature and from consuming large quantities of nutritious food; in the former, the obesity depends on a cold humid temperament, endowed with feeble activity, the courage is weak, and the passions are torpid. With the second there may be combined much strength and vital energy, together with great courage and tumultuous passions. It should be observed that, in death by drowning, as in shipwreck, the fat may have an advantage over the lean from their lower specific gravity, such persons being sometimes found of a less specific gravity than water. This was the case with the celebrated Neapolitan priest Paolo Moccia, (*Fodéré*, Méd. Lég. t. ii. p. 244,) who weighed thirty pounds less than an equal volume of water. He was, in consequence, able to float in that element, and perform all movements as freely as in air.

Disease.—A knowledge of the state of health of persons overwhelmed by a common accident is of value in questions of survivorship, since it is natural to suppose that invalids would have less means to resist the event than those in good health. The diseases which concur to facilitate death in an accident of this kind, may be divided into acute and chronic. The first are fevers, either inflammatory or typhoid, of which the latter seem the most powerful, in consequence of the great prostration of strength with which they are accompanied, so that the least cause superadded, fright particularly, is capable of extinguishing the feeble remains of life. Fodéré (Loc. cit.) mentions a circumstance corroborative of this position. The chimney of a military hospital to which he was attached took fire. All the patients, in a state of alarm, rose from their beds, but one of them, the subject of a typhoid fever, was so overcome by fright, that he died on the spot. Fodéré says he has seen many other similar instances in persons affected with malignant fever. Among the chronic diseases, scurvy is placed by the above author in the first rank, from its resemblance to malignant fever. After it, come those that affect the functions of respiration, circulation, and those of the brain and spinal marrow. Persons affected with these diseases are supposed to perish soonest in a common accident, whether it be that the causes of death are of such a nature as to affect the organs already diseased, or simply by the fright they have occasioned.

Moral condition.—A knowledge of the relative strength of mind of persons dying together may afford some assistance in judging of the order of survivorship. It seems reasonable to ascribe to fear some influence in expediting the death of weak-minded timid persons, for such have been supposed, in great catastrophes which were sudden and unforeseen in their invasion, to have died of fright, without the receipt of any direct violence. Fear is one of the most powerfully depressing affections of the mind, debilitating the brain and nervous system, producing languid action of the heart, and arresting the power of the muscles. Hence arises the impossibility of motion or of flying from approaching danger. In reference to this subject, Haller makes the following remarks: "Mortuus est, eodem die, quo mors, ei fuerat præsagita; ut metus esset pro morbo; mortuus est cui judicium fatale erat pronunciatum; et cui in sepulchro pes esset retentus; et qui intuebatur tendines, sibi dissectus; et qui notas variolarum in se ipso conspexerat; et alii, ex aliis causis." (Elem. Physiol. v. p. 585.) Sennertus reports many instances where the fear of death had effectually produced it in individuals who had received but slight injury, which would have been of no moment had the mental affection been less. It should be remembered, however, that such a consequence is not always to be ascribed to fear; for it has been observed that fatal results sometimes follow slight wounds received in action from fire-arms, arising out of a peculiar nervous agitation from which even the bravest are not exempt. This remarkable condition formed the subject of an interesting thesis (De agitatione nervosa vulneribus sclopetariis quandoque inflicta,) by Dr. Burton, at Edinburgh, in 1820, who had ample opportunity for observing it during the peninsular war, at Waterloo, and New Orleans. He describes it as supervening sometimes on very trifling injury. In one case that of an officer who was wounded just above the left patella, so slightly that the injury did not extend to the tendons, a collapse took place, from which it was impossible to rouse him, and he died that night. In another officer, who was wounded at the battle of Salamanca, the ball entered below the right breast, and ran round the thorax, under the skin, without penetrating the cavity; he was

seized with a similar nervous depression, and rapidly sank under it. Other cases are given by Dr. Burton, in which injuries, more or less severe, were followed by similar results. As we have alluded to this subject, we shall beg leave to transcribe the description of it given by the author:—"Indicia quæ frequentissimè consternationem universi corporis vulnere tormento inflicto demonstrant hæc sunt:—Æger frigoris sensu ad horrores plus minusve graves accedente, corripitur, vultu pallido collapso, labiis colore defectis, oculis cavis, retractis; pulsus exiguus, quandoque adeo imbecillus ut ægrè tactu percipi potest; spiritus lentus oppressus, sudores, non tamen generales, erumpunt, vomitus; membrorum jactatio ita ut membrum jactatio ita ut membrum læsum sæpe (quantum fieri potest) huc illuc jactitetur, nec dolorem quemquam excitare appareat; quod quidem ex pessimis signis est. Nonnunquam æger difficillime ad respondendum excitatur; atque si tandem respondeat, monosyllabis vocabulis responsum reddit. Discriminis raro conscius apparet, atque monitis curantium quibuscunque plerumque concedit." Dr. Burton does not attempt to account for the occurrence of this nervous agitation, but he states what we consider of importance with reference to our subject,—namely, that it is quite independent of the courage or pusillanimity of the individual. He concludes by saying "Hoc igitur prolusionom finiam, me sanctè credere istam virium conditionem a spiritûs virilis, veræque fortitudinis defectu, nequaquam provenire." From this it appears that death speedily following a trifling injury is not in all cases to be ascribed to fear, but depends on some peculiar idiosyncrasy with the nature of which we are still unacquainted, and therefore a previous knowledge of the fortitude or timidity is not of as much value in judging of the priority of death among several individuals, as Fodéré seems inclined to ascribe to it.

A consideration of the manner of life and education of individuals, with reference to the cause of death, seems to promise more aid in determining their respective survivorships; for we often find the minds of different persons affected in different ways when exposed to the same danger; some surveying with great dread what makes little impression on others. This difference in the susceptibility of alarm depends in a great degree on the habits and pursuits of each. Thus men who have borne their part with firmness in battle will tremble at the name of a disease or a trifling operation; while many who freely expose themselves to contagious disorders would no doubt feel very uncomfortable on being for the first time opposed to the enemy's fire. If, therefore, we find a person of good constitution joined to a confidence in his own powers, the result of early training in athletic exercises, as running, leaping, swimming, &c., if he has been accustomed to a hard life, and exposed to difficult and trying circumstances, we may reasonably conclude that he will be the least alarmed at any sudden calamity, and will be the last to struggle against the horrors of inevitable death.

Degree of exposure to danger.—Some presumption as to survivorship may be drawn from a consideration of the manner in which an event that has destroyed a number of persons together has acted in causing immediate or more tardy death. The respective situations of the individuals in the place where the catastrophe occurred, and the blows, wounds, or bruises observed on the corpses should be also taken into account. Severe wounds of the head and of the heart must be considered as giving a precedence in the order of death. Such injuries being in themselves mortal, evidently point out that, independently of the general cause, the death of those who have received them has been accelerated. After these may be ranked wounds of the lungs, great arteries, and abdominal viscera.

Besides these indications there are others, consisting of certain changes which take place in bodies after dissolution, that may assist in determining priority of death, or survivorship. These are loss of temperature, the occurrence of cadaverous stiffness, fading of the eyes, cadaverous lividities on the surface, and commencing putrefaction. It might be imagined that a body being found cold and stiff, at the same time that another is warm and flexible, is a certain indication that the latter survived the former. But the reverse may have been the case, for we have already shown in a former article (see PERSONS FOUND DEAD) that these changes are influenced by different circumstances relating to individuals, such as age, temperament, habit of body, disease, accident, &c. On these points it is unnecessary to enlarge in this place, and we beg to refer our readers to the article just mentioned. It will be sufficient to observe that the bodies of young persons preserve their heat and flexibility longer than those of old, when the cause of death has been the same in both; but there are certain forms of death that accelerate or retard these changes. For example, apoplexy and asphyxia cause the rate of cooling to be slow, and protract the occurrence of muscular rigidity, while hemorrhage expedites both. Therefore, although, *cæteris paribus*, we should expect to find the body of an old person cold and stiff before that of a young person who died at the same time, yet if the former has died of apoplexy or suffocation, and the latter from sudden loss of blood, this order will be inverted. Hence the necessity of ascertaining and weighing well the cause of death before these indications are adopted as grounds for determining questions of survivorship.

We will now proceed to consider some of the more common accidents by which a number of persons may be simultaneously destroyed.

Drowning.—Death from this cause may overtake a number of individuals together in inundations, shipwreck, upsetting of boats, &c. In this case a knowledge of swimming certainly gives an advantage to those who possess it over those who do not; and when it is ascertained that some of the company were skilled in this art, of which others were ignorant, it affords reasonable grounds to suppose the survivorship of the former. In engagements at sea and in shipwrecks, where a number of persons are precipitated together into the water, it has been remarked that the most courageous, those who have preserved their presence of mind so as to enable them to lay hold of any floating body, and those who know how to swim, are the last to yield to their fate. Thus, at the blowing-up of the French ship l'Orient, at the

battle of the Nile, some of the men escaped by seizing spars and fragments of the wreck. The locality should be attended to in all these cases, and if there is an opportunity of examining the bodies it should be done, to ascertain whether any mortal injury have been inflicted from striking against rocks or other resisting objects. A severe wound of the head, for example, would incapacitate a good swimmer from exerting his powers, and thus invalidate his claim to survivorship. It has been supposed that some opinion as to priority of death may be formed from the floating and sinking of the corpses; for it is known that at first they go to the bottom, there to remain until the putrefactive process has generated gas sufficient to buoy them up, at which time they rise to the surface; then the body, having discharged this gas by bursting, descends again, until a further quantity is formed in its tissues, on the occurrence of which they again float; and this process may be often repeated. If there was an interval of a day or two between the deaths of two individuals, these facts might assist in determining which had precedence; but when all are supposed to have died so nearly at the same time, they cannot be considered of much value. Besides, the occurrence of putrefaction is influenced by so many circumstances, (see PERSONS FOUND DEAD,) that no dependence can be placed on its manifestation when the interval between the deaths has been so small.

Suffocation.—This may take place from the exposure of a number of persons to the effects of noxious or irrespirable gases, or by the falling in of caves or buildings in which they may have happened to be assembled. If the gas be possessed of positive deleterious qualities, such as sulphuretted hydrogen and carbonic acid gases, it may be presumed that death was rapid in all, and occurred nearly at the same time. If it be only irrespirable from deficiency of oxygen, then those in whom the function of respiration is in the highest vigour, who stand most in need of a due supply of vital air, are those who most quickly suffer by its deprivation. In this case adults may be supposed to perish before infants or very young persons. Dr. Edwards (on the Influence of Physical Agents on Life,) has shown that young animals will live for a much longer time in the same quantity of air than adults. He found, by enclosing young and old sparrows in separate but equal portions of atmospheric air, that the former lived for fourteen hours and a half, while the latter perished in one hour and a half; and he obtained nearly similar results in experimenting on some of the mammalia. Attention should be paid to the manner in which the cause may have acted on the subjects exposed to its effects, and to the opportunity of escape that each may have had. In the ruins of Pompeii the bodies of the inhabitants that were discovered were found in different situations; some in houses, others in the streets, and others at the gate evidently in the act of flying from the impending danger. These last may be presumed to have outlived the former. Fodéré, to whose writings we are indebted for much valuable matter on this subject, mentions an accident that occurred at Marseilles, in which several persons were suffocated in the same house at night, by the carbonic acid gas from a neighbouring lime-kiln. The bodies were found in the morning in different situations—some in bed, and others on the stairs, giving evidence of an attempt at escape; and thus affording grounds for the presumption that the former perished before the latter. (Dict. des Sciences Méd. art. *Survie*.) In all cases where the fatality has been owing to the falling of buildings, &c., an accurate examination of the bodies should be made, to discover any lesions that may have been inflicted; for a hard heavy body having fallen on the head, chest, or belly, would naturally point out the speedy death of the individual thus wounded.

Hunger or Thirst.—It is well known that individuals who have not reached their full growth suffer most from deprivation of aliment; and hence those advanced in age support hunger better than children. This fact has been observed in famines at sea and in besieged towns; and is no less correctly than beautifully illustrated by Danté, in his account of the death of Count Ugolino and his family, who, shut up in a dungeon and condemned to destruction by starvation, are represented as perishing in the order of their age, beginning at the youngest; the father having survived to witness the death of all. Women consume less food than men, and are capable of supporting themselves better under its privation: hence they may be supposed to be the last to sink when exposed in common with men to the effects of hunger. Persons of a full and fat habit of body are likewise better able to support a long fast than those of a lean and active disposition. In judging of survivorship in cases from this cause, regard should be had to the means of procuring any cordial, such as wine, or spirits, or even water. In the case of the celebrated Viterbi, who starved himself to death in the island of Corsica, he prolonged his life for some days by having yielded to the call of thirst, and taken a draught of cold water on the thirteenth day. If, therefore, it be discovered that some of the party had access to any of these fluids, from which the rest were debarred, it would afford strong grounds for the presumption of their survivorship. In death from hunger, as in most of the accidents of which we have taken notice, vigour of intellect, by which the presence of mind is retained, gives an advantage to those who possess it. This was exemplified in the crew which embarked on the raft, after the wreck of the Medusa, in the year 1816. Of one hundred and fifty individuals thus exposed to hunger during thirteen days, but fifteen survived, and these were not the strongest and most vigorous in appearance, but those possessed of the greatest courage, and who maintained their presence of mind the longest.

Excess of Heat.—Although it is well known that animals cannot continue to live when exposed to very high temperatures, yet the true cause of death from this agent does not appear to be satisfactorily explained. From an experiment of Mr. Brodie, it seems probable that it acts by destroying the muscular energy of the heart and diaphragm. He placed a rabbit in a basket in an oven, the temperature of which was not more than 150°, and it died in a few minutes without any apparent

suffering; the heart was afterwards found distended with blood, on both sides, as in syncope. (Paris and Fonblanque's Med. Jur. vol. ii. p. 63.)

It appears from many recorded facts that a heat of the magnitude just mentioned, although sufficient to kill a small animal in a short time can be borne by man for a considerable space with tolerable impunity. Thus, individuals have gone into ovens hot enough to bake bread, meat, &c., and have remained inside during the process without suffering much inconvenience. Tillet and Duhamel (Mém. de l'Acad. des Sciences, 1764,) state that at Rochefaucault in Angoumois, in 1760, a baker's daughter, in their presence, entered into an oven, the temperature of which they estimated at 264° Fahr., and remained about twelve minutes in this excessive heat without being much incommoded by it. A young man, in Dobson's (Philosoph. Trans. 1775,) experiments at Liverpool, remained for twenty minutes without great inconvenience in a stove, the air of which was at 210°. M. Berger (Exp. sur les Effets qu'une forte chaleur produit sur l'Economie,) supported, for seven minutes, an atmosphere of the temperature of 229° Fahr., and Blagden that of 260° for eight minutes.

In the volcanic district in the neighbourhood of Naples, there is a deep cave running a considerable distance under ground, at the bottom of which rises a boiling spring; and it is a common feat for the ciceroni to carry in a number of eggs, plunge them into the hot water, and remain until they are completely cooked. The writer has witnessed this performance, and has seen the man come out bathed in perspiration, and certainly exhausted, but not otherwise perniciously affected. In the course of Dr. Apjohn's interesting and important experiments on respiration, he entered the heated room of a calico manufactory, the temperature of which was 152°. He remained in it for thirty-seven minutes, at the end of which time his pulse beat at the rate of 116 strokes in a minute, and the number of respirations was raised to thirty in the same period. These changes, however, did not take place suddenly, for it was not until he was twenty-five minutes in the room that the heart's action attained that rate. This experiment is important, not only on account of the conclusions arrived at respecting the changes effected on the air by respiration, but also in reference to the length of time that such a degree of heat can be supported by man. The effects of watery vapour are more intolerable than those of a dry atmosphere. M. Delaroche could not support, above ten minutes and a half, a vapour-bath which, at first at 99°, rose in eight minutes to 124° Fahr.; and M. Berger was obliged, in twelve minutes and a half, to come out of a vapour-bath, of which the temperature had risen from 106° to 128° Fahr. These gentlemen, however, supported for a considerably longer time, without much inconvenience, higher temperatures in dry air. (*Dr. Edwards*, op. cit.)

The effects of a high degree of atmospheric heat are witnessed on a large scale in the deserts of Africa and Arabia, where caravans so frequently suffer from exposure to a burning sun. Fodéré alludes to the loss sustained by the French army from this cause in traversing the sands of Egypt and Syria. He describes the effects to be vertigo, syncope, rarefaction of the blood, passive hemorrhages, and death. It would appear that men exposed to this cause of destruction survive in an inverse order to what takes place in exposure to cold, that is, that adults and strong persons sink under it before the young and weak, an instance of which is given by the author last named. An Englishman and his daughter, aged seven years, joined a caravan which left Aleppo in the year 1814, to cross the desert of Syria to the Persian Gulf. Both father and child rode on camels, and were placed under exactly similar circumstances, but the former could not resist the effects of the heat, and died; while the girl was able to continue the journey, and arrived safe. Other members of the caravan suffered similarly, but they were the strong and robust; the young suffered least.

Cold. — It appears from the observations of Dr. Edwards, that the power of evolving heat in infants is less than that possessed by adults. Thus, in ten healthy infants the limits of variation of temperature taken by M. Breschet were from 93° to 95° Fahr., the mean of the whole number being 94° 55′, while the temperature of twenty adults was found to vary from 96° to 98°, the mean being 97°, which agrees with the best observations. The temperature of the former is, therefore, inferior to that of the latter; a relative difference which analogy would lead us to expect. It follows, as a consequence of this, that when the faculty of evolving heat is not the same, the vitality will be different; for the need of warmth, and the power of supporting cold, cannot be the same, where the internal source of heat has not the same activity. In one experiment Dr. Edwards exposed a kitten, newly littered, removed from its mother, to the air at the temperature of 51° Fahr.; it was cooled down in 9 hours to 64°, and had become stiff and almost incapable of executing the slightest movements. In another experiment he exposed two kittens of one day old, and having a temperature of 98°, to the air of a room at 50°; in two hours and twenty-five minutes the temperature of one was reduced to 62°, and that of the other to 64, and they had become stiff and almost insensible. It is superfluous to observe that the adult animal would not have suffered the same effects. Similar experiments cannot of course be made on infants, but it is fair to infer that they would exhibit similar results. This variation between ages, in the power of resisting cold, seems to be extended to sex and temperament, for males have been remarked to endure low temperatures better than females; and those of bilious and sanguine temperament better than phlegmatic and nervous. In questions of survivorship arising out of a number of individuals destroyed by cold, besides the circumstances just mentioned, it is necessary to take into account the state of health or disease of each; and also their relative moral powers, by which a resistance to sleep, and a capability of continuing in motion, are maintained; two circumstances of the greatest importance in combating the effects of cold. The relative amount of clothing of each, and the opportunities of procuring nourishment or cordials, should also be considered. If spirituous liquors have been at

hand, a great deal will depend upon the manner in which they have been used. In the disastrous retreat of the French army from Russia, it was observed that those soldiers who rushed greedily on the casks of brandy and drank to intoxication were the first to perish from the cold; while those who used it in moderation were revived by it. Fodéré (Dict. des Sciences Méd. art. *Survie*) mentions that he witnessed similar effects in crossing Mont Cenis with the French army in 1789, but that the practice of taking small quantities of brandy every two hours assisted most wonderfully in enabling him to resist the cold.

SUSPENDED ANIMATION.—(See Asphyxia.)

SYCOSIS.—(*Syn.* mentagra, herpes pustulosus mentagra, mentagre, dartre pustuleuse mentagre,) from συκον, *a fig*, denotes a cutaneous disease of the bearded parts of the face and throat and also of the hairy scalp; it is characterized by pustules, viscid discharge matting together the hairs, and forming crusts by inflamed tubercles, and sometimes by prominent granulated ulcerations. The mixture of colours and unevenness of the surface give to the affected parts something of the appearance of the pulp of a fig; and hence this disease has received the name of sycosis. Dr. Bateman, (Synopsis, &c. p. 291,) and it appears from his statement, Dr. Willan also, regarded the initial form of this affection as truly tubercular, but of that form of cutaneous tubercle which usually ends in suppuration; while Alibert, (Maladies de la Peau, fol; also, Précis Hist. et pratique des Malad. de la Peau, 2 tom. 8vo.) Rayer, (Traité des Maladies de la Peau,) and Biett, (Dict. de Médecine, art. *Mentagre;* also *Schedel et Cazenave*, Abrégé pratique des Maladies de la Peau,) maintain that the disease is originally pustular, and that the tubercles, which however they allow are diagnostic,* arise during the progress of sycosis. Thus it appears that the French and English pathologists differ chiefly in the precedence as to time, and the degree of importance which the former attach to the suppurated points, and the latter to the tubercular elevations of the skin.

Dr. Bateman has divided the disease into two species, that which is seated on the bearded portion of the face, and that which appears on the hairy scalp: but we have also seen an affection of the same character situated on the pubes of both sexes, more especially the female. This last is usually of syphilitic origin.

1. **Sycosis menti,** sycosis of the chin. This disease is often preceded for months, sometimes for years, by a morbid irritability of the skin of the face, and partial eruptions of inflamed pimples, which, after suppurating, fade and disappear, and after a time are succeeded by others. These attacks become more frequent and severe, till at length the disease establishes itself on the chin or upper lip. Most commonly the development of sycosis is immediately preceded by heat, redness and tension of the skin covered by the beard, with tingling and pricking pains; numerous inflamed pimples now make their appearance, which ripen into pustules in three or four days, and in seven or eight burst and become covered with thin brownish crusts; but the oozing of fluid is generally inconsiderable. The crusts by degrees separate, and according to Biett, (Dict. de Médecine, art. *Mentagre;* also *Schedel et Cazenave*, Abrégé pratique, &c.,) the disease ceases entirely from the tenth to the fifteenth day, provided no new eruption takes place. The pustules are conical and most frequently single; at other times they are clustered together in circular groups, and very numerous, covering the upper lip and chin with small prominent tumours of various sizes, filled with a yellowish white pus, and each penetrated by a hair. Most commonly successive partial eruptions take place, the skin becomes inflamed and thickened, tubercular eminences form, and at length even the subcutaneous cellular tissue suffers, and small phlegmons from time to time make their appearance. In some protracted cases even the bulbs of the hair become affected, and parts of the chin are rendered bald: but in most instances when the disease subsides, the hairs are reproduced, at first pale and slender, but they afterwards acquire their natural strength and colour.

The extent of the disease is very various: sometimes it forms only one spot on the middle of the upper lip, covered by a dark prominent crust; (dartre pustuleuse labiale—Alibert;) at other times the whole of the bearded portion of the face and throat is covered by pustules, crusts, superficial ulcerations, and tubercles; and in some cases even the eye-brows are not exempt from the disease. Sycosis of the chin occasionally appears in a much less acute form, the eruption presenting more of a tubercular than a pustular aspect. Many of the tubercles continue as red, smooth, conoidal tumours, about the size of a pea, for three or four weeks or longer; while others suppurate very slowly and imperfectly, discharging a little thick viscid matter, which glues together the hairs. (*Bateman*, Synopsis, &c. p. 293.) When to these appearances are added partial ulcerations, the lower part of the face exhibits a very repulsive appearance, from the mixture of tubercles, crusts, ulcerations, and the strong hairs of the beard matted together; while the patient, in the mean time, suffers considerably from the hot itching and tenderness of the parts.

It has been supposed that the anatomical seat of sycosis is the sebaceous follicles; and it is probable that they often participate in the disease of the adjoining tissues, but this does not appear to take place in all instances. M. Gendrin made a dissection of a case of sycosis which had existed for a considerable period, and found that the diseased skin was thicker than natural; the rete mucosum under the pustules presented in different places small infiltrations of a yellowish substance like jelly, and each of these was observed, by means of a lens, to be surrounded by a very delicate net-work of vessels. The bulbs of the hairs appear, in this instance, to have been unaffected, and the sebaceous follicles are not stated to have been in any way diseased. (Histoire Anatomique des Inflammations, t. i. p. 457.)

2. **Sycosis capillitii,** sycosis of the scalp. This has been described by Dr. Bateman; but it

* "Enfin dans l'impetigo figurata, on ne rencontre jamais les tubercules, comme dans le Mentagre." Schedel et Cazenave, Abrégé pratique, p. 226.

does not appear to have been distinguished by French writers on cutaneous diseases from the porriginous affection of that part. It consists of the eruption of clusters of soft acuminated tubercles on the hairy scalp near to its margin and on the temples; sometimes spreading so as to involve the external ear. Perhaps they ought to be termed pustules rather than tubercles, for they all pass into suppuration in eight or ten days, run together, and form for each group an irregular elevated spongy ulceration, often presenting a granulated appearance, and discharging a quantity of thin fluid of a rank offensive odour. This uniform tendency to ulceration forms one of the diagnostic marks which distinguish sycosis from porrigo: they differ also in the more inflamed and elevated base of sycosis, and in the absence of contagion. The last is a diagnostic of no practical value, and one which can seldom be proved to our satisfaction.

Causes. — Sycosis of the chin has been met with, though very rarely, among women: it occurs chiefly in young men, soon after puberty; and in adults, having a coarse skin with a dark-coloured strong beard. Indulgence in the luxuries of the table and in strong liquors, gross dissipation, filth, and misery may all be regarded as powerful exciting causes of this affection: but even individuals of the most correct habits, and uniformly attentive to cleanliness, are not altogether exempt from its attacks. Those who are much exposed to the scorching glare of fires and furnaces, as cooks, glass-blowers, founders, steam-engine men, are most frequently affected with this disease. It has also been ascribed to the use of a foul or rough-edged razor, but probably on no sufficient grounds, although such an irritation must obviously hasten its development in those already disposed to it. Thus the causes of sycosis of the chin are to be sought for partly in a disordered state of the digestion and of the general health, and partly in local irritation; few cases, we believe, are met with, in which constitutional as well as topical influences do not concur to produce the disease.

[M. Gruby, of Vienna, has recently announced the existence of a new cryptogamic plant in mentagra. It is found at the roots of the hairs of the beard, and around that portion which is contained in the hair follicle. By the transmission of the seeds of this plant he considers the disease to be contagious, and he proposes for it the name *mentagrophyte*. The disease, according to M. Gruby, is limited to the hairy part of the face, but is most frequently seen on the chin, upper lip, and cheeks,—covering the parts with white, greyish and yellowish scales, which are slightly raised at the middle, have angular borders, and are pierced at all points by hairs. Examination with the microscope shows that the scales are composed of epidermic cells; but the whole of the dermic portion of the hair is surrounded by cryptogamic formations, which form a vegetable sheath around it in such manner that the hair implanted in the sheath may be likened to the finger surrounded by a glove. These cryptogamia are never seen to rise above the surface of the epidermis; they originate in the matrix of the hair, and in the cells of which the follicle is composed; and they ascend so as to surround all that portion of the hair which is included within the derma. They present every where a prodigious number of sporules, which are adherent, on the one side, to the internal surface of the follicle, and on the other to the cylinder of the hair. This disease of the skin M. Gruby regards as of purely vegetable nature. It may be so: but further evidence is needed. (E. Wilson, *A Practical and Theoretical Treatise on Diseases of the Skin*, Amer. edit. p. 300, Philad. 1843.)]

Sycosis of the scalp is of more obscure origin: the few cases of this nature which we have seen were in children of a delicate appearance; and the beautiful delineation of the disease given by Dr. Bateman is obviously taken from a child; yet it is remarkable that in his diagnosis of the disease he speaks of it as occurring *exclusively* in adults. (Synopsis, p. 294.)

Treatment.—The first step towards a cure is to remove, as far as lies in our power, all those circumstances which appear to have occasioned or aggravated this affection, as intemperance, neglect of cleanliness, exposure to scorching heat, and the irritation of the razor. It is of great consequence to get rid of the hair, in order to clear away the crusts and discharge, and to apply topical remedies with effect; shaving, however, is exceedingly painful, and in most cases quite impracticable; but the object may be gained by clipping the beard with scissors, which ought in no case to be omitted. The parts should then be cleansed with tepid milk and water, emollient poultices, and the topical vapour-bath. This last, both simple and combined with sulphur, will be found of great utility in soothing the affected skin and promoting the softening and absorption of the tubercles, which it often effects with remarkable rapidity. The raw and ulcerated parts ought to be bathed with the black mercurial wash, or with Bates's red lotion,* and dressed with ointment of white precipitate of mercury, or, if there be much irritation, with ointment of oxide of zinc, or subnitrate of bismuth. When the discharge is considerable, we have found great benefit from applying a strong solution of sulphate of copper. The removal of the tubercles is also much hastened by the application of sulphate of copper and nitrate of silver in substance; but the concentrated acids, which have been proposed, cause sloughing of the tumours, increase the inflammation, and retard the cure.† Such of the tumours as appear particularly prominent and fiery ought to be punctured with a lancet; thus the blood-vessels will be unloaded, and in many cases small collections of pus or gelatinous fluid discharged. When sycosis possesses an inflammatory type, as it usually does in its early stage, and the strength of the patient permits, it will be of service to apply leeches around or even upon the affected skin; and when the individual is robust, venesection or cupping will be proper; and the tartrate of antimony ought to be

* Sulphatis cupri.

given in frequent small doses. In all cases of this disease it is of consequence to commence the treatment by a smart mercurial purgative; and after the bowels have been cleared out, and the inflammatory symptoms have abated, our efforts ought to be directed to restore the digestive organs to a healthy state by bitters, alkalies, and, in more obstinate cases, by the continued employment of minute doses of mercury. When sycosis occurs in persons whose strength is much reduced, a nourishing diet with tonics, such as the preparations of cinchona and steel, has been productive of speedy amendment. If the disease be obstinately protracted, the arsenical liquor ought to be had recourse to, and a blister applied over the diseased surface; or this last may be tried in conjunction with a course of corrosive sublimate.

Sycosis of the scalp being more ulcerated, and accompanied with a thinner and more abundant discharge than that of the chin, it requires a more liberal application of astringents and caustics; and the same remark applies with nearly equal force to the corresponding affection of the genitals. In this last, cooling washes and the free use of sulphate of copper, conjoined with the internal employment of mercury, will very rarely fail to accomplish a speedy cure.

W. Cumin.

SYMPTOMATOLOGY, [*Semeiology*, or *Semeiotics*, is the branch of general pathology which treats of the symptoms or signs of disease. The word *symptom* is often—perhaps, generally—used in the same sense as *sign*; but, by many, *symptom* signifies the functional or vital phenomena of disease, whilst *sign* is applied to that which is more directly physical. A recent writer (Raige-Delorme, art. *Semeiologie*, in *Dict. de Méd.* 2d édit. xxviii. 297, Paris 1844.) considers every symptom to be a sign of disease, and defines semeiology to be "that branch of pathology whose object is the knowledge, the particular study of the phenomena, which occur in disease; or of symptoms, that is to say, of the perceptible changes that take place in the material state of the organs or in their action, and which being connected with the existence of diseases, become the indexes or signs of them." There certainly is convenience in the employment of the expressions, *vital phenomena* or *symptoms*, which are dependent upon the vital properties of organs, and *physical signs*, or the evidences that are afforded by percussion, auscultation, &c., which reveal the physical condition of the parts, and their vital manifestations. The writer is in the habit of employing these phrases, originally suggested by Bayle and Laënnec, on account of their convenience. (Dr. Williams, *Principles of Medicine*, § 601, Philad. 1844.)]

The diagnosis of disease constitutes the first part of the office of the physician in his actual visits to the sick. The sources of diagnosis are, the history, the symptoms, or changes in function, [the physical signs], the effects of remedies, and the morbid anatomy, or changes in structure.

The history teaches much of the probable progress of the disease, and of its effect in inducing changes in structure and devastations of the powers of the general system. The symptoms designate the organ principally affected. [The physical signs indicate altered mechanism.] The effects of remedies, carefully considered, throw an important light upon the nature and force of the disease, and upon the condition and energies of the system. The examination of the changes of structure affords an invaluable confirmation or correction of our previous opinions.

The study of the history of the disease greatly aids the diagnosis. The constitutional causes, which involve the hereditary predisposition, previous attacks, &c.; the external causes, which embrace those circumstances which induce and modify the disease; the duration, the past course of the morbid affection, &c. are all events which greatly assist us in forming the diagnosis, and in determining the particular condition of the organ principally affected, and of the general system, in the individual case.

But the symptoms doubtless constitute the chief source of the diagnosis. The form and violence of the symptoms, the particular order in which they appear, the particular manner in which they are conjoined, offer additional means of diagnosis.

[The physical signs are most important elements in the diagnosis of diseases of the chest more especially. They indicate various changes in the physical properties or actions of organs; for example, their density, greater or less capacity of causing or conducting sound, &c. Physical signs reveal "the nature, extent, and degree of organic affections, and may be regarded as the means or instruments of pursuing morbid anatomy on the living body. (Walshe, *The Physical Diagnosis of Diseases of the Lungs*, Amer. edit. p. 2, Philad. 1843.)]

One of the sources of diagnosis enumerated constitutes a department of knowledge which may be termed *new*: it is that of the effect of remedies, and especially of bloodletting, as a diagnostic of diseases, and as a criterion of the general powers of the system. In cases in which it is doubtful whether the pain or other local affection be the effect of inflammation or of irritation, the question is immediately determined by placing the patient upright and bleeding to incipient syncope: in inflammation much blood flows; in irritation, very little. The violence of the disease, the powers of the system, and the due measure of the remedy, are determined at the same time. There is, in our opinion, no single fact in physic of equal importance and value, in the diagnosis of acute diseases and the use of an important remedy.

But it must be acknowledged that it is to the study of morbid anatomy that we are principally indebted for the recent progress, and, indeed, for almost all that is solid, in medical science. It is by the investigation of morbid anatomy that we are principally enabled to establish correct species of disease; but it is equally true, that all the advantages which spring from our knowledge of changes of structure, must flow through that of the history and symptoms, as the channel to our individual patients. The progress of medicine as a science—might we not say, as an abstract science?—may be considered as greatly dependent on that of our knowledge of morbid anatomy; but the advancement of physic, as a practical art, is intimately linked with our knowledge of the history, symptoms, and the effects of remedies—with the diagnosis of the disease in the living patient.

The sources of diagnosis may be arranged in the following manner:—

I. *The history.*
II. *The symptoms, or changes of function.*
III. *The effects of remedies.*
IV. *The morbid anatomy, or changes of structure.*

I. *The history of diseases* comprises
  i. The causes, which are
    1. Constitutional.
    2. External.
  ii. The course, which is
    1. Acute.
    2. Chronic.
    3. Insidious.
    4. Sudden, &c.

II. *The symptoms, or changes of function,* are observed in
  1. The countenance.
  2. The attitude.
  3. The tongue.
  4. The general surface.
  5. The general system.
  6. The functions of the brain, the spinal marrow, and the nerves.
  7. The respiration.
  8. The circulation.
  9. The functions of the alimentary canal.
  10. The physical condition of the abdomen.
  11. The functions of the urinary organs.
  12. The functions of the urinary system.
  13. Examinations,
    1. Of the abdomen,
    2. Of the rectum,
    3. Of the vagina. &c.

III. *The effects of remedies* are
  i. Immediate.
  ii. Remote.
  iii. Curative.
  iv. Morbid.

They are principally seen in the administration of
  1. Bloodletting.
  2. Purgatives.
  3. Opiates.
  4. Mercury.
  5. Digitalis.
  6. Alcohol.
  7. Quinine, &c.

It is the *immediate* effects of bloodletting which are chiefly valuable in a diagnostic point of view.

IV. *The changes of structure* are
  1. Febrile.
  2. Eruptive.
  3. Inflammatory.
  4. Congestive.
  5. Arthritic,
  6. Rheumatic·
  7. Scrofulous—Tuberculous.
  8. Scirrhous.
  9. Encephaloid.
  10. Melanotic.
  11. Dropsical.
  12. Hemorrhagic, &c.

The observation of the history, symptoms, and effects of remedies, is strictly clinical, and can alone be beneficial to our immediate patient. The examination of the morbid anatomy may be viewed as the proper corrective of our clinical opinions, whilst it contributes, more than any other species of investigation, to the advancement and exactness of the science of medicine.

The true value and importance of the history and symptoms of diseases, and of morbid anatomy, depend alike on a due and correct association. The most perfect knowledge of symptoms would be utterly useless unless considered as signs and indices of the internal disease; and the most perfect knowledge of morbid anatomy would be inefficient, unless we were enabled by the symptoms to ascertain its existence in the living body. Our object, in both these studies, ought, therefore, to be to make them useful by the establishment of distinct associations of the symptom or the sign, and of the morbid state as the thing signified. It is in this manner only that the diagnosis and identification of diseases in the actual practice of physic will become more and more correct and complete.

The objects embraced in the history and symptoms of diseases are certainly more transitory and less palpable, and require more caution and reserve in the association as effects of diseases, than those of morbid anatomy. But, from the observation just made, that it is only by association of the morbid anatomy with symptoms indicative of the morbid change that even this becomes cognizable in the living body and useful in the practice of medicine, it is plain that the same difficulties apply in fact to both.

The study of the history and symptoms of diseases embraces an object unconnected with morbid anatomy, viz. such instances of morbid affection as consist in derangement of function and leave no trace under the scalpel of the anatomist. (See Baillie's Morbid Anatomy, Pref. p. 1.) And it is one of the objects of the history of diseases especially, to trace the transitions, in mixed cases, of deranged function into deranged structure, the extensions of diseases of structure from one organ or part to another, and the superinductions, from accident or natural consequence, of one disease upon another. It is a point of great importance, but of great difficulty, in the study of the history and symptoms of diseases, to determine the times of these transitions and extensions of disease.

It is an object of the history and symptoms of diseases to ascertain, in the coincidence of different morbid affections, whether their coexistence be accidental, or the result of their mutual relation as cause and effect.

Such is an imperfect sketch of the objects and relations of this department of medical science. It would be wrong to argue against the importance of the study of the history and symptoms of diseases from the imperfect manner in which they have hitherto been treated; whilst to consider perfection in this study to be unattainable would be to suppose that medicine cannot exist as a safe and useful art. It would be wiser and more true to say, that, hitherto, we have been too apt to form and to state our opinions, and to regulate our practice, on insufficient evidence; and then to

turn our attention to the real nature of the evidence for facts in medical science, and especially in clinical medicine, and to inquire whether its sources may not be multiplied, and its results rendered more sure and conclusive.

It is in this way alone that we can hope to remove from the practice of medicine the reproach of vacillation and uncertainty, and contradiction. [See the writer's remarks at the end of the Article Statistics, Medical.] The first step is clearly to distinguish and to identify the disease; the second, to appropriate the remedy, in its purity and simplicity, and with a due attention to the strength and constitution of the patient. When experiments have thus been carefully instituted, and the results collected by an assiduous observation, we may expect to become acquainted with the real effects of those agents which we consider as remedies,—both good and bad. An investigation conducted in this spirit would, we feel convinced, lead to some important results. We still want an essay on the morbific effects of remedies,—1. when misapplied, 2. when even appropriately, but perhaps injudiciously, administered, and 3, from idiosyncrasy. We may instance bloodletting, and purging, and opium, as productive of morbific effects of the most serious character, to which our attention has been particularly directed: it is needless to add to the list, mercury, digitalis, cantharides, &c., with which every practitioner has learnt to associate certain morbid conditions of the system. But this subject will be more particularly noticed in a subsequent part of this paper. We shall now proceed briefly to notice the advantages which result from each of the departments of the present article more distinctly.

The principal circumstances more particularly embraced by the history of diseases, are, the cause,—the progress, the stage,—the effect of remedies,—the season of the year, the prevalence of epidemics,—the constitution, and habits, and previous diseases of the patient, &c.

The principal subject in the history of diseases, in a diagnostic point of view, is its congruity or incongruity with the supposed disease. We frequently arrive at a negative result, especially, by observing such incongruity in the history; and in this manner, by excluding certain diseases, we narrow the sphere of our inquiries and have our attention directed upon a less numerous class of objects.

In the study of the symptoms, every circumstance which can become the subject of observation, and which is at all characteristic, must be considered as important. It is with this view that we carefully examine the countenance and the attitude of patients, as well as those other points which are more usually considered amongst the class of symptoms. The attempt to analyze, distinguish, and describe all the external appearances of disease cannot fail to assist the clinical student and the young practitioner, whilst it serves only to recall to the mind of the experienced those sources of evidence on which his judgments have been ever, though perhaps unconsciously, founded. For without having undertaken any distinct analysis of the general appearances in disease, the experienced physician has, notwithstanding, been struck with them in the coup-d'œil he has taken of these appearances and of the general manner of the patient. By these means he has recognised and identified the affection, when he may have been almost unconscious of the sources from which his discrimination flowed.

The countenance of the patient, although a source of information too much neglected by writers on medicine, is very peculiar and highly characteristic in many diseases, and affords to the physician of experience and observation an important means of diagnosis. The kind, the stage, the changes, the mitigation, and the progress of many morbid affections are accompanied and denoted by corresponding states of the countenance. Let us recall to mind the varied and distinctive appearances in the different kinds and stages of fever, in affections of the head, of the thorax, and of the heart, in inflammation of the abdomen, and in colic and other affections accompanied by spasmodic pain, in icterus and in chlorosis, and that class of morbid affections which, originating in derangements of the digestion, are accompanied by changes of complexion so characteristic of the original disorder. It is impossible not to be impressed with the importance of changes in the countenance so observable, so diversified, and so diagnostic, with a view to every practical purpose in the art of medicine.

Hippocrates, (Vide Προγνωστικον,) and Celsus, (Lib. ii. cap. 2, 6,) and other ancient writers, have, in their great attention to the study of symptoms, paid particular regard to the appearances of the countenance. Celsus observes, "medicus neque in tenebris, neque a capite ægri debet residere; sed illustri loco adversus eum, ut omnes notas, ex vultû quoque cubantis, perspiciat." (Lib. iii. cap. 6.)

[What may not inappropriately be styled *medical physiognomy*, or the changes of features indicative of, and peculiar to, different diseases and stages of diseases, is a subject of moment, and has not yet met with sufficient attention. In diseases of infancy, in particular, the appearance of the countenance will often materially aid us in discriminating the seat of the affection. There is a marked difference between the facial expression of one labouring under violent pain in the head, and one suffering from excruciating pain in the abdomen, even in the adult. Less degrees of pain are, of course, disregarded; and it is only in severe cases that physiognomy can be inservient to diagnosis; but in the infant, which readily gives expression to any pain or uneasiness, the countenance is an excellent medium of discrimination, and will frequently indicate, at the first glance, the seat of the derangement. The character, too, of the countenance, in serious disease, as to anxiety, convulsion, &c., is often a subject of watchful interest with the physician.

To what he termed *La Semeiologie Physiognomique*, in the study of the diseases of childhood, M. Jadelot, Physician to the *Hôpital des Enfans-trouvés*, of Paris, paid great attention, and was firmly impressed with its great importance. A work on the subject, from his pen, was promised upwards of twenty years ago, but it has never appeared. So satisfied was M. de Salle of its value, that he conceived the diseases of infancy would be recognised with such facility, that the

possessor of the most mediocre talent might know and cure them as readily as he who is more highly gifted. (*Traité des Maladies des Enfans de Michael Underwood;* par E. de Salle, p. 36; or a view of M. Jadelot's system, in the Prefatory Observations to the Writer's *Commentaries on Diseases of the Stomach and Bowels of Children.* Lond., 1824.)]

These observations are equally applicable to the subject of the attitude and motions of the body in general, in different diseases; for, although the attitude, in certain diseases, is so remarkable as absolutely to have challenged observation, yet, in general, this point has been too little noticed, and its indications too little explored. Hippocrates, (Vide Προγνωστικον,) and Celsus (Lib. ii. cap. 3, 4, 6,) have particularly noticed the attitude of patients.

It is useful to examine the state of the hands and feet of the patient, in connection with that of the general surface. But it is not our intention to enumerate all the subjects of the following pages in this place. We proceed, therefore, to notice in a cursory manner some points rather connected with the investigation of the symptoms of diseases than forming a part of them.

It is proposed, in the first place, to make each particular symptom the object of distinct and separate inquiry, and, considering it as a general phenomenon occurring under numerous and different circumstances of disease, to investigate, distinguish, and arrange its varieties, modifications, and peculiarities, in each.

It is insufficient to give to a particular symptom a particular name, and notice its occurrence in particular diseases; it is necessary to describe each symptom in general, and to distinguish each modification and peculiarity of it in particular. Dyspnœa is noticed as a symptom of inflammation within the chest, of hydrothorax, of asthma; but how widely different is the dyspnœa of pneumonia from that of asthma—how distinct the difficulty of breathing in asthma from the dyspnœa of hydrothorax, and from that of the numerous other affections in which this symptom is observed! How desirable, then, must it be to seize and describe these distinctions, and make the application of them to the discrimination of diseases!

It can seldom be said that any particular symptoms of disease are truly pathognomonic; but the kind and character of the symptom are frequently so. To ascertain, therefore, the form of each symptom as peculiar to different diseases, would be to establish that system of pathognomonics so much desired by the more ancient physicians. (*Cullen*, Nosologia Methodica, p. vii.)

The varieties and modifications in the form of symptoms must be traced, too, in immediate reference to particular instances of disease. Much has been written on the different states of the pulse; and numerous artificial divisions of this symptom have been formed; but in general this has been done in too abstract a manner. To study the pulse to any practical purpose, it should be constantly considered in relation to some individual disease, its character noticed, its changes traced, and its indications ascertained. Every thing must be as little general and as little abstract as possible.

A proper and full arrangement of the symptoms and their varieties must be of great importance in the investigation and identification of diseases. Some symptoms have been considered as real diseases, and it must be absolutely necessary to draw just distinctions between them, with a view to their cure. A similar arrangement and discrimination of the varieties of each symptom are of essential importance to the diagnosis, and of the greater moment in this place, because the investigation has been hitherto pursued in a very partial and inadequate degree. Dyspnœa, icterus, hydrops, &c. must be distinguished, as symptoms merely, from real diseases, and each form and variety of these affections must be carefully distinguished from the rest, and accurately associated with its particular cause.

There are also some other circumstances which claim our attention. The particular combination of symptoms, and the influence of one symptom in inducing and modifying the others, are observed to be characteristic of certain affections and stages of disease.

In our clinical visits, we naturally resort to the principles of analysis and synthesis, in order, first, to seize some particular points, such as several prominent and important symptoms, from which we proceed, in the second place, to collect such other symptoms as usually concur, and complete the character of the disease we have in view. We are thus confirmed or corrected in our opinions by the congruity or incongruity of the several parts; we perceive that the disease is simple or that it is complicated; and we trace its progress in itself, or its extension, and involution of other diseases, or of parts of the system not originally affected. It is, indeed, comparatively easy to observe and describe symptoms, or appearances in morbid anatomy, abstractedly; the task of difficulty, as well as of utility, is the proper and just association of them as signs of diseases.

Some symptoms are not only incongruous but incompatible; and by a careful and patient observation we often satisfy ourselves on a point which we could not decide by any inquiries. When a patient has complained of pain of the side, for instance, and it has been doubtful whether the pain were inflammatory, a spontaneous sigh has decided the question. In the same manner writhing of the body is unusual if not incompatible with inflammation. At least, although, as Celsus observes, "vix ulla perpetua præcepta medicinalis ars recipit," these circumstances afford great assistance in the investigation of diseases. We are thus frequently enabled to circumscribe our inquiries by ascertaining what the disease is not, before we have actually discovered what it is.

But without entering so minutely and carefully into this subject, there is something in the coup-d'œil, or general sum of appearances, which is of great utility to the experienced physician. There is in practical medicine a circumstance of the first importance, the recognition of a disease. The general appearance of the patient, the peculiar modification, the particular combination, and the mutual influence of the symptoms, give a general character to the whole disease, which is recognised and felt by the physician of experience and observation.

Accurately to discriminate the symptoms of

diseases, and their various forms, is to apply to the objects of clinical medicine the principle of analysis; and accurately to describe them will be to render the knowledge of them and of medical experience in general more communicable to others. It has long been remarked and regretted that practical knowledge in medicine is peculiar in this respect,—that it cannot be taught, and that the precious fruits of experience necessarily die with their possessors.* How unfortunately true this remark is to a certain extent, must be universally acknowledged. And from this admission, the importance of devising the means of rendering medical knowledge more capable of being imparted from one person to another is sufficiently manifest. Now it has happened to us that the difficulty in effecting this object may be in some degree obviated. On considering the nature of experience in medicine, it is plain that it consists, in a great measure, in an acquired capacity for receiving and acting on general impressions induced in the mind by the repeated contemplation of disease. The inexperienced practitioner is incapable of receiving these general impressions; the experienced are, in general, incapable of explaining them. Is it not, however, probable that, by presenting to the young clinical student an analysis of those general impressions which constitute the object of experience, he may be very materially assisted, and that experience may not only thus become more communicable, but that the young practitioner may thus also sooner become experienced, and earlier capable of acting on similar general impressions! If this be true, such an analysis of the general impressions of experience must prove highly useful. But such an analysis implies the observation and detail of every particular constituting the general sum of morbid appearances,—the enumeration and description of every phenomenon which can be presented to the observation of the physician.

It is true this general view of disease is inadequate to the purposes of practice; it is, however, of great assistance and utility; and the most experienced must not rest satisfied with his general knowledge, but must make the most particular inquiries, in the case of each individual patient; "etiam vetustissimus auctor Hippocrates dixit, mederi oportere et communia et propria intuentem." (Celsi, Præf. lib. i.) The general impression in question is chiefly useful by contracting the circle of our inquiries, and by leading us nearer that centre which consists in the individual case before us. It is especially useful in dispensary practice, in which many patients must be seen in a short time, and in which there is not, consequently, sufficient opportunity for entering fully into particulars.

In conclusion, we may remark that the objects of the history and symptoms of diseases may be divided into those of observation and those of inquiry on the part of the physician; the former are the more satisfactory; the results of inquiries are apt to partake of the vagueness and incorrectness of the answers of the patient. In conducting these inquiries, we ought to be careful not to put leading questions, and not to receive the replies implicitly, but to try their truth by ascertaining their congruity or incongruity with the character and history.

We must now revert briefly to that source of diagnosis which is afforded us in the effects of remedies. It chiefly refers to the effects of bloodletting, and consists in the fact, that inflammatory affections of the serous membranes and parenchymatous substance of organs induce great tolerance of loss of blood, in the perfectly erect position. The institution of bloodletting in this position affords therefore a diagnosis of acute diseases of the utmost moment. But the subject has been noticed more at length in its proper place.

I. The History of Diseases.

The principal objects of the history of diseases are, their causes and their course. We do not propose to enter now into details upon these subjects, as they will be treated of in a subsequent part of this article, but, supposing them known, to point out some of their practical applications.

It is of the utmost importance to observe the causes of prevailing epidemics,—as contagion,—season of the year,—state of the weather, &c.,—and of endemics, as marsh effluvia, peculiarity of situation,—prevailing occupations, &c. It is important to know what we may expect in our visits to the sick.

The influence of local situation in inducing typhus, intermittent fever, dysentery, phthisis pulmonalis, bronchocele, calculus, &c. is now well understood; the effects of sedentary occupations is to lead to the different forms of the dyspepsiæ. Typhus is frequently observed in new comers into crowded cities; (*Louis*, Recherches de Gastro-entérite, t. ii. p. 452. *Andral*, Clinique Médicale, ed. 2, t. iii. p. 448;) and intermittents, in the visitants or inhabitants of marshy districts. There seems to be good reason for supposing that where intermittents prevail, phthisis is less frequent in its occurrence. (Trans. for the Improvement of Med. and Surg. Knowledge; vol. iii. p. 471.) Calculus is less observed in sailors than in persons residing on shore. (Medico-Chirurgical Transactions.) It cannot be doubted that the careful observation of these external causes, and of their effects, must contribute materially to a knowledge of the diagnosis of diseases and of their various forms.

The next class of causes, which we shall briefly notice, are those of the habits and of the constitution of the patient. The habits of the patient relate chiefly to his occupation, and are sedentary or active, and to his mode of living with regard to diet, wine, &c. It has already been observed that sedentary persons are subject to the dyspepsia; those who eat and drink freely, are of course exposed to diseases of fulness, as apoplexy; whilst the spirit-drinker is exposed, on one hand, to attacks of the delirium tremens, or, on the other, to the slower inroads of organic disease of the liver, dropsies, purpura, &c.

The constitutional causes are chiefly those of the form, and of hereditary tendency or taint. The tendency to apoplexy, to phthisis, to gout, and even to calculus and gall-stones, is sufficient to illustrate the present subject. Nor can it be doubted that a careful inquiry into these points

* See Pearson on Cancer, Pref. p. vi. *Ουτε τεχνη ουτε σοφιη αφικτον, ει μη μαθη τις.* ΔΗΜΟΚΡΑΤ. ΦΙΛΟΣΟΦ.

must materially conduce both to the prognosis and to the diagnosis of these morbid affections.

In some diseases, however, both the character and prognosis are apt to be modified by complication, or by changes in the original affection. Typhus and other fevers are apt, from a simple form, to become complicated by some local organic affection. The dyspepsiæ are particularly apt to have their most prominent symptoms removed from one organ to another.

It is a point of great interest and importance to study the early history of insidious diseases, in order to prevent errors in the diagnosis and prognosis. It is of still higher importance to trace with accuracy the previous history of sudden and impending diseases, in order that we may, if possible, prevent them.

In other diseases, as inflammation, and especially organic diseases, the course is comparatively more regular and uniform.

The course of mesenteric disease is perhaps the slowest, and most regularly progressive, of all diseases eventually fatal; it usually occupies a space of from three to five years.

In many diseases it is necessary to watch the course or extension of the primary disease, as it involves different organs. It is a point perhaps of still greater interest, to trace the gradual superinduction of organic disease in cases originally consisting of derangement of function. True asthma may lead to disease of the heart. Protracted dyspepsia is, after excess in spirits, the most frequent cause of hepatic disease.

There is a point in the history of the diseases which still requires attention; viz. what has been termed the metastasis or conversion of diseases. This event has occurred in gout, rheumatism, erysipelas, cynanche parotidea, some cutaneous affections, suppressed hemorrhoids, (see the Edinburgh Journal, vol. xv. p. 106,) &c. But we think some of the events of the morbid affections which accompany the dyspepsiæ have been mistaken for metastases of diseases; and some of the effects of the treatment, as will be noticed immediately, are very apt to be mistaken for changes or consequences of the disease.

Various diseases are apt to succeed to each other from originating in one common cause; phthisis is apt to follow fistula ani; [such at least is the common opinion; yet M. Andral (*Clinique Médicale*, 4 ème édit. iv. 308,) met with it in but one of 800 cases; and M. Louis affirms (*Researches on Phthisis*; Sydenham Society, edit. p. 89, Lond. 1844,) that he had not been more successful,] syphilitic and syphiloid affections variously succeed to each other.

The study of the history of diseases, it has been already observed, is of essential service in dispensary practice, in which, from the considerable number of patients seen in a limited time, a prompt diagnosis is required. The following rules will be found extremely useful to the young physician on such occasions. It is only, however, as an approximation to the diagnosis, that such rules can be attempted. It will still be necessary to inquire into the particulars of the individual case.

The first question to be asked of the patient is, how long he has been ill. The reply resolves the case into the class of acute, or of chronic affections. The former are principally fevers, the acute dyspepsiæ, or acute inflammations; the latter are the chronic dyspepsiæ, the insidious organic diseases, or the insidious forms of inflammation, — especially of the brain, the pleura, and the peritoneum.

Having thus ascertained the class of the disease, we must proceed, in the case of the acute, to investigate the individual nature of the case. In chronic affections we may ask—

In the second place, whether there be a material and progressive loss of flesh.

The reply to this inquiry divides the cases into such as may subsist without influencing the nutrition, and such as gradually reduce the patient. The former cases are chiefly the chronic and protracted forms of dyspepsia, or diseases of such organs as are not engaged in the process of assimilation. The latter are merasmus, phthisis, mesenteric disease, chronic inflammation of the peritoneum, and, in general, diseases of the 'organs of supply.'

A third inquiry is into the state of the pulse. Increased frequency of the pulse is the usual attendant on the insidious forms of organic disease, whilst it is not observed in the less serious cases of the chronic dyspepsiæ.

Other questions are, what is the seat of pain or uneasiness?—what are the functions disordered?

It is needless to enter more minutely into the subject, as it would be only repeating the observations, to be detailed forthwith, on the general aspect of the patient, and the general character and course of the disease.

II. The Symptoms of Diseases.

The Morbid Appearances of the Countenance.—The particular circumstances embraced in an examination of the morbid states of the countenance, are the changes induced in the cuticular surface, the cutaneous circulation, the cellular substance, the muscular system, some particular features, and the general expression.

The cuticular surface is morbidly affected in some long-continued disorders, chiefly of the digestion, especially round the eye and the mouth, giving a peculiar appearance to the complexion. But the complexion, as well as the surface of the countenance, is principally affected by the condition of the cutaneous circulation; on this depend chiefly the state of pallor or flushing, and of the sallow and icterode hues of the complexion observed in some disorders, — the state of tumidity or shrinking,—of heat or coldness, — of dryness or moisture, or cutaneous exudation.

The state of emaciation, so important to observe and trace in chronic diseases, depends on the loss of cellular and muscular substance, and must be always distinguished from mere vascular shrinking.

The muscular system is principally affected by diseases attended with pain, languor, or paralysis.

Amongst the particular features, it is of moment to observe the eye, the prolabia,—the brow, the nostrils, the lips, &c. The eye, in particular, affords the opportunity of judging of the degree in which the serum is loaded with bile, in cases of icterus, and of distinguishing that disease from those morbid affections in which the complexion becomes sallow and icterode from the state of the cuticle and cutaneous circulation. The state of

the prolabia affords an index of other states of the blood,—as of a too serous condition, or of a defective arterialization. The nostrils, carefully observed, denote the condition of the respiration.

Of the general expression of the countenance we shall rarely venture to speak. It affords an important and essential source of information in dispensary practice, and assists the experienced physician in discerning the nature of the diseases where the superficial observer sees only the general look of indisposition.

The morbid condition of the cuticular surface and of the cutaneous circulation is accompanied with peculiar affections of the hands, and of the general surface, and of the tongue. These associations it will be our object to trace in the subsequent pages. We now proceed to describe the appearances of the countenance in reference to particular diseases; we have already stated, that it is with such reference alone that the knowledge of symptoms becomes of practical utility.

In the acute synochus there is a diffused, vivid flushing of the countenance, frequently with considerable turgidity, especially in the young and sanguineous; the tunica albuginea is apt to be suffused, and there is great febrile heat. There are also general anxiety, tremor of the lips in speaking, and a rapid movement of the nostrils from hurry in the respiration. The tumidity diminishes as the fever runs its course, and either declines or assumes the slow and protracted character.

In the acute inflammations, especially of the serous membranes, or parenchymatous substance, the countenance has a very different aspect, which it is important to observe, especially in a diagnostic point of view. The heat, turgidity, and flushing, the suffusion of the eyes, the tremor of the lips, and the hurried movement of the nostrils, are absent, whilst the surface is frequently affected with perspiration. There is also usually an appearance peculiar to the primary disease.

From the state of countenance described, the transition is often imperceptible to that observed in the protracted synochus; sometimes, on the contrary, the appearances of this febrile affection come on insensibly from similar causes, without being preceded by the acute form. Instead of tumidity and suffusion, there are shrinking, partial flushing of the cheeks only, emaciation, and frequently a pallid and sallow hue; the cheeks become fallen, and the malæ, maxillæ, and other bony parts, appear prominent; the surface becomes dry and rough; the lips, like the tongue, are dry and tremulous, and not moved with the usual freedom in articulation; the teeth are frequently somewhat affected with sordes or mucus.

In chronic inflammation the appearances are peculiar. There is a characteristic expression of disease which strikes the common observer, and still more the experienced physician; the surface and complexion are cool and pale, or affected with transient or partial heat and flushing, usually without sallowness, frequently with slight lividity, sometimes with cool moisture; there are emaciation and shrinking, the cheeks falling in, the action of the muscles becoming apparent, and the skin forming into greater or smaller folds. These appearances of the countenance are, however, greatly modified by the nature and seat of the original disease, as will be particularly noticed hereafter.

In the milder form of typhus the countenance is equally unattended by deep flushing and tumidity, or with shrinking; but it is highly characterized by an expression of languor, feebleness, anxiety, and indisposition, and by tremor observed in the lips and on speaking; the eyes are frequently suffused; the cheeks slightly flushed; the surface is affected with a moderate degree of warmth. (See Currie's Medical Reports, vol. i. p. 12. Bateman on Contagious Fever, p. 28, &c.)

In the severe forms of typhus the countenance is marked by great debility and tremulousness of the muscles, and by great shrinking; the bones are more prominent, the intervening spaces more sunk and depressed than natural; the surface is sometimes slightly flushed, and sometimes cool and clammy. The eye-lids are frequently partly closed, and the eyes suffused, dull, and covered with a film of mucus; the mouth is apt to be partly open, the teeth and lips affected with dark-coloured glutinous sordes; the articulation is difficult and imperfect, and attended with great effort, and with tremor and an inadequate action of the lips and of the tongue, which is put out with tremor and difficulty. There is often superadded the appearance of delirium, or of coma, of congestion, or of collapse or sinking.

The countenance in continued fevers is liable to receive a modification from their complication with a morbid affection of the head, the viscera of the thorax, or of the abdomen, the detection of which is amongst the most important objects in the study of these diseases.

The different stages of intermittent fever are attended by peculiar states of the countenance, and especially of the cutaneous circulation. In the cold stage there are shrinking and paleness, pale lividity of the prolabia, trembling of the lips and maxillæ: in the hot stage there are heat, flushing, and tumidity, and suffusion of the eyes, and the features are restored from their collapsed condition: in the sweating stage the surface, complexion, and heat become more natural, whilst there is greater or less perspiration. In the interval there are, at first, languor and slight paleness; after a time paleness, shrinking, and emaciation.

The different fevers are so varied in themselves, and so various in their different stages, and in different individuals, ages, and habits, that the countenance, together with the symptoms of the disease, must necessarily be much diversified. But of all the diagnostics of the different fevers, and of all the indications of their progress, stages, and changes, none is more distinctive and characteristic than the appearance of the countenance. From this source the diagnosis and prognosis of fevers equally flow; and it cannot, therefore, be too strongly recommended to the attention of the clinical student and young practitioner.

The same remark may be extended to some of the eruptive fevers, in which there is, exclusively of the rash, a characteristic modification of the features. In rubeola the eye-lids are frequently red and swollen, and the eyes injected, before the appearance of the rash, and there is usually catarrhal affection; the rash begins in spots on the

face; and there are sneezing, intolerance of light, &c. In scarlatina the rash becomes more general and less interrupted, and it is accompanied with more general tumidity and fulness; there is frequently an appearance of fulness about the throat, and the voice is affected; but the symptoms of catarrh are usually absent.

We now proceed to notice some morbid appearances, chiefly of the complexion, which appear to us not to have obtained hitherto the degree of attention which they deserve. The appearances to which we allude occur in the very varied forms of disorder of the digestion, or dyspepsia, of which we have treated in another work, (Commentaries on the Diseases of Females); the especial object of which was accurately to trace their distinctive characters, as seen in the countenance, the tongue, the hand, &c.

The most severe, or acute form of this affection is accompanied with some paleness and sallowness, and a dark hue about the eye; the cutaneous vessels exude a little oily perspiration; the prolabia are slightly pale and livid; the muscles of the face, and especially of the chin and lips, are affected with a degree of tremor, particularly on any hurry or surprise, or on speaking. With this state of the countenance there are conjoined peculiar morbid states of the tongue, and of the hands, which will be described in their proper place.

A state of sallowness of complexion, unaccompanied with the appearances just described, usually attends the more chronic form of this affection, denominated dyspepsia.

The next variety of this morbid affection is that which is usually denominated chlorosis, of which we have described three stages. The incipient stage is denoted by paleness of the complexion, an exanguious state of the prolabia, a slight appearance of tumidity of the countenance in general, and of puffiness of the eye-lids, especially the upper one. There is sometimes superadded a tinge of green, or yellow, or of lead colour, and frequently darkness of the eye-lids. In the confirmed stage the countenance is still more pallid, the prolabia and the gums are exanguinous; or the prolabia, and especially the upper one, have a slight lilac hue, and the integuments in general are puffy and tumid. In the inveterate stage these appearances are gradually modified by the supervention of emaciation, or œdema. With each of these stages is associated a peculiar state of the tongue and general surface. These appearances in the different stages of chlorosis seem to depend partly on the state of the cutaneous capillary vessels, and partly on the state of the blood itself; at least, this fluid has become, in some instances, so serous as scarcely to tinge the linen as it has dropped from the nose.

In the more chronic form of this morbid affection, to which the epithet *decolor* is very applicable, there is a state of sallowness, of yellowish or icterode hue, of darkness or of lead colour, of a squalid or sordid paleness of complexion, or a ring of darkness occupying the eye-lids, and extending a little perhaps towards the temples and cheeks, and sometimes encircling the mouth. There is in this form of the affection little or no tumidity, pallidness of the prolabia, or tendency to œdema; and the tunica albuginea of the eye is free from the tinge of icterus. This morbid state of the complexion appears, indeed, to depend principally on the condition of the cutaneous surface of the countenance. The tongue is apt to be affected chiefly in the form of its surface only, in a peculiar manner, to be described hereafter; and the general surface of the body is apt to be more or less affected in the same manner as that of the countenance.

From this icterode appearance of the complexion it is important to distinguish the different shades of icterus itself: in this disease the tunica albuginea are tinged proportionately to the general surface; and it is in this manner that these two morbid affections are discriminated. The term icterus is merely expressive of a symptom of disease, although it is daily named and has long been arranged as a distinct disease. The shade varies from yellow to green or blackish. But the most important and only practical distinction with regard to icterus is that of its causes, or of the primary disease; the principal of these are,—1. constipation, or loaded bowels; 2. acute disorder of the digestive functions; 3. diseases of the liver; 4. gall-stones; 5. hydatids in the gall-ducts; 6. organic tumours in the abdomen, situated near the biliary ducts; 7. the pregnant uterus; 8. diseases of the right kidney; 9. or even of the right lung, or cavity of the pleura.

Besides the morbid affections of the complexion already mentioned, there are others consisting in different shades of lividity, and depending principally on a languid circulation, on a defective arterialization, or on a venous fulness of the blood.

In some cases of acute dyspepsia, there is a remarkable tendency to a livid hue of the prolabia, nose, and cheeks, as well as of the hands, accompanied with coldness and apparently dependent on languor in the cutaneous circulation.

A similar state of lividity, but frequently much greater in degree, is observed in cases of tuberculous disease of the mesentery, attended with great tendency to coldness and great sensibility to external cold.

A degree of lividity in the prolabia is frequently, though not universally, observed in phthisis pulmonalis. This appearance seems to depend on the part and on the extent of the pulmonary structure involved in the tuberculous disease, and on a defective arterialization, as well as a languid cutaneous circulation of the blood.

Besides the diseases attended with lividity of the countenance already mentioned, this appearance occurs, for the most part together with tumidity, in cases in which the brain, the lungs, and the heart are severally oppressed, in apoplexy, in pneumonia, and in some diseases of the principal organ of the circulation. The appearances in these diseases will be noticed immediately.

In the attack of apoplexy there is usually at first general tumidity, flushing and lividity of the countenance; the pupils are contracted, then dilated, and often unequal; the features frequently lose their symmetry, those of one side of the face being unusually acute, whilst those of the other are relaxed; and the whole countenance is drawn, of the expression lost in coma. At a subsequent period the countenance becomes pale, fallen, cold,

and often variously distorted. Heberden observes, "apoplectici, qui prope absunt a morte, in spirando ambas buccas inflare solent;" and indeed the oppressed state of the respiration always adds a characteristic appearance to the countenance: the pupils are dilated, perhaps unequal, or irregular in form; the eye is dull and flaccid; the jaw frequently falls, the saliva flows, the lips are pale, and the mouth is foul. A similar state of the countenance to that last described sometimes exists from the beginning in cases of what has been termed the serous and nervous forms of apoplexy.

Paralysis is a usual concomitant or consequence of apoplexy. The effects of cerebral paralysis on the countenance are very various: the muscles of one side of the face fall into a state of relaxation, whilst those of the opposite side are unusually contracted from want of power in their antagonists; the forehead is often unequally affected by wrinkles, the eye-brow of one side falls down, the eye-lids do not open or close so readily as usual, or the eyes are not converged on the same object; one nostril, one angle of the mouth, and one cheek fall, whilst the others are usually drawn, especially on speaking; the tongue is frequently protruded awry, and with difficulty; the articulation is indistinct, and some particular letters, especially the labials, as *b* or *p*, cannot be pronounced. Deglutition is also sometimes affected, and there is a danger of choking; frequently mastication is impeded by the collection of the bolus of food into one side of the mouth; sometimes the saliva flows out of that angle of the mouth which is now become the lower one. There is frequently a difficulty in shaving, from the torpor of the skin, and the loss of power in the muscles which in health put it upon the stretch.

The countenance in epileptic coma has sometimes the deep suffusion observed in apoplexy, but it preserves its symmetry; the lip or tongue is liable to be bitten and wounded, and there is then frequently a bloody foam in the mouth, a point of great importance in the diagnosis.

The countenance in deep intoxication is at first bloated and suffused, then pallid and sunk; the muscular power is defective, the expression lost, the articulation indistinct, and the saliva flows from the mouth; the sensibility is impaired or lost; the breath tainted with the intoxicating liquor.

Hysteric stupor is distinguished by the absence of the suffusion, distortion, and loss of character, observed in apoplexy.

Syncope is characterized by pallor, coldness, cold perspiration, pale lividity, shrinking, and collapse of the integuments and features,—appearances which do not concur in the commencement of any other morbid affection.

In inflammation of the brain there is at first an expression of pain or uneasiness manifested usually by knitting of the eye-brows, with delirium or coma: afterwards the pupils, from being contracted, become dilated; there are strabismus, grinding of the teeth, spasms or distortions of the muscles of the face, &c. with profound coma, and without the appearances observed in idiopathic fever.

In pleuritis the degree of the pain is marked by a proportionate contraction of the features in general, and by acuteness and elevation of the alæ nasi; the nostrils are moved and dilated by the alternate acts of the respiration; there is sometimes a degree of vivid flushing, terminating abruptly and bounded by whiteness towards the nose; the heat is inconsiderable, and there is frequently perspiration.

In pneumonia there is less contraction of the features, but there is greater appearance of dyspnœa, very important to be observed in this disease, and the nostrils are widely dilated before each inspiration: there is little heat, but frequently a degree of perspiration.

In inflammation of the chest with clogged bronchi or air-cells, there is usually a general and deep suffusion of the countenance, sometimes amounting to great lividity, conjoined with turgidity; there is great anxiety and dyspnœa, the nostrils are widely dilated on inspiration, and drawn in above the lobes; during inspiration the pomum adami, and even the chin, are sometimes drawn downwards; the surface is cool and sometimes damp.

The dawn of phthisis pulmonalis is marked by a delicate and often waxy paleness, alternated with transient gentle flushing, slight lividity of the prolabia on exposure to cold, an appearance of indisposition, frequently motion of the nostrils from the respiration, and frequently a quivering of the chin and lips on speaking. Its progress is denoted chiefly by gradual emaciation, in addition to an aggravated state of the other morbid appearances just mentioned.

In hæmoptysis there is usually a florid state of the complexion, and frequently the effects of dyspnœa are observed in an acuteness and movement of the nostrils. If the hemorrhage has been very great, there may be paleness, lividity, coldness, and a clammy perspiration, with great anxiety.

In hæmatemesis, on the contrary, the complexion is generally pale and sallow, and frequently affected as already described; there is less anxiety and an absence of the movements of the nostrils.

In organic diseases of the heart the expression and complexion are frequently much affected.* In those cases in which the pulmonary circulation is not impeded, the complexion simply becomes unusually vivid and florid. But when the nature of the disease affords an obstacle to the freedom of the pulmonary circulation, this vivid colour passes into a livid or violet colour, especially in the prolabia, cheeks, and nose; and there is superadded more or less of turgidity, and frequently of coldness. There is great anxiety on mental emotion and bodily exertion, with an increase of the appearances just enumerated, and the head, the ends of the patient's cravat, &c. are frequently moved by the violence of the beating of the heart. During the progress of the disease, these appearances become aggravated, the complexion is still more livid, the turgidity of the countenance passes into œdema, the eyes at length start, and the head

* M. Corvisart observes, "la figure, la physionomie, le *facies propria* enfin, sont, pour le practicien exercé, le guide le plus sûr, à mon avis, pour arriver au diagnostique d'un assez grand nombre de maladies tant aiguës que chroniques; mais c'est surtout dans les cas de maladies du cœur qu'il importe de considerer attentivement ce signe, qui, je le repète, peut seul, dans bien des cas, les faire reconnaître."—Essai sur les Maladies du Cœur, ed. 2d, p. 371.

is often moved about, denoting great distress and inquietude.

In the paroxysm of true asthma there is the most urgent anxiety of expression, and a great and rapid movement of the nostrils, usually without lividity; the breath is generally tainted, the tongue much affected, and there are frequent eructations.

In inflammation of the abdomen with severe pain there is a continued state of contraction of the muscles of the face, inducing an unnatural acuteness of the features; the forehead is wrinkled and the brows are knit; the nostrils are acute, drawn upwards, and moved by the alternate and irregular acts of the respiration; the wrinkles which pass from the nostrils obliquely downwards are deeply marked; the upper lip is drawn upwards, (see Laennec, ed. 1st, tom. i. pp. 90, 398,) and the under one, perhaps, downwards, exposing the teeth; the chin is often marked with dimples. This state of the features is aggravated on any increase of pain, from change of position, muscular effort, or external pressure. Indeed, in cases of abdominal affection, it is better to press on the abdomen, or to beg the patient to raise the head and shoulders, and watch the effect on the expression of the countenance whilst the patient's mind is occupied with some other subject, than to ask the direct question whether pressure induces pain, as is usually done; for patients naturally suppose that every painful part must also be tender, and are therefore apt to answer in the affirmative, although incorrectly. In cases attended with spasmodic abdominal pain the contractions of the muscles of the countenance are more violent but less permanent; during the paroxysms, the distortions of the countenance take place in a degree scarcely observed; in the interval, the countenance recovers a calm, unusual, if not incompatible, with inflammation. The transition of spasmodic into inflammatory pain may often be traced with great distinctness, by carefully observing these changes and modifications in the expression of the countenance.

The degree, increase, or diminution of the disease may also be observed and ascertained by the concomitant increase or diminution of the acuteness and contraction of the features.

The transition of inflammation into the state of sinking, or the supervention of gangrene, is denoted by a fallen state of the features, the muscles becoming relaxed, the surface cold, with cold perspiration, shrinking, and pale lividity, the cheeks sunk, the malæ prominent, the nostrils, &c. affected by a laboured respiration.

The appearance of the countenance affords a valuable source of distinction between the chronic dyspepsiæ and insidious organic disease. In the former, the appearances are as have been already described; in the latter, there is a characteristic, early, and progressive loss of flesh, with paleness, perhaps slight flushing, but without sallowness, the bony and muscular parts become exposed, the integuments are drawn into deep wrinkles, and there is often coldness and perhaps lividity. Such a state of the countenance, with an expression of pain, uneasiness, or anxiety, often leads to the detection of slow and insidious pleuritis or peritonitis, as well as of other diseases which would long remain hidden, from being unattended with acute pain.

Scirrhus and cancer are apt to induce sallowness [straw colour] and emaciation — a circumstance by which they are sometimes distinguishable from other tumours or ulcers.

Polysarcia is distinguished from anasarca in the face, by observing that in the former the tumour is deposited with a certain regularity, so that in general the symmetry of the countenance is not destroyed, nor the features much disfigured. In anasarca, on the contrary, an inelastic tumour is dispersed unequally over the face, the features are obscured, the symmetry of the countenance is destroyed, the expression lost, and the person is scarcely recognised: the posture of the patient during sleep influences the distribution of the swelling, and often occasions one side of the face to be more affected than the other; but the eyelids, the lips, and the cheeks, and in general the parts of loosest cellular texture, are most distended.

In general it may be observed that the brow is contracted by pain within the head, the nostrils are drawn acutely upwards by pain of the chest, and the upper lip is raised and stretched over the gums or teeth in painful affections of the abdomen.

Alternate dilations and contractions of the nostrils arise from any effort in respiration, and are observed in great debility, in the synochus and typhous fever, in acute inflammations of the chest or abdomen, in organic diseases within the thorax, &c.

Extreme pallor of the prolabia is observed in excessive hemorrhage, purpura, chlorosis, &c.; deep lividity denotes a defective arterialization of the blood, and occurs in disease of the heart, &c.; pale lividity occurs in cases in which the circulation at the surface is languid and imperfect.

One of the most important points embraced in the symptoms of diseases, and one particularly observed in the countenance, is the circumstance of emaciation. It may be said to be the surest index to the detection of those diseases which are characterized at once by their insidious character and serious and dangerous tendency.

It may be observed, in conclusion, that to notice every morbid appearance of the countenance would be almost impossible, and even useless. The object of such an attempt as the present is rather to lead to observation; the remarks which have been made are sufficient, we trust, to point out the importance of the inquiry. Many of the morbid appearances of the countenance, like the morbid states of the pulse, respiration, &c., are, after all, to be observed and felt, and scarcely admit of description. Our object has therefore been to select a few instances of morbid affections particularly distinguished by the state of the countenance, in order to invite the attention of the medical student more particularly to a source of judgment and information applicable also to those fainter shades of diversity and change, the perception of which so much distinguishes the physician of observation from the mere practitioner. Sufficient has been done, however, to prove that the countenance, in its various morbid conditions, affords characteristics of many diseases, and denotes, in a remarkable degree, the state, course,

increase, or decline of nearly all. The prognosis is greatly prompted by the condition of the countenance, as may still be learnt from the writings of Hippocrates and Celsus.

2. On the Morbid Conditions of the Attitude.—We employ the term attitude in rather a comprehensive sense, intending to embrace, under this head, the consideration of the postures and motions of the body, the state of muscular debility, power, contraction, and motion, some particular actions, and the general manner of the patient.

In general, the supine position, and tremulous motions of the body, denote muscular debility,* and distinguish, in an early stage, the acute forms of idiopathic from symptomatic fever.

Augmented power and action of the muscular system, with quick and forcible changes of position, denote a state of delirium, of spasmodic pain, of internal suffering, or of inquietude.

Certain positions adopted and retained with caution, and restrained movements of the body, are the usual effects of inflammatory pain: other fixed positions depend on the state of the respiration, and of the circulation through the heart.

Certain movements of the head, certain actions of the hand, and certain peculiarities of the general manner, also occur as characteristic of particular diseases, and will be noticed hereafter.

The morbid states of the attitude will appear more distinctly marked, by being contrasted with the more usual and natural positions of the body.

In healthy and undisturbed sleep, the usual posture is that on one side, the body being frequently inclined rather to the prone than to the supine position; the head and shoulders are generally somewhat raised, and, together with the thorax, bent gently forwards; the thighs and legs are in a state of easy flexion. The position is apt to be changed from time to time, the person lying on one or other side alternately.

In acute synochus, one of the earliest and most characteristic symptoms is a deep sense of debility, with tremour, and an incapability of supporting the erect position; this posture, if assumed, induces also the feelings of vertigo and faintness.

In acute inflammation there is comparatively little or no tremour or muscular debility, or tendency to vertigo or faintness; the patient is capable of moving, and even of walking, even in a late stage of the disease.

In protracted synochus there is, in some cases, for a considerable time, a supine position, with scarcely the ability to change or support the position on the side; there is tremour, consisting of less rapid but more considerable movements than those observed in the acute form; the knees are apt to be raised.

In the milder form of typhous fever the patient sometimes gets up or continues out of bed, but appears feeble and trembling, and as if incapable of such a degree of exertion, whilst he draws near the fire from susceptibility to cold. In cases in which, however, the patient cannot get out of bed, he experiences vertigo, and perhaps faintness, on being requested to sit up in bed for a minute or two.

In the severe forms of typhous fever the position of the patient becomes gradually more and more supine, and the actions more and more tremulous: from being able to retain the posture on the side, perhaps, the patient falls upon his back, with the lower extremities extended, and sometimes with a tendency to sink towards the bottom of the bed; the hands and arms are moved with effort and tremour, and at length there is constant subsultus tendinum. To this state, picking of the bed-clothes, or flocci volitantes, delirium, or coma, is superadded.

Hippocrates (Προγνωστικον,) and Celsus (Lib. ii. cap. 3, 4, 6,) have accurately described the posture of fever. Celsus observes, "ubi vero febris aliquem occupavit, scire licet non periclitari si in latus aut dextrum aut sinistrum, ut ipsi visum est, cubat, cruribus paulum reductis, qui fere sani quoque jacentis habitus est; si felice convertitur, &c. Contra gravis morbi periculum est, ubi supinus æger jacet, porrectis manibus et cruribus," "ubi deorsum ad pedes subinde delabitur; ubi brachia et crura nudat et inæqualiter dispergit." As this position is occasioned by extreme debility, any change of posture is of favourable omen, as denoting a return of strength. The patient perhaps raises the knees, or puts the arms out of bed, or places them above his head. These movements are amongst the first symptoms of recovery. At length the patient is capable of supporting the position on the side—a certain mark of returning muscular strength, and an indication of favourable change in the disease.†

Tremour is amongst the first and most characteristic symptoms of continued fevers; but it occurs also in some other morbid affections, united with less muscular debility. It forms so remarkable a symptom in the delirium tremens, as to have been adopted as part of its designation. In one instance the tremour had preceded the delirium several days, and we were enabled to predict the occurrence of delirium: in another case, the effect of drinking, the affection consisted of great tremour, and, being cut short, delirium never occurred. It is scarcely necessary to advert to the more constant state of tremour observed in hard drinkers.

Tremour on holding out the hand, in writing, in carrying a cup to the mouth, in walking, and in articulation, is a usual symptom of acute dyspepsia; it is generally conjoined with an appearance of nervousness and of susceptibility to hurry and agitation.

Tremour is far less and later observed in cases of local inflammation or organic disease; it does, however, occur in phthisis pulmonalis, and in cases in which the general strength suffers.

* We restrict, in this place, the application of the term debility by the epithet muscular, because it is now well known that this species of weakness is frequently the effect of oppression and the associate of increased vascular action: just as a throbbing pulse may accompany the state of exhaustion.

† There are two points in the treatment of typhous fever, connected with the attitude, of the utmost importance:—sometimes the supine position is retained so long, that ulceration takes place on the compressed parts, especially about the sacrum or pelvis. Dr. Arnott's very ingenious proposal of the hydrostatic bed seems admirably adapted to obviate this calamity. The second point is cautiously to guard against the effects of muscular exertion during the period of convalescence. By far the greater number of relapses are occasioned by early and undue exertion and fatigue: the effect is speedy, or gradual, sinking of the powers; the inference is obvious, and of the utmost consequence.

The form of tremour which we have described seems to depend on muscular debility, and perhaps on a morbid condition of the brain and nervous system. There is a kind of tremour of a more spasmodic character, which occurs from various causes, and which we shall notice towards the conclusion of the present section.

The effect of particular postures is of importance to be noticed as distinctive of affections of the head. In the idiopathic affections, as in the state of threatening of apoplexy, vertigo and other morbid feelings are apt to be experienced on stooping: in the symptomatic affections, as in fever, acute dyspepsia, intestinal irritation, exhaustion, &c. vertigo is usually experienced on assuming the erect position.

An attention to the posture of the patient is also of importance in the treatment: the recumbent position is as injurious in the case of apoplexy, as it is beneficial in that of syncope.

It is scarcely necessary to point out the effect of hemiplegia, paraplegia, or partial paralysis, on the attitude. In hemiplegia the patient is apt to lie or fall more or less upon the paralysed side, and especially upon the paralytic arm. In paraplegia the posture in sitting is manifestly marked by the defective muscular power, the patient being constantly apt to slide off the chair or sofa. In the partial paralysis it is found that the hand cannot be moved so freely or clasped so firmly, or the foot and toes are lifted imperfectly from the ground in walking.

The attitude is peculiar in the different forms of inflammation of the chest. In pleuritis the patient usually reposes on the affected side, which is thus kept free from movement. In pneumonia the patient almost invariably assumes and retains the posture on the back. In those cases which are attended with much dyspnœa, the patient is frequently obliged to have the head and shoulders raised, and even to assume the erect position. We have observed, in some cases attended with great dyspnœa, that the patient has lain on the side, with the arm of the other side placed upright before the chest, the hand pressing forcibly on the bed: in this manner the shoulder became fixed, and afforded a firm attachment from which the pectoral muscles acted to expand the chest.

In phthisis pulmonalis the posture is various. Frequently, however, one particular position is chosen and preserved — pain, cough, dyspnœa, or oppression, being induced in any other: this is usually on the side most diseased, as that in which pleuritic pain is most apt to exist, early in the disease, or cavities, in its later stages.

In extreme hydrothorax, the position of the patient is frequently highly characteristic; it is less so probably, according as the effusion has taken place more gradually and slowly. In the less severe form, the patient, when in bed, usually lies with the head, shoulders, and chest gently raised by additional pillows; when out of bed, he is often observed to sit up, with the arms placed along the side, and the hands fixed and pressing forcibly on the chair, or sofa, on which he sits: in other cases he leans a little backwards, still supported by the arms and hands, which are placed behind the back. This kind of posture is often constant, or immediately resumed if any accident occasions it to be changed: it gives rise to an elevation of the shoulders, from which the body is supported, or as it were suspended. In the severer forms, the attitude varies with the degree and progress of the disease: at first, the patient lies with the head and shoulders greatly raised; afterwards the posture becomes more and more erect; at a still more advanced period, and in a more aggravated form of the disease, the patient is sometimes incapable of remaining in bed, and is obliged to sit up, with the legs hanging down; sometimes an arm-chair is obtained, on each arm of which the patient presses and supports the hands or elbows, thus suspending the shoulders; sometimes a second chair is required, on the back of which the patient reposes the forehead, or both hands and forehead, pressing with considerable force, thus fixing the upper attachments of the sterno-mastoid muscles. This aggravated state of the attitude is certainly most frequently observed in cases of hydrothorax complicated with organic disease of the heart or lungs, or of the liver or other organ situated in the abdomen. In some cases of hydrothorax in its simpler forms, the patient has retained a nearly horizontal position; in cases of complicated hydrothorax, he has even expired out of bed, supported by his friends.

In organic diseases of the heart, the attitude—at first the effects of bodily exertion, and afterwards the particular posture of the patient—is very characteristic. In incipient and dubious cases, the diagnosis is assisted by observing the effects of muscular effort, especially such as involves much change of position and general motion of the body: if the patient be requested to run up stairs, the symptoms are invariably produced in cases in which they would be quiescent in a state of repose, or aggravated if permanent. In a more advanced stage of the disease, the sufferings of the patient become more acute and permanent; a certain restlessness, anxiety, and dyspnœa, aggravated extremely by every muscular effort or motion, take place, and distinguish the case from simple hydrothorax, in which muscular motion induces far less inconvenience. In a still more aggravated form of the disease, the patient requires to be raised in bed more and more, until the erect posture, or even a posture inclined upon the thighs, becomes necessary; and at length there is an inability to sit erect even, while the lower extremities are placed horizontally, and the patient is obliged, perhaps, to sit on the side of the bed, with the legs hanging down and the feet on the floor; the night, as well as day, is sometimes spent sitting up in a chair near the fire, sometimes with the head supported on the back of a chair, and the body leaning considerably forwards; in this stage of the complaint there are an inexpressible restlessness and anxiety. At any period of disease of the heart, a sudden change of posture from the horizontal to the erect frequently becomes necessary, from the aggravation of the symptoms and general agitation induced by a turbulent or terrific dream; frequently, too, the patient is obliged to get out of bed and repair to the window to respire the open air.*

* It need scarcely be observed how important an attention to the attitude becomes in the treatment of diseases of the heart. In the incipient stage, the patient ought

In the paroxysm of asthma, by which term we designate the cases of sudden attack of dyspnœa arising, at first, from a disordered state of the digestive organs, the erect position is usually necessary; and there are great anxiety and urgency of suffering, frequently with active restlessness.

In inflammation in the abdomen with acute pain, a certain position of the body is chosen and retained, and all muscular exertion, motion, or change of position, is carefully avoided:—the patient lies on the back with the thighs raised, or he is supported in a somewhat elevated posture by means of pillows placed under the head and shoulders, or he lies on the side, with the thorax and the thighs in a state of gentle flexion on the abdomen; if he be desired to raise the head by muscular effort, an expression of aggravated pain is immediately visible in the countenance: the hands, and perhaps the bed-clothes, are carefully removed from pressing on the abdomen; the arms are put out, and the knees raised or depressed with great caution; the manner is soft, and the voice low and plaintive, with moaning, and a suppressed kind of complaining.

In spasmodic pain of the stomach, or in colic, the reverse of this state of general attitude is observed: the patient usually writhes to and fro, and constantly changes his position or mode of lying, instead of observing the cautious stillness of inflammation; he often lies on the abdomen, or in the supine position, pressing violently on the bowels, or even grasping a portion of the abdominal parietes with the hands; or he sits in bed, bending forcibly forwards on the thighs; he cries out during the paroxysm of pain, and speaks in a loud and irritated tone of voice. All this violence, both in general manner and posture, forms a remarkable contrast with the subdued motions of inflammation.

After the paroxysm of pain in colic, the patient resumes an easy position; in the absence of an aggravation of pain in inflammation, the same cautious posture and manner are still observed as before. The transition from spasm or colic into inflammation may be easily traced by cautiously observing the characters of these different affections.

The termination of inflammation in gangrene, or sinking, is marked by the fallen and supine position, and extreme debility; the patient lies extended on the back without the flexion and precaution previously observed in the stage of inflammation; the manner of the patient still remains soft and plaintive.

In strangulated hernia the posture is at first, perhaps, attended with writhing, but soon becomes the same as in inflammation, especially with the precaution of bending the thighs on the abdomen.

In inflammation of the kidneys, the patient, when up, often inclines somewhat to the side affected, and a little forward, especially in walking: and, in a painful state of the affection, he walks with unusual precaution.

In inflammation of the bladder, the patient frequently bends forward on the pelvis, evidently with the view of giving protection and relief to the parts contained in it, and of using as little as possible those muscles whose action might give pain; he walks cautiously, and often bends forward still more during this action of the muscles.

Retention of urine, as a symptom in acute diseases, is often denoted by a state of constant elevation of the knees, which is inexplicable until the cause is discovered.

In organic diseases in general, the patient soon becomes affected with a serious, continued, and unvaried debility, stoops in walking, and moves with slowness and caution. All deep-seated pain or uneasiness is often experienced from the succussion induced by sitting down or making a false step in walking, especially when there is a state of tenderness from inflammation.

In the appearance of the *hand* it is often easy to read a state of pain, anxiety, or other suffering: it is closed or expanded, or variously moved. We do not, however, deem it necessary to enter into any detail respecting points so perfectly obvious.

There is another symptom of importance to be noticed, viz. the state of jactitation and inquietude; it occurs in different states of the system, and in some diseases, but principally in cases of irritation, exhaustion, and sinking, and in diseases of the heart.* We reserve the consideration of these subjects for a subsequent part of this article.

Besides the morbid states of the general attitude already described, there are some other more partial affections, chiefly of muscular action, which deserve to be noticed; these are principally spasmodic tremour, paralysis, and contraction. And there are some more general affections of a similar kind constituting convulsion and rigidity. It may be sufficient to enumerate the principal cases of these morbid affections, observing that the subject still presents ample scope for resumed inquiry.

Spasmodic tremour occurs in a remarkable degree in the shaking palsy, (see Mr. Parkinson's interesting pamphlet on this subject,) in chorea, as an effect of the poison of mercury, (Bateman's Reports of the Diseases in London, p. 192,) of drinking spirits, &c.

Paralysis, the usual consequence of disease of the brain, the spinal marrow, or the nerves, is observed as an effect of the poison of lead, of exposure to cold, &c.

Contraction, of the hand for instance, is a rather remote effect of paralysis, epilepsy, chorea, hysteria, of the various morbid affections termed fits, &c., and is usually observed on one side of the body only. A singular state of contraction of the hand occurs in children, and is described by Dr. Kellie. (Edinburgh Medical and Surgical Journal, vol. xii. p. 448.)

General convulsion occurs in cases of diseases of the brain, especially of the parts about its base, epilepsy, puerperal convulsion, hysteria, hooping cough, &c. The effect of convulsive action on the circulation within the head has not hitherto been sufficiently attended to by physicians. Hysteric convulsion assumes, from long and frequent

to vegetate, as it were, and carefully avoid every kind of exertion, as well as of emotion: in this manner, life and a comfortable state of existence may frequently be long insured. In the latter stages, every attention should be paid to enable the patient to support with ease the position which affords the greatest relief.

* In all cases of this kind, as well as in the erethismus mercurialis, death sometimes occurs from suddenly assuming the erect position, or from other muscular effort or exertion.

repetition, an epileptic character; epileptic convulsion often induces an apoplectic coma; and pertussis, from the violence of coughing, frequently leads to fits, and even to hydrencephalus, &c.

General rigidity occurs in tetanus, and in some cases of epilepsy and hysteria.

3. **On the Morbid Appearances of the Tongue, &c.**—The circumstances to be noticed in an examination of the morbid conditions of the tongue, and in immediate connection with them, are, its surface, form, papillæ, colour; its mode of being protruded; the teeth, gums, and internal parts of the cheeks; the taste; the breath, &c. The surface is apt to be affected with whiteness, load, fur, dryness, blackness, chaps, &c. The form of the tongue is frequently modified by its becoming swollen, indented, fissured, and lobulated. The papillæ are, in some cases, morbidly prominent and enlarged, and in others almost obliterated, leaving a smooth and perhaps tender surface. The tongue is protruded with difficulty, from dryness, tremour, or paralysis, and is left protruded in cases of imperfect sensibility.

The internal mouth, the breath, and the taste are apt to be affected, conjointly with the tongue, especially when the latter is swollen and indented.

In the acute synochus, the tongue is usually extremely white and loaded, with much thirst, an impaired taste, and sometimes a tainted breath, but usually without dryness.

In acute inflammation, the tongue is not necessarily much affected; in some cases it has preserved nearly its natural state; it is, however, frequently whitish or furred; it is frequently moist, and free from indentation, unless it be modified by the conjunction of a disordered state of the alimentary canal.

In the protracted synochus, the tongue is at first white and perhaps loaded; afterwards it is apt to become clean, red, and dry, and sometimes unnaturally smooth, and perhaps tender; the teeth become a little affected with mucous sordes.

In chronic inflammation, the tongue, mouth, taste, and breath are frequently unaffected; in the later stages, there are frequently aphthæ and soreness of the tongue, internal mouth, and fauces.

In the milder form of typhus fever, the tongue is white and rather loaded, with a tendency to dryness: it is generally protruded with tremour.

In the severer forms of typhus fever, the tongue becomes dry, parched, and tender, and dark brown or black; it is often protruded with great difficulty, from its state of dryness and of tremour; the internal mouth is also dry and foul; the teeth are affected with brown mucous sordes; the breath has a peculiar odour. The state of dryness is increased during sleep, the mouth being then usually open. It is important to remark whether, with a given state of the tongue, the tendency is to an augmentation or diminution of its morbid character.

In intermittent fevers, the condition of the tongue varies greatly in the different stages and in the interval. In the cold stage it becomes dryish and clammy; in the hot stage the tendency to dryness is still greater; in the sweating stage and in the interval the tongue approaches more to its natural state, remaining only whitish and rather loaded.

It may be justly remarked that the tongue affords one of the best diagnostics of the different kinds and degrees of idiopathic fevers, of idiopathic from symptomatic fevers, and of their complications; and its changes and tendencies denote, in a particular manner, those of the fever itself.

Scarlatina is frequently distinguished from rubeola by numerous, elongated, florid papillæ, which protrude through the white load.

In variola, pustules sometimes appear on the tongue and in the internal mouth. The occurrence of salivation and of tumefaction of the countenance, followed by swelling of the hands and feet, is familiar to all.

The most ordinary effect of an occasional or accidental derangement in the stomach and bowels is a loaded state of the tongue, the superior surface of this organ becoming covered with a layer of whitish, soft, mucous substance, admitted of being partially removed by the tongue-scraper; the whole internal mouth is at the same time more or less disagreeable and clammy, the taste depraved, and the breath offensive; and frequently the substance of the tongue is a little swollen, œdematous, and marked by its pressure against the contiguous teeth.

In the acute dyspepsia noticed above, the state of the tongue already described is observed, with some modifications: the tongue is in general loaded, the mouth clammy, the taste bitter or nauseous, the breath fetid, whilst the surface of the face is frequently oily. In some severe cases the load has been very thick, and has eventually pealed off, leaving the tongue red, smooth, and tender: the substance of the tongue is generally swollen, œdematous, and impressed by the contiguous teeth; the gums are often red, tumid, and somewhat separated from the teeth by tartar, and are easily made to bleed; the inside of the cheeks, also, frequently partakes of the œdema, and receives, like the tongue, impressions from the adjacent teeth; sometimes the cheeks and the gums of the posterior part of the mouth have been so swollen as to protrude a little over the teeth, and are either ulcerated by the pressure or wounded by being bitten—circumstances which are apt to be induced or aggravated by cold. Through the load on the tongue the red papillæ are frequently seen, either over its whole surface or at its point principally; frequently the tongue is not only indented, but formed into creases or folds; sometimes deeper and more numerous sulci are formed, the edges of which are sharp and the sides in contact, requiring to be separated by the two fingers, or by protruding the tongue farther; in some cases the tongue is less loaded and indented, and its edges are red and even.

In cases of the acute dyspepsia, we have seen the tongue affected with deep foul ulcers, resulting from the slow suppuration of hardnesses about the size of a horse-bean or nut, situated just under the surface of the tongue, which is loaded, swollen, and foul, with a copious flow of saliva, and a fetid breath.

In chronic dyspepsia the tongue is sometimes affected, in a slighter degree, in the manner just described, being somewhat tumid, indented, and sulcated; it is in general, however, less pasty and œdematous; it is frequently covered with a sort

of viscid mucus; sometimes it is slightly white, from numerous, minute, white points crowded over its surface; it is also frequently affected with fur, consisting of short fibres resembling those of coarse velvet, and admitting of being separated by the finger. In this affection the tongue is frequently rather dry; and I have seen it, in several instances, sulcated longitudinally.

In very protracted cases, the tongue assumes several remarkable modifications of form and surface. In the first case there is a universal enlargement of the papillæ over its surface, which is now generally clean; in two instances the papillæ at the most posterior part of the tongue became particularly enlarged, causing pain on swallowing, and some alarm to the patients; in the second modification the surface of the tongue is formed into lobules, sometimes deeply intersected and resembling in form those of the base of the cerebellum, at other times of less regular form, and, lastly, assuming the form of squares; in the third variety the tongue acquires an absolute and morbid smoothness of surface, which appears as if glazed, and is tense and unyielding. In all these cases the tongue is morbidly clean—the mouth, taste, and breath being nearly natural—and its colour, although perhaps rather paler, frequently little changed; the complexion is usually rather pale and sallow, but the surface of the face is free from oiliness, and the integuments from tumidity.

The condition of the tongue in chlorosis is very characteristic: in the beginning, the tongue becomes rather pallid and tumid, and has frequently enlarged papillæ over its surface; it is somewhat loaded, indented, and sulcated; the gums and prolabia are pallid, and the breath is somewhat tainted. At a more advanced period, the tongue becomes cleaner, smoother, still more exanguious, and acquiring a peculiar semitransparency, and a very pale lilac hue; it remains a little swollen and indented, but the papillæ disappear and give place to a morbid smoothness; the complexion, prolabia, gums, and tongue are alike exanguious, and perhaps a little tumid; the breath is still less tainted, and even acquires an odour of new milk; and the mouth becomes less clammy and disagreeable.

It has already been observed that a particular state of the tongue accompanies a particular condition of the complexion and general surface, and that, by observing the latter, the state of the former may frequently be anticipated; the loaded and swollen tongue is usually associated with an oily and swarthy state of the surface and complexion; the pale, tumid, and clean tongue, in chlorosis, is accompanied by a tendency to tumidity of the integuments in general and œdema of the ankle; and the clean, papulated, lobulated, fissured, or morbidly smooth tongue is united with a nearly natural state of the general surface. The morbid secretions of the mucous membrane of the tongue and internal mouth are thus connected with a morbid secretion of the skin; the exanguious and tumid state of the tongue, with a similar condition of the integuments, both apparently originating in the same state of the capillary circulation; the nearly clear tongue accompanies the icterode complexion without tumidity or extreme pallor; and the morbidly clean tongue is attended with little change of the complexion and general surface.

The appearance of the tongue in these cases denotes, in a particular manner, their duration:—the mere load is often soon induced and soon removed; a swollen tongue has required a longer time for its formation, and demands a longer use of remedies; the states of tongue in chlorosis are of still slower formation and removal; and those described in protracted cases of chronic dyspepsia are often the effect of years of disorder, and are probably never totally remedied. By an accurate knowledge of the different morbid states of the tongue and of their concomitant morbid affections, the physician is frequently enabled to speak to his patients in a manner which excites their surprise, by indicating his distinct and accurate information respecting their diseases, especially in respect to the history and symptoms.

In true asthma the tongue has, at first, the appearances observed in the acute dyspepsia.

In long-continued cases, both of disorders and of diseases, it is not unusual for aphthæ to occur, and they are occasionally seen in acute affections. The tongue, inside of the cheeks, posterior part of the mouth, and the fauces, are covered with white, minute, tender vesicles, which are apt to be recurrent, soon assume the form of white exfoliations, and leave the subjacent parts smooth, red, sore, and tender. Sometimes the œsophagus, stomach, and alimentary canal appear affected, and obstinate sickness and diarrhœa occur, with a sense of burning. The affections in which aphthæ are most apt to occur, are protracted cases of the more serious forms of dyspepsia, phthisis, mesenteric disease, and chronic pleuritis or peritonitis.

As an effect of cold, and especially in conjunction with disorder of the digestive organs, there is frequently an eruption of one, two, four, or more aphthæ, or small circular ulcers, of from one to three or four lines in diameter, on the inside of the lip or cheek, on the point or near the root of the tongue, &c.; there is great tenderness, and a minute slough, surrounded by an inflammatory border; the state of tenderness continues several days, and the whole course of this affection, like the one about to be mentioned, occupies from six to ten days.

With or without the last-noticed affection, and from similar causes, there is frequently an eruption of herpes, or of a cluster of small vesicles, occupying some part of the prolabium or the angle of the mouth. It generally denotes that the patient has taken cold.

There is a chronic affection of the prolabium and immediately adjoining skin, which we have not seen described:—it consists of a repeated dry splitting, and exfoliation of the cutis of these parts, and occupies a ring, of about one-fourth of an inch across, all round the mouth; it varies in severity at different times and in different cases; it is long-continued, and appears to result from a protracted state of disorder of digestion; it occurs chiefly in early youth.

Fur, with a tendency to dryness of the tongue, usually denotes great local irritation,—such as violent inflammation,—from an accident,—of a joint, &c. This appearance is also common in cases of intestinal irritation. It occurs in some

forms of the dyspepsia, especially the chronic and cachectic. The state of fur of the tongue appears to arise from very different causes from that of load; its indications are therefore very different too; it is also in general more difficult of removal.

In disease of the heart, with great lividity of the prolabium and countenance, the tongue and internal mouth frequently participate in the general discoloration.

There are sometimes great peculiarities in the odour of the breath. We have mentioned the fetid odour observed in acute dyspepsia; and in some very protracted cases of chlorosis, we have observed an odour of the breath resembling that of new milk; in some morbid affections of the lungs, the breath has an extremely offensive taint; and there is occasionally in some diseases, and we may particularize dysentery, a cadaverous odour, affording a most unfavourable prognosis.

An attention to the odour of the breath is of great use in detecting the case of intoxication, and even of some cases of poisoning.

The mode of protruding and of withdrawing the tongue is often worthy of notice. We have already named the tremour of idiopathic as distinguished from symptomatic fever. In cases of stupor from fever, or from disease of the brain, the tongue is sometimes protruded imperfectly, and not immediately; and sometimes it is left out until the patient is told in a loud voice to draw it again within the mouth.

In cases of paralysis the tongue is often protruded to one side, and frequently the saliva flows from the angle of the mouth.

The tongue is frequently severely bitten during the fit of epilepsy.

4. **On the Morbid conditions of the General Surface.**—The objects comprised under this head are the temperature, the state of dryness or moisture, of tumidity or shrinking, or of roughness or smoothness of the skin, the colour, the occurrence of emaciation, or of œdema or anasarca, and the condition of the hands and feet.

The temperature of the general surface and of the hands and feet is greatly modified by febrile, functional, and organic affections, and has been found, in some affections of the heart, to form a striking contrast with that of the internal mouth or of the rectum. (Farre's Essay on Malformations of the Heart, p. 32, et seq.)

The state of heat, tumidity, dryness, and roughness seems to characterize the idiopathic fevers and to distinguish them from the symptomatic, in which an opposite state of the surface is more usual.

The colour is modified by the condition of the cutaneous circulation, of the blood itself, and of the cuticular surface.

It is of the utmost moment to remark the occurrence of emaciation or of œdema, as important sources of the diagnosis of functional and organic morbid affections.

The condition of the hands and feet, and the appearance of the nails especially, vary with the state of the blood and of the circulation, of which they afford a sort of index, and, in some protracted cases, with that of the cuticular and cutaneous surface.

The acute synochus is characterized by a tumid, smooth, soft, and dry state of the surface, with a sense of glowing heat and a florid colour: this state is apt, however, to be modified by the occurrence of rigor or of perspiration.

In acute inflammation, the surface is, on the contrary, frequently nearly natural, of moderate heat, and inclined to perspiration.

Profuse perspirations have been particularly observed in the acute fever symptomatic of rheumatism, inflammation of the mamma, and in some affections of the kidney.

In the protracted synochus, the surface gradually becomes dry, rough, and harsh; the cellular substance shrinks; the skin communicates a sense of acrid heat; and the cuticle is often in a state of exfoliation, and sometimes raised on the neck and breast into miliary vesicles.

[In the typhoid affection, rose-coloured spots—*taches rouges*—are seen over the abdomen and thorax. At times these can only be detected by careful examination. Sudamina are also often present.]

In chronic symptomatic fever there is usually an absence of this state of the surface, copious perspirations being opposed to the constant dryness, and a natural warmth or even coldness to the acrid heat; the perspirations are apt to be peculiarly profuse in the last or early morning sleep; the coldness, often joined with lividity, is sometimes constant, at other times the consequence of the least exposure to cold.

The chronic symptomatic fever is, however, much modified by the nature of the primary disease; in tuberculous phthisis there is often the alternation from chilliness to hectic heat and perspiration during sleep; in strumous disease of the mesentery there are greater chilliness and sensibility to cold, and cold lividity, with early morning perspirations; and in organic disease of the liver there are frequently few or none of these symptoms.

In typhous fever, the state of the general surface is various, and usually less distinctly characterized than in the morbid affections already mentioned. In the milder form the temperature is moderately augmented, especially in the young or plethoric; but there is rarely great heat or dryness. In the severer form the surface is sometimes a little parched and the cheek flushed; sometimes cool and affected with clammy perspiration; sometimes there is an eruption of miliaria with a dry skin; and sometimes there are petechiæ. In the state of sinking a cold and clammy perspiration affects the nose, cheeks, hands, and general surface. In the fever described by Dr. Currie, "the temperature rose, in one case, to 105° Fahr.; but was in general from 101° to 103°, and towards the latter end of the disease scarcely above that of health."* Dr. Bateman observes, "the

* Medical Reports, vol. i. p. 11. Dr. Currie observes, with regard to continued fever, that "one exacerbation and one remission in the twenty-four hours seem generally observable. The exacerbation usually occurs in the afternoon or evening, the remission towards morning. These exacerbations are marked by increased flushing, thirst, and restlessness. If the heat of the patient be, at such times, taken by the thermometer, it will be found to have risen one or two degrees in the central parts of the body above the average heat of the fever, and still more on the extremities."

heat seldom exceeded 99° or 100°." (On Contagious Fever, p. 36.)

The three stages of intermittent fevers are highly characterized by the state of the general surface; in the cold stage there is great shrinking, and the skin becomes pale, cold, and rough, and in the state termed cutis anserina, and the temperature has been observed as low as 74°; in the hot stage the integuments become tumid and injected, and the skin is hot and dry, and the temperature has sometimes been as high as 105°; in the last stage the tumidity, heat, and injection cease and yield to a general perspiration.

It is in the scarlatina anginosa that the greatest degree of tumidity, injection, and temperature is observed; the rash is continuous and imparts a deep red hue, and the surface in general is turgid, hot, smooth, soft, and dry—a state which is succeeded, on the decline of the fever, by dryness, roughness, and exfoliation. There is much diversity in the degree of these appearances, as in that of the fever itself; but in severe cases the heat and tumidity are greater than in any other febrile affection of this climate; the thermometer applied to the surface of the body rises to 105° and 106° even in mild cases, and in the more violent cases to 108°, 109°, 110°, and even 112°, the greatest heat ever observed in the human body by Dr. Currie. (Medical Reports, vol. ii. p. 46.)

In the scarlatina maligna there is frequently an entire absence of tumidity, injection, and heat of the surface; sometimes there are shrinking, cold moisture, and a pale or livid rash. It is of the greatest importance to attend to the state of the surface, in a curative as well as a diagnostic point of view.*

After the decline of the tumidity and rash of scarlatina, an anasarcous welling of some parts of the surface is occasionally observed; it usually affects the extremities and face, and sometimes the sole of the foot has been raised into one entire blister.

In rubeola there is comparatively little tumidity, injection, and increased temperature of the general surface; the face, and especially the eyes and eyelids, are, however, often considerably tumid; the heat of the skin is in this disease, and in the influenza, from 99° to 101° and 102°. (Medical Reports, vol. ii. p. 78.)

In the variola discreta, except in its mildest forms, there are considerable general tumidity and heat, frequently a warm perspiration, a full state of the pustules, and a soft condition of the intervening portions of skin.

In the variola confluens, the surface is shrunk and flaccid, the temperature little or not at all augmented, and the skin is frequently affected with a clammy perspiration, whilst the pustules are flat and flaccid, participating apparently in the state of the cutaneous circulation.

In the course of variola, and usually about the eighth day, there is frequently a state of tumefaction of the face and eyelids, with a flow of saliva; this state recedes, and about the eleventh day the tumefaction affects the hands and feet.

In the morbid affections already noticed, the temperature of the surface is, for the most part, augmented. There are some diseases, however, in which there is a tendency to diminished temperature and frequently great sensibility to cold.

There is a certain degree of this tendency in acute dyspepsia, and perspiration is excited by the slightest hurry or fatigue.

In some cases of protracted dyspepsia, the nose is livid and cold, and the feet are habitually cold. The case is distinguished from that to be next noticed by the absence of frequency of pulse, and of progressive emaciation.

But the case in which this peculiarity is most observed is the tuberculous disease of the mesentery. In this disease the patient is highly sensitive to external cold, and to the least draught of air, and, in cold weather especially, constantly draws near or hangs over the fire,—sometimes until the hands and legs assume a brown colour from the influence of its heat. With this sensibility to cold, there is also frequently a great tendency to early morning perspirations, which appear to be induced by sleep, and to be in part avoided by keeping awake, which is often done purposely.

A slighter degree of chilliness is observed in phthisis pulmonalis, and in other organic diseases, together with a greater or less tendency to perspiration.

Decided shivering occurs in the commencement of febrile and inflammatory diseases in general; [although it is not uncommonly absent] in the beginning of each paroxysm in intermittents. This symptom also occurs in cases of intestinal irritation, and in a more marked degree than in inflammation. It is an attendant upon suppuration; and then, being repeated, frequently excites the idea of intermittent.

There is no point of deeper interest, in a practical view, than that of the loss or return of flesh. The continued loss of flesh adds, in obscure cases, to the fear of organic disease, whereas the least return of flesh determines the question favourably. [This, however, is a rule liable to exceptions. The author has known many pounds of flesh regained even in fatal pulmonary phthisis, under change of climate, or some agency, which has arrested or diminished for a time the morbid action.]

In acute dyspepsia it is highly interesting to watch the gradual return of flesh under judicious treatment. In tuberculous disease, on the other hand, there is a daily loss of flesh, however slow. In hepatic disease, the case is favourable or unfavourable according as the patient continues to lose or begins to regain flesh. In doubtful cases, the patient's weight may be registered, and the result will frequently be contemplated with anxious feelings. In the study of all, but especially of chronic diseases, there is, indeed, no point of greater importance than that of emaciation. Much might

* Dr. Currie observes, "Before I conclude the subject of scarlatina, I must *again* enforce the superior advantage of using the affusion early in this disease; and the propriety of ascertaining that the skin is dry, and the heat of the patient greater than natural, in all cases, especially in such as are advanced, and where, of course, the strength is considerably impaired. It has come to my knowledge, that in two cases of scarlatina, of the most malignant nature, the patients have been taken out of bed, under the low delirium, with the skin cool and moist, and the pulse scarcely perceptible. In this state, supported by the attendants, several gallons of perfectly cold water were madly poured over them, on the supposed authority of this work! I need scarcely add, that the effects were almost immediately fatal."—Vol. ii. p. 76.

certainly be learned by a constant attention to this subject.

The degree of emaciation which takes place in patients, depends in part on the nature of the disease, and in part on the nature and office of the organ affected. Emaciation is more observed, in a given space of time, in fevers than in inflammations. Loss of flesh takes place in the acute dyspepsia, but is scarcely observed in the chronic forms of that disorder—a circumstance by which they are therefore distinguishable from insidious organic diseases or protracted inflammations. Emaciation is the usual effect of tuberculous and scirrhous affections of any organ; it is less early observed in some other diseases, as in the encephalosis, (*Laennec*, de l'Auscultation, tom. ii. p. 62), &c. Emaciation is little observed in diseases of the head, heart, and even the lungs, compared with those of the mesenteric glands, the stomach and bowels, the liver, the pancreas, &c. In diseased mesentery the emaciation and loss of strength are nearly, if not absolutely, although very slowly, progressive. In disease of the liver there may be, for some time, even for years, a degree of recovery; and weakness and loss of flesh, and even icterus and anasarca occasionally disappear.

There are some highly interesting remarks on this subject in Dr. Pemberton's work on the Diseases of the Abdominal Viscera. (Chapter vi.) He observes that, in the organic diseases of the liver, the pancreas, the mesenteric glands, the stomach, the small intestines, and the spleen, as "glands of supply," there is considerable emaciation; whereas in the diseases of the kidneys, of the breast, and of the large intestines, which are "glands of waste," the loss of flesh is less, and less rapid.

Next to emaciation as a consequence of disease, it is important to remark the occurrence of œdema, or of its aggravated form of anasarca. The principal causes of this affection are organic disease of the heart or lungs, enlargement of the liver, phthisis pulmonalis, organic tumours in the abdomen, pregnancy, &c.

Anasarca is frequently observed in the late stages of chlorosis. It is often, indeed, an effect of debility merely, and occurs, consequently, in the last stages of chronic diseases in general, from want of nourishment, and in old age, and as an effect of profuse hemorrhage or purging. Anasarca is also occasionally the effect of long exposure to cold and wet.

The causes of anasarca sometimes induce other kinds of dropsy, as hydrothorax, ascites, &c., which are, indeed, like anasarca itself, far more frequently effects of diseases than primary diseases themselves. It is important to trace the succession of links in this chain of causes and effects; but it is to be observed that these morbid states come at length to constitute diseases in themselves, and produce, in their turn, their peculiar effects and symptoms.

The appearances of the general surface in cases of cachexia are peculiar; but they do not appear to require description in this place.

There is a singular morbid affection of the surface, which has not, we think, been noticed by any practical writer; the face, and some parts of the surface of the body, become suddenly and remarkably puffed and swollen; this affection appears to be occasioned by the presence of some indigestible substance in the stomach, and generally yields to the operation of an emetic and purgative.

We now proceed to notice some morbid states observed chiefly in the hands and feet, although partly, too, over the general surface. The nails, like the prolabia, afford an opportunity of observing the state of the blood; the hand, in general, often denotes, by the condition of its surface, the degree of force or feebleness of the circulation, at least in the capillary vessels, and by its steady or tremulous movements, the strength or weakness of the muscular system.

Continued fevers and inflammations in general are distinctly characterized by the morbid affection of the surface, and by the state of tremour, so generally observed in the former, and so little, comparatively, in the latter.

In the acute synochus there is generally considerable tremour and burning heat; in acute inflammation these affections are usually absent. In the slow synochus the hand is still more tremulous, and its surface becomes dry, parched, and exfoliating; in chronic inflammations the surface is generally totally different, and there is only the tremour of weakness. In typhous fever the tremour frequently assumes the aggravated character of subsultus tendinum. It is scarcely necessary to make any allusion to the circumstances of the picking of the bed-clothes, flocci volitantes, &c.

There is one morbid affection in which tremour is so characteristic as to have been chosen for its denomination,—the delirium tremens. From the occurrence of this symptom in a remarkable degree, we were enabled, in one case, to foretell that delirium would follow.

In acute dyspepsia, a degree of tremour is observed on desiring the patient to extend the hand and arm; the surface of the hand is apt to be cold and clammy, and the nails to assume a lilac hue, and their tips to become white and opaque. These appearances are, in some instances, very long continued, and they are always very characteristic.

In chlorosis, the hands, fingers, and nails become characteristically pale and exanguious; the skin is frequently opaque and puffy, and usually dry; there is a tendency to œdema, and at length to anasarca.

In very protracted cases of dyspepsia, the skin becomes gradually dry, branny, and sallow, or brownish, and the nails become brittle, break off in lamellæ, so that the patient is incapable of taking a pin out of her dress, and sink in irregularly in their middle part. This state of the nails is by no means unfrequent.

In common dyspepsia even, the hands and feet are apt to be cold.

In organic disease of the heart, the hands, like the nose and cheeks, frequently become deeply livid and very cold, whilst the heat within the rectum and under the tongue is sometimes even higher than natural, (see Dr. Farre's Essay on Malformations of the Heart, pp. 32, 34); in young subjects the finger-ends become expanded, especially laterally.

The finger-ends are swollen, and perhaps affected with a sense of tingling, especially in young

subjects, in some cases of organic disease of the liver, and sometimes in tubercular phthisis pulmonalis, and in the latter disease they become adunque.

In inflammation of the bowels, and in cholera, and dysentery, there is a characteristic tendency to a cold, clammy, and livid state of the surface of the hands and feet, and of the nose, whilst the pulse is frequent and small.

We have already mentioned the tendency to coldness and lividity of the extremities in tuberculous disease of the mesentery.

There is a loss of temperature in cases of paralysis, sometimes with lividity and shrinking.

In the action of the hand and fingers we may frequently observe the expression of pain, of anxiety, or of suffering; but this subject properly belongs to a subsequent section.

5. On some Morbid Conditions of the General System.—Before we proceed to notice the symptoms of disease referable to the functions of the encephalon, and of the viscera of the thorax and abdomen, we wish to call the attention of the reader to some morbid affections of the system at large.

In the first place we shall just refer to those various morbid states of the general system denominated fever. But we shall principally, though briefly, notice some other conditions of the system, which have not hitherto obtained the degree of attention they demand, and which may be denominated the states of irritation, of exhaustion, of erethismus, and of sinking.

All these morbid states are characterized by affecting many or all of the organs and functions of the body at once, although one particular organ frequently suffers much more than the rest.

Continued fever is particularly distinguished from inflammation by the characteristic just mentioned. The contrast has already been drawn between the states of the countenance, of the attitude—including the muscular system,—of the tongue, and of the general surface, in these different affections; and differences not less marked will be observed in the functions of the encephalon, and of the organs of the thorax and abdomen.

A similar remark also applies to the dissimilar but characteristic effects of local irritation and inflammation on the general system. These effects, although in general sufficiently distinct, are frequently confounded. How often have we known that symptom stated as evidence of the existence of inflammatory action, which, in fact, was connected with irritation, and with nothing so remotely as inflammation!

It is, perhaps, of still greater moment to observe that some affections of the system in general, resembling and often mistaken for local inflammation and effects symptomatic of inflammation, are, in fact, effects of exhaustion. The mistake, in both these cases, is full of danger; the investigation of the diagnosis is, therefore, of the utmost importance.

It is also a remarkable circumstance, as we shall observe hereafter, that the phenomena and effects of exhaustion are extremely similar to those of erethismus, and especially of the erethismus mercurialis.

Lastly, there is a state of constitutional affection which may be termed the state of sinking, which occurs in various diseases, and is characterized frequently by inducing false appearances of amendment, dissolving as it were the series of morbid actions, and, in a certain sense, curing the disease, but subsequently leading to sudden, or at least early, dissolution.

We shall now proceed to sketch the principal phenomena observed in these states of the constitution. It would require too great a space to enter into their detail; and it is unnecessary, because we have attempted this, in some measure, in the latter part of this article.

The principal sources of irritation to which we shall allude here, are the presence of indigestible substances in the stomach, and especially intestinal disorder or load. The effects of these sources of irritation are either gradual or sudden. The gradual effects are, those observed in the dyspepsiæ, in chlorosis, &c. It is the more sudden effects of intestinal irritation to which we wish to direct the attention in this place.

The more sudden effects of intestinal load and irritation are, acute pain of the head, of the side, of the loins, of the iliac region, or of some other part of the abdomen; attacks of vertigo, of dyspnœa, of palpitation, fainting or feeling of dissolution, of vomiting, and of hiccup; there are often anxiety and distress; and there are severe rigors, followed by great febrile heat, jactitation, and flushing. The attack is apt to be mistaken for a disease of the organ principally affected, and bleeding is injuriously prescribed when enemata and purgative medicines are the only remedies. The effects of intestinal irritation are particularly apt to occur after any exertion or agitation, after the pain and fatigue of delivery, and especially when this cause is conjoined with any cause of exhaustion, as misapplied or undue bloodletting, hemorrhage, or purging, and in the course of diseases; and we are persuaded that their influence in these circumstances is still only half apprehended.

The principal sources of exhaustion are undue bloodletting and uterine hemorrhage, especially when they occur with intestinal irritation,—hypercatharsis, and diarrhœa. The effects of exhaustion may be referred to the head, heart, the viscera of the thorax and of the abdomen, and the muscular system. The symptoms which affect the head are, severe pain; beating and throbbing; rushing or cracking noises; vertigo or turning round of the room, especially on raising the head or assuming the erect position; intolerance of light and of sound; wakefulness; starting during sleep; awaking hurried and alarmed, with faintness, palpitation, feeling of sinking, of impending dissolution, &c.; being overcome by noise, disturbance, or even thinking; and delirium. The heart is, in different cases, affected with palpitation, fluttering, irregular and feeble action; there are beating and throbbing of the carotids, and sometimes even of the abdominal aorta; a frequent, bounding, and sometimes irregular pulse; faintishness or fainting, urgent demand for the smelling-bottle, fresh air, fanning, bathing of the temples; feeling of impending dissolution; incapability of bearing the erect position, and sometimes early fainting from the use of the lancet. The respiration is affected,

in different cases, with panting, hurry, sighing, great heaving, gasping, blowing, moaning, catching, &c., and, as has been stated, with urgent demand for fresh air. There is sometimes a sense of great and alarming oppression about the chest. There is in some cases an irritative cough, in violent fits, or in the form of continual hacking; this cough appears to originate in the larynx or trachea. The stomach is liable to become affected with irritability, sickness, retching, vomiting, hiccup, and eructation; the bowels with constipation or diarrhœa, pain, flatus, distension, &c. There are very frequently urgent restlessness, tossing about, and jactitation. In some cases, various spasmodic affections have occurred. We have often to combat the effects of exhaustion in the puerperal state, and in cases in which bloodletting has been improperly employed for diseases not inflammatory, or too lavishly in cases of inflammation.

There is an extraordinary similarity, as we have already observed, between the effects of exhaustion, as just noticed, and the symptoms of the disease termed erethismus mercurialis, so well described by Mr. J. Pearson, (Observations on Lues Venerea, 2d edit. ch. xii.) and so painfully experienced, and so amply and accurately detailed by the late Dr. Bateman. (Medico-Chirurgical Transactions, vol. ix. p. 220.) The descriptions of these authors do not, however, enumerate the affections of the head; otherwise they would be almost identical with that of exhaustion just given: disturbed sleep, hurried wakings, palpitation, languor, fainting, feeling of impending dissolution, want of air, fits of coughing, and of retching, &c. occur in both these morbid states; and sudden and unexpected death from muscular effort has alike terminated the patient's sufferings.

The morbid effects of digitalis, and of some other vegetable remedies, are also not dissimilar from those of exhaustion and erethismus.

The constitutional symptoms in some cases of local disease, as in the phagedenic and sloughing ulcers, appear also to partake of the characters of erethismus.

The state of sinking occurs under very different circumstances, and accordingly presents very dissimilar phenomena. It occurs sometimes as a gradual and simple feebleness of the brain, decline and cessation of the functions of circulation and of respiration, as in cases of dissolution in very advanced age: at other times it takes place with the more active symptoms of inquietude and jactitation, catching respiration, hiccup, &c.: sometimes it has the remarkable effect of dissolving the chain of morbid actions and sensations constituting the disease under which the patient has laboured, and of presenting to his friends, and perhaps to his unwary physician, the appearance of amendment, when life is soon to terminate in an unexpected dissolution: lastly, the appearances of sinking quickly follow the accession of gangrene.

The gradual decline of the powers and functions of the heart and of the respiration scarcely requires any description: there are dozing, and insensibility to external impressions; the breathing becomes irregular; there is a collection of phlegm in the trachea or larynx, with cough, rattling, and hoarseness; the powers of the bladder are often impaired, with retention of urine; the pulse becomes small and feeble, and the extremities and the nose and cheeks cold.

In the second form of sinking, there are constant restlessness, with throwing about of the arms and throwing off of the bed-clothes, delirium or incoherency of mind, catching, sighing, or gasping breathing; a frequent, small, and perhaps intermittent pulse; hiccup; an indescribable feeling of approaching dissolution; a constant necessity for the windows to be opened, and for the fan, and sal volatile, &c.; the countenance becomes pallid and sunk, and, with the extremities, cold, clammy, and perhaps livid, especially the prolabia.

In the third case, the pain and symptoms of the disease often cease, and the patient has even got up or enjoyed sleep, and yet dissolution has been at hand; the pulse, perhaps, suddenly becoming very frequent, and the extremities cold, pale, livid, and clammy. This phenomenon is, we think, most frequently observed in cases of inflammation and other diseases of the intestines, as we had remarked long ago.* It also occurs in other states of the disease: delirium, cough, and pain have ceased, and suppression of urine has yielded, under the influence of the state of sinking.

That extraordinary man, Mr. J. Hunter, had accurately observed the state of sinking, and has described it under the term dissolution. (Hunter on Inflammation, part ii. ch. ix. sect. 3.) "The first symptoms," he observes, "are those of the stomach, which produce shivering: vomiting immediately follows, if not an immediate attendant; there is great oppression and anxiety, the persons conceiving they must die. There is a small, quick pulse, with every sign of dissolution in the countenance: as it arises with the symptoms of death, its termination is pretty quick." "I have seen dying people whose pulse was full and strong as usual on the day previous to their death; but it has sunk almost at once, and then become extremely quick, with a thrill: on such occasions it shall rise again, making a strong effort, and, after a short time, a moisture shall probably come on the skin, which shall in this state of pulse be warm, but, upon the sinking of the pulse, shall become cold and clammy: breathing shall become very imperfect, almost like short catchings, and the person shall soon die." "It would appear in many cases that disease has produced such weakness at last as to destroy itself: we shall even see the symptoms, or consequences of disease, get well before death." Sir Henry Halford has also noticed this subject in a late paper published in the Transactions of the College of Physicians, (vol. vi. art. 15,) and has applied it to the prognosis of diseases.

The symptoms of sinking in cases of gangrene are familiar to every observer.

From the preceding observations it will appear that there is a similarity in the symptoms attending intestinal irritation, exhaustion from loss of blood, the erethismus mercurialis, the morbific effects of digitalis and other poisonous vegetables, sinking, and dissolution, which is really remarkable. It is a question of great importance how far

* See the first edition of the Treatise on Diagnosis, part i. p. 47. See also Dr. Abercrombie's paper in the Edinburgh Journal, vol. xvi. p. 22, 185.

the existence of one of these states tends to the superinduction of another: the effects of exhaustion are certainly very apt to supervene in cases of intestinal irritation, and are far less liable to occur, from the same application of its causes, during the existence of internal inflammation; a given degree of intestinal irritation, on the other hand, produces unusual effects in cases of exhaustion. We do not know whether the same relation exists between irritation or exhaustion, and the erethismus of mercury or of digitalis.

The symptoms of irritation or of exhaustion are not only particularly apt to supervene when the cause of the other state respectively coexists; but it appears to us that the causes of one state are also apt to induce those of the other. Thus the state of intestinal disorder and irritation, at least, is very liable to steal on in cases of exhaustion from loss of blood; and when it exists primarily, it is extremely apt to induce diarrhœa, and even some kinds of hemorrhage, as epistaxis, hæmatemesis, and melæna, and even uterine hemorrhage or discharge.

When the state of exhaustion terminates fatally, it is either by sudden death or by more or less gradually passing into that of sinking. Sudden death is apt to occur from any muscular or bodily effort in a change of the position; one patient rose up to make water, sank down, and soon afterwards expired. The transition of the state of exhaustion into that of sinking we have an opportunity of witnessing at the moment of writing these lines: great pain of the head, with beating, throbbing of the carotids, agitation from sudden noises, as knocks at the door, violent palpitation of the heart, with fulness and bounding of the pulse, alarm and hurry on awaking, &c., have gradually subsided and passed into a tendency to doze, first with snoring, then with blowing-up of the cheeks and lips, and moaning; slight rattling or crepitus heard in the trachea and bronchi during respiration, becoming gradually augmented; slight catching, laryngeal cough, especially when asleep, gradually increasing and becoming painful and almost incessant, but afterwards almost ceasing; oppression in breathing, with blowing through the mouth and lips, the nostrils being very acute, and dilated below and drawn in above the lobes; much flatulency: at length the fæces are passed at each attempt to void urine, of which there may be retention or involuntary flow, conjointly or separately. The countenance is pallid and sunk, the features acute, there is much inquietude, sometimes jactitation, and delirium, especially on awaking, and, to employ the patient's own expression, "a dying feel."

The subjects sketched in this section, we do not hesitate to say, are of extreme importance. We should not have devoted so much space to them, did we not consider it an imperative duty to call the attention of the profession to them in the most earnest manner of which we are capable.

6. **On the morbid states of the Functions of the Brain.**—The consideration of the morbid affections of the functions of the brain embraces a view of the derangements observed in its energies in general, the sleep, the mental faculties and the temper, the senses and sensations, and the motions—voluntary, functional, and sphincter.

It is extraordinary that the energies of the brain should become affected in a very similar manner from the two opposite states of undue action or fulness, and of depletion of that organ. Stupor and morbid obtuseness of the nerves and senses on one hand, and delirium and morbid sensibility on the other, occur alike, varied only in form and degree, in each of these states of the encephalon; and the remark equally applies to the function of respiration as influenced by these different and opposite conditions of the brain; indeed, the affections of the respiration just described as obtaining in the state of sinking from exhaustion, bore the most marked resemblance to those observed in apoplexy, the difference being chiefly observed in the state of the countenance, general surface, and pulse, and in the degree of the mental stupor.*

Augmented energy of the brain, denoted by delirium and augmented sensibilities, occurs in cases of fever and of irritation, and in the opposite states of this organ observed in inflammation and exhaustion.

Diminished energy of the brain, on the other hand, occurs in apoplexy and in the state of sinking from exhaustion; in both cases there are stupor or dozing, rattling in the breathing from defective absorption of the mucus of the bronchi, oppressed and laboured respiration, snoring, blowing-up of the cheeks and lips, defective power of the sphincters, &c.

In regard to sleep we observe, in different morbid affections, the opposite states of lethargy and wakefulness, the occurrence of frightful dreams and hurried wakings, and various effects on the functions of the skin, of the heart, &c.

The return of sleep must, in general, be deemed a good sign; but a longer sleep than usual is frequently an effect of exhaustion, and the patient awakes from it 'overcome;' dozing and sleep again are frequently observed in the state of sinking, and then only give rise to a false hope of amendment.

Drowsiness is frequently an antecedent sign of apoplexy; it may forebode icterus, and it may arise from a disordered state of the stomach. It is in other cases, and especially in the diseases of children, one of the first symptoms to awake alarm and fear of disease within the head.

Profound sleep, which has received various names, as somnolentia, coma, lethargy, veternus, cataphora, carus, &c. according to its degree, usually denotes a state of oppression of the brain from vascular fulness, effusion upon the membranes, &c. and occurs as a symptom in apoplexy and organic disease of the brain in general; as a complication in typhous and other fevers; as an effect of the convulsive efforts in epilepsy, puerperal convulsion, fits, hysteria, the hooping-cough, &c.

Heaviness for sleep also occurs, as has been stated already, in a state of the brain the opposite

* A similar remark is made by Dr. Percival in relation to the opposite states of congestion and collapse of the brain, in his interesting Essay on Typhus Fever. He observes, "in truth, the state of congestion and the state of collapse, which resemble each other both in vascular and sensorial appearances, deserve a fuller comparison than has yet been made of their common character."—p. 69.

to fulness, and is observed in some cases of exhaustion, in the state of sinking, and in syncope.

Wakefulness and restlessness occur in mania, in puerperal delirium, in the delirium tremens, &c. in connection with delirium, as their names import; but they also arise, independently of delirium, in cases of great irritation or exhaustion, especially intestinal irritation and exhaustion from loss of blood: the same observation applies to the erethismus mercurialis, (see Dr. Bateman's case, Med. Chir. Trans. vol. ix. p. 223,) which, as we have had occasion to remark before, resembles in so many particulars the morbid effects of the causes just mentioned.

But perhaps the most extraordinary phenomena belonging alike to these three morbid affections, in connection with sleep, are frightful dreams and hurried wakings; these circumstances sometimes occur in the form of incubus, sometimes with great palpitation of the heart and hurry, and sometimes with the feeling of impending dissolution.

There is often much starting in the sleep in cases of indigestion; and children frequently start, get up in bed or even out of bed, or perhaps scream violently, and are affected with fright or temporary delirium from this cause.

Hurried wakings, with a sense of suffocation or of impending dissolution, also occur in organic disease of the heart; the patient, agitated and alarmed, hastens to the open window for air.

Sleep would appear to exercise a peculiar influence over the circulation: many children perspire profusely during sleep, especially in a state of weakness; sleep often induces flushing during the progress of febrile complaints; and in cases of hectic or tubercles, the last morning sleep, as we have already observed, is particularly apt to be attended with profuse perspiration, to prevent which many patients purposely keep themselves awake.

The mental faculties are affected in various ways,—by delirium, stupor, imbecility, unfounded hope or despondency, &c.

Delirium occurs in fevers, in most violent affections general and local; and in inflammation or disease of the brain. In the former case delirium is often long continued; in the latter it usually, earlier or later, passes into stupor, as increased action induces effusion. Delirium is also observed in some cases of exhaustion with reaction; and, in its low and muttering form, it occurs in the state of sinking.

Not only fever, and any severe derangement of the general health, but a violent accident, a severe operation, the occurrence of gangrene, &c. are generally attended by delirium.

It is scarcely necessary to allude to the occurrence of this symptom as a frequent puerperal affection, and as the effects of habits of drinking spirits. In the former case it is frequently an effect of the loss of blood.

Stupor also occurs in fevers, but especially in apoplexy, and towards the termination of all affections of the brain inducing compression of that organ.

Imbecility of mind, with talkativeness or with lethargy, is not unfrequent in old age. In these cases there is often a state of chronic inflammation of the substance or of the membranes of the brain. Paralysis is apt to be superadded to the other symptoms.

After attacks of apoplexy a state of mental imbecility often remains, with loss of memory, unmeaning laughter, proneness to tears, &c.

The temper of the patient is singularly modified by different disorders and diseases. The state of despondency in cases of indigestion forms a remarkable contrast with that of hopefulness in phthisis pulmonalis and other serious organic diseases.

Despondency on the part of the patient may, however, excite a well-founded alarm in cases of great debility and inquietude.

In cases of serious and fatal disease, and especially, we think, in diseases of the intestines, the patient frequently expresses his conviction of an approaching dissolution—"tanquam conscia foret natura, vitam ad finem properare."

The senses and sensations become preternaturally acute or defective.

Acuteness of hearing and of sight, and intolerance of sound and of light, are usual symptoms in the dawn of inflammation of the brain, and frequently occur in idiopathic fevers: but they occur in the most remarkable degree as effects of intestinal irritation and of exhaustion.

The physician is often called to cases in the following circumstances:—Straw is spread before the door, the knocker is tied, the lights are screened or the room is darkened, and every source of noise or disturbance is carefully avoided. The cases in which these precautions are necessary are principally those of intestinal irritation and exhaustion; but they are also frequently necessary in the acute synochus, and in some forms of puerperal affection; and the precautions respecting noise and disturbance are sometimes requisite in diseases of the heart, not from increased susceptibility of the nervous system, but of the action of the heart itself.

The sense of hearing becomes defective and obtuse in some cases of typhous fever; defective vision is a usual occurrence in diseases of the brain; and torpor or defective touch is a usual precursor or consequence of apoplexy or paralysis, and occurs in some instances of hysteria. We need scarcely allude to the *flocci volitantes*, *tinnitus*, the *epileptic aura*, &c.

Under the head of deranged sensations may be noticed pain and vertigo. Pain of the head in the recumbent, and vertigo in the erect posture, are usual and early symptoms in typhous fever and acute synochus, in cases of intestinal irritation and of exhaustion, and in the dyspepsiæ; and they are frequently precursory and admonitory signs of apoplexy or paralysis.

Pain of the head alone is usually amongst the first symptoms of inflammation of the brain. Severe pain of the head occurs in the dyspepsiæ, and especially in chlorosis; it is then attended by the other symptoms of those affections; but it is frequently so severe as to lead to the erroneous employment of the lancet.

We need scarcely advert to the frequent occurrence of headach and vertigo in hysteria, hypochondriasis, asthenia, syncope, &c. It is important, however, to remark that they rarely

occur in local or organic diseases, except those of the head itself.

Intermittent headach constitutes a peculiar affection, and is removed by the arsenic.

The sense of an iron finger on some part of the head, or of an iron hoop round the head, is an effect of exhaustion from loss of blood.

7. On the morbid affections of the function of Respiration.—In treating of the morbid affections of the function of respiration, we shall attempt a description of the different kinds of dyspnœa, of cough and expectoration, of the effects of full inspiration and expiration, of the affections of the voice and articulation, &c.

Healthy respiration is performed with ease and freedom, and without the aid of the auxiliary muscles, in any of the usual positions of the body. It is effected by a nearly equal elevation of the ribs and depression of the diaphragm, except in females, in whom the thorax is observed to move more than in men; each side of the thorax moves also in an equal degree; and inspiration and expiration occupy nearly equal spaces of time.

The kinds of dyspnœa, and the other morbid affections of the act of respiration, are so numerous, that it would be difficult to discuss them fully. In treating the subject, we shall proceed on the practical principle already pointed out, and describe the different modifications of the respiration in reference to particular diseases.

In the acute synochus there is generally a little hurry in breathing, and sometimes a degree of anxiety and of panting.

The respiration in typhous fever is generally anxious and tremulous; when the fever is complicated with stupor, the respiration becomes still more affected—frequently deep and sibilous, irregular and unequal, still more tremulous, and sometimes each inspiration is begun by the diaphragm and completed by the thorax; in the other complications of this fever the respiration is variously affected according to their seat and nature.

In apoplexy the respiration becomes irregular, slow, deep, frequently suspended, and sighing, with rattling or stertor, or blowing of the cheeks and lips, or with catching in the larynx. M. Serres observes that, when there is paralysis, the two sides of the thorax are moved unequally, the muscles of the paralytic side having lost their power. (Annuaire Medico-Chirurgical, 1819.)

We have already noticed the similarity which obtains between the breathing in apoplexy and that observed in the state of sinking.

In other diseases of the head with congestion or compression, as inflammation or hydrencephalus, the breathing gradually becomes irregular and unequal, with alternate suspension and sighing; the duration of the interruption appears sometimes to be commensurate with the degree of oppression of the brain.

In inflammation of the chest, with acute pain, the respiration is sometimes performed exclusively by the diaphragm, the chest or part affected being quite motionless; the alternate movements of the respiration are also short, cautious, and suppressed. This peculiarity of the breathing is proportionate to, and varies with, the degree of acuteness of the pain.

The part affected is sometimes carefully kept unmoved, the rest of the thorax or abdomen being moved as usual. This is observed in ordinary respiration, still more in a deep inspiration: the patient can draw a deep breath without causing pain; but if this be done incautiously, pain is immediately induced. The patient is frequently awoke from sleep by this cause: the caution ceases, perhaps a deep sigh is drawn, and acute pain being induced, the patient starts and awakes.

In inflammation within the abdomen, with acute pain, the respiration is, on the contrary, performed principally and often exclusively, by the chest, the abdomen remaining unmoved. This peculiarity of the breathing may be distinctly observed by looking on the chest and binding the bed-clothes tight over the abdomen. The respiration has sometimes the appearance of heaving of the chest: every movement of the diaphragm is cautiously avoided. In this disease the patient is also frequently observed to rest, for a few seconds, on a full breath. The abdomen begins to move as the pain diminishes, whether from a mitigation of the disease, from sinking, or from gangrene. By an attentive observation of the modifications of the respiration, inflammation of the pleura is distinguished from inflammation of the peritoneum covering the liver, &c. The very part inflamed is frequently ascertainable by a simple but careful inspection. Nothing is more interesting than this exercise of the faculty of pure observation. The thorax and abdomen should be exposed and watched.

Inflammatory pain within the abdomen is, in the same manner, distinguished from spasm or colic, in which there is a state of breathing altogether incompatible with inflammation attended with acute pain and tenderness.

In inflammation of the lungs, the respiration is characterized by labour, and by crepitus heard on applying the ear to the chest: these peculiarities are augmented as congestion and hepatization take place; and when much mucus is secreted, bronchial rattle is superadded. In chronic cases of pleuro-pneumonia, the shoulders are elevated, the pomum adami is drawn downward, and the lower part of the sternum retracted toward the spine, on each inspiration—the abdomen being, at the moment, suddenly protruded, and the upper part of the chest raised.

In tuberculous phthisis pulmonalis, an effort is early visible in the respiration, and its effects are seen in a movement of the alæ nasi: the breathing is also early observed to be short on any muscular exertion, especially on going up stairs; at a late period of the disease there are generally constant labour and shortness of breathing, and sometimes attacks of suffocating dyspnœa.

On examining the chest in a recumbent position, it will frequently be found that its motions are not free, and that respiration is more than usually performed by the diaphragm. Sometimes one side of the chest moves more than the other.

In the later stages of hydrothorax, there is, in connection with the peculiar state of the attitude, a characteristic affection of the respiration:—the acts of respiration are performed with very unusual

degrees of labour; inspiration is often quick and sudden, effected with great effort, principally or exclusively by an elevation of the thorax, and afterwards by a forcible contraction of the auxiliary muscles of respiration; in expiration these movements are reversed, the chest appears to fall spontaneously and without effort; the action of the auxiliary muscles—the sterno-mastoids, the pectorals, &c., is seen or may be felt on applying the finger; the head is often moved, and the chest has, in protracted cases, the appearance of being unusually high.

A state of the respiration not dissimilar from that just described is observed in cases of complicated disease in the thorax and in the abdomen—the latter giving origin to what may be termed the thoracic breathing, and to a suppression of the action of the diaphragm. A painful affection of the upper portion of the peritoneum would be apt to induce the state of breathing observed in hydrothorax; whilst the latter affection, by pressing the diaphragm downward, has often been mistaken for disease of the liver. (*Portal*, Mémoires sur plusieurs Maladies.)

In diseases of the heart, the dyspnœa is generally first experienced, and is ever particularly aggravated by any particular muscular exertion or mental emotion, and especially on going up stairs: it appears, therefore, to be particularly liable to recur in paroxysms, and it is thus distinguished, in some degree, from the dyspnœa of hydrothorax, which increases progressively perhaps, but more uniformly and slowly.

Besides the kinds of dyspnœa already described, there are others which require to be accurately distinguished from them:—

In the acute dyspepsia, and in the more accidental cases of indigestion, a paroxysm of dyspnœa often takes place, and appears to us to constitute, in the greater number of instances, the first attack of true asthma.

The dyspnœa of asthma is extremely peculiar:—there are great anxiety and almost gasping; the inspiration is quick, the expiration longer, laboured, and wheezing. In extreme cases, the chest is raised, the scrobiculis cordis retracted, and the abdomen protruded, with abruptness, on inspiration; expiration reverses these movements, and is attended with labour and wheezing. In protracted cases a state of constant dyspnœa is observed, denoted by labour and wheezing, with a peculiar cough. At length, organic disease of the heart and of the lungs is superadded to the primary state of disorder of function.

In the other forms of dyspepsia, and especially in chlorosis, paroxysms of hysteric dyspnœa are observed, frequently attended with pain and tenderness of the chest or of the abdomen; it combines a degree of hurry and heaving in the respiration, altogether incompatible with inflammatory pain. With this state of the respiration there is often a total loss of voice, and occasionally the cough and crowing of croup.

In the cases of intestinal irritation, and in those of exhaustion from loss of blood or other causes, the respiration becomes affected with hurry, panting, sighing, heaving, moaning; laboured, and gasping; and there is an urgent demand for the fan and the fresh air.

As these states pass into that of sinking, a gasping, catching, laryngal cough, snoring, blowing, slight rattling in the larynx or trachea, &c. supervene, and increase as the energies of the brain, heart, and lungs decline. There are three symptoms connected with the exhaustion, which denote the sinking state, and which are consequently of the most unfavourable omen:—the first is an audible, hurried breathing; the second gasping, however slight, with descent of the pomum adami; the third, a slight crepitus heard in the breathing, with, or even without, the stethoscope.

A similar state of catching in the respiration occurs, as a fatal symptom, towards the termination of many diseases.

Rattle occurs not only in apoplexy, bronchitis, &c. but also in the last and fatal stages of debility and sinking, and of many diseases.

The different modifications of the breathing which have been described, might be designated and distinguished by some epithet chosen from their most prominent character. But we have avoided this from the fear of fixing the attention too exclusively on one point, which, however prominent, still only obtains in common and in connection with others little less remarkable.

There is one remark respecting the respiration which we think important. In some instances of chronic inflammation of the larynx or trachea, we have observed that the patient is incapable of performing the action of snuffing-up the nostrils so as to draw in the alæ nasi, (see Medico-Chir. Trans. vol. x.); this was not observed in some cases of ulcer of the larynx. The remark may not only enable us to determine the degree, but the diagnosis of the morbid effects of laryngitis.

The respiration is tracheal or croupy in inflammation of the larynx, and in cases in which a tumour, as aneurism or scirrhus, presses upon the larynx. The latter case is often distinguishable by the addition of dysphagia to the dyspnœa, or the tumour may be obvious to the eye or touch. In ulcer of the larynx the sound of respiration is rather hoarse and husky than croupy.

We now proceed to notice some of the more remarkable varieties of *cough*.

This symptom is modified by the seat and nature of the disease, and, in the same disease, by the state of pain, or of expectoration, and by the strength of the patient.

The laryngal cough often occurs in fits, with hoarseness and incapability of speaking, and is sometimes so violent as even to induce vomiting. The tracheal cough is lower, less violent, and without hoarseness. The bronchial is deeper still. By observing the kind of effort, and the particular character of the cough, the seat of irritation or disease is often distinctly observed to be in the larynx, in the trachea, in the bronchi, or in the cellular structure of the lungs.

Not only the seat but the nature of the disease, is frequently ascertained by an attention to the peculiarity of sound of the cough. Ulcer in the larynx induces a very different sound from that of inflammation of the same part, the former being hoarse, the latter croupy; the sound of the cough in tuberculous phthisis is very different from that of catarrh or of some forms of bronchitis; the

cough in asthma has a very peculiar dull sound; and the sound of the cough, or rather the resounding of the chest on coughing, frequently serves to indicate a healthy state of the lungs and thorax in general, and to distinguish it from various morbid conditions. The presence of mucus or of pus in the bronchial passages also gives a characteristic sound to the cough.

The effort of coughing is sometimes repressed. This occurs in acute inflammations of the pleura, of the peritoneum, &c. in rheumatic and hysteric affections of the muscles about the thorax, &c.

Sometimes the cough assumes a spasmodic character. This occurs in pertussis, hysteria, in cases of intestinal irritation, or of irritation about the larynx or trachea, &c.* In other cases the coughing is continued, but not sufficiently violent to be termed spasmodic. Cough of this character is observed in some cases of less severe irritation in the intestinal canal, or in the larynx or trachea; it occurs also from circumstances of exhaustion and sinking, and appears to originate in the larynx; it is observed in some instances of bronchitis, and of asthma, and frequently when the strength of the patient is too much reduced to enable him to expectorate.
