recovery taking place without the supervention of any serious symptoms. The limbs were frightfully crushed, and the operation was performed within a short time after the accident. The arm being removed first, the pulse immediately sank, but under the influence of stimulants it rose sufficiently in five minutes to justify amputation of both legs below the knee. So excessive had been the shock of the system that the boy hardly experienced any pain during the operation.

The synchronous double operation may be performed by two surgeons, or by one alone, the latter being perhaps the preferable method. In either event, it is a matter of paramount importance to protect the patient from the loss of blood, the slightest effusion of which might prove prejudicial to his safety. Dr. Carnochan is in the habit of cutting off both limbs before he ties any vessels, and this is undoubtedly the preferable plan if we can be certain of having perfect control over the hemorrhage, as we may be if we have proper assistants, and the removal is effected rapidly by the flap operation.

SECT. V.—AFFECTIONS OF THE STUMP.

These affections are either of a primary or consecutive character, and both may be purely of a local, or of a local and constitutional origin. The primary consists of hemorrhage, spasm of the muscles, excessive pain, undue inflammation, osteomyelitis, and inordinate retraction of the soft parts, thereby permitting exposure of the bone. Among the secondary effects may be mentioned necrosis and exfoliation of the bone, degeneration of the nerves and neuralgic pain, aneurismal enlargement of the vessels, and contraction of the tendons in the neighborhood of the stump, by which the latter is drawn out of its proper position, and so made a source of inconvenience and discomfort.

1. PRIMARY AFFECTIONS.

a. Hemorrhage may come on soon after the dressing of the stump, or not until some time has elapsed; perhaps not for several days. It is usually occasioned by the want of a sufficient number of ligatures, in consequence of the retraction of some of the smaller arteries, thereby escaping the surgeon's attention while he is looking out for the principal and more accessible branches; or it may be that the vessel has been cut obliquely, and that it has not been tied high enough up; or, finally, that the arterial tunics are so much diseased as to give way under the pressure of the cord before the formation of an adequate internal clot, as when the bleeding supervenes several days after the operation. However induced, or whatever may be the circumstances which give rise to the hemorrhage, the proper remedy consists in exposing the open artery, and securing it with the ligature, either by separating the flaps, or, if adhesion is already far advanced by dilating the canal along which the blood flows over a grooved director. The main artery of the limb is not tied unless it be found impossible, on account of disease, or some other cause, to make the application of the ligature at the stump.

Sometimes the hemorrhage is purely venous, the blood flowing away lazily, in a dark purple stream, without any jet; and when this is the case it will generally be found to depend upon the want of accurate coaptation of the flaps, or some defective application in the bandage, making either too little or too much pressure; in the former case enabling the vessels to remain open and gaping, and in the latter interfering with the passage of their contents. Occasionally the blood oozes out at different points, as water oozes out of a sponge, and this may take place either from the soft parts, or from the Haversian canals of the bones, or from the medullary membrane and the

marrow. Arrest of the bleeding is usually effected simply by compression of the stump, the compress and roller being made to bear steadily against the offending vessels, aided by elevation and cold applications; when this fails, the ligature may be required, or, what is preferable, because altogether free from the danger of phlebitis, constriction of the vein by inclusion in the surrounding tissues. For this purpose, after being carefully dissected from its attachments, it is transfixed by a curved needle, armed with a small double cord, and drawn through an opening made for it in one of the adjoining muscles. Both ends of the cord are then brought out at the nearest angle of the wound, and retained for twenty-four hours, or removed at once, if there be no probability that the vessel will lose its hold. When the vein has been cut off unusually high up, so as not to admit of this procedure, I never hesitate to tie it, even if it be one of large size, such, for instance, as the femoral, although the operation should always, if possible, be avoided for the reason just stated. When the blood proceeds from the Haversian canals it will generally be necessary to undo the flaps, and apply a compress directly to the surface of the bone, the wound being kept open until the flow is arrested. Caustic applications must not be used for fear of causing necrosis.

b. Spasm of the muscles, which is frequently a source of great distress, and which presents itself in the form of jerks or twitchings, usually sets in within a few hours after the operation, and is generally most severe in persons of a nervous, irritable temperament. No patient, however, is ever entirely exempt from it after amputation, and it is always sure to be materially aggravated on the occurrence of inflammation. In regard to treatment much is to be done in the way of prophylaxis; by the judicious use of the roller to give equable support to the muscles of the stump, together with elevation of the part to favor venous return, and also by the early exhibition of a full anodyne. The use of morphia, or of morphia and antimony, along with warm fomentations, will be required if the spasm is at all severe when no such precautionary measures have been adopted.

c. The degree and continuance of the *pain* which follows an amputation will be influenced very materially by the character of the case, the size of the limb, the presence or absence of complications, and, above all, by the temperament of the patient. Coming on usually as the system emerges from the influence of chloroform, it is sometimes remarkably slight, while at other times it is so severe as to require large quantities of anodyne medicines for its subjugation. When the pain is complicated with spasmodic twitching of the stump, as it generally is during the first twenty-four hours, it must be promptly met with morphia and antimony. In order to render these two phenomena as light as possible, I have long been in the habit of administering a full anodyne, generally a grain and a half of morphia, about two hours before the operation, and have never been disappointed in my expectations.

d. The *inflammation* consequent upon an operation of this kind may be either of the ordinary character, or it may be erysipelatous, the determining circumstances not being always appreciable. In general, however, the danger of erysipelatous action will be considerable when there has been severe shock, or excessive loss of blood, conjoined with previous bad health or habits of intemperance. It usually makes its appearance within the first forty-eight hours, and is characterized by the ordinary phenomena, such as a red dusky state of the skin, more or less throbbing, a sense of tension, and burning, smarting pain, with marked disorder of the general system. Whatever may be the degree or character of the inflammation, it is always hostile to the adhesive process; some parts may, it is true, unite in this way, but suppuration will be almost certain to follow, so as to lead to the necessity of healing the greater portion of the wound by granulation. In persons of a very dilapidated constitution the inflammation may pass into gangrene. I have

found this termination most commonly in patients of a scrofulous habit of body and in those whose system has been contaminated by syphilis.

The treatment of this disease must be conducted upon general antiphlogistic principles. Special attention must be paid to the state of the system, and with this view it will generally be necessary to employ a mildly stimulating course, consisting of quinine and milk punch, with blue mass and ipecacuanha to evacuate the bowels and correct the secretions. Morphia is given in liberal doses to allay pain and procure sleep. The best local remedies are the dilute tincture of iodine, with fomentations, or cataplasms, medicated with solutions of acetate of lead and opium. Leeches will generally prove prejudicial. Sometimes the disease is promptly arrested by the application of a large blister. If mortification is threatened, the parts are freely touched with nitrate of silver, sulphate of copper, or the dilute acid nitrate of mercury, and enveloped in a fermenting poultice. The chlorides are used for allaying fetor, and the syringe for washing away secretions from beneath the flaps.

e. Bad effects occasionally follow amputation in consequence of the development of *osteomyelitis*; an affection which has only recently begun to attract particular attention. In the Crimean war it was of such frequent occurrence that the question was seriously debated by a number of surgeons whether it would not be best to abandon amputation altogether in the continuity of the larger bones, and resort to disarticulation as a substitute. The disease is also sufficiently common in hospital and private practice, especially in cases of railway and other severe accidents, attended with violent concussion of the osseous tissues. The probability is that it is occasionally caused by injury inflicted in the act of sawing off the bone. However induced, it generally sets in within a short period after the operation, so that by the time the dressings are removed, as they usually are on the fourth or fifth day, it is found to have already made considerable progress, the marrow being of a brownish, blackish, or greenish appearance, of a soft, putrilaginous consistence, excessively fetid, and partially detached from the bone, which is itself either dead, or in a dying state, and more or less denuded of periosteum. The disease is generally attended with considerable pain, although in some of the cases that I have seen there was almost an entire absence of local suffering; it is not unfrequently coincident with pyemia and erysipelas. Hence the prognosis is often exceedingly unfavorable.

The treatment of *osteomyelitis* must be conducted upon general antiphlogistic principles, modified by the peculiarity of the constitutional symptoms. Great attention must be paid to cleanliness; the dressings must be frequently changed, and free use must be made of the chlorides. The judicious application of the nitrate of silver to the affected structures might possibly assist in circumscribing and ultimately arresting the morbid action. If the bone die, no attempt should be made to remove it until the part and system have sufficiently recovered from the effects of the disease to bear the shock of the operation.

f. Finally, amputation is occasionally followed by inordinate *retraction* of the muscles, so as to uncover the bone, and perhaps lead to the necessity of its removal. The accident is most liable to happen after amputation of the thigh, in consequence of the action of the numerous, large, and strong muscles in that situation, and cannot always be prevented even when more than ordinary care is taken in forming the stump. The occurrence is always to be deprecated, inasmuch as it not only interferes with the union of the flaps but is very apt to cause the death of the bone. The remedy consists in bandaging the limb firmly from above downwards, preceded by the application of long adhesive strips, and in placing the parts in the best condition for relaxing the affected muscles. When these means are unavailing, we may, pro-

vided the bone remains sound, divide some of the muscles of the stump subcutaneously, and then draw them forward, either with or without incision of the integuments, as the case may seem to demand. If the bone, however, be diseased, the best plan will be to saw it off higher up; but such an operation is often more hazardous than the original one, and should, therefore, always, if possible, be avoided.

2. SECONDARY AFFECTIONS.

The most common, as well as the most serious, secondary defects of amputation are, as was previously stated, necrosis of the bone, neuralgia, development of synovial bursæ, varicose enlargement of the arteries, and permanent shortening of the tendons in the vicinity of the stump.

a. Disease of the *bone*, eventuating in a loss of its vitality, is induced in various ways; in general, it is caused by injury inflicted upon it during the operation, consisting either in the laceration and separation of the periosteum, or in the violent and destructive jarring of its substance. Uncovering of the bone, in consequence of too great a brevity of flap, and the accumulation around its extremity of pus, are also very apt to produce it. In rare cases it would seem to perish from excess of inflammatory action. The loss of vitality is indicated by the peculiar whitish or pale yellowish aspect of the bone, the absence of bloody points upon its surface, and the fact that it emits a characteristic hollow noise when it is struck with the handle of the knife. The marrow and its enveloping membrane generally retain their vitality for a short time after the osseous tissue has died, and this is the more likely to happen if the bone perishes only in a part of its circumference. I believe it will be found that necrosis, as a result of amputation, is more liable to occur in the thigh-bone than in any other piece of the skeleton, depending probably upon some peculiarity of organization. The tibia is also occasionally affected, and a similar occurrence is sometimes met with in the humerus. The dead bone may come off in the form, first, of an exfoliation, consisting merely of a part of its outer compact substance; or, secondly, as an osseous ring, with long, narrow, sharp spicula; or, finally, as a complete cylinder, as when it involves the entire circumference of the bone over an extent of several inches in length. The more common appearances exhibited by the necrosed bone are well displayed in fig. 171.

The management of these cases must be left very much to the operation of time, especially when the bone has perished high up, and when, in order to reach it, extensive dissection would be required. If, on the other hand, the necrosis is very limited, an attempt may be made to get rid of it with the saw, cutting-forceps, or trephine; but too much caution cannot be used even in such an operation, trifling though it may seem. I have seen death produced by it in two cases, and similar instances have been witnessed by others. It would seem, when a bone is thus affected, as if the system were more than usually intolerant of instrumental interference and loss of blood; the parts are generally excessively irritable, and the constitution rarely fails to sympathize with them in the most lively manner. Besides, the operation is necessarily attended with some de-

Fig. 171.

The sequester detached; at its lower part, *a*, including the whole thickness of the bone, but gradually shelving upwards, as such pieces usually do.

gree of hemorrhage, and I am not certain that a patient may not be destroyed in this way alone, especially if he be very feeble and irritable at the time.

Instances occur in which the dead bone, or sequester, is firmly, and even obstinately, imprisoned by the remains of the living, or, more properly speaking, by the new matter thrown out upon its surfaces; thus occasioning great difficulty in regard to its removal. Dr. Markoe, of the New York Hospital, had the kindness, a few years ago, to communicate to me the particulars of a case, wherein the sequester, consisting of an inner shell of the femur, was retained for many months by a spur of new osseous substance extending through an opening in its sides, in such a manner as to nail the dead and living parts together, but at the same time allowing the former to be moved freely backwards and forwards upon the latter. It was not until after several attempts had been made at extraction, attended with much pain and constitutional suffering, that riddance was finally effected by means of the chisel and forceps. For some very ingenious notions respecting the causes of necrosis in the bones of the stump after amputation, the reader is referred to a short paper by Dr. Markoe, in the Louisville Medical Review for July, 1856.

b. Another disagreeable, frequently, indeed, a most distressing effect of this operation, is *neuralgia*, coming on at a variable period after its performance, and often continuing, despite the most judicious and persevering efforts at relief, to molest the patient during the remainder of his life. Supervening generally without any assignable cause, it is usually most common in nervous, irritable persons, who are subject to the disease in other parts of the body. Females are more prone to it than men, and in them the attack frequently coincides with the eruption of the menses. Sometimes the disease is periodical, especially in residents in malarious regions, the paroxysms coming and going very much as in intermittent fever. Most commonly, however, the pain is omnipresent, one portion of the day being as liable to bring it on as another. It is generally of a darting, shooting nature, or dull, heavy, and aching, and is invariably aggravated by damp states of the atmosphere, fatigue, and disorder of the digestive apparatus.

In the more violent forms of this affection the immediate cause of the difficulty is a bulbous enlargement of the nerves ramifying through the stump, as

Fig. 172.

Neuromata of stump, after amputation of the arm. A large mass at *a*; opposite *b*, the tumors are more defined.

in fig. 172. This degeneration takes place, to a greater or less extent, after nearly every amputation, and is therefore to be considered as a disease only when it exists in excess. Under such circumstances the tumor, which sometimes attains the size of a hickory nut, or even of a pullet's egg, is of a firm, dense consistence, and is composed of a strong fibrous stroma, inlaid with hypertrophied and curiously interlaced nervous trunks and filaments. It is, in fact, a true neuroma. The accompanying pain is exquisite, and the part is so sensitive as to be intolerant of the slightest touch; the general health is much affected, and the patient is remarkably susceptible of atmospheric vicissitudes, every change in the weather from warm to cold and dry to wet being followed by an increase of suffering. The malady is of a much more

serious character than the other, and requires proportionably stronger measures. In general, nothing short of removal will avail; by excision, if the

tumor be single and easily accessible, by amputation, if it be multiple and deep seated.

For the milder varieties of neuralgia the ordinary remedies will sometimes suffice, the same as in neuralgia in other parts of the body; especially quinine, or, if the patient be anemic, quinine and iron, combined, in either case, with strychnine and arsenious acid, belladonna, stramonium, or aconite; the effects of the articles being studiously watched, lest an overdose be given, and life placed in jeopardy. Sometimes good effects accrue from the exhibition of colchicum and morphia, administered in full doses at bedtime, as one drachm of the wine to a grain of the salt. The remedy is particularly valuable in subjects of a rheumatic state of the system. Locally, iodine, blisters, issues, and other counter-irritants are used, along with anodyne embrocations. The stump is well protected from cold, friction, and pressure.

c. A *bursa* sometimes forms upon the stump, generally immediately over the end of the bone, in consequence of the long-continued pressure of an ill-constructed and ill-adapted artificial leg. The tumor, in time, becomes exquisitely tender and painful, compelling the patient to seek relief. The seat and character of the disease are usually pointed out by the discoloration and swelling of the part, which often fluctuates on pressure. The history of the case, aided by the exploring needle, will readily serve to distinguish it from abscess, the only lesion with which it is likely to be confounded. The proper remedy is excision in the severer grades of the affection, and in the milder a more happy adaptation of the artificial to the natural limb.

d. Varicose enlargement of the *arteries* of the stump is extremely rare, only a few instances of it being upon record. Unless the disease is unusually extensive, which, however, it is not likely to be, nothing need be done for its relief, as it does not generally act even as an inconvenience.

e. Permanent shortening of the *tendons* in the immediate vicinity of the stump is sometimes a source of great discomfort, as well as of serious interference with the usefulness of the limb. The accident is most liable to happen in the tendons of the hamstring muscles after amputation of the leg, and in the tendo Achillis after removal of the foot by Chopart's method. Much may be done, in both cases, in the way of prevention by attention to position during the after-treatment; it is, in fact, the neglect of this precaution that usually occasions the difficulty. When the accident is unavoidable, or is already fully established when first brought under the notice of the surgeon, rectification is attempted, generally with a fair prospect of success, by the subcutaneous section of the shortened tendons, and the subsequent use of an extending apparatus, constructed on the principle of the double inclined plane, with such modifications as may be required to adapt it to each particular case.

SECT. VI.—CONSTITUTIONAL EFFECTS OF AMPUTATIONS.

The most common constitutional occurrences after amputations, especially of the larger limbs, are excessive prostration, traumatic fever, pyemia, congestion of the lungs, tetanus, retention of urine, and, as a secondary consequence, hectic irritation.

a. The *shock*, consequent upon amputation, is frequently extremely severe, and may be due, either partly or exclusively, to mere depression of the nervous system, caused by the extent, violence, and duration of the operation, to loss of blood, or to the effects of anæsthetic agents, or to all these circumstances combined. More or less nervous depression will almost necessarily occur during such an operation, however slight, but it generally passes off without any particular treatment, simply under the influence of repose, expo-

sure to the air, and a drink of cold water. In the more severe forms of the affection, however, it may endanger life by its long-continuance or excess, and then demands prompt attention. The most appropriate remedies are lowering of the head, so as to facilitate the flow of blood to the brain; the administration of brandy and ammonia, by the mouth, if the patient can swallow, or by the rectum, if the power of deglutition be lost; a full dose of morphia; and sinapisms to the spine, extremities, and precordial region.

b. Traumatic fever generally sets in within from six to twelve hours after the operation, and will be violent or otherwise according to circumstances, of which the most important are, the extent of the previous shock and the loss of blood, and the temperament, habits, and state of health of the patient. It is characterized by heat and dryness of the skin, flushed countenance, suffusion of the eyes, headache, restlessness, excessive thirst, rapid respiration, and a frequent, hard, and irritable state of the pulse, attended, when there has been much hemorrhage, by a peculiar jarring impulse. These symptoms, in the milder cases, will often speedily subside spontaneously, but under opposite circumstances they will require attention, and, if the surgeon is not fully on his guard, he will be very apt to do a great deal more than is either necessary or proper. The fact is, this is not unfrequently the critical point in such cases; if we do too much, the patient is irretrievably gone, the consequence being death either from exhaustion, pyemia, erysipelas, or a low state of fever, which nothing can cure. Hence the greatest caution is to be observed; the symptoms must be watched, and the utmost care must be taken that they do not deceive us by their violence, which is often rather apparent than real, and therefore extremely apt to entrap the unwary and inexperienced. In general, it will suffice to administer a mild aperient, as a little Epsom salts, or a Seidlitz powder, to sponge the surface frequently with tepid water, and to give cooling, acidulated drinks, which are always very grateful in these cases. If the fever threatens to be obstinate, a little antimony is prescribed, either alone or in union with morphia, to promote perspiration, allay the heart's action, and induce sleep. The lancet is scrupulously withheld, unless the symptoms are of extraordinary urgency, and the patient is very plethoric, without having been weakened by shock and loss of blood. Then a vein in the arm may be opened, and the effect of the stream carefully watched, the bleeding being arrested as soon as the pulse evinces signs of flagging.

Very often after amputations of the larger limbs, especially those performed for compound fractures and dislocations, gunshot wounds, and railway accidents, a low form of fever ensues, the system reacting badly, the countenance looking pale and haggard, the skin being icterode, cold, and doughy, and the pulse shattered, with great depression of spirits, and an utter indifference on the part of the patient as to his fate. It is difficult to say what is the real condition of the system under such circumstances, but if we may be allowed to indulge in conjecture, we may suppose that the disorder is mainly due to the loss of blood and nervous fluid consequent upon the excessive shock to the system at the time of the accident, heightened, perhaps, by the effect of the operation. However this may be, the system being depressed and withered, the issue is usually most disastrous, very few persons recovering, no matter what course may be adopted for their relief. Our chief reliance must obviously be upon stimulants, as brandy, quinine, ammonia, and nutritious broths and jellies, with opium to allay pain and procure sleep.

c. Amputations, especially those of the thigh, are often followed by *retention of urine*, caused apparently by partial paralysis of the bladder, or, rather, as it seems to me, by a want of proper volition, the bladder retaining its power, but the patient being unable to call it into action. It usually supervenes within the first twenty-four hours after the operation, and seldom lasts

less than two or three days, when it gradually passes off. From what I have seen of this affection, in this class of cases, I am not disposed to ascribe to it, as some have done, an inflammatory origin; that such a condition occasionally exists is certain, but, in general, I am sure it does not. Knowing how frequent retention of urine is after this and other capital operations, the attendant should be diligently on the watch for it, and promptly use the catheter, if it should arise.

d. A not unfrequent event after amputation is *pyemia*. Experience shows that it is most to be dreaded in cases preceded by excessive shock of the system; hence it is very common after gunshot, railroad, and steamboat accidents, attended with extensive laceration of the soft parts, and after compound fractures and dislocations. From an interesting paper "On the Causes of Death after Amputation," by Mr. Thomas Bryant, of London, it appears that of 300 cases of this operation collected from Guy's Hospital, pyemia occasioned death in 42 per cent. of all the fatal cases, and in 10 per cent. of the entire number, the affection having been most frequent after amputation of expediency, and least so after secondary amputation. The attack generally comes on within the first six or seven days, being ushered in by violent rigors alternating with flushes of heat, and followed by a bad state of the stump with aching pains in the limbs and joints, excessive thirst, restlessness, and a tendency to delirium even early in the disease. When the joints are involved there is commonly an erysipelatous blush upon the overlying skin, with great tenderness on pressure and exquisite pain on motion. The case generally proves fatal in less than a week from its commencement, and examination after death usually reveals the existence of small and ill-defined abscesses in some of the internal organs, particularly in the lungs, liver, and spleen.

The treatment is by stimulants and tonics, as brandy and milk, quinine, and opium, given in large quantity to support the rapidly sinking powers of nature. Mercury, in the form of calomel, is sometimes useful, administered in doses of three grains every four or six hours, with a view, if possible, of touching the gums. The bowels are moved by enemata, all active purgation being inadmissible. Locally, the ordinary remedies are employed, generally only such as are of a soothing character.

e. *Congestion of the lungs*, if not actual inflammation of these organs, is another effect of this operation, occurring either alone, or in conjunction with pyemia, erysipelas, or an adynamic state of the system. It generally comes on in a slow, insidious manner, and is therefore apt to make serious, if not fatal, inroads before its true nature is even suspected, none of the characteristic signs of pneumonic disease being present. The only way in which it is usually detected is by auscultation and percussion, or by the changes perceptible in the respiratory movements and the sounds of the chest. These changes are generally most conspicuous in the lower and posterior portions of the lungs, where the greatest amount of blood, in debilitated states of the system, is, in obedience to the laws of gravity, most liable to accumulate, and, consequently, to produce the greatest degree of mischief. In most of the cases of pulmonary congestion that I have met with after amputation of the larger limbs, there was either an entire absence of pain and cough, or these symptoms were so trivial as, of themselves, to attract hardly any attention. The patient is able to lie upon his back or on either side, and it is not often that the respiration is materially hurried or embarrassed. Cupping and blistering are the most reliable local remedies, and the system must be supported with stimulants and tonics, aided by morphia and minute doses of tartrate of antimony and potassa. The prognosis is generally unfavorable, especially if the disease has made considerable progress and the patient is much exhausted.

f. The occurrence of *tetanus* after amputation is uncommon, especially in the more temperate regions of this and other countries. Mr. Curling, in his work on this disease, gives a table of 128 cases of traumatic tetanus, three of which only were caused by amputation. The affection is much more frequent in military than in civil practice, and is most liable to be produced in persons of a nervous, irritable temperament, in consequence of exposure to direct currents of cold air. A few years ago I lost a man on the third day after an amputation of the thigh solely from this cause; he had been moved, during my absence from the hospital, to an open door, so as to allow the wind to blow upon him in a full stream. I am familiar with the history of other cases that have been induced in a similar manner; and I refer to the fact in order to attract special attention to it. The treatment of this disease being discussed elsewhere, it is unnecessary to refer to it here.

g. *Hectic irritation* is observed only, or chiefly, as a secondary effect of amputation, being caused either by profuse suppuration, or a poisoned state of the blood and solids, from shock, hemorrhage, or the absorption of pus. The symptoms are characteristic, and the treatment consists of such means as are calculated to sustain the flagging powers of the system, especially quinine and iron, with aromatic sulphuric acid, milk punch, and nutritious food.

SECT. VII.—ARTIFICIAL LIMBS.

The stump, after the cicatrization of the wound, gradually undergoes, as might be expected, important changes in its several structures, so as to adapt it the better for the various hardships which it is destined to experience in the daily routine of a business life, and especially for the support of an artificial limb. The muscles, deprived of the power of motion, soon become pale and wasted, and are eventually transformed into hard, dense, cellulo-fibrous bands, entirely destitute of their primitive properties. The bloodvessels are

obliterated as high up as their first large collateral branches, and converted into solid, rigid cords; the extremities of the nerves are expanded into large bulbous masses, of an elongated, cylindrical shape, exhibiting more of a fibrous than of a nervous structure; and the ends of the bones are rounded off, and covered in by a thin shell of osseous matter, which thus effectually closes the medullary canal, as seen in fig. 173. The cellulo-adipose substance gradually disappears, and the skin, unless habitually subjected to pressure, is rendered abnormally thin and sensitive. These changes are, of course, the work of time, and hence they are always more conspicuous in proportion to the age of the stump.

Appearances of bony stump after amputation.

The period at which the stump may be in a condition for the reception and support of an artificial limb must necessarily vary according to circumstances; if the operation has been well done, and the cicatrization has gone on favorably, the substitute may be used as early as the sixth or eighth week, though in general it will be better to wait some time longer, inasmuch as too early a recourse to it will be likely to render the parts sore and sensitive, if not the seat of ulceration and severe pain. So much, indeed, is the patient's comfort influenced by attention to this point that it is hardly possible to be too cautious respecting it. The

stump should be tightly bandaged for several weeks previous to the application of the artificial limb, to promote absorption of redundant material, and thus impart to it a somewhat conical shape. Washing it well several times a day with a strong solution of tannin and alum will have the effect of hardening the integuments, so as to moderate their sensibility and prevent excoriation.

Great improvement has of late years been effected in the construction and adaptation of artificial limbs, and there is reason to believe that the inconvenience and suffering occasioned by their use are more frequently attributable to the misconduct of the surgeon than to the want of skill on the part of the manufacturer of the substitute. It has been only within a comparatively recent period that operators have hit upon the correct principles of making good and serviceable stumps; Allanson, nearly three-quarters of a century ago, understood the subject much better than it has been understood since, if we except the last ten or fifteen years. He strongly insisted upon a long and well-shaped stump, and exerted himself with great ability, but in vain, to induce the profession generally to follow his example. The happy changes which have lately been introduced into this department of operative surgery are, I believe, mainly due to the manufacturers of artificial limbs, who, with an ingenuity and a perseverance worthy of so good a cause, have reduced the whole process to one of principles founded upon the study of anatomy and mechanical philosophy. It would be difficult to conceive of any apparatus more beautiful in its construction, or more admirably adapted to the end proposed, than the artificial substitutes of Mr. Palmer, of this city, who obtained the prize medal at the great exhibition in London in 1851. Combining lightness with strength, and neatness with symmetry, they are worn with great comfort and satisfaction, and are apparently as perfect as any piece of human mechanism of the kind can well be made. The joints, constructed on the principle of the ball and socket articulation, are situated at the proper points, and their surfaces being well secured, move upon each other with great accuracy and facility, through the intervention of cords, wires, springs, and levers, the whole arrangement being a close imitation of the natural muscles and tendons, if not in shape, at least in position and function. The socket is made with special care, neatly fitting the stump, in every portion of its extent, and is well padded to prevent friction and excoriation, the pressure being diffused over the entire circumference of the stump, while the extremity of the latter is perfectly free in the interior of the former. The annexed cut, fig. 174, affords an illustration of this apparatus.

To enable the patient to wear his artificial limb with comfort and convenience, it is necessary that he should have a good long stump, well covered, perfectly even, and of proper shape, being neither too square and fleshy, on the one hand, nor too thin and conical, on the other. A short, thick, ill-formed stump is a great evil, from which the patient can promise himself no good; but which can hardly fail to be a constant source of annoyance and pain, becoming sore and excoriated under the slightest exercise. The duty of the surgeon is, therefore, one of great responsibility, and cannot be discharged without properly weighing, in every instance, the probable consequences of the operation. When he has his choice, his invariable aim should be to make a long stump, so as to afford an

Fig. 174.

abundant leverage and support for the artificial contrivance. In the leg and thigh its length should not, if possible, be less than nine or ten inches; hence the place of election, for the former, should be only about from three inches to three inches and a half above the ankle, and for the latter about the same distance above the knee. It is not always by any means, however, in the power of the surgeon to select the point where he might otherwise cut off the limb, and under such circumstances he must be contented in leaving as much substance as he can. If the leg is amputated very high up, the weight of the body may be supported upon the knee, especially if the patient's social position is such as to prevent him from wearing an expensive substitute, and this will be the more necessary because it is often very difficult, if not impossible, to preserve the straightness and flexibility of the joint in the event of a very short stump, on account of its incessant tendency to retraction and ankylosis. It is for this reason that some surgeons have advised amputation of the thigh just above the knee, when accident or disease interferes with the formation of a suitable stump below; but, if we consider the difference in the danger of the two operations, we should hesitate before we give our sanction to such counsel, not forgetting that the risk increases with every inch the nearer we approach the trunk. In amputation of the thigh, the principal pressure of the artificial limb upon the stump is concentrated near the body, but care is taken not to apply any direct pressure to the perineum, lest it should produce excoriation.

I subjoin Mr. Palmer's instructions for the formation of suitable stumps in amputations of the leg and thigh, as they are now generally acted upon by the more accomplished operators of the country. For the leg, the first choice is the inferior third or fourth of the limb; the second, the lowest point between this place and the upper third of the leg; and the last, immediately below the tuberosity of the tibia, if not practicable to save four inches below the patella with the full use of the knee-joint. Whatever the seat of the operation may be, the best stump will be one made of flaps.

In amputations of the thigh, the first point of election is the lower third of the limb, so as to give at least ten inches from the perineum; if performed near to or at the knee, there must be complete removal of the condyles of the femur. Secondly, if necessary to go above this point, the object should be to save as much of the thigh as possible. In either case, the flap operation makes the best stump for the comfortable use of an artificial substitute.

In amputations in children, the development of the limb is always partially arrested, so that, by the time the individual attains his full stature, it will be several inches shorter, as well as thinner, than its fellow of the opposite side. Now, surgeons in applying this knowledge to amputations of the inferior extremity, have advised that it should never be cut off below the knee, but at the lower third of the thigh, on the ground that, if this precaution be neglected, one knee will ultimately be elevated a considerable distance above the other, thereby imparting to the gait a peculiar grotesque appearance. Experience, however, has shown that amputation of the leg, even if the stump is only a few inches in length, instead of being an objection, is a decided advantage, the limb thus affording a much longer leverage than when it is cut off through the thigh, for the adaptation of the artificial substitute, the knee-joint of which can always be made to correspond, in situation, with that of the sound limb. Moreover, by adopting this procedure, the weight of the body, provided the stump is not too long, is supported upon the knee; another most important desideratum under such circumstances.

An ingenious artificial limb was recently devised by Dr. Bly, of Rochester. Besides combining lightness with elegance, durability, and strength of construction, it claims the advantage of admitting of lateral motion at the

ankle-joint, with a view of facilitating progression. The contrivance appears well in the model, and is said to work admirably in practice.

The annexed drawing, fig. 175, conveys a good idea of the artificial limb usually worn by the laboring classes after the loss of a leg or thigh. It may be made very light, and, when the stump is of proper length, affords an admirable substitute, the person being able to walk nearly with the same facility as in the natural state.

Various attempts have been made to construct artificial hands and arms. Mr. Palmer, after many trials,

Fig. 175.

Fig. 176.

has at length devised a limb, fig. 176, which, in point of neatness and adaptability, leaves hardly anything to be desired upon the subject.

SECT. VIII.—MORTALITY AFTER AMPUTATIONS.

The mortality from amputations is so much influenced by extraneous and intrinsic circumstances, and requires such a vast amount of statistical material for comparison and contrast, that it is extremely difficult, if not impossible, in the existing state of the science, to arrive at any satisfactory conclusions respecting it. It has long been known that the danger of the operation is greater in proportion to its proximity to the trunk and the size of the limb. Hence, amputation of the leg is less hazardous than amputation of the thigh, and of the thigh in its continuity than of the thigh at the hip-joint. The mortality of the operation is also greater, as a general rule, in hospital than in private practice, in military than in civil practice, and in private practice in cities than in the country. Amputations on account of railway accidents are extremely dangerous, and are liable to be followed by the worst consequences, even in subjects perfectly healthy at the time of the accident, owing to the excessive tendency to mortification and pyemia.

The circumstances which mainly influence the mortality after amputation may be conveniently arranged into four classes, one of which refers to the age, previous health, and social position of the patient; the second to the causes necessitating the operation; the third to the nature, seat, and extent of the operation; and the last to the after-treatment.

1. It will readily be granted that the condition of the *patient* at the time of the accident rendering amputation necessary must exert an important influence upon his fate. If he be old, broken in constitution, or in a state of poverty, so as to preclude the possibility of receiving proper attention after the operation has been performed, the chances are that he will die, either

from shock, erysipelas, pyemia, or congestion of the lungs. The previous state of his health exerts no little influence upon the recovery; not, perhaps, however, to the extent that is generally imagined. A person who is in bad health at the time he is severely injured cannot be expected to bear the shock of an amputation with the same impunity as one whose health is good. The system, exhausted by previous suffering, is ill qualified in such a case to react favorably after the nervous depression consequent upon a severe operation.

Age also exerts considerable influence over recovery. Children, as a general rule, bear amputation better than adults and elderly persons, being less subject to attacks of erysipelas and pyemia, and making a more rapid recovery. The parts, too, unite more frequently by the first intention. At the Hôpital des Enfants in Paris, Guersant, who annually performs from fifteen to twenty operations of this kind, including all the larger limbs, and also occasionally the hip and shoulder joints, does not lose more than one out of about nine cases. He ascribes his extraordinary success mainly to two circumstances; first, a thorough preparation of the system, and secondly, the use of an abundance of good, wholesome, and nutritious food immediately after the operation, on the well-known principle that children do not tolerate abstinence nearly as well as adults. It should be added that nearly all the cases in this Institution demanding amputation are of a scrofulous nature.

The social position, or the habits and occupation of the patient, will influence the result of an amputation. The poor man cannot command the same care and attention as the rich; he often suffers for want of proper food and nursing, and even medicine, at a time, perhaps, when he is most in need of them, and there is no doubt that many patients perish from this cause alone that might otherwise be saved. Intemperance in eating and drinking, and unwholesome occupations must necessarily produce a prejudicial influence upon the result.

2. The influence of the *causes* necessitating amputation has long been a subject of remark on the part of practitioners, both in private and public. Thus, it is an established fact that a person who undergoes amputation of one of the larger limbs on account of a severe injury, as a compound fracture, or a lacerated and contused wound, is much more likely to perish from its effects than one who loses a limb on account of chronic disease. The system, in the former case, deeply depressed by the shock of the accident, often reacts very slowly and imperfectly, and is therefore ill prepared for the approaching ordeal of another severe commotion, the effect of which is felt by every organ and tissue of the body. In disease, on the contrary, the constitution, although perhaps extensively implicated, has become inured to suffering, and, unless too much prostrated, will generally be immensely benefited by the removal of the offending parts. The chief exception to this rule is in malignant affections, in which, in consequence of the vitiated state of the solids and fluids, amputation is often followed, and that very rapidly, by the worst results.

3. In considering the probable result of a case of amputation, we must not forget to take into view the nature, seat, and extent of the *operation*. Experience has proved that, in civil practice, primary amputation is, other things being equal, a decidedly more dangerous procedure than secondary. The very fact that such an operation is required shows that the accident for which it is performed must have been a severe one, involving, perhaps, the most dreadful lesions of the bones, muscles, joints, and bloodvessels, with frightful depression of the nervous system. Now, it is surely impossible that a patient thus circumstanced should be in a favorable condition to submit to another severe shock, such as must necessarily attend the removal of the affected limb, within a short time after reaction has been established. The statistics, both of private and hospital practice, in America and Europe, are decisive upon this subject, proving beyond the possibility of doubt, the greater mortality

after primary than secondary amputations. Thus, of 48 primary amputations of the thigh, leg, and arm, performed in the London hospitals from June, 1855, to June, 1856, inclusive, 26 terminated fatally, or upwards of one-half, while in 156 secondary ones the number of deaths was only 35, or in the ratio of about 1 to $4\frac{1}{2}$.

In military practice, on the contrary, the results of amputations are reversed, the primary being incomparably more favorable than the secondary. This has been the result of the experience of surgeons in all ages and in all countries since the invention and use of gunpowder. Larrey and Guthrie saved three-fourths of their cases after primary operations, and the returns of the British surgeons in the Crimea are of a similar character, although the rate of mortality here was considerably higher, owing to the fact that most of the wounds were inflicted with the conical ball; whereas, in the campaigns of Bonaparte, and in the Peninsular war, they were made with the round ball, the effects of which are, as a general rule, much less destructive than those of the former.

The differences between the results of primary and secondary amputations in civil and military practice, are no doubt due to the circumstances under which they are performed and the causes which lead to their necessity. In the first place, there is generally less shock in injuries received on the field of battle than in those received in civil life. Secondly, the soldier usually submits to the removal of his limb with greater *sang-froid* than the civilian, and often glories in his loss, believing that the world will regard it as an evidence of his prowess and patriotism; whereas, the latter finds in his misfortune nothing but regret and private calamity. Thirdly, the operation is commonly more promptly performed in military than in civil practice, delay, in the latter case, being frequently occasioned by the doubts of the surgeon and the interference of the patient and of his friends; and, lastly, a soldier has not much chance of recovery from an amputation, when, an attempt being made to save his limb, he is subjected to rough and tedious transportation, and is afterwards obliged, when the operation has been performed, to breathe the contaminated atmosphere of a crowded hospital, tenanted by persons borne down by similar accidents. Under such circumstances the mortality from erysipelas, pyemia, and typhoid fever will, other things being equal, be much greater than in private practice. Faure, from these and other causes, lost 270 out of 300 secondary amputations consequent upon injuries received in battle.

The size and situation of the wound exert an important influence upon the recovery. Here again the statistics furnished by various authorities are most eloquent and decisive. They have conclusively established the fact, now regarded as a great general law, that the larger the wound is and the nearer it is to the trunk, the greater is the danger to life. Thus, Malgaigne, in his statistics of amputations of all kinds in the hospitals of Paris, found that the mortality after removal of the great toe was in the ratio of one to six, whereas that of one of the smaller toes was only as one to twenty-six. In amputations of the foot the proportion of deaths was about twenty-five per cent., of the leg fifty-six per cent., and of the thigh sixty-two per cent. These results have been abundantly verified by the statistics of other institutions, as well as by those of military and private experience, and they are full of interest, as establishing a law, which should never, if possible, be violated in practice.

The causes which induce this difference in the larger and smaller amputations are chiefly shock, hemorrhage, pulmonary congestion, pyemia, erysipelas, profuse suppuration, and gangrene of the stump. Tetanus, too, is more frequent after the former than the latter, although the mortality from this affection is not great under any circumstances, especially in the more temperate regions of this and other countries. It is certainly not difficult to understand the reason why the removal of a large limb should be attended with so much more risk than that of a small one. In the former case, the patient has to

contend not only with the shock of the accident necessitating amputation, which is often of itself almost sufficient to destroy him, but as soon as reaction is established he is subjected to another source of depression, perhaps almost equally great, from the operation, frequently involving copious hemorrhage, and liable to be followed by profuse suppuration and high febrile excitement, all tending to depress and exhaust the vital powers. In the latter, on the contrary, there is little or no shock, either from the accident or the operation; the loss of blood is inconsiderable; and the inflammatory effects, local and constitutional, are comparatively trivial. In short, there is no disorganization of the blood as there is in the former, and hence no predisposition to pyemia, or purulent infection, and pulmonary congestion, which are a source of so much mortality after the large amputations performed for severe injuries.

The result of an amputation may be materially affected by the situation at which the bone is divided. Experience has shown that, in the femur, tibia, and humerus, more particularly, the danger is much greater when the bone is sawn through its shaft than when it is cut off at its articular extremity, owing to the injury inflicted upon the endosteum, and the consequent liability of this membrane to diffuse suppuration, and other bad effects.

4. Finally, it needs no labored argument to prove that the mortality from amputation must be materially affected by the nature of the *after-treatment*. That many persons perish after such an operation from sheer neglect, bad nursing, or bad surgical management, is a fact too well known to require comment. This is true both of private and of hospital practice, but the remark applies with increased force when it is made with reference to military practice, which, however well the surgical staff of an army may be organized, must often, from the very necessity of the circumstances in which the operations are performed, and the difficulty of conducting the after-treatment in a proper and satisfactory manner, be followed by the most disastrous results, many lives being lost that might, under more auspicious circumstances, as to locality, comfort, and convenience, be saved. The state of the atmosphere, as it respects purity and temperature, the prevalence of epidemic diseases, mental depression, want of proper diet, severe depletion, and inattention to the dressings, all exert a more or less powerful influence upon the issue of such an operation. The crowded wards of hospitals in large cities, incessantly pervaded by foul air, are notoriously prejudicial to recovery after amputations; gangrene, exhausting suppuration, erysipelas, and pyemia are the common lot of such patients, and the consequence is that many of them perish. Hence it is that private practice, especially that of the country, always shows a much more favorable result than that of large public institutions, or that of large towns and cities. During epidemic diseases, the percentage of deaths from amputations always exhibits a great increase; for it is then that patients are particularly prone to erysipelas, pyemia, and congestive pneumonia. Starvation and depletion are a serious source of mortality after this operation, establishing, as it does, a tendency to purulent infection and a typhoid state of the system, from which often no stimulants, however powerful and well-directed, can afterwards rouse it. I regard such treatment after amputation of a large limb, as, indeed, after every other capital operation, as a great evil, and one which, in my judgment, demands thorough reform on the part of our civil and military practitioners. Finally, I may mention, as another source of mortality, want of attention to the dressings, which, if allowed to remain on too long, not only taint the surrounding atmosphere, but favor the absorption of pus, much to the detriment both of the part and system.

I subjoin the following summary of the statistics of the amputations performed at the Pennsylvania, New York, and Massachusetts Hospitals, because it seems to place the whole subject of the mortality after these operations

in a clear and satisfactory light. It is founded upon the reports of Dr. Norris, Dr. Lente, and Dr. Hayward, and embraces the results of five hundred and forty-six cases.

Dr. Norris's statistics of amputations at the Pennsylvania Hospital comprise a period of twenty years, extending from 1831 to 1850 inclusive. The whole number of operations upon large limbs is 174, of which 44 proved fatal, thus exhibiting a mortality of 25.2 per cent. The whole number of amputations of the thigh was 33, of which 8 were fatal, or nearly one in four; of the leg 69, with a mortality of 29, or 42 per cent.; of the knee 1, which was successful; of the arm 32, of which 5 perished, or one in six and a third; and of the shoulder-joint 6, of which 1 proved fatal.

Of 52 primary amputations of the lower extremity 25 were fatal, while of 28 secondary operations only 8 were fatal, thus exhibiting a mortality of 28.6 per cent. as compared with 48 of the former. Of 22 amputations of the inferior extremity for disease 4 were fatal, yielding a mortality of 18.1 per cent.

The ages of the patients operated upon were as follows:—Of 49 under 20 years, 4 died; of 56 between 20 and 30, 11 died; of 47 between 30 and 40, 18 died; of 37 between 40 and 50, 13 died; and of 5 over 50, 1 died.

The above summary will be found, on comparison, to differ essentially, in one particular, from that given by Dr. Norris himself, in his statistics. Thus, he makes 115 primary amputations of the thigh, leg, arm, and forearm, yield a mortality only of 27, or at the rate of 23.4 per cent., while 41 secondary amputations of the same limbs afford a mortality of 16, or at the rate of 39.3 per cent. Now such a result is, as is well known, wholly at variance with general experience, for it is universally admitted that secondary amputations are less fatal than primary; and it must always be so from the fact that primary amputations are commonly performed for more serious injuries than secondary, injuries which are often of themselves almost inevitably fatal under any treatment, such as the crushing of limbs by railway cars, heavily-loaded wagons, ferry-crossings, high falls, and gunshot wounds, involving joints, large vessels, and other important structures. On the other hand, the very circumstance of waiting for secondary amputation indicates a comparatively slighter lesion, and generally a fair prospect not only of saving life but of limb also. But the explanation in the discrepancy in Dr. Norris's statistics is discovered in the fact that he classes as primary only those cases in which the operation was performed during the first twenty-four hours after the occurrence of the accident, whereas the general rule is to regard every instance as primary until a sufficient degree of reaction has taken place to justify the use of the knife, without taking lapse of time into account at all. Thus, if we wait for the system to come up, an amputation performed on the second day has as much claim to be classed as primary as though it had been performed on the first day, and, indeed, it seems almost impossible, if we reject Dr. Norris's rule, to specify any certain demarcation, as to time, between a primary and a secondary operation. We therefore consider those amputations as secondary which are performed after the occurrence of inflammation, or of inflammation and suppuration. Thus, many of the amputations at the New York Hospital, classed as primary, were performed on the second, third, or fourth day, and some even as late as the sixth or seventh. Frequently the delay was caused only by the circumstance that the patient had to be conveyed from a long distance in the country to the hospital; the shock of the injury and the fatigue of the journey preventing such a degree of reaction as to constitute inflammation. It would certainly be improper, and lead to much confusion, in attempts at classification and generalization, to rank such operations as secondary merely on account of lapse of time. In order, therefore, to make a useful comparison of Dr. Norris's very extensive and valuable

tables with those of other statisticians, I have taken the liberty of drawing my own deductions. It may also be noticed that no distinction has been made between the relative mortality of primary and secondary amputations of the upper extremity in its continuity, because the mortality is so small as to render such a distinction practically useless.

Dr. Lente's account of the amputations at the New York Hospital embraces a period of eighteen years, commencing in 1839, and terminating in 1857. The whole number of cases was 305, of which 139, or 45.5 per cent., proved fatal. The thigh was amputated in 97 cases, of which 51 were fatal, showing a mortality of 52.5 per cent.; the leg in 102, with a mortality of about 34 per cent.; the arm in 58, with a mortality of 15 cases, or at the rate of nearly one in four; and the forearm in 39, with a loss of 8, or at the rate of 20.5 per cent. Of 4 cases of amputation at the hip-joint all were fatal; of 9 at the knee-joint 4 died; and of 19 cases at the shoulder-joint 11 proved fatal.

It will thus be seen that the number of cases of amputation of the lower extremity was 212, of which 86 terminated fatally, showing a mortality of 40.6 per cent.; and of the upper extremity 106, of which 31 died, the rate of mortality being 30 per cent.

Of the amputations of the thigh 33 were by the double flap method, with a loss of 14, or at the rate of 42.4 per cent.; and 28 by the circular, with a loss of 15, or 53.6 per cent. Of the operations upon the legs 21 were by the flap method, and 58 by the circular, the mortality in the former being 38.1 per cent., and of the latter 22.4 per cent.

Of 70 primary amputations of the thigh and leg, 39 were fatal, exhibiting a mortality of 55 per cent.; and of 73 secondary 32 were fatal, or 24.1 per cent.

The ages of the patients operated upon, with their respective mortality, were as follows: For the lower extremity, under 10 years, 2 cases, both recovered; between 10 and 20, 18 cures and 14 deaths; between 20 and 30, 23 cures and 18 deaths; between 30 and 40, 15 cures and 12 deaths; between 40 and 50, 7 cures and 10 deaths; over 50, 2 cures and 2 deaths.

It would seem that the ratio of mortality after amputations at the New York Hospital, during the above period, was very different in different years. Thus, from 1848 to 1851, of seventeen operations upon the thigh, only four were successful. From 1851 to 1857, the number of amputations of the thigh was forty-six, of which eighteen were cured. During the three years above alluded to, there was a remarkable fatality attending all operations at the institution, owing to the prevalence of erysipelas, hospital gangrene, purulent infection, and kindred diseases. This circumstance led to a remodelling and rebuilding of the establishment, and the good effect is seen in the very great decrease in the mortality which has since occurred. Similar facts have been noticed, from time to time, in other hospitals, both in America and Europe.

The statistics of the Massachusetts General Hospital have been furnished by Dr. Hayward, of Boston, and relate to amputations of the large limbs which occurred from the opening of the establishment to January 1, 1840, the whole number of cases being 67, of which 15 proved fatal, the mortality being thus 22.4 per cent. Of these cases 34 were amputations of the thigh, of which 9 proved fatal, or at the rate of 26.5 per cent.; 23 of the leg, with a mortality of 5, or 21.7 per cent.; 4 of the arm, which all recovered; and 6 of the forearm, of which one proved fatal.

Of 10 primary amputations of the lower extremity 5 were fatal, and of 10 secondary 4 were fatal. Of 37 operations performed for disease 5 died, and it is worthy of note that 23 of these cases were amputations of the thigh.

The ages were as follows:—Under 20 years, 13, of which 1 died; from 20 to 30, 31, of which 8 died; from 30 to 40, 9, of which 3 died; from 40 to 50, 10, of which 2 died; from 50 to 60, 3, of which 1 died; and over 70, 1, which recovered.

Having thus given the results of amputations at each of the above hospitals, it will not be uninteresting to state their aggregate results. The whole number of cases, as already mentioned, is 546, of which 198 proved fatal, thus showing a mortality of 36.2 per cent. The thigh was amputated in 164 cases, of which 68 died, or 41.4 per cent.; the leg in 194 cases, of which 68, or 35 per cent., perished; the arm in 94, of which 20 died, or 21.2 per cent.; and the forearm in 85, with a mortality of 11, or 12.9 per cent.

Of 133 primary amputations of the lower extremity in its continuity 69 died, or 51.9 per cent.; while of 111 secondary amputations only 44 were lost, or 39.6 per cent. Of 117 operations performed for disease 23 died, that is, 19.5 per cent. These cases include several double operations of the legs, and of these a majority recovered. Four amputations at the hip-joint are included in the tables, and all these proved fatal. Of 10 amputations at the knee 5 were lost. Five of the ten were primary, one secondary, and three for disease; of the first two died, of the second one, and of the third two. The shoulder-joint was the seat of operation in 25 cases, of which 12 were fatal, or 48 per cent.

In regard to the ages of the patients operated upon in the three hospitals, the mortality in all under 20 years, was 20 per cent.; between 20 and 30, 29 per cent.; between 30 and 40, 40 per cent.; between 40 and 50, 40 per cent.; and over 50, 33.3 per cent.; the number of cases, however, being only 12, and therefore too small to justify any general deduction as to the rate of mortality.

Respecting the relative mortality of the circular and flap operations, the statistics of the Pennsylvania and Massachusetts General Hospitals are silent, and I am therefore unable to compare it with that of the New York Hospital.

A comparison may next be instituted between the mortality of amputations in the practice of American and European surgeons. In doing this, I shall take as my guide the statistics of the above establishments, and those furnished by Mr. Benjamin Phillips, of London. Of 545 cases, analyzed by the English author, embracing primary and secondary amputations, and amputations for various diseases, of the thigh, leg, arm, and forearm, in France, Germany, and Great Britain, 127 proved fatal, thus exhibiting a mortality of about 23 per cent. Of 491 cases in the three American hospitals, 134 died, giving a mortality of 27.30 per cent., a result somewhat higher than the foreign practice. It is worthy of remark, however, that a number of Mr. Phillips's cases were taken from the private practice of European hospital surgeons, and if we bear in mind the fact that the mortality after amputations is always, for obvious reasons, less, the world over, in private than in hospital practice, it will be found that the ratio of mortality is about the same in the two countries, that is, about 23 per cent.

CHAPTER XVIII.

EXCISION OF THE BONES AND JOINTS.

THE term excision serves to denote the removal of a bone whether in its continuity or at its extremity, whether it be limited to a portion of its extent or embrace its totality. When only the head of a bone is concerned in the operation, the word decapitation is occasionally used, and, as meaning the same thing, some authors have adopted the name of exsection. Excision differs from amputation in this, that, while in the latter the bone is removed along with the soft parts which surround it, in the former the bone alone is cut away, the integuments, muscles, and other tissues being retained, in order that they may contribute to the future usefulness of the limb; or, in other and more comprehensive language, while in the one case all the structures are destroyed, in the other as many of them as possible are preserved. Hence this department of surgery has very appropriately been denominated *conservative* surgery, and it is most gratifying to know that it constitutes one of the leading characteristics of the healing art of the present day. It is not to be expected that excision of the bones and joints will ever entirely supersede the necessity of amputation, for as long as the various tissues of the body are subject to disease and accident, so long will they require removal by the knife, in order to prevent the extension of their effects; but that the frequency of the operation will eventually be greatly diminished, the experience of the last fifteen years abundantly attests. Conservative surgery is still in its infancy, and it is needless to conceal the fact that it will take a long time to determine its legitimate limits. Up to the present moment we have no adequate statistical information respecting excision of any of the bones and joints to justify us in delivering a definite judgment upon its true value. The facts that have transpired in relation to the operation are too widely scattered to render them available for the purposes of a rigid and faithful analysis. Such a task would involve a profound consideration of the history of the operation, in all its varied bearings, and would demand an amount of time, labor, and talent, which few professional men are able to command.

Dr. Oskar Heyfelder, of Vienna, in his work on resections, published in 1861, has tabulated 2,662 cases of these operations, in 2,241 of which only, however, the result is known. Among these cases there were 452 deaths, and 1,616 complete cures; in 1,789 cases life has been preserved, and 173 cases have been unsuccessful.

Although incidental mention of excision of the bones occurs in the writings of some of the earlier surgeons, yet it is probable that, if such an operation was ever performed by them, it was in great measure, if not entirely, limited to the removal of the protruding ends of fractured bones. However this may be, it is certain that there is no well authenticated case of excision of the heads of any of the bones until 1762, when Mr. Filkin, of Northwich, removed those of the knee-joint. Soon after this a similar service was performed for the superior extremity of the humerus by Vigaroux, David, and White. In 1781, Mr. Park, of Liverpool, repeated Filkin's operation, and, from the gratifying success attending it, he was led to propose its extension to all the principal articulations, much to the surprise of most of his contem-

poraries, who looked upon the measure as harsh and reckless. The consequence was that the proceeding met with much opposition, and it might even have been entirely lost sight of if it had not been for the boldness and skill of Moreau, the elder, of Bar-sur-Ornain, who, towards the close of the last century, excised, in rapid succession, the articular extremities of the shoulder, knee, and elbow. The success of the French surgeon was followed up by that of his son and successor, who obtained great celebrity for his operations upon the joints, attracting patients from all parts of France, and who, at various intervals, embodied the results of his observation and experience in separate monographs addressed to the Academy of Surgery at Paris and other learned societies. In the early part of the present century excision of the joints received a powerful and salutary impulse from the French army surgeons, particularly Larrey, Percy, Willaume, and Bottin, who repeatedly performed extirpation of the heads of the bones, especially those of the shoulder, on account of gunshot injury. The operation, indeed, was performed, at one time, upon a large scale, and many limbs, as well as lives, were doubtless saved by it. Notwithstanding this, however, the procedure was generally regarded with suspicion in Great Britain, where, although it originated there, it made no real progress until thirty years ago, when, chiefly through the example of Mr. Liston and Mr. Syme, it began to attract the universal attention of medical men. During the last few years the operation has been performed in numerous instances, by surgeons of the highest eminence, upon nearly all the principal articulations, and the results have been such as to warrant the belief that this department of the healing art is destined rapidly to undergo a most salutary change. In this country excision of the joints has hitherto been greatly neglected, both in hospital and private practice; that this, however, will be the case any longer is not at all probable when we reflect upon the intelligence, zeal, and skill of our surgeons. All innovations require time for their adoption, and what De Condillac said of another subject is equally true of this. "*Il est rare que l'on arrive tout-à-coup à l'évidence: dans toutes les sciences et dans tous les arts, on a commencé par une espèce de talonnement.*"

Excision of the bones in their continuity has been practised, for various purposes, for a long time, and modern surgery is indebted to it for many of its most brilliant exploits. It is in this department, more particularly, that American operators have displayed their greatest skill. Commencing with excision of the inferior jaw by Dr. Deadrick, of Tennessee, in 1810, we may with just pride point to the operations of Mott upon the clavicle, of Mussey, McClellan, and Gilbert upon the scapula, of Butt and Carnochan upon the ulna, and of the latter upon the radius, not to mention numerous minor cases, which, although less known, have reflected the highest credit upon the scientific character of the profession, and conferred the greatest benefit upon a class of sufferers who would otherwise have been doomed to loss of limb and life.

Instruments.—Various instruments are required for the ready and successful performance of this operation, and it is always desirable to have rather too many than too few, so that every emergency may be promptly met as it arises. The incisions through the skin and muscles are made with ordinary scalpels, but for detaching the bones from the soft parts and dividing the ligaments, stout, probe-pointed knives, with broad, steel handles, convex and semi-sharp at the end, will be necessary. Excision of the bone is effected with a hand-saw, a pair of pliers, or the gouge and chisel, according to the structure, size, and situation of the affected piece. The saw, which may be a common amputating one, should be from six to ten inches in length by from three to twelve lines in width, its teeth being sharp and widely set, and its handle long and thick. A saw, lately introduced by Mr. Butcher, of Dublin,

and bearing his name, will be found very useful, especially when there is but little space, or when it is necessary to divide the bone obliquely. It has, as will

Fig. 177.

Butcher's saw.

be perceived by a reference to the engraving, a very narrow blade, the angle of which can be changed at pleasure. In addition to these instruments, it will

Fig. 178.

Hey's saw.

be well to have upon the tray a Hey's saw, fig. 178, and also a very narrow concave saw, fig. 179, with a blunt end, in the event of its being necessary

Fig. 179.

Curved saw for small bones.

to divide the bone from behind forwards. As to the chain saw, fig. 180, even in its most approved forms, it may well be dispensed with, as its use is generally only productive of delay, vexation, and disappointment.

Fig. 180.

Chain saw.

Bone forceps or pliers, figs. 181—2—3, usually known as Liston's, although long ago described and delineated by Scultetus, should be at hand, of various shapes and sizes, as they may frequently be used with great advantage in places where it is impossible to introduce and work the saw. The surgeon should also be provided with several gouges and chisels, a strong mallet, trephines, scrapers, and a large elevator, together with a thick leather strap or leaden spatula for protecting the soft parts during the division of the bone, suitable instruments for holding the flaps apart, and a syringe for washing out the wound or clearing away sawdust and the debris of diseased bone and cartilage.

From this catalogue of instruments I have purposely excluded the tourniquet,

which is not only unnecessary, but absolutely hurtful in excision of the bones and joints. If proper care be used, the surgeon will seldom lay open any of

Bone forceps.

the more important arteries, none certainly which may not be readily secured by the ligature; there is, therefore, no need of such an instrument, which would only serve to dam up the blood in the larger veins, and thus cause injurious waste.

Position of the Patient.—The position of the patient, the surgeon, and the assistants, as well as the number of the latter, varies in different cases and under different circumstances, and does not admit of any precise rule. Generally speaking, the recumbent posture will be the most suitable, especially if chloroform is given and the operation is at all likely to prove tedious. In cases of any magnitude, as in exsection of the knee-joint, the number of assistants should not be less than five or six; one administering the anæsthetic, two holding the limb, one handling instruments and tying arteries, and another having charge of the sponges.

As it respects the operation itself, it may be conveniently considered as consisting of three stages, the division of the soft parts, the excision of the bone, and the dressing of the wound.

Incisions.—In planning the incisions, care must of course be taken not to interfere with any structures, the division of which might compromise in any way the result of the operation. The sheaths of the tendons are to be especially avoided. To lay them open would be to invite inflammation and plastic deposit, which could not fail to impair their usefulness. The nervous trunks are turned aside, out of harm's way, and the larger vessels, both arterial and venous, are studiously protected from injury.

The number and direction of the incisions will necessarily vary in different cases. Sometimes a single longitudinal cut will be sufficient, even in such a joint as that of the shoulder; in general, however, they should be so arranged as to enable us to form a good-sized flap, either of a semi-lunar, horseshoe, or square shape, as this will afford more ready access to the affected bone, as well as greater facility for sawing it. Incisions made after the manner of some of those depicted in the chapter on minor surgery will afford the surgeon an opportunity of adapting his operations to any case that will be likely to come under his observation.

The elliptical incision may be adopted, if it be necessary to remove any integument on account of disease. Whatever plan be pursued, the great rule

is to sacrifice as little soft substance as possible. Even when the flap is very large and unseemly, it must not be retrenched, experience having proved that it will always contract down to the proper dimensions during the progress of the cure. In separating the bone from its muscular and ligamentous connections, the knife must be kept as close as possible to its surface; any deviation from this rule will be likely to be followed by the division of structures which should not be meddled with, especially important bloodvessels.

Removal of the Bone.—Insulation of the bone having been effected, it is next to be pushed through the wound, and sawn off, the parts around being carefully protected from injury by a piece of leather, or a metallic spatula placed underneath. Whenever it is feasible, I prefer sawing off the bone to cutting it away with the pliers, as the surface thus made is more smooth, as well as less bruised, and, consequently, more liable to heal well. In operating upon the smaller bones, as those of the carpus and tarsus, we are generally obliged to make free use of the gouge and chisel. In whatever manner the excision be accomplished, the invariable rule is to cut through the healthy structure; and this is applicable even when the bone is merely denuded of its periosteum, observation having shown that, when the osseous tissue is divested of its natural covering, it is either already dead, or will soon die. In excision of the long bones, the condition of the medullary canal and its contents should always be carefully scrutinized, with a view of ascertaining whether the part should be still further retrenched or not. Imperfect excision is worse than useless, as no thorough cure can take place after it without another operation. Finally, when two bones require to be removed, as, for example, in excision of the tibia and fibula, they should be sawn off upon the same level, otherwise the limb will be apt to be forced to one side, and so be rendered comparatively worthless.

Dressing.—Bleeding having been arrested, the wound is washed out with cool water thrown in with a large syringe, in order to get rid of the sawdust, which, if allowed to remain, never fails to act as a foreign substance, liable to provoke suppuration and erysipelas, if not worse consequences. Any sinuses that may exist are also pared or laid open. The edges of the wound are then approximated by the interrupted suture and adhesive plaster, aided, if necessary, by a compress and bandage. The most dependent portion of the wound, however, should always be kept patent by means of a small tent or tube, to admit of the necessary drainage. If this precaution be neglected, the result will be that the secretions, which are always more or less profuse after such an operation, will accumulate in the wound, thus not only impeding the cure, but often inducing necrosis of the bones, and affording an opportunity for the easy entrance of pus into the system.

Before the patient is returned to bed, the limb should be placed in the position in which it is to rest during the after-treatment, and kept perfectly quiet by means of appropriate apparatus. In excision of the inferior extremity osseous union is usually desired, as the limb would hardly be useful without it, and hence it will not be proper, as a general rule, to make passive motion. In the upper extremity, however, this rule is not applicable; here motion is both sought for and attained at all hazard, an ankylosed wrist, elbow, or shoulder being of little value.

The great sources of danger after excision of the bones and joints, are excessive suppuration, pyemia, and erysipelas. These accidents are to be carefully guarded against by the ordinary means, and treated upon general principles in the event of their occurrence. If the convalescence be unusually protracted, and especially if the wound be slow in healing, if sinuses form, or if there be much discharge of an unhealthy character, there will be reason to suspect that the bones have again become diseased, and that further interference will be required before a cure can finally be brought about.

CHAPTER XIX.

ANÆSTHETICS, OR THE MEANS OF AVERTING PAIN.

THE prevention of pain in surgical operations has been an object of anxious solicitude with practitioners from time immemorial, and we accordingly find that suggestions, more or less plausible, have been made at different periods with a view of meeting this important end. One of the most remarkable of these suggestions, inasmuch as it was a clear foreshadowing of the anæsthetics of the present day, occurs in the surgical writing of Theodoric, in the latter part of the thirteenth century. The means recommended by him consisted in thoroughly impregnating a sponge with a strong aqueous extract of various anodyne articles, especially opium, hemlock, hyoscyamus, lettuce, and mandragora, and then, after having been immersed for an hour in warm water, holding it to the nose until the patient fell asleep, when the operation was proceeded with. In order to rouse him when the operation was over, another sponge, dipped in vinegar, took the place of the "*spongia somnifera*," as the former was denominated; if this expedient failed, the juice of the root of fennugreek was freely injected into the nostrils. In India, the extract of the hemp plant, *cannabis Indica*, indigenous to that country, has been employed for the same purpose for ages past. Near the close of the last century, great hopes were entertained that a successful agent had at length been found in the inhalation of nitrous oxide gas, either alone, or variously combined with other vapors, but after numerous experiments, in which Sir Humphrey Davy and other eminent philosophers took an active part, the project was at length abandoned as chimerical. Some time prior to this period, Mr. Moore, of London, had suggested the possibility of diminishing pain in surgical operations, especially in amputations, by compression of the principal nerves, by means of an instrument, somewhat similar to a tourniquet, but so constructed as to touch the limb only at two points, one of the pads being regulated by a screw. The experiment was tried at St. George's Hospital, by Mr. John Hunter, upon a man whose leg was cut off below the knee on account of a large irritable ulcer of the foot, and the suffering is said to have been exceedingly slight. Very few, however, seemed inclined to repeat it, and the consequence was that it was soon given up; a result which might have been anticipated by the originator of the plan, as the instrument used for the compression was not only uncertain in its operation but productive of great uneasiness during its application.

In 1819, Mr. James Wardrop, of London, proposed to diminish the sensibility of the patient in surgical operations by means of copious venesection, and in a paper which he published on the subject in the tenth volume of the *Medico-Chirurgical Transactions* he cites several cases illustrative of its beneficial influence. He thought the practice particularly adapted to persons of a nervous, irritable temperament, and he recommended that it should be carried to the extent of syncope, so as completely to annul all sensation during the dissection. In one of his cases, he bled the patient, a young robust woman, to fifty ounces before he began the operation, which consisted in the extirpation of a small tumor from the orbital plate of the frontal bone, during which she remained perfectly unconscious, expressing great surprise

when she found it was over. As might have been expected, however, she remained very weak for several days after the operation, although she made a rapid recovery. I am not aware that this recommendation met with any particular favor.

The administration of the different preparations of opium for the purpose of lessening the pain of surgical operations is an old practice, highly lauded by some, and as greatly condemned by others. I was myself in the habit of employing it for many years in almost every case that fell into my hands previously to the discovery of anæsthetics; I generally preferred morphia to laudanum or opium in substance, and always gave it in full doses, either alone, or, when the patient was strong and plethoric, combined with a moderate quantity of tartrate of antimony and potassa, with a view of inducing a greater degree of relaxation and insensibility. I became very fond of the practice, and never, so far as I could determine, experienced any bad effects from it; on the contrary, I knew that it was commonly productive of great benefit, not only blunting sensibility but preventing shock, and, consequently, severe reaction.

Notwithstanding these various attempts to prevent suffering in surgical operations, no anæsthetic agent, using the term in its legitimate sense, was discovered until 1844, when Dr. Horace Wells, a dentist of Hartford, Connecticut, wishing to have a tooth extracted, rendered himself completely insensible by inhaling nitrous oxide gas; and he soon afterwards administered the same remedy to several of his patients with effects equally gratifying. Shortly after this, Dr. Wells repeated his experiments before the Medical Faculty and Students of Harvard University, at Boston, but owing to mismanagement either in the apparatus or in the gas itself, the attempt signally failed, and the only reward which he received for his pains was ridicule, which, in his case, was the more cruel, because he was a man of uncommon sensibility. Two years after this, Dr. Morton, also a dentist, who had been a pupil of Wells, resorted to the inhalation of sulphuric ether, first in his own person, and afterwards in some of his patients, until he became convinced that it might be taken not only with impunity, but with the most perfect certainty of preventing pain in any operation, however severe or protracted. Fortified with this knowledge, he applied at the Massachusetts General Hospital, at Boston, for permission to repeat his experiments upon a man who was about to undergo an operation for the removal of a tumor of the neck by Dr. John C. Warren. The result was everything that could have been desired. The next day, Morton etherized a patient for Dr. Hayward; and the news of the remedy rapidly spreading, its use soon became general, both in the United States and in Europe. In the latter country, the subject attracted perhaps even greater attention than at home, and soon led to the discovery of chloroform by Dr. Simpson, of Edinburgh, in 1847. Various other articles possess anæsthetic properties; of this description are chloride of hydrocarbon, nitrate of ethyl, aldehyde, benzin, the Dutch liquid—a compound of chlorine and olefiant gas—bisulphuret of carbon, amylene, and kerosoline; but, with the exception of the latter two, it is questionable whether any of them are sufficiently innocuous to justify their exhibition.

Practically it is of no importance to know who the discoverer of anæsthetics was; but, if we carefully inquire into the history of the matter, we cannot fail to award to Dr. Wells the credit of having made the first successful application of this class of agents for the prevention of pain during a surgical operation. Nearly fifty years previously, Sir Humphrey Davy had, it is true, employed nitrous oxide gas for the relief of a severe headache, brought on by the intoxication caused by the rapid drinking of a bottle of wine for experimental purposes, and afterwards as a means of preventing the pain of cutting a wisdom tooth; but, as every one knows, no further use was made

of the remedy, until it was resumed by Dr. Wells, and applied with express reference to the production of its anæsthetic effects. He was beyond doubt the first to establish the possibility of preventing pain in surgical operations; and had his experiments at Boston not eventuated in chagrin and disappointment, he would unquestionably have pushed his researches much farther, and perhaps speedily hit upon the very articles which were afterwards found by Dr. Morton and Professor Simpson to possess such valuable properties. To both the latter gentlemen the world owes an immense debt of gratitude for having brought to light the wonderful anæsthetic effects of ether and chloroform.

It is somewhat singular that the two countries in which the anæsthetic virtues of ether and chloroform were discovered should each, respectively, prefer its own remedy; America, ether, and Great Britain chloroform. There are, however, in the United States, numerous practitioners who prefer the latter article, both in surgical and obstetrical practice, and I have myself constantly used it ever since its introduction among us in 1848, believing it to possess decided advantages over ether, although its administration unquestionably requires greater care and attention. Among the more important of these advantages are, first, the more rapid manifestation of the anæsthetic action of the remedy, the system becoming affected much sooner, as a general rule, than it does by ether; secondly, a smaller amount of laryngeal and bronchial irritation; thirdly, the more easy maintenance of the anæsthetic influence, after the system has once been fairly affected; and, lastly, the less liability to cause vomiting and other unpleasant consequences. The very odor of ether is to many persons excessively offensive, and there are very few in whom the inhalation does not produce more or less cough and vomiting. On the other hand, it certainly requires less caution in its administration, and thus far it has furnished but few deaths, whereas the mortality from chloroform already reaches about a hundred. Dr. Maddin, of Nashville, who has carefully investigated the subject, finds that most of the fatal cases of anæsthesia have occurred in minor surgery, or in operations of a comparatively trifling nature, and in which, consequently, the remedy might probably have been entirely dispensed with. For a number of these cases the dentist is accountable, nearly all the earlier and not a few also of the later having happened during the extraction of teeth, probably from the want of precaution in not sufficiently depressing the head during the operation.

It is remarkable that most of the fatal cases have happened in private practice, or in small institutions, a circumstance which would seem to show that there had been some fault in the mode of administration of the remedy. At Guy's Hospital, London, chloroform had been used in upwards of 12,000 cases before there was any serious accident; and in the war in the Crimea, according to the testimony of Mons. Flourens, it was administered more than 25,000 times without a single death. It has been asserted by the opponents of chloroform that the rate of mortality in the great operations of surgery has been essentially increased since the introduction of that article into practice, and Mr. Arnott, of London, has taken pains to collect elaborate statistics with a view of establishing the fact upon an irrefragable basis. On the other hand, the statistics of Dr. Simpson, the discoverer of the anæsthetic properties of chloroform, go to show that the number of deaths is not only not increased, but absolutely diminished. Perhaps the truth lies between these two statements. Dr. Macleod, in his *Notes on the Surgery of the War in the Crimea*, recently published, declares it as his conscientious belief that the use of chloroform in the British army saved many lives, and that numerous operations were performed by its assistance which could not otherwise have been attempted. It is not improbable that, if there has really been an increase in the mortality after operations since the introduction of anæ-

thetics, it has been owing, not to the pernicious effects of the remedy, but to the fact that surgeons have been emboldened to undertake operations in cases which were formerly regarded as unfit for the employment of the knife, and, above all, to the circumstance that of late years there has been a fearful increase of railway and other terrible accidents, many of which are necessarily fatal, no matter to what treatment they may be subjected.

I have now given chloroform for more than ten years, and during all that time no serious accident has befallen me. There was one case, however, in which I experienced much alarm; the patient was a boy, thirteen years of age, who was about to undergo an operation for the repair of his lips and cheek, which had been much mutilated by salivation. He took chloroform very badly, and had tried my patience for an unusual length of time, when, determined to make him inhale more rapidly, I began my incisions. Instantly his struggles became furious, compelling me to suspend further proceedings. Provoked at the occurrence, I requested the assistant to hold the sponge closely over the nose, while I carefully watched the pulse and respiration. Fifteen seconds had hardly elapsed, when they both ceased, the face assuming at the same time a pale, livid aspect, too clearly denotive of asphyxia. In an instant the boy was turned upon his side, and artificial respiration instituted; cold water was dashed upon his body, and a free access of cold air invited by raising the windows of the apartment. Animation was speedily re-established, and the operation proceeded with, chloroform being again given towards its close, but of course with great caution. In this case it is evident that the patient was on the very verge of dissolution; but whose fault was it? Certainly not that of the chloroform, but the manner in which it was administered.

I ascribe my good luck in the use of chloroform to the great caution with which, except in the above case, it has always been given in my practice, and to the purity of the article employed by me. During my residence at Louisville, Dr. D. D. Thomson for many years superintended the inhalation in almost every important operation that I performed, either in private or public, and when he was not present, I either gave it myself or confided the task to a trustworthy assistant.

The mortality from anæsthetics has lately been placed in a very satisfactory light by Dr. Charles Kidd. In a paper in the *London Medical Times and Gazette* for May, 1860, he states that, up to that period, about 125 cases of death from chloroform had occurred in Europe, 25 from ether, and several from amylene. Of 121 deaths from chloroform, 54 happened immediately before operations; 42 during the operations; and 25 after the operations. The statistics of Dr. Kidd show that the mortality from chloroform has hitherto been more than twice as large in males as in females, and that the danger from the inhalation of this substance, as had been previously ascertained by Dr. Maddin, is much greater in trivial than in large, tedious operations, the latter establishing apparently a chloroform tolerance. Of the number of deaths from chloroform and other anæsthetics in this country, we have no accurate data, but it is much less than in Europe. As an offset to the above fatal cases, it may be stated that chloroform, the use of which is unquestionably more dangerous than ether, has now been administered in hundreds of thousands of operations with perfect safety.

Anæsthetics not only prevent pain and thus save a vast amount of suffering, but by placing the patient in a passive condition give the surgeon a control over him which he could not possibly obtain in any other manner. Deprived of sensibility and consciousness, the former is virtually dead to all external impressions, and the latter is therefore enabled to conduct his dissections and other manual processes with as much ease and deliberation as if he were operating upon the cadaver. The advantages thus gained are ab-

solutely incalculable, and he who would fully appreciate them must be able to put himself in the twofold situation of patient and surgeon, and then, in imagination, contrast their condition with that of the patient and surgeon of former times, before the discovery of anæsthetics, when the one was writhing in pain and agony during a tedious dissection, and the other had his progress incessantly interrupted by the cries and struggles of the sufferer.

The exhibition of anæsthetics is important not merely as a preventive of pain, but as a means which enables us to examine our cases more thoroughly prior to operation. Sounding for stone in the bladder, formerly a source of so much suffering, may now be performed without the slightest uneasiness, and the same is true of stricture of the urethra, diseased bones, affections of the anus and rectum, and of various other lesions. The use of anæsthetics affords immense advantages in the examination of dislocations and fractures, enabling us to handle the parts more satisfactorily than formerly, and therefore often leading to a much more certain diagnosis.

There are some operations in which the use of anæsthetics is usually regarded as inadmissible; thus, in harelip, excision of the tongue, and removal of the jaw, the patient, as a general rule, should be under the influence of these remedies only at the beginning of the operation; after the dissection has been fairly commenced, he should be sufficiently conscious to enable him to co-operate with the surgeon, otherwise the blood, passing down into the windpipe, might cause severe cough and other inconvenience, seriously embarrassing the procedure. The same remark applies to excision of the tonsils, although I have frequently removed these organs while the patient was so far under the influence of chloroform as to render him incapable of offering any resistance. Extirpation of the jaws I have repeatedly performed under similar circumstances, passing through the different stages of the operation while the person was in a state of perfect unconsciousness. Even the more delicate operations upon the eye, as the establishment of an artificial pupil, and the extraction of cataract, may be safely performed with the aid of anæsthetics; as it respects the latter, however, it should not be forgotten that the vomiting which occasionally attends their use might destroy the organ.

An advantage which has often been claimed for anæsthetics is that there is apt to be less hemorrhage during operations; I am, however, in doubt whether this is true, and, even if it were, any good that might thus accrue would be more than counterbalanced by the liability to secondary bleeding, caused apparently by a partial loss of tone in the smaller vessels, interfering with the formation of protective clots. Possibly the blood itself may be more or less at fault.

Chloroform, a terchloride of formyl, is a clear, colorless liquid, very volatile, of an agreeable, aromatic odor, of a pungent, saccharine taste, very dense, of the specific gravity of 1.497, almost insoluble in water, non-inflammable, and perfectly neutral, neither reddening nor bleaching litmus paper. It is a compound of two atoms of carbon, one of hydrogen, and three of chlorine. Various impurities are liable to be mixed up with it, especially the chlorinated pyrogenous oils, ether, and alcohol. The presence of oils is readily detected by pure, strong sulphuric acid, to which they impart a change of color, varying from yellowish to reddish brown, according to the quantity of the extraneous substances. A still more simple test consists in pouring the suspected fluid upon the hand, where, rapidly evaporating, it deposits its oily impurities, which are easily recognizable by their offensive smell. Dropped upon white paper, pure chloroform speedily disappears without leaving any stain. The existence of alcohol is detected by dropping a small quantity of chloroform into distilled water; if pure, it will retain its transparency at the bottom of the glass, whereas, if the reverse be the case, each globule will ac-

quire a milky appearance. The presence of ether may be detected by a lighted taper, or the inflammable character of the fluid. It is practically important to know that chloroform deteriorates by exposure to heat and to a strong light. The most reliable article is that prepared with methylated spirit.

Mode of Administration.—There are five principal circumstances which should be closely attended to during the exhibition of chloroform, and if this be done it will be difficult, unless the article be a bad one, or the patient have some idiosyncrasy, to produce any unpleasant effects with it. These are recumbency, an empty state of the stomach, a free play of the diaphragm, an abundance of atmospheric air, and a gradual administration.

1st. During etherization the patient may sit up with impunity, but this is not the case during the inhalation of chloroform, owing, apparently, to the greater relaxation of the muscles, and, consequently, to the greater difficulty in maintaining the circulation of the brain through the influence of the heart's action. Not only should the body be recumbent, but care should be taken to depress the head and shoulders, bringing them nearly to a level with the trunk. Lying upon the side, when this is practicable, is perhaps the safest posture of all, as the breathing will then be less likely to be interfered with by the falling back of the tongue.

2d. An empty state of the stomach is desirable for two reasons; first, because if chloroform be given soon after a hearty meal it will be almost certain to induce vomiting; and, secondly, because a crowded condition of the organ interferes materially with the movements of the diaphragm. Food must not be taken for at least four hours before the exhibition; but, on the other hand, the interval should not be too protracted, lest serious exhaustion result from the want of the necessary stimulus.

3d. Care must be taken, before the inhalation is commenced, that the patient's clothes are sufficiently loose to prevent constriction of the chest and abdomen. Any compression from this source would necessarily impede the action of the diaphragm, and might thus become a cause of mischief.

4th. The importance of having an abundance of atmospheric air during the inhalation of an article so potent as chloroform is self-evident; in etherization this is of comparatively little consequence, but in the exhibition of chloroform for surgical and obstetrical purposes, it is absolutely indispensable to the safety of the patient.

5th. The inhalation must be effected gradually, not hurriedly, time being allowed to the system to accommodate itself to the influence of the remedy, thus avoiding the shock which might otherwise result to the heart and brain. From six to eight minutes should usually be spent in producing the full effects of the anæsthetic.

When the patient is very feeble, or pale and timid, it will be advisable to give him, immediately before the operation, from half an ounce to an ounce of brandy; and the dose may afterwards be repeated, if the effect is obliged to be maintained for an unusual length of time, sufficient consciousness being permitted for the performance of deglutition.

The best mode of administering chloroform is to pour the fluid upon a napkin or handkerchief, previously folded into a kind of cup-shaped hollow, and held securely in the hand. Or, instead of this, a small, hollow sponge may be used. As to the various inhalers that have been devised for the purpose, they are all objectionable on account of their inconvenience and the difficulty of obtaining a sufficiency of atmospheric air. The patient having taken his place upon the table, and emptied his lungs by a deep and protracted expiration, the napkin, impregnated with a drachm of chloroform, is held over the mouth and nose, at a distance of about two inches, being gradually brought nearer and nearer until it is within half an inch, beyond which it

should not be carried, the chest being at the same time regularly and powerfully distended. The pungent effect of the liquid upon the skin should be prevented by anointing the face with some protective unguent, otherwise vesication might arise. All unnecessary conversation is avoided, lest the attention of the patient should thereby be unduly distracted. The assistant having charge of the administration gives it his earnest and undivided care; wetting the napkin from time to time with the fluid, and seeing that the patient gets an abundance of air, his vigilance increasing as the effects of the medicine become more and more apparent. As soon as the sensibility is completely abolished, the operation is commenced, a return to consciousness being prevented by holding the napkin, wet with a small quantity of the vapor, occasionally before the nose, and thus the impression is maintained, steadily and cautiously, not only until the knife has fully accomplished its object, but until the principal arteries have been secured, and, in some cases, even until the dressings have been applied.

As soon as the inhalation has been fairly entered upon, one of the attendants should sedulously watch the state of the pulse, of the respiration, and of the countenance. Any sudden failure in any one of these should at once create alarm, and induce a suspension of the operation, or provision for the admission of a greater quantity of atmospheric air. I do not deem it necessary that a finger should be constantly kept upon the pulse, for the color of the face and the nature of the breathing will always sufficiently indicate the effects which the anæsthetic is exerting upon the system, and thus afford abundant opportunity for preventing any unpleasant occurrence.

The *quantity* of chloroform required during an operation, and the time during which its effects may be safely maintained, must, of course, vary according to the exigencies of each particular case. In general, from half an ounce to an ounce may be regarded as a fair average, but very frequently it takes three or even five times that amount, depending upon the severity and duration of the operation, and the susceptibility of the individual. In some instances almost an incredibly small portion answers the purpose. Children usually require comparatively little; and it is well known that women are, as a general rule, more susceptible to its influence than men. Persons exhausted by hemorrhage are very easily affected by it, owing to the rapidity of its absorption, and hence it should always be administered to them with unusual care. In obstetric practice, the effects of chloroform may be maintained, with impunity, for many hours together, and the same remark is true of severe and tedious surgical operations. Thus, in an attempt to reduce a chronic dislocation of the shoulder-joint, I kept the patient steadily under the influence of the remedy for two hours, during which time not less than twenty ounces were given.

Age is no bar to the use of anæsthetics. I have given chloroform repeatedly to very young children, and, in one instance, I administered it, with excellent effect, to an infant under two months. Old persons also bear the inhalation well. Certain diseases are usually regarded as contra-indicating the employment of anæsthetics, particularly organic lesions of the heart and brain; but, for my own part, I have never allowed any affection whatever to stand in my way, and I can really, upon general physiological principles, see no reason why they should, since, by tranquillizing the system, they effectually prevent the mental and bodily perturbation which is so apt to attend operations performed without the aid of these agents. In giving chloroform to infants and very young children, only a few drops should be poured upon the napkin at a time, and care should be taken to hold the cloth at a considerable distance from the mouth and nose, so that the fluid may enter the lungs well diluted with atmospheric air.

Effects.—The effects of chloroform upon the system may, for practical purposes, be divided into two stages, namely, that of excitement, and that of insensibility. The first begins soon after the commencement of the inhalation, and is characterized by various cries and struggles, as if the patient, feeling alarmed, were anxious to escape from the table. The face becomes flushed, the eye has a wild and staring expression, the pulse is preternaturally frequent, and the mind is incoherent; as the effects increase, the brain falls into a species of exhilaration closely akin to that of intoxication. It is now that the individual usually exhibits his peculiarities of temperament and habit. Thus, if he be of a boisterous disposition, he will be very apt to be noisy, to swear, or to fight, and to make the most violent efforts to disengage himself from the assistants. One man will laugh and joke; another will weep, or moan and sigh; the sportsman will fancy himself occupied in the pleasures of the chase; the wily craftsman in driving a good bargain; the lawyer in addressing a jury; the preacher in exhorting his congregation, and the physician in prescribing for his patient. The mind is in a dreamy, perverted condition, and whatever is most predominant at the time in thought and feeling is sure to exhibit itself in expression.

This excitement varies much both in degree and duration; in many cases it is very slight and transient, while in some it is even entirely wanting, the patient being perfectly tranquil throughout. When considerable, it is very liable to be reproduced, to a greater or less extent, as the effects of the remedy wear off, so that the individual will perhaps be quite as boisterous after the inhalation is over as he was soon after its commencement. In very nervous, excitable persons the intoxication may last for several hours, although this is uncommon.

In the second stage, which succeeds imperceptibly to the first, the individual gradually lapses into a state of entire unconsciousness; the muscles, thoroughly relaxed, are no longer under the control of the will, the limbs retaining any position in which they may be placed; the eyelids are closed and the balls turned up, the pupils being contracted, and insensible to light; the respiration is calm and easy; and the pulse is soft and undisturbed, or, if it be at all changed, it is rather below than above the normal frequency. Feeling and intellection are suspended, and everything indicates that the patient is in a quiet and pleasant sleep, wholly unconscious of surrounding objects, and therefore completely insensible to pain. If this state be carried a little farther, coma will arise; the patient will snore as if he were apoplectic, the pulse and respiration will diminish in force and frequency, and the pupil will become notably dilated. As yet, all is safe, but a few more whiffs, and an important link in the chain of life may give way, and the patient be sent into eternity. In the administration of chloroform we should always strive to prevent coma. The most unexceptionable form of anæsthetization unquestionably is that in which there is a perfect suspension of sensibility without the complete abolition of consciousness; but it need hardly be added that it is, practically, extremely difficult to produce such a nice result in any case. In general, the patient, on recovering from the effects of the remedy, has no distinct recollection of anything that passed while he was under its influence.

The effects of chloroform seldom completely disappear under several hours. After the more characteristic symptoms have gone off, the mind will still remain somewhat bewildered, the muscles relaxed, and the feelings perverted. In some cases, especially in children, the patient, after having passed through a most severe operation, will fall into a tranquil sleep, and perhaps not wake up fully for an hour or two. In other cases, again, the effects will go off very rapidly, and the individual will not only be roused to a state of consciousness, but to severe pain. If the vapor has been inhaled largely,

there will frequently be some degree of nausea or even vomiting, either during the operation, or at its close, upon the return of consciousness. Emesis is most frequent in children and in persons of a nervous, irritable temperament. Headache, although not common, is occasionally met with, and sometimes lasts for a number of hours. It is most liable to come on if the chloroform is impure.

Chloroform, inhaled to excess, sometimes produces effects which disappear only after a considerable length of time; as abolition of the sense of smell, perversion of taste, and loss of power in the bladder and rectum. In two cases, observed by Dr. Happoldt, of South Carolina, these effects did not completely wear off for two months.

Although chloroform is one of the greatest boons which a kind and beneficent Providence has bestowed upon man for the prevention and alleviation of pain, yet, like every other remedy, it is capable, when abused, or injudiciously administered, of producing the most deadly effects. These effects are those of a narcotic poison; and as they may follow, in persons of unusual susceptibility, the inhalation of the smallest quantity of the liquid, it is of the utmost importance that they should never, for a moment, be lost sight of in the use of the article. An over-dose may destroy life almost instantaneously, or death may occur at a variable period after the exhibition; sometimes after partial reaction has taken place. The phenomena indicative of danger are, stertorous respiration, a small and feeble pulse, lividity of the features, dilatation of the pupils, relaxation of the sphincters, and rapid diminution of the temperature of the body. It seems probable, although the question does not admit of positive adjudication, that these effects are mainly, if not wholly, due to the action of the carbonic acid gas contained in the chloroform primarily upon the blood and nervous centres, and secondarily upon the respiratory organs, thereby disqualifying them for the performance of their functions, death being caused by asphyxia. What corroborates this view of the subject is the fact that the danger from the inhalation of chloroform is generally in proportion to the impurity of the article, or the quantity of its pyrogenous oils, and the want of a sufficiency of atmospheric air, or the most essential constituent of this fluid, namely, oxygen, during the administration of the remedy.

The *treatment* for the relief of the poisoning consequent upon an over-dose of chloroform must be prompt and efficient; for everything depends upon the presence of mind of the surgeon and the rapidity and energy with which he applies his remedies. The first thing to be done is to desist from the further administration of the remedy; the second, to draw the tongue out of the mouth with a tenaculum, so as to lift it away from the glottis; the third, to cause a full access of cold air, by throwing open the doors and windows of the apartment, and making free use of the fan; the fourth, to dash cold water upon the body, or, still better, to pour it from a height of several feet; the fifth, to institute artificial respiration, by introducing a tube into the windpipe, and percussing the body or by blowing air into the mouth; the sixth, to stimulate the surface, especially over the spine and heart, with hot mustard water, or dilute spirits of hartshorn; the seventh, to administer an injection of turpentine; and the last, to apply galvanic electricity, passed through needles inserted in different parts of the body. As soon as the patient is able to swallow, free use is made of brandy and ammonia. These means should be employed with great diligence and regularity until it is perfectly evident that life is irrecoverably extinct.

For the minor effects of chloroform very little is necessary, beyond a discontinuance of the inhalation, sprinkling the face and chest with cold water, allowing a free access of cold air, and holding a smelling bottle near the nose, but not to it. If vomiting occur, the patient must immediately be turned

upon his side—not on his abdomen, lest the action of the diaphragm be impeded—with the head inclining downwards, otherwise the contents of the stomach, as they are lazily ejected from the œsophagus and fauces, might easily descend into the larynx, and thus induce suffocation.

I cannot conclude these remarks upon the subject of anæsthetics without expressing a hope that practitioners of every description will cease to administer these remedies to females except in the presence of witnesses. The cases of the two dentists, the one of this city and the other of Montreal, which have lately created so much excitement both in and out of the profession, should serve to inculcate proper caution in this particular, without which no man's reputation and character, however pure or exalted, may altogether escape censure, if, indeed, ruin. The remarkable instance which, a few years ago, occurred at the Philadelphia Hospital, of a woman who, while under the influence of anæsthesia, went through all the movements of the sexual congress, and analogous examples reported in the medical journals, clearly show how strongly the imagination of the patient may be impressed in this way, while thus affected, and how vividly the idea may remain after the effects of the remedy have passed off. The case that occurred, not long ago, at Louisville, might have been followed by a vexatious and disgraceful law suit, if it had not fortunately been witnessed by several medical gentlemen. Practitioners should take care of their own character not less than of the lives of their patients.

Inhalation of Ether.—The inhalation of ether is best effected by means of a large hollow sponge held closely over the nose and mouth, although a folded napkin will be found to answer the purpose sufficiently well. No special attention need be paid to the admission of atmospheric air, as this fluid possesses none of the poisonous qualities of chloroform and other kindred articles. Not less than half an ounce should be poured upon the sponge at a time, and the administration should be diligently maintained until a full anæsthetic effect is produced, which usually requires a considerably longer period than in the case of chloroform. At first a short cough is generally provoked, but this soon subsides, and the system gradually lapses into a calm, quiet condition, attended with muscular relaxation, closure of the eyelids, and mental unconsciousness, followed, in many cases, by stertorous respiration.

The quantity of ether consumed in an ordinary operation is seldom less than from four to eight ounces, while in the more protracted cases twice or even thrice that amount may be necessary. Sickness and vomiting are common effects of the use of this agent, and there is also not unfrequently a great deal of headache after the patient has recovered from his unconsciousness, sometimes lasting upwards of twenty-four hours. In administering chloroform the patient always lies down; in etherization, on the contrary, he may sit up, or be recumbent, as may be most convenient to the operator, no injury resulting even from the protracted maintenance of the erect position. The inhalation too may be carried on more rapidly, and, as already stated, without any special reference to the admixture of atmospheric air, a sufficiency always entering through the sponge. Any bad effects that may arise from etherization should be treated upon the same general principles as those produced by an over-dose of chloroform. The cold douche in particular will be of much service in recalling the patient to consciousness. All the different varieties of ether possess anæsthetic properties; but the one universally preferred is the sulphuric, thoroughly washed, and divested of impurities. It is the article which Dr. Morton originally introduced to the notice of the profession under the name of letheon, or pain-destroyer, and which is now so much employed in surgical and midwifery practice in this country.

Some practitioners prefer a mixture of ether and chloroform to either of these articles alone, considering it as equally efficient, and at the same time

more safe. I have myself frequently employed them in this way, and regard the combination as unobjectionable in every respect. The ordinary proportion is three parts of sulphuric ether to one of chloroform; but the quantity of either agent may be increased or diminished, according to the exigencies of the case, or the whim, fancy, or caprice of the surgeon. A mixture, composed of equal parts of chloroform and alcohol, was recommended by Dr. Snow, and is generally regarded as a very safe and efficient anæsthetic. In administering it to very young children, it may be diluted with rectified spirits, although, if proper care be taken, this is not at all essential, either to safety or convenience.

Amylene.—With amylenes, as an anæsthetic agent, I have no experience. The article has seldom been employed either in Europe or in this country, and future observation must determine its merits and the degree of confidence to be reposed in it. It has been condemned by the Academy of Medicine of Paris, as too hazardous for inhalation; and it is well known that two fatal cases occurred from its exhibition in the hands of Dr. Snow, soon after he introduced the remedy to the notice of the profession in 1856, and after he had administered it successfully in one hundred and forty-three cases. He was inclined to believe that it occasioned death by inducing paralysis of the heart. It produces anæsthesia more rapidly and in smaller quantity than chloroform, at the same time that it is less liable to cause vomiting, coughing, struggling, muscular rigidity, or profound coma. The patient generally wakes up from its effects in a few minutes after the discontinuance of its use. Its odor is extremely offensive. The same care should be exercised in its exhibition as in that of chloroform.

Kerosoline.—Within the last few months kerosoline has been presented to the notice of the profession of this country, as a new anæsthetic, by Dr. E. Cutter and Professor H. J. Bigelow, of Massachusetts. Its effects are sudden and powerful, but pleasant, pervading the whole system, and diminishing the force of the pulse and respiration. In a few cases it has caused slight convulsions. It is administered in the same manner and with the same precaution as chloroform, from one to two ounces being required to produce complete insensibility.

Kerosoline is a beautiful, colorless, volatile liquid, of the specific gravity of about .634, highly inflammable, tasteless, and of a faint odor, not unlike that of chloroform, but much more readily dissipated by the air. It seems to be a very pure hydrocarbon, analogous to highly rectified naphtha, and as it does not contain any oxygen, it should be used with great care. Its entire safety as an anæsthetic has not been fully determined.

Local Anæsthesia.—Various plans have been tried for the purpose of inducing local anæsthesia, but the results have not been such as to hold out much encouragement for their practical application. When we consider the absorbent powers of the skin, it might reasonably be supposed that the endermic use of the more potent anodynes, as opium and its different preparations, aconite, belladonna, hyoscyamus, and other kindred articles, might be employed beneficially in this wise, but experience has proved that any effect of this kind that they may possess is exceedingly transient and altogether incapable of serving as a preventive of pain during the application of the knife. The employment of ice, or frigorific mixtures, recommended by Mr. James Arnott, of London, is hardly entitled to more confidence; my experience with it is, it is true, very limited, but I have seen enough of it to satisfy myself that its value has been greatly overrated by its best advocates, and it can never, except, perhaps, in the most trivial cases of injury and disease, be carried to a sufficient extent to prevent pain in surgical operations. I tried it on one occasion upon an old lady during the removal of the mammary gland; and, although the skin and subcutaneous cellular tissue were

partially congealed, the ice in the latter producing a crackling noise, yet she suffered most severely, especially during the dissection of the deeper structures, where the effects of the freezing mixture had evidently not penetrated. No one can deny that, in this case, the remedy had not been carried to a sufficient extent, and yet it certainly exercised but a very feeble influence as an anæsthetic. Besides, the application is not without risk, as the part, if not carefully watched, may be frost-bitten, and thus occasion unpleasant secondary effects.

Mr. Arnott's freezing mixture consists of two parts of ice and one of common salt, the former being previously reduced to a fine powder in a canvas bag, pounded with a flat-iron. The latter should also be pulverized. The two articles are then thoroughly and quickly mixed, either with a knife, or by stirring them together in a gutta-percha or other non-conducting vessel. The mixture is now inclosed in thin gauze netting, and as soon as the action of the salt upon the ice is rendered apparent by the dripping of the brine, it is placed upon the part to be benumbed, which is held in a horizontal position during the application. The netting should occasionally be raised to watch and equalize the effect of the remedy. About a quarter of a pound of ice and half that quantity of salt suffice for an ordinary application.

The first effect of the remedy is to chill the part, but this rapidly disappears, and is succeeded by pallor of the surface and a sense of numbness. Very soon the skin is found to be notably shrunken, and to assume a deadly, tallow-like appearance, at the same time that it is rendered somewhat stiff and perfectly insensible. If the application be continued longer, the subcutaneous cellular and fatty tissues become partially congealed, as is proved by the fact that they feel hard, and crackle slightly under the finger. When the application is properly made, that is, gradually and cautiously, the netting being occasionally raised for the purpose of inspection, it is perfectly harmless and almost unattended with suffering. It is only when it is continued too long that it is likely to be productive of mischief. Ordinarily from fifteen minutes to half an hour will be required to afford the desired anæsthetic effect.

CHAPTER I.

DISEASES AND INJURIES OF THE SKIN AND CELLULO-ADIPOSE TISSUE.

SECT. I.—ERYSIPELAS.

ERYSIPELAS is so frequent and formidable an occurrence that every practitioner should be perfectly familiar with its nature and symptoms. Produced by various causes, both local and constitutional, it may exist as a primary affection, or show itself as a complication of other lesions, modifying their character, interfering with their evolution, and even, at times, entirely supplanting them. Observed from time immemorial, it is distinctly mentioned by Hippocrates, and has been a subject of particular investigation in the present century, as is evinced by the numerous papers and monographs that have been published respecting it during the last fifty years. The names and titles alone of these productions would fill many pages.

Erysipelas was at one time supposed to be peculiar to the skin and cellular tissue, but this is not the fact, modern researches having shown that it is liable to attack various other structures, particularly the mucous and serous. By dermatologists this affection is usually ranked among the exanthematous diseases, on account of the discoloration which forms so striking a feature in its symptomatology. The term by which it is commonly designated is a Greek compound, signifying a tendency to spread.

The disease is generally arranged under different heads, according to the symptoms which attend it, or the parts of the body which it implicates. Thus, there may be erysipelas of the head, face, trunk, genital organs, and extremities. The most common, as well as the most proper, division, however, is into simple, phlegmonous, and œdematous. To this some authors have added a fourth, namely, the gangrenous. To such an arrangement no valid objection can be made, provided it be borne in mind that it is altogether artificial, and that it is intended to denote merely a difference in the degree, but not in the kind, of the morbid action. There is reason to believe that this distinction has not been sufficiently heeded in practice. Erysipelas is said to be idiopathic or traumatic, according as it depends upon some constitutional vice, or upon external injury.

The malady occurs at all periods of life, and in both sexes, but in what ratio has not been ascertained. The idiopathic variety is perhaps most

common in women, the traumatic in men, owing to the greater liability of the latter to all kinds of injury.

There are no facts to show that *temperament* exerts any influence in the production of this disease. Bilious, or bilio-sanguineous, and nervous, irritable persons are said to be most prone to it; but in what proportion, or for what reason, remains to be determined. The malady is more frequent, at least in America, in the latter part of autumn, in winter, and early in the spring than at any other season of the year, not a day of which, however, is anywhere exempt from its invasion in either of its two forms. Locality, doubtless, exerts an important influence in its causation; it is well known that it is particularly liable to occur in the narrow, crowded, and filthy streets of large cities, in the confined and ill-ventilated wards of hospitals, and in marshy, malarious districts. The effect of occupation in producing erysipelas has not been determined; but there is no question that cooks, blacksmiths, foundrymen, and persons habitually exposed to dry heat are particularly obnoxious to its attacks.

No *region* of the body is exempt from this affection, though some are more liable to it than others. The idiopathic form is most frequent in the face, scalp, neck, and trunk, while the traumatic appears to be most common in the extremities, particularly the inferior. It has been observed by most writers that the eyelids, nose, and forehead are especially prone to be attacked; a fact for which it is impossible, in the existing state of the science, to assign any satisfactory reason. Old, decrepit subjects, and persons worn out by intemperance and disease, often suffer from erysipelas of the scrotum, the vulva, feet, and legs. In infants a very common seat of the disease is the lower part of the abdomen, around the umbilicus. Injuries of the scalp, tendons, and aponeuroses frequently give rise to erysipelas, and are liable, in consequence, to be followed, in many cases, by the worst results.

Erysipelas occasionally assumes an *epidemic* type. Hippocrates had already observed this fact. During the middle ages a gangrenous erysipelas repeatedly ravaged France, where, from its excessive violence, the disease was called the plague of fire. In times of war erysipelas has occasionally prevailed as an endemic in camps, barracks, hospitals, and prisons. In modern times it has been observed in both of these forms in various localities. Dr. Gregory expresses the belief that there is not a single hospital in London which has not, occasionally, been visited by the endemic variety of the disease. At St. George's Hospital, in that city, he has repeatedly seen erysipelas so prevalent that all important surgical operations were obliged to be postponed for fear of the supervention of the malady. The inmates of the Hôtel-Dieu, of Paris, are frequently assailed in this way, and the mortality thence arising is said to be quite great. Calmiel states that there are periods when erysipelas prevails so extensively in the lunatic asylums of the French metropolis that the physicians of those institutions are compelled to suspend all treatment by counter-irritants, as blisters, setons, issues, and moxas, because it is almost certain to be followed by an outbreak of this affection. Velpeau describes an epidemic erysipelas which prevailed at La Pitié in 1831. In 1844, '5, and '6, the disease was so common in the Louisville Hospital, and also throughout the city of Louisville, that I was obliged, on numerous occasions, to postpone the performance of all operations in which delay was admissible, for fear of giving rise to it. Such was the tendency, at that period, to its occurrence, that the most trivial incision, the slightest puncture, and the most insignificant scratch were almost sure to be followed by an attack. For a long time we were obliged, in consequence of this proclivity, to refrain from the application of blisters and leeches, venesection, the introduction of setons, and the establishment of issues. Chancres, buboes, and common ulcers were often invaded in the same manner. But the epi-

demic was not confined to that city; it prevailed more or less extensively in different sections of the Union, and carried off an immense number of all classes of people. In many localities there was a marked connection between the affection and puerperal peritonitis, the latter of which proved very fatal.

The question as to the *contagiousness* of this disease is not fully settled. Much may be said both against and in favor of such a view. My own opinion, founded upon considerable experience, is that the affection, at times, possesses such a character. It is very well known that it is inoculable. Thus, a sponge impregnated with the matter of an erysipelatous sore will very readily communicate the disease to an ulcer or an abraded surface in a sound person, and the same thing is true of poultices, salves, and other dressings. Facts which show that the nurses and friends of individuals affected with erysipelas often contract the disease are of frequent occurrence. In this way whole families are sometimes cut down. A gentleman in Davies County, Kentucky, in 1852, lost his only son by this disease. A cousin and a female acquaintance who attended on him soon became ill with it, and both died; it then spread to other members of the family, producing serious ravages before it was finally arrested. In 1846, when erysipelas reigned as an epidemic at Louisville, a man was received into the Louisville Hospital with an ulcerated bubo, and about the same time a woman, who had been his mistress, was also admitted with the prevailing distemper. In consequence of an inability to obtain a female nurse, the man was permitted to attend upon her in that capacity. He soon cohabited with her; in a few days he became excessively ill, the sore in the groin assumed an erysipelatous aspect, and in less than a week from the time of his admission he died from the effects of the malady. In the wards of hospitals erysipelas often spreads from one person to another, and in private practice the disease, there is reason to believe, is occasionally carried by the physician from one house to another. In this way it is no doubt sometimes communicated by the accoucheur to parturient females.

Causes.—The causes of erysipelas are too numerous and diversified to admit of any very definite specification. As a general rule, it may be assumed that whatever has a tendency to disorder the digestive, hepatic, or, in short, any other important function, is capable of producing the disease. So true is this that there is seldom, if ever, a case of the complaint in which such derangement does not play a more or less conspicuous part. The fact is important, as leading to valuable therapeutic considerations. Certain articles of diet either predispose to or induce the malady. Thus, there are some persons who can never eat shell-fish or particular kinds of fruits, as strawberries, nuts, and similar substances, without suffering an attack. The retention of vitiated secretions and undigested food in the alimentary canal often leads to similar results. Derangement of the uterine function, suppression of the cutaneous perspiration, great mental excitement, the habitual use of ardent spirits, loss of sleep, hard study, inordinate sexual indulgence, and whatever else has a tendency to weaken the corporeal faculties, may be enumerated as so many causes of the disease. A vitiated state of the atmosphere, as is witnessed in hospitals and other charities, often powerfully predisposes to its attacks and its continuance.

Erysipelas frequently supervenes upon wounds, both accidental and artificial, interfering with the healing process, and, at times, seriously compromising both part and system. The period at which this occurs varies from twenty-four hours to several days, according to the nature and extent of the lesion, the presence or absence of complications, the habits of the patient, the condition of the system, and the state of the atmosphere. Lacerated, punctured, gunshot, and poisoned wounds are much more liable to be assailed in this manner than incised wounds, though the latter are by no means exempt from

it, especially if they involve the scalp, hands, or feet, or if they affect old, intemperate, or debilitated individuals.

When the disease is epidemic, it often shows itself within a very short time after the reception of an injury, however slight or insignificant. Under such circumstances, indeed, I have, as already stated, known it to follow upon the most trifling wound, scratch, or puncture, as a leech-bite, venesection, vaccination, or the application of a blister. Fractures, dislocations, sprains, contusions, and various other injuries not unfrequently give rise to it. Ulcers, whether common or specific, are often invaded by it, especially when the patients are of a broken-down constitution. Lying-in females are, in certain conditions of the atmosphere, particularly prone to suffer from erysipelas of the uterus and pelvic veins.

Finally, erysipelas frequently ingrafts itself upon other diseases. During the winter of 1857, when the malady was endemic in this city, a number of instances occurred where it supervened upon measles, scarlatina, and typhoid fever. During an outbreak of epidemic erysipelas in Louisville, in 1844, '5, and '6, every case of disease that was admitted into the public hospital of that city received its peculiar impress, and wore, for a time, its peculiar livery. When the affection was raging at its fullest height in the institution, many of the patients who were convalescing from other maladies were suddenly seized with diarrhœa, pneumonia, and bronchitis, over which the usual remedies exercised no control, and which generally proved fatal in a few days.

When erysipelas supervenes upon wounds, its approach is usually denoted by an arrest of the adhesive process, by a tensive, burning sensation in the affected part, by a discharge of thin, sanious matter, or an entire suspension of secretion, and by an œdematous appearance of the surrounding structures. Finally, the characteristic blush occurs, and gradually diffusing itself often spreads over a considerable extent of surface.

When erysipelas seizes upon ulcers, as it may do at any time, whether they be benign or malignant, simple or specific, the local symptoms closely resemble those which characterize the complaint when it follows upon wounds and contusions. The granulations, if any exist, assume a pale, glossy, unhealthy aspect, the pus is replaced by a thin, ichorous fluid, the part is rendered uncommonly painful, and the edges of the sore, along with the adjacent surface, exhibit a reddish, œdematous appearance. In chancres and dissection wounds the presence of the malady is indicated by reddish, tender lines, formed by superficial lymphatic vessels, generally extending as high up as the neighboring ganglions, which, in turn, become swollen and exquisitely painful. The morbid action may, in both cases, be simple or phlegmonous, and is almost always dependent upon derangement of the digestive organs, or the suppression of some habitual discharge.

Erysipelas, consequent upon fractures and dislocations, generally displays itself within the first forty-eight hours after the reception of the injury, and often spreads very rapidly over a large extent of surface, as the greater portion of a limb, one side of the trunk, or the whole scalp and face. The accident is particularly liable to supervene upon the compound forms of these lesions, and is always to be viewed with distrust, as it not unfrequently compromises the patient's recovery. Erysipelas of the scalp, caused by wounds or fracture of the skull, generally appears from the second to the third day, and often proves dangerous by its extension to the brain and its envelops, through the intervascular communications between the pericranium and the dura mater. Such cases always demand the greatest vigilance on the part of the practitioner.

Varieties.—Erysipelas occurs under several varieties of form, as the simple, phlegmonous, and œdematous, each of which merits brief attention. To this

division may be added erratic erysipelas, so called from its disposition to wander from one part to another.

The term *simple* is employed to designate that form of the disease which is confined exclusively to the skin. It manifests itself in a bright, vivid, almost scarlet discoloration of the skin, a pungent, smarting, or burning pain, and a sense of stiffness, with, perhaps, here and there a little vesicle, not larger than the head of a pin, and filled with a serous fluid. The swelling is very slight, and, unless the extent of disease is considerable, there is no particular constitutional disturbance. The attack is usually of short duration, and the subsidence of the local disease is always followed by a furfuraeous desquamation of the epidermis.

Phlegmonous erysipelas is a much more serious lesion than the simple, all the symptoms existing in a higher degree, and the disease often terminating in extensive suppuration, abscess, and even gangrene. The discoloration varies from scarlet to deep purple; there is extensive swelling; vesication soon arises; and the pain is of a violent, burning, tensive, and throbbing character, the part feeling heavy, stiff, numb, and as if it were on fire. The inflammation extends deeply into the different tissues, affecting skin, cellular substance, muscle, and, in short, everything that comes in its way. As it progresses, suppuration takes place, leading to the formation of extensive abscesses, and the destruction of large portions of the cellular and adipose tissues. If the morbid action be very intense, mortification will be apt to arise, its approach being indicated by the development of large blebs, filled with bloody or muddy serum, and by a dark, livid, brownish, or ash-colored appearance of the skin. The constitution sympathizes early and deeply, the symptoms being at first of a sthenic character, but soon becoming typhoid.

The *œdematous* variety depends entirely upon accidental circumstances, its name being derived from the circumstance of the parts being infiltrated with serosity, and, consequently, pitting under pressure. It is most commonly met with in the eyelids, scrotum, prepuce, vulva, and inferior extremities, in persons who are debilitated by previous disease, or who naturally possess a feeble constitution. The swelling is often considerable, but the discoloration and pain are comparatively trivial. The diseased surface has a glossy, distended appearance, and retains the mark of the finger for some time after it has been withdrawn. The inflammation is attended by constitutional disorder, generally of a typhoid character, and is apt to terminate in mortification rather than in abscess, though the latter is often present in the more severe cases.

Erratic erysipelas is characterized, as the name imports, by a disposition to extend from one point to another; it is most commonly met with on the face and forehead, from which it frequently spreads, on the one hand, to the hairy scalp, and, on the other, to the neck and ears. I recollect a case of this form of erysipelas, which, commencing on the left nates, finally extended over the whole trunk. The disease is generally superficial, and is characterized by an erythematous appearance of the surface, with pungent pain but little swelling.

If a *dissection* be made of a limb in a state of erysipelas, it will exhibit various appearances, according to the amount of the diseased action. In the milder grades, there will merely be some degree of induration of the skin, unusual distension of the vessels, and slight effusion of serum, or of serum and lymph, in the subjacent cellular substance. In the phlegmonous variety, there is generally extensive infiltration of the ordinary inflammatory products; the lymph has a spoiled and unnatural appearance, looking like lard or a mixture of flour and water; abscesses exist in various situations; the cellular tissue is converted into grayish, or ash-colored sloughs; and the muscles are

extensively separated from each other. In a case which occurred in the Louisville Hospital in 1846, during the prevalence of epidemic erysipelas, the abscess reached from the hip to the ankle, extensively detaching the muscles from each other and from the bones, which might have been lifted almost bodily from the diseased mass, so completely were they severed from their connections. Pure blood is sometimes extravasated in considerable quantity; and the matter, which varies much in its color and consistence, is often excessively offensive. Metastatic abscesses are occasionally found in the internal viscera, and effusions in the serous cavities.

An epidemic erysipelas, of a very singular character, prevailed in various sections of this country, from 1842 to 1847, its first appearance having been noticed in Vermont and New Hampshire. It had previously shown itself in Canada, and soon after it broke out in the southwestern States, where, as well as in other parts, it proved exceedingly fatal. In Louisville, where I then resided, it prevailed for several years, and afforded me an excellent opportunity of studying its character. It usually began in the throat and fauces, or simultaneously in these parts and upon the cranio-facial region, in the form of a deep red, glossy, œdematous swelling, which gradually extended until it involved the whole of the neighboring structures, the countenance being generally distorted in the most hideous manner, so that the patient could hardly be recognized even by his most intimate acquaintances. The tongue, uvula, and tonsils were enormously swollen, deglutition and breathing were extremely difficult, and death was often produced by suffocation. Delirium and excessive prostration were early and prominent symptoms, and many of the cases perished within the first five days. The disease remained generally confined to the parts originally affected. If the patient survived any time, profuse suppuration, and sometimes even extensive sloughing, occurred; abscesses formed in various regions of the body; and, after much suffering, the patient either recovered, or died from exhaustion. In some of the persons whom I attended there was extensive ulceration of the tonsils and arches of the palate; and, in several, complete destruction of the parotid gland of one side. In one case, almost the whole of the occipital bone was stripped of its pericranium. Dissection disclosed deep engorgement of the lungs, accompanied, in many cases, by inflammation of the bronchial tubes, and even of the pulmonary parenchyma, and by effusion of serum, or of serum and pus, in the pleura and arachnoid sac. The abdominal and pelvic viscera were generally sound, except in lying-in females, who usually exhibited high evidence of peritonitis, metritis, and phlebitis. In one instance, which occurred quite early in the epidemic, the immediate cause of death was a large metastatic abscess in the left lung, the erysipelas being seated in the corresponding leg.

The disease which I have thus briefly described was generally known in the west under the name of "black-tongue," "swelled head," or "erysipelatos fever." It seldom attacked any one under fifteen years, but from that period up it was indiscriminate in its selection of subjects. Females seemed to suffer quite as frequently as men. The poor and the intemperate were its most common victims.

Constitutional Symptoms.—Whatever form it may assume, erysipelas is usually preceded by symptoms denotive of general indisposition, such as a feeling of *malaise*, or discomfort, creeping, chilly sensations, lassitude, pain in the head and limbs, impaired appetite, and an indisposition to exertion. After continuing in this state for a period varying from twenty-four to thirty-six hours, the disease declares itself in a more open manner. The patient is now suddenly seized with shivering, or violent rigors, followed by, or alternating with, excessive heat, and accompanied by severe cephalalgia, nausea, intense thirst, restlessness, and a great sense of muscular prostration. The

tongue is dry and coated, the skin hot, the pulse strong and frequent, the urine high-colored and scanty. As the disease progresses, the system becomes more and more exhausted, the mind wanders, and the case soon assumes a typhoid character. Or, typhoid symptoms may be present almost from the very commencement, especially if the patient be old, or depressed by previous suffering. In the milder forms of erysipelas, there is often very little, if any, constitutional disturbance.

If blood be drawn during the progress of the disease, it will generally be found to exhibit a sizzly appearance. Sometimes it is deeply buffed and even capped. What internal, or intrinsic changes, the mass of blood undergoes in this affection has not been satisfactorily determined.

Diagnosis.—Erysipelas is generally so well marked as to render it impossible to confound it with any other disease. The only form which is liable to cause error of diagnosis is the simple, which may be mistaken for erythema, which it certainly very much resembles. The signs of discrimination are, the peculiar character of the pain, which is sharp, pungent, and smarting in erysipelas, and almost absent in erythema; the deeper redness in the former than in the latter, and the tendency also to the evolution of vesicles, which does not exist in erythema.

Pathology.—The pathology of erysipelas has been a fruitful subject of discussion almost from time immemorial, and yet, notwithstanding all that has been said and written about it, it is still involved in impenetrable obscurity. How it is induced, what is its seat, or where it originates, are points concerning which we are wholly ignorant. We only know that it has a peculiar predilection for the dermoid and cellular tissues, and that it is usually, if not invariably, connected with disorder of the general system, affecting, probably, both solids and fluids. So thoroughly am I convinced of the latter fact, that I do not believe it would be possible for erysipelas ever to appear in a perfectly sound individual. If this be true, as I think multiplied and carefully conducted observation authorizes me to affirm, then derangement of the general health, especially as displayed in a vitiated condition of the digestive organs, must be regarded as a most important element in the pathology of this affection, and one which must exert a marked influence upon our curative agents. The opportunities constantly afforded the surgeon, in cases of accidents and operations, of testing this point, peculiarly qualify him for pronouncing upon the question. I am not now, of course, speaking of epidemic erysipelas, to which every one is more or less liable, but of the ordinary form, the development of which, as is well known, is so much influenced by intrinsic and extraneous circumstances, as the health and habits of the patient, his residence, the nature of his diet, and the state of his mind. When a person is intemperate, breathes a foul air, eats bad food, or has a troubled mind, the most trivial injury, as the merest prick of the finger, is often followed by a fatal attack of the disease, whereas another, although severely hurt but enjoying better health, will, perhaps, escape entirely, or suffer only in a slight degree. The surgeon, aware of this circumstance, constantly acts upon it in practice, making it a rule never to perform any serious operation until he has put his patient in a proper condition for it by the rectification of his secretions and the improvement of his general health.

Erysipelas has sometimes been regarded as consisting essentially in a bad form of capillary phlebitis, it being alleged that the smaller veins are generally found to be involved in the disease, as is shown by the inflamed condition of their coats, and the existence, in their interior, of various kinds of substances, as lymph, pus, and coagulated blood. Such changes undoubtedly occur, to a greater or less extent, in all severe cases of the malady; but they occur, not as a cause, but as a consequence of the morbid action. Other

pathologists, again, consider erysipelas as being essentially an affection of the lymphatics; and, lastly, there is another class who look upon it as originating in both these vessels. All these views, however, amount to nothing but conjecture, their truth or falsity remaining to be established.

Prognosis.—The prognosis in erysipelas is influenced by the character, extent, and seat of the morbid action, by the age and habits of the patient, and by the absence or presence of complications. Phlegmonous erysipelas, other things being equal, is generally more dangerous than the simple or œdematous, as it is more liable to end in extensive suppuration, gangrene, and metastatic abscesses. A simple erysipelas, however, if of great extent, is hardly less dangerous to life than a phlegmonous one, the shock to the nervous system being nearly as severe as in a superficial but extensive burn, which often kills on this account. When the disease attacks the head it is always more to be dreaded than when it makes its appearance upon other parts of the surface. Infants, young children, and old persons bear the disease badly; as do also the habitually intemperate. Erysipelas is particularly dangerous when it occurs during the progress of other maladies, as measles, scarlatina, and typhoid fever. Epidemic erysipelas is always a more destructive disease than a sporadic one, the malady, under such circumstances, impressing itself with peculiar force upon the constitution. Traumatic erysipelas often kills in a surprisingly short time. In the summer of 1856, I attended a young butcher, who died in less than three days from a violent attack of this disease of the hand and arm, brought on by a punctured wound inflicted by a hook used for hanging meat upon in the market-house.

TREATMENT.

Erysipelas being capable of being developed by such a variety of circumstances necessarily demands a corresponding variety of treatment. Experience long ago showed that remedies which afford relief in one case are productive of no benefit in another, and hence it is all important, in every instance, that our curative measures should be based, if possible, upon a correct appreciation of the nature of the exciting causes. If the practitioner should attempt to combat it upon any other principle, he will find himself sadly mistaken.

The treatment of this disease may conveniently be divided into constitutional and local, and it is hardly necessary to add that each head embraces a great variety of means, which it will be necessary to pass briefly in review. The constitutional remedies upon which our reliance is mainly to be placed are, bloodletting, emetics, purgatives, diaphoretics, mercurials, and anodynes.

Bloodletting is not applicable in all cases of erysipelas; on the contrary, there are some in which it inevitably proves mischievous, if not fatal, by augmenting the debility of the system, already, perhaps, greatly depressed by the violence of the morbid action. The circumstances which, in my judgment, render a resort to the lancet proper in this complaint are, first, a strong, full, and frequent pulse; secondly, a robust and vigorous state of the system; thirdly, excessive pain and tension of the parts; and, lastly, the involvement, threatened or actual, of important internal organs, as the brain, lungs, and throat. The amount of blood to be abstracted must depend upon the effects which the operation exerts upon the system. One moderately copious bleeding, performed early in the disease, will usually be sufficient, and will answer a much better purpose than two or three small ones. It should be borne in mind that venesection should never be carried as far in epidemic as in sporadic erysipelas, and in old, sickly, or intemperate persons, as in the young, robust, and plethoric. In the epidemic erysipelas which prevailed so extensively a few years ago in various sections of the United States, the abstraction of

blood was generally borne very badly, and many lives were lost by its injudicious employment. In the Louisville Hospital not a single patient recovered that was bled for this disease. In erysipelas supervening upon capital operations and severe accidents, as compound fractures and dislocations, wounds, and contusions, proper allowance must be made by the practitioner for the effects of shock and loss of blood, and the resulting suppurative discharges. Children affected with erysipelas rarely, if ever, require bleeding in any form.

Great contrariety of opinion has prevailed among writers respecting the employment of *emetics* in this disorder, some having pointedly condemned them, while others have expressed themselves most warmly in their favor. In the hands of Desault and his disciples the greatest benefit seems to have attended their exhibition. The probability is that here, as elsewhere, in similar cases, the truth lies between the two extremes; for it can hardly be supposed that a class of remedies of such acknowledged potency in many cutaneous affections should be altogether useless in erysipelas. The cases in which, according to my observation, emetics are mainly indicated are those in which there is marked biliary derangement, along with nausea, loathing of food, headache, pain in the back and limbs, great restlessness, and dryness of the surface. These symptoms, so distressing to the poor sufferer, are often promptly relieved by full emesis, excited by ipecacuanha and tartrate of antimony and potassa, ipecacuanha alone, or salt and mustard, and encouraged by the free use of tepid drinks. In protracted cases, and in the erratic form of the malady, attended with derangement of the digestive organs, gentle emetics often operate like a charm in breaking up the chain of morbid action.

When it is remembered that this disease is often directly dependent upon an overloaded state of the bowels, the presence of irritating ingesta, and the suppression of the secretions of the digestive organs, it is not difficult to discover a reason for the high estimate which has always been placed upon the administration of *purgatives*. Indeed, it would be hard to find a case in which it would be altogether improper to dispense with them. In my own practice I have always derived from them the most signal benefit, especially in the earlier stages of the complaint, although there is no period in which they can perhaps be entirely omitted with safety. The articles upon which I mainly rely are calomel, rhubarb, and compound extract of colocynth, variously combined, and given in sufficient quantity to produce two or three free and consistent motions. Sometimes the addition of a little tartar emetic or ipecacuanha proves beneficial, especially when there is an arid state of the skin and mouth; while occasionally they may be advantageously replaced by others, as castor oil and spirits of turpentine, oil alone, senna, or Epsom salts. When there are nausea and headache, with a highly coated tongue, the best cathartic, in general, is calomel and ipecacuanha, in the proportion of about fifteen grains of the former to two grains of the latter, followed, if necessary, in six or eight hours, by a stimulating enema, or a dose of sulphate of magnesia. When the bowels have been once thoroughly evacuated, a moderate passage should daily be induced by some mild laxative, as blue mass and rhubarb, Seidlitz powder, or colocynth and hyoscyamus.

Diaphoretics constitute a valuable class of remedial agents in the treatment of this affection, and can seldom be entirely dispensed with, as there are few cases in which the cutaneous function is not more or less interrupted, perverted, or suspended. After proper depletion by the lancet and purgatives, or, at all events, thorough evacuation of the bowels, and the restoration of the secretions of the digestive organs, the administration of medicines calculated to act upon the skin often proves eminently serviceable. Among the best of this group of articles are Dover's powder and the salts of antimony and morphia, aided by tepid sponging, or, when the patient's strength

admits of it, the warm bath. In children and debilitated persons, the spirit of Mindererus and wine of ipecacuanha may be advantageously resorted to. Aconite, in doses of three drops of the tincture, every two, three, or four hours, generally answers an excellent purpose, especially when there is a hot and arid condition of the surface, and inordinate excitement of the heart. The same is true of veratrum.

There are few cases of erysipelas, even of the milder grades, in which the use of *anodynes* is not indicated, either for the purpose of allaying pain, or of inducing sleep. When the malady occupies, as it not unfrequently does, an unusual extent of surface, the system is very apt to suffer in the same manner as in severe burns and scalds, and requires, at a very early stage of the complaint, the employment of soothing measures. The remedy, which is commonly one of the salts of morphia, is administered upon the same principles as in other inflammatory affections, either by itself, or in union with other articles, especially diaphoretics, in quantities proportioned to the exigencies of each particular case. As a general rule, the object is best attained by a full dose, repeated once or twice in the twenty-four hours. To an adult, laboring under great pain and restlessness, provided there is no cephalic trouble, not less than half a grain of morphia should be given at a time. Thus administered, the effects of the remedy are much more decided and beneficial than when it is exhibited in smaller doses, as is too often the case with practitioners, not only in this, but in other inflammatory maladies. Delirium, or cerebral disorder, does not necessarily contra-indicate the use of anodynes; on the contrary, persons so affected are often immensely benefited in a short time by their judicious exhibition. To no class of patients is this remark more applicable than to habitual inebriates, and individuals worn out by previous disease, loss of blood, protracted drainage of the system, or constitutional irritation. Such persons absolutely require, at an early period, and in every stage of the malady, the use of anodynes in large doses, in order to prevent exhaustion, and afford time and opportunity for the more efficient action of other remedies.

Mercurials are sometimes usefully exhibited in this disease. They are particularly valuable in the erratic form of erysipelas, and when there is a tendency in the malady to linger in the system, after its principal force has been exploded, but when it is still disposed, as it were, to dispute with the practitioner every inch of its possessions. In such cases, they occasionally act like a charm, even when they are not carried to the extent of ptyalism, which, however, is often necessary, before the disorder will relinquish its grasp. During the epidemic erysipelas which prevailed in Louisville and its vicinity in 1844, '5 and '6, I treated quite a number of cases upon this plan, with the most happy results, although now and then a patient was lost, even after the establishment of slight salivation. Mercurials should be most scrupulously avoided in erysipelas attended with a low, typhoid state of the system in old, worn-out subjects, and in persons exhausted by intemperance and dissipation. The best form of exhibition, when the remedy is indicated, is calomel with a small quantity of opium and ipecacuanha, or Dover's powder, to restrain its action on the bowels and allay nervous irritation. In urgent cases two grains of the metal may be given to an adult every four or six hours, combined with half a grain of the anodyne. When a less rapid impression is desired, blue mass, iodide of mercury, or the gray powder may be used. In whatever form or manner the remedy be given, its effects should be most carefully watched, and they should never be carried beyond the limits of the slightest possible ptyalism.

The late Professor John K. Mitchell informed me that he had, for years past, derived more benefit, in this disease, from the use of *iodide of potassium* than from any other remedy. His plan was, after gentle alvine evacua-

tion, to begin at once with the article, giving it, largely diluted with water, every two or three hours, in doses of from five to ten grains, until the attack was arrested, which, it would seem, usually happened in a few days. In the few trials which I have made of this remedy, I have witnessed no material benefit, and in several cases I was obliged to suspend it at an early period, on account of its disagreeing with the stomach.

Stimulants and tonics are required when there is, as occasionally happens even in the early stage of the disease, a tendency to excessive prostration. A hard, dry, and brownish tongue, sordes on the teeth, a small, feeble, and frequent pulse, twitching of the muscles, coolness of the surface, and copious sweats, with or without delirium, clearly indicate the necessity of the employment of this class of remedies, which are sometimes alone capable of arresting the disease and of establishing convalescence. The articles ordinarily resorted to for this purpose are ammonia, wine, brandy, porter, or ale, along with quinine, or some of the mineral acids, and nourishing broths. Of all these substances, the best by far is brandy, in the form of milk punch, julep, or toddy. Quinine may also generally be used with great benefit, and there is no internal remedy which I so frequently employ in the latter stages of erysipelas, or in cases demanding a decided tonic. The proper dose is from three to five grains every four, six, or eight hours.

Lately, the tincture of the *chloride of iron* has been much employed by practitioners of this city, and apparently with very gratifying results, in doses varying from fifteen to thirty drops, from three to six times in the twenty-four hours. It is particularly serviceable where a tonic effect is indicated, and is, therefore, best adapted to feeble, delicate subjects, laboring under a deficiency of hematin, or the coloring matter of the blood. Like iodide of potassium, however, and some other articles, it is apt to disagree with the stomach, and should, therefore, be given with some degree of caution, the best plan being to suspend it in some pretty thick demulcent fluid.

Throughout the whole treatment, the greatest attention should be paid to the ventilation and temperature of the patient's apartment; the body and bedclothes should be daily changed, and the cutaneous surface should be frequently sponged with tepid salt water, or some slightly alkaline solution. As disinfectants, free use is made of the chlorides. As soon as his strength admits of it, the patient should take gentle exercise in the open air, and, if possible, sleep in another apartment.

All *topical* remedies in the treatment of this disease are to be regarded rather as auxiliary than as curative agents. Looking upon the cutaneous eruption merely as a local manifestation of a constitutional disorder, the philosophical practitioner will place his reliance mainly upon internal means, and consider all external ones as of secondary moment. Nevertheless, it would be wrong, even in many of the milder cases, wholly to neglect these, since experience has abundantly attested their utility. A vast variety of applications, many of them of the most opposite character, have been recommended with this object, as warm and cold, dry and moist, astringent and relaxing, stimulating, vesicant, and anodyne. It would seem, indeed, as if almost every article of the materia medica had been called into requisition, as if to show what little confidence, as a general rule, is to be placed in their efficacy.

At the head of the list of local remedies may be placed *leeching*, concerning the efficacy of which, however, practitioners are still divided in opinion. My own belief is that it may often be employed with great advantage, though, in general, it is, I think, entirely unnecessary. The fact that the operation is occasionally followed by erysipelas does not, in my judgment, prove that it may not at times be beneficial. It is only in rare cases, and under peculiar circumstances, as when the patient is of a very irritable habit, or the leeches

are sickly, that such a result is at all likely to occur. Against such a contingency the judicious practitioner will, of course, always guard. The use of the remedy is particularly indicated in erysipelas of the throat and larynx, the scalp, eyelids, vulva, toes, and fingers. The number of leeches must vary according to circumstances, as the intensity of the morbid action and the vigor of the patient; and the flow of blood should always be encouraged by warm fomentations until the desired quantity is obtained.

One of the great topical remedies at the present day for the cure of erysipelas is *iodine*, either in the form of tincture or solution. I generally give the preference to the former, diluted with an equal quantity of alcohol, and laid on by means of a large camel-hair pencil, the end of a stiff feather, or a soft cloth mop, until the surface is of a yellowish, brownish, or mahogany color. The application should embrace a small portion of the sound skin, and should be repeated at least twice, if not thrice, in the twenty-four hours. In the milder grades of erysipelas a single application will occasionally suffice for a cure; while in the more aggravated a considerable number may be required before the disease is finally discussed. The remedy is sometimes productive of severe pain, especially in nervous, irritable, and thin-skinned persons, which may persist for several hours, and which hardly anything, save time, will allay. To obviate this occurrence, the first application should always be very light; if no inconvenience arise, the medicine may afterwards be used more freely, and may even, in some instances, be advantageously carried to the extent of vesication. If, notwithstanding this precaution, the pain be very severe, the part should be freely sponged with a weak solution of iodide of potassium, and covered with a starch poultice.

I have employed the tincture of iodine in the form and manner here indicated for many years, both in the sporadic and the epidemic varieties of the disorder, and can confidently assert that I have derived more benefit from it than from any other article of which I have any knowledge. Resorted to in the early stage of the disease, it rarely fails promptly to relieve the pain and tension, which form such prominent features in the symptomatology of the affection, and which add so greatly to the patient's suffering. The beneficial effects of the remedy appear to be due to its stimulant and sorbefacient properties, which rapidly promote the removal of effused fluids, and assist in checking morbid action. When applied very freely it occasionally vesicates, and is thus instrumental in unloading the cutaneous capillaries. Doubtless, it also acts advantageously upon the blood and its vessels, indisposing them to further effusion.

Another highly valuable agent for the cure of this disease is the *nitrate of silver*, employed either in substance, or in strong solution. It is applied either directly to the affected surface, or a belt is drawn around it upon the healthy skin, to prevent its further spread, which constitutes such a distinguishing trait in its symptomatology. I commonly prefer the former method, using the solid nitrate instead of the solution, so strongly recommended by Mr. Higginbottom. In order to apply this substance properly, it is necessary, as a preliminary step, that the surface should be divested of all greasy and perspirable matter, otherwise it will refuse to unite with the epidermis, and so prove, in great measure, inert. The part should then be gently moistened with cistern water, when the caustic is passed firmly and efficiently over it until the whole has been thoroughly touched. Thus employed, the application speedily blackens the epidermis and coagulates its albuminous matter, thereby forming an excellent defence to the delicate tissues beneath. When used more freely it generally vesicates, elevating the scarf-skin into tolerably large blisters. Mr. Higginbottom applies a strong solution of the nitrate of silver, consisting of three drachms of the salt to the ounce of water, with the addition of a small quantity of nitric acid. I have no ex-

perience with the remedy in this form. The probability is that nitrate of silver produces its beneficial effects very much in the same manner as the tincture of iodine, changing the tone of the capillary vessels and promoting the absorption of effused fluids, besides serving as a direct defence to the cutaneous surface by its union with the albuminous matter of the superficial layer of the skin.

Professor Gilbert, of this city, has been in the habit of using, for a long time past, pure *creasote* as a remedy in erysipelas. He applies it lightly, once a day, to the affected surface with a camel-hair pencil, and has found it more effectual in arresting the disease than any other article he has ever tried. It destroys the cuticle, converting it into a whitish substance, which thus defends the inflamed surface from the contact of the air.

Solutions of acetate of *lead* and opium, Goulard's extract, alcohol, chloride of sodium, carbonate of potassa, sulphate of copper, and quinine, often prove beneficial in this disease. They are employed of varying strength, and are generally most grateful when used tepid, upon flannel cloths, frequently renewed. In warm weather, and in strong, plethoric subjects, they may be applied cold, but when this is done their effects should be sedulously watched, lest they repel the disease, or force it upon some internal organ.

Dr. Pitcher, of Detroit, strongly recommends, as an external application, the bichloride of *mercury*, in the proportion of twenty grains of the salt to the ounce of alcohol. During the prevalence of the epidemic already so frequently alluded to, I had occasion to try this treatment in quite a number of instances, and came to the conclusion that it possessed no advantage whatever over iodine and nitrate of silver. In nearly all the cases, upwards of twenty, the application was promptly followed by vesication and excessive pain, and, in a few, by pretty profuse *ptyalism*; effects which greatly aggravated the local and constitutional suffering, and rendered a speedy discontinuance of the remedy necessary. I have since tried the medicine in weaker solution, but without any encouraging results.

Velpeau has great confidence in the use of sulphate of *iron* as a local remedy in erysipelas. The praises, however, which he has lavished upon it have not been realized by practitioners generally, and the probability, therefore, is that they are undeserved. In the trials which I have made with it, I have been sadly disappointed. It may be employed in solution, in the proportion of half an ounce to two-thirds of a quart of water; or as an ointment, prepared by mixing one drachm of the impalpable powder with an ounce of lard. The former is applied by means of compresses, frequently moistened; while the latter is rubbed on freely several times in the twenty-four hours.

Professor Holston, of Washington City, has recently strongly recommended the local use of *chloroform* in the treatment of erysipelas, washed over the affected surface for a few minutes with a large camel-hair brush, the parts being immediately afterwards covered with wadding, and the application repeated, if necessary, at intervals of from three to four hours. Prompt relief, it is asserted, usually follows, the disease, even if extensive, often yielding in a very short time.

In the milder varieties of erysipelas I have occasionally witnessed excellent results from a *liniment* of equal parts of laudanum, ammonia, and olive oil, applied with a soft, thin compress. When the skin is very delicate, the proportion of ammonia may be diminished. The common soap liniment, with the addition of a small quantity of tincture of iodine, is also a valuable remedy in simple erysipelas.

Various *greasy substances*, cerates, and unguents have been recommended by practitioners, and employed by the vulgar, in the treatment of this affection; but there are few surgeons who place much reliance in any of them.

Perhaps the best is the mercurial ointment, first advised in this complaint by Dean and Little, of Pennsylvania. A thick layer of this is spread upon cloth, and secured to the part by means of a bandage; or, what is preferable, rubbed gently but efficiently upon the surface. The article has been highly lauded by Rayer and others, but my own experience has not supplied me with any facts in its favor. The opinion at the present time appears to be that the mercurial ointment of the shops does not possess any particular advantage over common lard, or simple cerate, and, from all that I can learn, the remedy would seem to have become nearly obsolete. I should certainly place no special confidence in it in the more severe forms of the malady, while in the more simple I should not deem it necessary to resort to it. In infantile erysipelas, I have sometimes derived good effects from the application of calamine cerate, diluted with two parts of lard. Professor Gibson has sometimes used, with marked benefit, the preparation known under the name of British oil; and Dr. Coates, of this city, has successfully employed tar ointment.

Dusting the affected surface with starch, flour, arrowroot, prepared chalk, carbonate of zinc, pearl powder, and similar substances, is a popular remedy, which is sometimes useful in the more simple varieties of erysipelas, but entirely unavailing when the disease is deep-seated, or of a phlegmonous character. In the former, they sometimes prove beneficial by relieving the disagreeable itching, smarting, or burning sensation of the skin. In superficial erysipelas, I have occasionally obtained advantage from painting the inflamed surface with collodion; the application appears to impart a healthful stimulus to the cutaneous capillaries, to incite the absorbents, and to contract the skin and subjacent cellular tissue.

The treatment of erysipelas by *blisters*, formerly so much in vogue in this country, has of late fallen into undeserved neglect. In my own practice I have frequently resorted to it, and in hardly any case has it disappointed my expectations. The remedy is peculiarly valuable in the phlegmonous form of sporadic erysipelas, and in erysipelas supervening upon wounds, ulcers, chancres, buboes, and abrasions. My practice is to apply the blister directly to the inflamed surface, with a small margin for the sound skin, and to retain it until it has produced thorough vesication. The serum is then discharged with a needle, and the part dressed with a light starch, elm, or some other emollient poultice. In children, and old or sickly persons, the blister must be removed at an earlier period, otherwise serious mischief may ensue from its overaction.

Much has been said, of late years, respecting the importance of *punctures* and *incisions* as means of relief in this complaint. Of the propriety of this mode of treatment, no one acquainted with its character can entertain the slightest doubt in any case, accompanied by suppuration, great tension, and impending gangrene. Under such circumstances, indeed, all other means must be regarded as of secondary moment; the knife alone is to be trusted, and the sooner it is resorted to the better. A few incisions, or a number of large punctures, will obviate an immense amount of mischief, by affording vent to effused fluids, as serum, lymph, pus, and even blood, relieving capillary strangulation, and removing pain and tension. The period for putting this practice in force is the moment there is the slightest perceptible fluctuation, and, in violent cases, even as soon as pain and throbbing show themselves. By thus anticipating the suppurative process, the patient escapes much suffering, as well as loss of texture; for, if the matter be retained in the parts, its inevitable tendency is to burrow among the surrounding structures, and, by being absorbed into the system, to contaminate the constitution. From neglect of this practice, many patients perish that might otherwise be saved, and many limbs are lost, or rendered useless for life.

In practising incisions for the relief of erysipelas, it is not necessary that they should be made three, four, or five inches in length, as recommended by Mr. Lawrence and other British surgeons. Such a procedure is eminently cruel and reprehensible, and it is difficult to conceive how it should ever have received the sanction of enlightened practitioners. Independently of the pain which attends it, it is liable to be followed by copious hemorrhage, which, occurring at a time when the patient is perhaps ill able to bear it, is well calculated, in many cases, to hurry him on to a fatal issue. I must, therefore, enter my solemn protest against such a barbarous practice. Incisions, I repeat it, are often eminently serviceable, if, indeed, not indispensable both to the part and system; but let them be made in a proper manner, and of proper dimensions. A cut from half an inch to an inch and a half in length, and deep enough to liberate the pent-up fluids, ought to be sufficient in any case, unless there has been great mismanagement on the part of the patient, or his professional attendant. In such an event, the incisions may be multiple, being placed at suitable intervals from each other. It is hardly necessary to add that, in performing the operation, the knife should not be carried in the direction of any important structures, as large vessels, nerves, or joints. If hemorrhage be unavoidable, it is to be arrested by the usual means, as compression, styptics, or ligation. The best application after the bleeding has ceased is an emollient poultice, or the warm water-dressing, either simple or medicated. The loss of a small quantity of blood is often of essential benefit in relieving the disease.

Punctures are more particularly useful in the œdematous forms of the disease, to evacuate the serous fluid upon which the distension depends, and which often forms a source of so much mischief. When suppuration or gangrene is threatening, punctures, as already stated, give way to incisions. The number of punctures, the depth to which they should be carried, and their proximity to each other, must depend upon circumstances. The best instrument for making them is a very narrow, sharp-pointed bistoury, introduced perpendicularly to the surface, with the necessary care to avoid important structures.

Finally, valuable aid may be derived, in almost every case of erysipelas of the extremities, from the application of the *bandage*. It is particularly efficacious in the early stages of the disease, being well calculated, if judiciously employed, to afford support to the affected structures, and to prevent vesication and suppuration. The application should be made as equably as possible, and with a certain degree of firmness, its effects being carefully watched, and aided by simple or medicated lotions.

SECT. II.—FURUNCLE, OR BOIL.

A furuncle, vulgarly called a boil, is a peculiar inflammation of the skin and cellular substance. Liable to occur upon any portion of the body, excepting, perhaps, the palm of the hand and sole of the foot, it is most common upon the face, nape of the neck, buttocks, and fingers, often forming in considerable numbers, either simultaneously or successively, although generally there is only one. Both sexes, and all periods of life are subject to it; the young, however, suffer more frequently than the old and middle-aged. Some persons are habitually affected with boils, being seldom entirely free from them at any time for years. Now and then they disappear for a while, and then suddenly break out again. Attacks of boils are a very common sequel of eruptive affections, as smallpox, measles, scarlatina, and typhoid fever. Children during dentition, and during chronic attacks of cholera, occasionally suffer enormously from this cause. I have often, in these com-

plaints, seen the whole surface literally covered with boils, the patient experiencing great torment and bodily weakness.

The causes of furuncle are generally inappreciable. Occasionally we can trace their formation to external violence, as a contusion, or the concussion sustained by the skin and cellular substance in riding on horseback. In the majority of cases, if not in all, it is obviously connected with a disordered state of the digestive organs, or with some derangement of the secretions. Thus, persons who labor habitually under disease of the liver, and females who are troubled with irregularity or suppression of the menses, are very prone to suffer from its attacks.

A boil consists essentially in a circumscribed inflammation of the skin and subcutaneous cellular tissue, eventuating in suppuration and sloughing. It usually begins as a small, hard, red pimple, which, as it proceeds, gradually assumes a conical figure, the apex being formed by the skin, and the base by the cellular substance, its volume varying from that of a current to that of a pigeon's egg. The pain which accompanies it is, at first, of a burning, smarting character, but afterwards, especially when matter is about to be deposited, it becomes throbbing and exceedingly severe. A sense of tension is also commonly present. The skin is of a dusky, reddish aspect, and exquisitely sensitive to the slightest touch. As the tumor increases, a little vesicle forms at its apex, containing a drop of serum, and indicating the point where the boil will discharge itself. If the furuncle be large, or multiple, there will usually be more or less constitutional disturbance, as manifested by the want of appetite, a bad taste in the mouth, headache, chilliness, and a feeling of great uneasiness. Finally, if the disease occur in the lower extremity or upon the buttock, there will often be sympathetic enlargement of the glands of the groin, and in the upper extremity of the glands of the axilla. The period required for a boil to reach its height varies from three to eight days.

If a section be made of a boil, with a view to the examination of its structure, it will be observed to consist of a mass of dead cellular substance, ordinarily called a core, immersed in thick yellowish pus, the parts around being very hard, matted together with lymph, and preternaturally vascular. The skin is also indurated, and abnormally tense, red, and injected. Occasionally the contents of the swelling are almost wholly made up of blood, or of a mixture of blood, pus, and slough. This form of boil, to which the term hematoid may be applied, is most common in elderly persons of a broken constitution, and is generally attended with a great deal of local and general distress.

It is seldom, under any circumstances, that a furuncle can be made to abort, or to terminate in resolution, its invariable tendency being to suppurate and slough. In its very incipency, I have occasionally, though very rarely succeeded in arresting its course by a brisk purge, and the application of iodine, but if it have already made some progress, such an attempt will prove altogether futile. The best plan generally is at once to poultice the part, and make an early and free incision to let out its contents. The relief experienced from the operation is always prompt and decided. If the sore is slow in healing, either from the retention of dead cellular tissue, or want of healthy action from other causes, its surface should be well touched with nitrate of silver; the same article, iodine, or a small blister being applied to the surrounding surface. In most cases the patient will be benefited by purgative medicine and light diet.

When there is a decided furuncular diathesis, as when a great number of boils exist simultaneously, or form in pretty rapid succession, benefit may be expected from an emetic, and from mercurial purgatives, with the internal use of iodide of potassium and Donovan's solution. Sometimes Fowler's solution of arsenic answers a good purpose, or, what I prefer, arsenic in sub-

stance, from the twentieth to the thirtieth of a grain three times a day. In very obstinate cases slight ptyalism may be required before the disease finally yields. When boils are developed as a consequence of exhausting diseases, tonics, mineral acids, a nutritious diet, and country air are indicated. Alkalies should be used when there is evidence of acidity of the stomach and bowels. Daily bathing with salt water, or water impregnated with potassa, will occasionally be serviceable, especially when there is unusual torpor of the skin.

SECT. III.—ANTHRAX, OR CARBUNCLE.

The most accurate definition that can be given of a carbuncle is that it is a boil on a large scale, it being, like that affection, a peculiar inflammation of the cutaneous and cellular tissues, but, instead of being circumscribed, as in that disorder, it manifests a disposition to spread. Its most common seat is the posterior part of the trunk, particularly the nape of the neck, near its junction with the occiput. The gluteal and sacral regions are also liable to the disease, but it is very seldom that it occurs in the extremities. A bad form of carbuncle occasionally exists upon the chin and lower lip.

Elderly persons are most prone to carbuncle, and it is generally believed that such as are fat and indolent, or addicted to the pleasures of the table, are more frequently attacked than the lean and active. In my own practice, however, this has not been the case. On the contrary, the greatest number of instances has occurred in thin subjects, after the age of fifty, whose constitution had been broken down by long-continued intemperance, impoverished diet, deficient clothing, and mental anxiety. In London carbuncle is said to be remarkably common among the lower orders, in consequence of the enormous quantities of ale and porter which they habitually consume. The disease is more frequent in winter than in summer, and in men than in women; occasionally it displays an epidemic tendency. Carbuncle is one of the symptoms of plague. The extent of the inflammation varies from that of a dollar up to that of a large saucer, its average being about that of the palm of a small adult hand.

Of the exciting *causes* of carbuncle nothing whatever is known. Most commonly the outbreak of the disease is ascribed to the effects of cold, to disorder of the stomach, over-eating, constipation of the bowels, loss of sleep, excessive venery, and other debilitating influences; but how far, or in what degree, these circumstances tend to favor its development it is impossible to say. I have myself long regarded the malady as essentially of a constitutional nature, resembling, in this respect, erysipelas and some other affections; and a careful study of the history of the disease certainly warrants such an inference. A long course of debauch, or indulgence in the pleasures of the table, attended with a vitiated state of the secretions, is, as is well known, eminently conducive to the development of carbuncle in its worst forms. When a person has been for years in this condition, eating and drinking luxuriously, and taking hardly any exercise, the slightest exposure to cold, suddenly checking the cutaneous perspiration, would, it may easily be imagined, tend to produce the disease in a part habitually congested and enfeebled in its action. But there is then not merely a bad state of the solids; the blood also comes in for a share in the proceeding, surcharged, as it must be, with irritating materials which the solids have long been unable to throw off as recrementitious substance. Whether, however, this conjecture be correct or not, the fact is indisputable that carbuncle is rarely, if ever, of traumatic origin, or found in persons of a vigorous and healthy circulation.

The first *symptom* of carbuncle is generally an itching, burning, or smarting, with a sense of numbness, in a particular part of the skin, which, on

examination, is found to be of a dusky, reddish color, slightly tumid, and somewhat tender on pressure. As the disease progresses, the local distress sensibly increases; the pain soon becomes throbbing and exceedingly violent, the part feeling as if it were in contact with melted lead; the surface assumes a livid hue; the swelling spreads both in circumference and in depth; and the slightest touch of the finger is intolerable. Along with these phenomena, the patient usually experiences a sense of weight and tension, which greatly adds to his suffering. The part is hard, and circumscribed, feeling like the rind of bacon, and occupying a space from the size of a dollar to that of the palm of the hand. Presently vesicles begin to form at the focus of the inflammation, containing a dirty turbid, yellowish, or sanguinolent fluid, and generally not exceeding the diameter of a pea, though occasionally they are quite large. Upon bursting, these vesicles expose a corresponding number of openings in the true skin, giving the surface a cribriform appearance, and leading down into the cellular substance, which is already in a state of mortification. The ulcers, for so they may be called, have an irregular, ragged appearance, and are the seat of a foul, irritating discharge, which is often very abundant and exhausting.

Upon dividing the affected structures, the skin is found to be remarkably dense and firm, cutting very much like the rind of bacon. The cellular substance beneath is converted into a slough, having the appearance of a mass of wet tow, being bathed with ill-looking matter, and intermixed with flakes of lymph, or matter like putty, thick pus, or curds. When the disease is of unusual extent, there may be considerable involvement of the aponeuroses and muscles, but in general these structures are excluded from the morbid action, the skin and subjacent cellular tissue alone suffering. At the periphery of the disease the parts are always uncommonly dense, the boundary between it and the healthy structures being established by a deposit of plastic matter, less organizable, however, than in furuncle, the morbid anatomy of

Fig. 184.

Carbuncle in its forming stage.

Fig. 185.

Ulcerated carbuncle.

which that of a carbuncle so closely resembles. The subjoined sketches, figs. 184 and 185, represent this disease in its earlier and more advanced stages.

The *constitution* always, at an early period of the disease, strongly sympathizes with the part affected. Hence, fever is generally present soon after its

commencement, and sometimes, indeed, almost before there is any marked evidence of the local affection, the first symptom being often a severe rigor, followed by high vascular excitement. However this may be, the case soon assumes an asthenic type, indicative of the depraved condition of the solids and fluids so intimately concerned in the production of the disease. The tongue speedily becomes dry, hard, and brown, sordes collect upon the gums and teeth, the appetite fails, gastric derangement exists, the bowels are constipated, the urine is scanty and high-colored, the skin is hot and arid, the mind is disposed to wander, and the pulse is frequent, soft, and without force. Vomiting is often present to a considerable extent, and the alvine evacuations are generally excessively fetid.

There is no disease with which carbuncle can be *confounded*. Its large size, the severity of the attendant pain, and the great constitutional disturbance will always readily distinguish it from furuncle at its commencement, and afterwards the diagnosis will be still further aided by the vesicated and cribriform condition of the skin, so characteristic of carbuncle. The only affection which it at all resembles is a bedsore, but the history of the case, and the situation of the swelling, will always serve as means of discrimination. Malignant pustule begins as a little circumscribed pimple, not as a diffused swelling, as in anthrax, and soon forms a large vesicle, raised above the surrounding level, and resting upon a hard, solid base, which rarely acquires much extent, at least not until the affection has made considerable progress.

A carbuncle is generally a *dangerous* disease, especially so when it is multiple, or when it occurs in old, fat subjects, addicted to indolence and over-feeding. The site of the disease will also exert a marked influence upon the issue of the case. Thus, a carbuncle situated on the back part of the head and neck will, other things being equal, be more likely to produce death than when it occupies the back, nates, or extremity, inasmuch as it is extremely apt to involve the brain and arachnoid membrane, causing effusion of serum and lymph. Young and comparatively healthy persons will often recover, though generally not without great suffering, whatever may be the site of the malady.

Treatment.—The treatment of carbuncle must be conducted with special reference to the improvement of the secretions and the support of the system. Few patients will be found to bear bleeding, or anything like active purgation. It is only when there is extraordinary plethora, combined with great vigor of constitution, that these means should be carried into effect. In all other cases, their inevitable tendency will be to do harm, by bringing on premature exhaustion. Efficient purging, however, may be regarded as an indispensable remedy in almost every instance, the object being not only to get rid of irritating fecal matter, but to produce a change in the secretions. For this purpose the medicine should be given early in the disease, and a mercurial cathartic should always be preferred to any other. When marked gastric derangement exists, as indicated by nausea, headache, and pain in the limbs, no time should be lost in administering an efficient emetic, or an *emetocathartic*, as ten grains of calomel and from ten to twenty of ipecacuanha, followed by large draughts of chamomile tea, or infusion of valerian. Clearance having been effected, and function improved or restored, stimulants and tonics will come into play, exhibited warily, especially if cerebral trouble is threatened, yet efficiently if evidence of exhaustion is present, the most suitable articles being ammonia, quinine, chloride of iron, and brandy, with nourishing broths. Anodynes will generally be required, in large doses, to allay pain and procure sleep. After the first few days a mild laxative, as blue mass or castor oil, is occasionally given. Determination to the brain must be promptly met by a large blister applied as near as possible to the occiput.

The best *topical application*, in the early stage of carbuncle, is the warm

water-dressing, medicated with acetate of lead and opium. Pencilling the surface well with tincture of iodine, and then covering it with a mixture of equal parts of olive oil, laudanum, and spirits of turpentine, sometimes produces a very soothing effect. In many cases, there is nothing so promptly beneficial as a blister, large enough to include a considerable portion of the healthy skin, and retained until it has caused thorough vesication; it drains the vessels of serum, allays pain, and makes a salutary impression upon the general system. Leeches are commonly inadmissible, as they cause severe pain, and undue depletion. But the great remedy for carbuncle, as for furuncle, is free incision, the knife being carried into the healthy substance beneath, not at one point, but at a number. The operation, which should be practised as soon as possible at the focus of the disease, and afterwards towards the periphery, should there be any necessity for it, at once relieves the horrible pain and tension of the part, affords nature an opportunity of casting off the sloughs, and puts an effectual barrier to the further extension of the morbid action. I cannot see any reason why practitioners should still continue to apply caustics in these cases when the knife is so much more prompt and effectual in its action. If the dead tissues are slow in coming away, their extrusion may be expedited with the scissors, the surface of the ulcer being well touched immediately afterwards with the dilute acid nitrate of mercury, or nitrate of silver, to promote the formation of healthy granulations. As soon as this has been brought about, the part is dressed with some mild unguent, as the opiate cerate, elemi ointment, or ointment of the balsam of Peru.

After recovery, the tendency to a recurrence of carbuncle, which is sometimes very strong, should be counteracted by a change of air, attention to diet, a proper regulation of the secretions, and the avoidance of exposure to cold and fatigue, aided by an alterative course of iodide of potassium, the dose of which should not exceed two grains and a half thrice in the twenty-four hours. If there has been much disorder of the secretions, a very minute quantity of bichloride of mercury may be advantageously conjoined with the potassium. When there is marked derangement of the digestive functions, attended with acidity and flatulence, recourse may be had to the chlorate of potassa, given three times a day, in doses of from five to ten grains, until there is manifest improvement in the tone of the stomach and of the general health. A change of air is often indispensable to complete convalescence.

SECT. IV.—GANGRENE AND BEDSORES.

The skin is liable to gangrene, both idiopathic and traumatic, simple and specific, acute, and chronic; but as these several varieties have already received a sufficient share of attention, nothing need be said respecting them here. There is one species, however, which may be briefly described in this place, inasmuch as no special mention has been made of it elsewhere. I allude to what is called *white* gangrene of the skin; an affection whose true character is still involved in obscurity, nothing that has yet transpired having thrown any light either upon its pathology or treatment.

White gangrene usually comes on without any appreciable cause, or premonitory symptoms, in patches of irregular shape, from one to three inches in diameter. The sloughs are of a dead, milky color, and of a hard, dryish consistence, yielding little, if any, moisture on pressure. Any portion of the body may be the seat of this affection; but observation has shown that the arms, back, and chest are the regions most frequently implicated. The disease has hitherto been observed chiefly in old persons of a broken, anemic constitution. The treatment is to be conducted upon general principles,

special reference being had to the improvement of the health by tonics, brandy, and nutritious diet.

Bedsores.—There is another variety of gangrene of the integuments which, from the frequency of its occurrence, and the severity of the attendant suffering, merits special attention here. The immediate cause under whose influence it is developed is steady and protracted pressure, impeding, and generally arresting, the circulation; hence it is exceedingly liable to arise on the sacro-lumbar region, the iliac projections, on the nates, and over the great trochanter, in consequence of long-continued confinement to one particular posture, as happens in typhoid fever, in severe fractures and wounds, and after surgical operations. Persons who have received violent injuries upon the back, eventuating in paralysis of the lower extremities, are more than commonly prone to this variety of gangrene, or bedsore, as it is usually called. I have at this moment under my charge a tall young man, affected for the last six months with paraplegia, who has a large and excessively painful ulcer upon the left buttock, merely from the pressure sustained in sitting on a chair.

The disease is always necessarily preceded by inflammation, but in consequence of the absence of the usual symptoms, the want of proper care in examining these parts and keeping them clean, or the impossibility which the patient experiences in communicating a knowledge of his suffering, as when he is exhausted by typhoid fever, or other causes, it does not always attract attention until great mischief has been done, eventuating in extensive sloughing, and the establishment of painful, irritable ulcers, which it is often extremely difficult to heal. In some instances the first intimation which the patient has of the approaching mortification is a sense of prickling in the affected parts, as if he were lying upon some rough substance, as sawdust, or coarse salt. At other times, he feels severe pain, of a stinging, burning, or biting character, within a few days after he has been exposed to the pressure, and which is often so constant and distressing as to deprive him both of appetite and sleep. Upon examining the parts to which the suffering is referred, the surgeon finds that they are red, or marked by an erythematous patch, slightly swollen, with a dense base, congested, and excessively tender on pressure. Ulceration, if it have not already taken place, will be sure to begin in a short time, unless suitable measures are adopted for the patient's relief, and will be speedily followed by mortification, or mortification may take place without being preceded by ulceration.

The extent to which the gangrene may proceed is variable; we occasionally see it occupying an immense surface, perhaps as large as the crown of a hat, and reaching down to the very bones; at other times it is more limited both in diameter and depth, laying bare merely the muscles, or being even in great degree confined to the skin. In rare cases, the ravages are not limited to the soft structures, but involve also the osseous tissue.

Bedsore, unless of very trivial extent, are among the most formidable complications liable to arise during the progress of fevers and other diseases, as well as after accidents and operations. As they seldom occur until the vital powers have been materially depressed, the excessive pain and drainage occasioned by them are often so severe as to destroy the patient, or, at all events, greatly retard his convalescence.

The *treatment* of bedsore, or gangrene from pressure, is prophylactic and curative. In the first place, whenever there is any probability from the nature of the case that the confinement is destined to be a tedious one, and attended with constant decubitus, or a helpless state of the patient, means should be promptly adopted for hardening those parts of the surface which long experience has taught us as being most likely to suffer under such circumstances. For this purpose they should be brushed once or twice a day

with tincture of iodine, at first diluted, and then pure, or washed repeatedly with a saturated solution of alum and tannin. The greatest possible attention should be paid to cleanliness, and to the arrangement of the sheets and clothes, that they may not be rolled up under the body, and thus become a source of suffering and disease, as too often happens in the hands of careless and thoughtless practitioners. As to the use of plasters, I have very little patience with them, for, unless they adhere well, they are extremely apt to become rumpled, much to the detriment both of the part and system. Change of posture should receive early attention, though this is not always practicable, from the inability of the patient to maintain himself in any other situation than that on the back. When the patient can afford it, he should use an air bed.

The moment any decided suffering is experienced, or the parts become red and inflamed, a ring-shaped air-cushion should be provided for the purpose of equalizing the pressure, or, in the absence of this, an ordinary cushion, with a suitable central hole, the edges being broad and well padded with wool or horse hair. Such a contrivance, however, is a very imperfect substitute for the air or water cushion, which should therefore always have the preference.

When gangrene is threatened, the best application is the tincture of iodine, aided, if there be much pain and tension, by one or two moderately free incisions, and followed by a yeast or port-wine poultice, sprinkled with laudanum, morphia, or powdered opium. Cleanliness is promoted by the liberal use of the chlorides and by the early removal of the sloughs. When granulations begin to spring up, the best dressing will be opiate cerate, balsam of Peru ointment, or a mixture of equal parts of castor oil and balsam of copaiba.

The constitutional treatment of bedsores must be conducted according to the general rules followed in typhoid states of the system from whatever cause proceeding. Nutritious food, wine, brandy, milk punch, quinine, and anodynes are the means chiefly to be relied upon for upholding the flagging powers of nature. This treatment can hardly be commenced too soon whenever there is any tendency to the formation of bedsores, for the very fact that such a tendency exists is a sufficient reason for redoubling our efforts to support the patient's system.

SECT. V.—BURNS AND SCALDS.

There are few accidents which are of more common occurrence than burns and scalds, or which entail a greater amount of suffering and deformity. The progress of civilization, and the improvements in the arts and sciences, have greatly multiplied their frequency and severity, and call for corresponding attention on the part of the surgeon. From what I have seen of these lesions, I am satisfied that few practitioners understand their character, or treat them with the success of which they are capable. One reason, perhaps, of this is that every one has a remedy for them, and that hardly any two agree as to the kind of treatment best adapted to their relief.

Burns and scalds differ from each other simply in this, that the one is the result of dry heat, and the other of moist. They both present themselves in various degrees, from the slightest erythematous blush of the skin to the total destruction of all the structures of a limb. Their extent also is exceedingly variable, both as it regards their depth and their superficial area. Thus, while in one case they may involve only a little patch of skin hardly the size of half a dime, in another they may occupy an immense extent of surface; or, instead of being diffused over a large space, the injury may be

concentrated upon a small spot, but penetrate to a considerable depth. These differences are of great practical importance, on account of the influence which they exert upon the issue of the case. The division of Dupuytren of burns and scalds, so generally adopted at the present day, seems to me to be most complex and unscientific, and therefore well calculated to embarrass the progress of the inquirer. No one can doubt that the more simple the arrangement of a subject is, the more easily, in general, it is understood. In accordance with this idea, I shall describe burns and scalds as consisting of two classes, the simple and complicated; comprehending under the former term those lesions which, however extensive, produce only inflammation, and under the latter those which cause the death of the parts, either on the instant, or within a short time after their infliction.

Burns are most common in winter, among the poorer classes, who are very liable to have their clothes set on fire in consequence of the manner in which they crowd around the hearth and grate to keep themselves warm. Women, on account of the peculiarity of their occupation, are more subject to them than men, and children than grown persons. Blacksmiths, plumbers, glass-blowers, and foundry men are particularly exposed in this way. The introduction of gas and camphene has been a fruitful source of these accidents. Scalds, on the other hand, are most common in kitchens, breweries, in different kinds of factories, especially soap and candle, and in all places where steam is employed, whether for domestic or public purposes. On our western waters, where steamboat explosions are of frequent occurrence, many persons are annually destroyed by the effects of hot water. Those parts of the body which are habitually exposed, as the hands and face, are most liable to suffer both from burns and scalds, especially the latter, steam often penetrating the clothes in every direction. Dry and moist flame, hot water, and steam often enter the mouth and throat, producing violent, if not fatal, effects. A heated iron has been known to be thrust up the rectum for the purpose of homicide, as in the famous case of Edward II.

It is well known that different agents possess different degrees of capacity for caloric, and that, consequently, they are capable of producing different effects when brought in contact with the living tissues. Thus, experience has shown that boiling metal will cause a more severe impression than boiling oil, and boiling oil than boiling water. The intensity of the injury, however, is not always in proportion to the relative capacity of the substance for heat; for it is well ascertained that copper will, other things being equal, occasion a more violent effect than iron, although the latter possesses a greater capacity for caloric. This fact can be explained only on the assumption that some articles are not only better conductors of heat than others, but that they adhere more firmly to the surface, thus favoring its protracted extrication. Alcohol and ether, from their great volatility, usually produce only superficial burns.

In the milder forms of these accidents there is merely an erythematous appearance of the skin, such as may readily be produced by exposing the back of the hand for a few moments to a stove, or by applying hot water to it. The discoloration is usually very temporary, but at times it is more permanent, lasting for a number of hours, and being perhaps soon followed by slight vesication. The pain is of a smarting, pungent character, but comparatively trifling, and soon goes off. The constitution remains unaffected.

The application of heat, whether dry or moist, unless sufficient instantly to destroy the vitality of the part, or so slight as to make only the most superficial and transient impression, is always speedily followed by an evolution of vesicles, containing a thin, watery fluid, identical with the serum of the blood, from which it is derived. When the vesicles are more slow in forming, as when they are the product of the resulting inflammation rather than of the

immediate effect of the caloric, their contents are, in general, partly fluid and partly solid, the latter consisting either of lymph or of fibro-albuminous matter. Their volume varies from that of a pin-head up to that of a fist, their number being usually in an inverse ratio to their dimensions. Cases are occasionally met with where the epidermis nearly of a whole limb, or the greater portion of the trunk, is elevated into one enormous blister, establishing a most frightful drainage upon the blood.

The surface around the vesicles is of a scarlet color, more or less tumefied, and exquisitely tender on pressure, or on exposure to the atmosphere. The pain is of a burning, scalding character, and so severe as to cause the most intense agony. The part rapidly swells, feeling stiff and tense, and the pain assumes a throbbing character. Well-marked constitutional symptoms are always present, especially if the lesion is at all extensive, and the patient may be delirious, excessively restless, and intensely thirsty.

These injuries are said to be *complicated* when they are attended with the destruction of the vitality of the part, or some other serious lesion, as a wound, fracture, or dislocation. The loss of life may be limited to the skin and subjacent cellular tissue, or it may extend much deeper, involving muscle, aponeurosis, vessel, nerve, and bone all in one common eschar. Such accidents are never produced in any other way than by burns, as when a person falls into the fire, or gets his limb in a stove, grate, or furnace. Dreadful scalds, however, sometimes occur from the protracted application of boiling fluids, as happens now and then in breweries and soap factories. Under such circumstances, the loss of vitality, although not as extensive as we sometimes find it from the operation of dry caloric, is yet sufficient to be productive of the most terrible ravages. The epidermis comes off in large sheets, no vesicles exist, or only around the border of the injured surface, and the skin is of a dirty grayish, cineritious, or yellowish color, sodden, insensible, and marked, here and there, by a purplish line, indicating the course of a subcutaneous vein.

Besides the pain which invariably attends all burns and scalds, no matter how slight, or wheresoever situated, there is apt to be more or less *constitutional* disturbance, coming on at a variable period after the accident; sometimes immediately, and at other times not for several hours, days, or weeks. When the injury is at all extensive, the patient will have all the symptoms of one laboring under a severe shock. He will feel exceedingly cold, or, perhaps, have violent rigors; the pulse will be small, frequent, and feeble; the respiration will be oppressed; and there will be extreme restlessness, along with great thirst and sickness at the stomach. The patient, in fact, lies in great torture, pale, prostrated, agonized. Reaction taking place, he will have violent fever, a flushed countenance, and a quick, frequent pulse, with a tendency to delirium; pain, of a pungent, burning character, forming all the while a prominent symptom. If the excitement run high, there will be danger of over-action in the part, and of inflammation of some of the internal viscera, of the arachnoid membrane, and of the mucous lining of the bowel. Numerous cases have been published within the last fifteen years going to show that ulceration of the duodenum is one of the most frequent lesions which supervene upon scalds and burns of the cutaneous surface; and, in the more chronic forms of these accidents, the same disease is sometimes widely diffused over the colon, thus accounting for the profuse and obstinate diarrhœa which is so often present under these circumstances.

Among the more common local *consequences* of burns and scalds are, the formation of vicious scars, the adhesion of contiguous surfaces to each other, the retraction of the affected parts, ankylosis of the joints, and various transformations of the cicatricial structures, especially the keloid. The scars, which are often of frightful extent, and horribly disfiguring, possess an ex-

traordinary contractile power, which does not cease for a long time, which it is almost impossible to counteract, and which frequently draws out of place every tissue that is brought under its influence, bone not excepted. Owing to this circumstance, the chin is occasionally drawn down against the sternum, as seen in fig. 186, and the lower maxilla singularly changed in shape. The fingers may be retracted like claws, or literally buried in the palm, the hand thrown back at a right angle with the wrist, or the forearm drawn up against the arm, which is itself, perhaps, firmly pinioned to the side. Similar effects occur in the inferior extremity. Thus, the foot is sometimes tied to the forepart of the leg, and the leg to the posterior surface of the thigh. In neglected burns of the hand, the fingers are often united to each other, so as to give them a webbed appearance.

Fig. 186.

Vicious cicatrices of the face and neck, caused by a burn.

Burns and scalds are among the most *dangerous* of accidents. If at all extensive, they often terminate fatally from mere shock of the system, without, perhaps, even the slightest attempt at reaction; or, if reaction should occur, life may afterwards be assailed by inflammation of some internal organ; or death may take place at a more remote period, in consequence of the secondary effects of the lesion. A superficial injury of this kind is generally dangerous in proportion to its extent. Thus, a scald involving an entire limb or the greater portion of the trunk, although merely affecting the external layer of the true skin, is always a most serious accident, liable to be followed by the worst results. On the other hand, the danger is hardly less when the lesion is very deep, although it may not be more than a few inches in diameter. When depth and great extent of surface are combined, the chances are that death will occur without reaction, or, at all events, soon after reaction has taken place, from constitutional irritation. A prognosis, therefore, should not be given without due regard to these circumstances.

These injuries, moreover, are more dangerous in infants and children than in adults, on account of the greater susceptibility of their nervous system. Old persons, too, are very intolerant of them, and are liable to suffer severely, both primarily and secondarily. Pregnant females occasionally abort from their effects; and in the intemperate they often lead to the development of delirium tremens and other distressing symptoms. A burn on the neck and scalp is liable to cause arachnitis; of the chest, inflammation of the lung and pleura; of the abdomen, peritonitis and enteritis. Finally, a patient, after having manfully struggled against ebb and tide, as it were, for weeks and months, may finally be worn out by profuse discharge and hectic irritation.

Treatment.—The indications in the treatment of these lesions are, first, to produce reaction and calm the system; secondly, to limit the resulting inflam-

mation; thirdly, to promote the sloughing process, when death has taken place, and to favor the development of granulations; fourthly, to moderate contraction, and prevent ankylosis; and, lastly, to sustain the strength during the wasting effects consequent upon the protracted suffering which so often occurs when the patient has escaped from the primary effects of these injuries.

To raise the system from the *depression* or collapse into which it so frequently sinks, even in comparatively slight burns and scalds, immediate recourse should be had to the exhibition of a full anodyne, along with hot toddy, ammonia, sinapisms to the extremities, and artificial warmth. The quantity of morphia, or whatever form of opium may be used, should be at least double what it is in ordinary accidents, the system being always, under these circumstances, uncommonly tolerant of the medicine. A large dose will not only be conducive to speedy reaction, but will greatly assist in allaying pain and calming the system. If the shock has been unusually severe, it may be necessary, in addition to these means, to use stimulating injections and to rub the spine with some irritating lotion. In the child and old man, care is taken not to urge on the reaction too rapidly, or to give opium without a certain degree of caution, lest the subsequent excitement should overtax the enfeebled brain and heart, thereby leading to visceral effusion. As the circulation comes up, the stronger stimulants are gradually withdrawn, the more simple alone being now trusted to for relief.

The second indication is to moderate the resulting *inflammation*. With this view various remedies may be employed; but what these remedies ought to be is a point respecting which there is still much contrariety of sentiment; nor is it at all probable that the question will soon be settled one way or another. In the milder forms of these accidents the practitioner can hardly go amiss if he employs almost any of the numerous articles that have been recommended by the profession and the people. He will find that, at one time, the part and system are most comforted by cold applications, and, at another, by warm; that to-day the one is borne best, and the other to-morrow; that one patient is benefited by an ointment, and another by a lotion; that in one case he may use moist applications with most advantage, and in another dry; in short, that the utmost diversity obtains in regard to the tolerance of this remedy or that. I am sure that the force of these remarks must often have been felt by every one at all extensively engaged in the practice of surgery. It is not surprising, therefore, as was stated at the opening of this section, that there should still be such a diversity of sentiment in relation to the proper management of these accidents.

Cold applications are chiefly adapted to very young, robust subjects, during the heat of summer, but even then they should not be resorted to without great care, for fear of internal congestion and effusion. The proper plan is to use them only so long as they are grateful and soothing to the system, and to discontinue them the moment they are found to be disagreeable. They may consist simply of cold water, spirits and water, or weak solutions of acetate of lead; and the same articles may be applied warm, care being taken, when the one class follows the other, that the transition is gradual and gentle, not sudden and violent. If the lesion be very slight, the surface may be covered with poultices of scraped potato, apple, turnip, starch, arrowroot, or slippery elm; carded cotton; saturnine unguents; or cloths wet with soap liniment, or a liniment made of lime-water and linseed oil. The latter constitutes the famous application so much used at the Carron Iron Works in Scotland; it is, however, exceedingly filthy and disgusting, and should therefore be discarded from genteel practice. Carded cotton, an American remedy, has always stood high in the estimation of the public, and there are few articles that are more constantly or more advantageously employed in the treatment of burns

and scalds. A remedy from which I have often derived signal benefit in the milder varieties of these affections is the dilute tincture of iodine, in the proportion of one part to two of alcohol. It is only applicable, however, when the skin is unbroken.

In my own practice, I have experienced the most signal benefit in the treatment of burns and scalds from *carbonate of lead*, in the form of white paint; and in 1845 I called the attention of the profession to the subject in a short article inserted in Dr. Bell's Bulletin of Medical Science. Numerous observations made since that time have only served to confirm the views then expressed. From its great efficacy, and the readiness with which it can usually be employed, this mode of treatment deserves to come into more general use. It is not applicable merely to the milder forms of burns and scalds, but it may often be advantageously used, no matter what may be the extent or depth of the injury.

As the lead of the shops is very stiff, and, consequently, unfit for use, my invariable plan is to incorporate with it a sufficient quantity of linseed oil to make it of the consistence of thick cream. Thus prepared, the affected surface is thickly and thoroughly coated with it by means of a large camel-hair pencil, a soft mop, or a small paint-brush. If vesicles exist, their contents are evacuated with a fine needle, and the parts are well dried; otherwise, the lead will not adhere. The dressing is completed by covering the painted surface with a layer of carded cotton, or a piece of old muslin or linen, supported by a moderately firm roller. In mild cases, one application of this kind, allowed to remain on four or five days, will usually suffice to effect a cure. In the more severe forms of the lesion, on the contrary, a considerable number may be required. Whenever the dressings become stiff or saturated with secretions, they should be removed, others being immediately substituted.

I have never witnessed any bad effects from white lead paint, applied as here stated, although I have used it very freely in quite a number of cases. In one instance, that of a negro girl, sixteen years of age, who had a most severe and extensive burn of the neck, chest, and abdomen, I maintained the application upwards of five weeks, consuming more than a quart of the lead, without observing the slightest injury. In short, my experience induces me to believe that the treatment is perfectly safe in all cases, whatever may be the extent or depth of the lesion, or the age of the patient. Where a counter-poison, however, is deemed necessary, it will be readily found in the occasional exhibition of a dose of sulphate of magnesia, which, while it keeps the bowels in a soluble state, combines with the lead, forming an inert sulphate.

White lead paint probably produces its good effects in two ways: first, by forming a varnish to the affected surface; and, secondly, by directly obtunding its nervous sensibility. In many cases, it acts literally like a charm; the patient, in a few moments, becoming perfectly calm, and passing, as it were, from torment into Elysium.

Professor T. G. Richardson, of New Orleans, has recently employed with excellent effect the *subnitrate of bismuth* in the treatment of burns and scalds, his experience inducing him to give it a decided preference over white lead. His mode of using it is to rub the bismuth in a mortar with a sufficiency of glycerin to convert it into a thick paint, which is then freely spread upon the affected surface with a suitable brush, the parts being afterwards covered with carded cotton, retained by a roller. In the milder forms of the accident a single application often effects a cure.

In Boston, a plan of treating burns and scalds is used with much advantage, consisting of the application of a thick coating of mucilage of gum Arabic, which is immediately after well dusted with dry powder, the whole forming a complete defence to the raw surface beneath. Mr. Meadows, of London, has recently recommended, for a similar purpose, a mixture of col-

iodion and castor oil, in the proportion of two parts of the former to one of the latter. The preparation, which may be kept ready for use for any length of time in an air-tight bottle, is applied by means of a camel-hair brush, and is speedily converted into a firm, adherent covering, the thickness of which may afterwards be increased if deemed proper. In the more simple forms of scalds and burns, the application of glycerin is occasionally very beneficial.

Where a stimulant effect is required, as when the parts are in a condition verging upon gangrene, the most eligible dressing, perhaps, is Kentish's ointment, composed of one ounce of basilicon ointment and one drachm of spirits of turpentine, and spread upon strips of old muslin, bound on lightly by a roller; or, instead of this, the surface may be carefully pencilled with a weak solution of nitrate of silver, nitric acid, or acid nitrate of mercury, and then covered with a yeast, port wine, or tannin poultice.

Along with these means, proper attention is paid to the state of the constitution, the bowels are maintained in a soluble state, diaphoretics are given to restore the functions of the skin, and the diet is carefully adapted to the emergencies of the particular case. The internal organs, particularly the brain and lungs, are sedulously watched, the avenues to disease being guarded by leeches and other suitable remedies for preventing inflammation.

If, despite the utmost care and attention, the injury terminates in *mortification*, or if the vitality of the parts was destroyed in the first instance, an effort should be made to check its further progress, and to promote the separation of the sloughs. The most suitable remedies for this object are such as are in use for ordinary gangrene. Feter is corrected with the chlorides. If the sloughs are very firm, the knife may be used, but not without the greatest caution, lest pain and hemorrhage be induced.

As soon as the sloughs have dropped off, the indication is to promote the development of granulations; a circumstance which often requires much judgment and practical skill. The best remedies are the warm water-dressing, with the use of a very weak solution—not more than two drops to the ounce of water—of nitric acid. Sometimes the calamine cerate is very soothing, and seems to do good when almost everything else fails. If the granulations manifest a tendency to become exuberant, as they are very apt to do, they must be repressed with the scissors, nitrate of silver, and systematic compression, tonics being given to support the system. Cases occur in which these bodies are rendered exquisitely sensitive, the slightest touch being followed by the most lively pain. We usually find that this condition is attended with an irritable state of the constitution, and that, consequently, it requires something more than mere topical medication to get rid of it. A judicious course of anodynes and tonics, with the occasional application of nitrate of silver, and the constant use of an elm poultice, constitutes the proper treatment. Occasionally, no local remedy is so soothing as white lead paint. Whatever means may be employed, it will be found that they will require to be frequently varied; as one loses its effects another taking its place.

To obviate *deformity* constitutes the fourth indication in the treatment of these injuries. The points to be attended to are threefold: first, to prevent adhesions between contiguous surfaces; secondly, to counteract the tendency to vicious contraction; and, thirdly, to obviate ankylosis.

Allusion has already been made to the tendency which contiguous surfaces have to unite to each other during the progress of these accidents. This tendency is not confined to the fingers and toes, but is exhibited also in other parts of the body, as between the arm and trunk, the two labia, the thigh and scrotum, the ear and scalp. Whenever it appears, it must be carefully counteracted by the use of the bandage and the interposition of lint, aided, if need be, by splints. It does no credit to a surgeon to send forth his patient, after the completion of cicatrization, with webbed hands and feet, or with his arms

pinioned to the side of the chest, although such occurrences are not always entirely avoidable.

The disposition to contraction in burns and scalds attended with loss of substance is always great, and is often productive of the most frightful deformity. To counteract this disposition, recourse should be had, early in the treatment, to carved splints and tin cases, judiciously applied, and steadily used, not only until the parts are well, but for a long time afterwards; experience having shown that the tendency to contraction continues for months, if not years, after the completion of the cicatrization.

If, from neglect, mismanagement, or unavoidable circumstances, the contraction has seriously impaired the usefulness of the part, or greatly marred the person's beauty, relief should be attempted by the division of the offending cicatrice, or, perhaps, by its excision, the raw edges being afterwards united by suture, or adapted to a flap of integument from the neighborhood.

This operation, constituting what is termed *dermoplasty*, should not, however, be undertaken without due preparation of the system, for it will readily be observed that when the cicatrice is very large, two most extensive wounds will be made, thus inflicting a violent shock upon the constitution, extremely liable to be followed by erysipelas and a low form of fever, under which the patient might easily sink. At least a fortnight should be spent in this kind of preliminary treatment.

The operation should be performed while the patient is under the influence of chloroform, and great care should be taken to dissect out every particle of the inodular tissue. To accomplish this, the surgeon is sometimes obliged to pass deeply among important vessels and nerves, which must, of course, not be interfered with. In conducting such an operation about the neck, the precaution must be used of preventing the entrance of air into the veins. The bleeding which attends the excision of the cicatrice is generally trifling, and is easily arrested by torsion: when the ligature is unavoidable, it should be brought out at the nearest point of the wound, or through a small opening in the transplanted integument.

The skin for filling up the gap left by the removal of the inodular tissue, should always be taken from the immediate vicinity of the part. Thus, in the neck, it is usually obtained from the shoulder or top of the chest, and, when the wound is very large, two flaps are generally made, one on each side, the object being to guard against sloughing from inadequate nutrition. Due allowance must always be made for shrinkage. Hence, the flap should invariably be at least from one-fourth to one-third larger than the wound, have a good broad pedicle, and be well stitched in its new position, although care must be taken not to place the sutures too near each other for fear of embarrassing the circulation. The central portions of the flap must be loosely confined with adhesive strips, and the edges covered with charpie, soaked in oil. The wound made by the transplantation of the integument is immediately closed in the usual manner. The parts are kept perfectly at rest, being immovably fixed by suitable apparatus, and the case is afterwards managed according to the general principles of plastic surgery.

The results of this operation have been much lauded; I have not, however, I must confess, much confidence in its ultimate efficacy, experience having taught me that, sooner or later, the deformity is sure to return, though not always in its original extent. I have seen enough of these procedures, both in my own practice and in that of others, to convince me that they ought not to be classed among the triumphs of surgery. It is only when the cicatrice is very soft and superficial that they hold out any prospect of a very favorable result. When the contraction affects the muscles, tendons, fibrous membranes, and bones, forcing them out of their natural shape and position, the art of surgery can be of no avail.

Joints often become involved during the progress of burns and scalds, either from direct inflammation, or in consequence of the contraction of neighboring muscles, tendons, and aponeuroses. The parts are carefully watched, being moved from time to time, and constantly retained in splints, until all tendency to ankylosis has ceased.

Finally, the secondary *constitutional irritation* and drainage, so common, and so hazardous in the more severe forms of these accidents, must be met by stimulants, tonics, and anodynes, along with a nutritious diet, and exercise in the open air. The wasting diarrhœa, which is so often present, must be checked with opium and astringents, of which acetate of lead and sulphate of zinc deserve particular mention, the former being given in two, and the latter in one grain doses, with half a grain of opium, three times in the twenty-four hours. Night-sweats are controlled with quinine and elixir of vitriol.

Secondary amputation may be rendered necessary, when, an attempt having been made to save the part, death is likely to happen from the excessive discharge and hectic irritation; or when the part is found not only to be useless but to be greatly in the way of the patient's comfort and convenience.

SECT. VI.—FROST-BITE AND CHILBLAIN.

Man, as is well known, possesses in an eminent degree the faculty of resisting the influence of physical agents. His constitution is able to bear almost any amount of heat and cold, provided the transition from the one to the other is not too great or sudden, and that he himself is at the time in the full enjoyment of his bodily powers. The experiments of Fordyce, Blagden, and others, show what an amount of artificial heat may be endured without entailing any serious effects, and the experience of travellers, as Banks, Solander, and Kane, is equally decisive in regard to his capacity of withstanding the effects of low degrees of temperature. It is only, or chiefly, when the alternation from heat to cold is very rapid, or when the application of cold is made in a very concentrated form, upon a part of the body whose circulation is naturally very languid, that severe consequences are apt to ensue. Baron Larrey, who enjoyed extraordinary opportunities of studying the effects of cold, during Bonaparte's celebrated retreat from Russia, was forcibly struck with the little suffering which the soldiers experienced when exposed even for several successive days to the influence of a very low, dry, uniform temperature. Thus, after the battle of Eylau, although the mercury had fallen fifteen degrees below zero of Réaumur's thermometer, none of the French troops complained of frost-bite, notwithstanding many of them had remained in the snow, in an almost inactive state, for upwards of twenty-four hours. Presently, however, a fall of sleet coming on, during which the temperature rose suddenly from eighteen to twenty degrees, immense numbers of those who had been exposed began to suffer from the effects of cold, consisting principally in sharp, pricking pains in the remote parts of the body, especially in the feet, and in a disagreeable sense of numbness and weight. Severe swelling soon followed; the skin assumed a dusky, reddish appearance; the joints became stiff and insensible; feeling and warmth rapidly diminished; and black spots formed on the roots of the toes and on the back of the foot, announcing the occurrence of gangrene, the extremity looking dry and shrivelled, as in chronic mortification. It was observed that those who had warmed themselves at fires suffered more severely than those who had been more discreet in this respect.

Frost-bite was very prevalent among the English troops during their first winter in the Crimea, and the French suffered in still larger numbers, as well

as more severely. The habit which the men had of sleeping in their wet boots, at one time almost universal, contributed greatly to its production, wet and cold combined diminishing the circulation and vitality of the feet and toes. On the 21st of January, 1855, when, according to Dr. Macleod, the thermometer stood at 5° , no less than 2500 cases of frost-bite were admitted into the French ambulances, and of these 800 died, death in many having no doubt been expedited by the effects of erysipelas, pyemia, and hospital gangrene.

The first effect of dry, cold air is a sense of numbness and weight with a peculiar prickling or tingling, and an afflux of blood to the surface, giving it a lively reddish appearance. If the impression be maintained for any length of time, the parts become stiff and perfectly insensible; and the blood, retreating from the surface, leaves it of a pale, whitish aspect, contrasting strikingly with the previous discoloration. When the cold is intense, and suddenly applied, so as speedily to overwhelm the parts, the surface occasionally exhibits a mottled appearance, depending upon the presence of coagulated blood in the subcutaneous veins.

The effects of moist cold are very similar to those of dry cold. Upon immersing the hand, for instance, in iced water, there is generally an immediate rush of blood to the surface, and a decided augmentation of its color, soon succeeded by an unpleasant tingling sensation and a marked degree of numbness. By and by, however, the surface becomes white, the skin contracts, exquisite pain arises, and the whole limb sensibly shrinks. There is thus, in fact, no essential difference in regard to the effects of these two varieties of cold; and the reader cannot fail to observe how closely the first impressions of both resemble those produced by the application of artificial heat, especially in its dry form.

All parts of the body are liable to suffer from the effects of cold; excepting, however, those rare cases, where the impression has been maintained for an unusual length of time, the toes, feet, heels, fingers, hands, nose, and ears, together with the lips and cheeks, will be found to be more frequently affected than any other parts. Accidents of this description are most common among the poorer classes, those wretched beings whose system is broken down by starvation, intemperance, and every kind of exposure and hardship, calculated to depress the vital powers, and predispose to the development of disease. Sailors and the boatmen on our lakes and rivers are particularly prone to frost-bite, and there are few seasons that do not furnish a large supply of such cases.

The primary effects of cold upon the general system are those of an agreeable stimulant; the circulation is increased in force and frequency, a slight glow pervades the surface, and the individual is universally exhilarated. By and by, this agreeable feeling is changed into one of pain and torpor; the brain is oppressed as if under the influence of a powerful narcotic; the whole body is cold and benumbed; and the person, overwhelmed by drowsiness, is obliged to make the most powerful efforts to keep awake. If, in an unlucky moment, he should yield to his inclinations, away from friends and assistants, he sleeps to wake no more; the blood rapidly settles in the internal organs; the nervous fluid ceases to be generated; the respiration becomes heavy and stertorous, and death takes place very much as in ordinary apoplexy. Should the individual, after long and severe exposure, be suddenly brought into a hot room, or placed near a fire, he will run the risk of speedily perishing from asphyxia, brought on by the repulsion of the blood to the brain and lungs; or, should he survive a short time, the frost-bitten parts will be seized with gangrene, the spread of which, as observed by Larrey, is often so rapid and striking as to be perceptible by the eye.

Such are some of the more important local and constitutional effects of

cold, when applied in its more severe and protracted forms. As just seen, it may prove destructive both to the part and system, or, reaction taking place, the patient may recover, although he will be likely afterwards to suffer more or less in various parts of the body, especially the feet, ears, nose, and fingers, from the secondary effects of his accidents, which are often as distressing to him as they are perplexing to the practitioner.

The *treatment* of frost-bite requires no little judgment and adroitness to conduct it to a successful issue. The great indication is to recall the affected parts gradually to their pristine condition by restoring circulation and sensibility, in the most gentle and cautious manner, not suddenly, or by severe measures. The first thing to be done is to immerse the part in iced-water, or to rub it with snow, the friction being made as carefully and as lightly as possible, lest over-action be produced in a part necessarily greatly weakened. If no ice or snow be at hand, the coldest well water that can be procured must be used; and if immersion be inconvenient, wet cloths are applied, with the precaution of maintaining the supply of cold and moisture by constant irrigation. Moderate reaction is aimed at and fostered. All warm applications, whether dry or moist, are scrupulously refrained from; the patient must not approach the fire, immerse his limbs in hot water, or be even in a warm room. Attention to these precepts is of paramount importance, and should on no account be disregarded, since its neglect would be almost certainly followed by mortification or other disastrous consequences.

As soon as the natural temperature has been in some degree restored, slightly stimulating lotions will be found serviceable, such as weak solutions of camphor, soap liniment, or tincture of arnica with the addition of a few drops of ammonia to each ounce of fluid. The parts are placed at rest, in an easy and rather elevated position, and lightly covered with a blanket, or, what is better, exposed to the warm air of the apartment, there being now no longer any necessity of keeping the patient in a cool room, as there was in the earlier stages of the treatment. Some mild cordial may now also be given in small quantity, and the patient may eat a little warm gruel or panado. If the local reaction threaten to be severe, it must be checked by astringent and cooling lotions, by attention to position, a properly regulated diet, and the exhibition of a purgative. For incipient mortification, consequent upon cold, the best remedy is dilute tincture of iodine.

Dr. Hayes, the companion of Dr. Kane in his last Arctic voyage, gives an account of a mode of treatment of frost-bite pursued by the Esquimaux, which deserves brief mention, although it does not differ essentially from that just laid down. A native, says the writer, who had his leg frozen above the knee, to such an extent that it was stiff, colorless, and apparently lifeless, was placed in a snow-house at a temperature of 20° below zero. The parts were now bathed with ice-cold water for about two hours, and then enveloped in furs for about twice that period. At the end of this time frictions were commenced, first with the feathery side of a bird skin, and then with snow, alternately wrapping the limb in furs, and continuing the rubbing for nearly twenty-four hours. The limb was now carefully covered, and the temperature of the room elevated by lamps above zero. On the third day the man was removed to his own house, and in seventy hours he was able to walk about, with only a slight frost-bite on one of his toes.

When a person has been overpowered by cold, or is nearly frozen to death, the attempts at restoration must be conducted upon the same general principles as when he is suffering merely from the local effects of cold; that is, he should be put in a cool room, and be gently but efficiently rubbed with flannel, wet with brandy, spirits of camphor, or ammoniated liniments, gradually followed by dry frictions and warm covering. If he can swallow, brandy should be given by the mouth, or this or some similar article should be thrown

into the rectum ; stimulants should be cautiously applied to the nose, especially snuff, and sinapisms to the precordial region, the stomach, and spine. As the circulation and respiration improve, the temperature of the apartment may be gently elevated, and warm broths, or wine-whey, or, what is better, warm toddy, administered. The efforts at resuscitation should not be discontinued too soon, since they have occasionally been crowned with success long after all reasonable expectation of recovery had ceased. The practice formerly recommended of immersing the whole body in cold water, under these circumstances, cannot be too much deprecated, as it cannot fail to prove exceedingly injurious.

Pernio or chilblain.—The secondary effects of cold are usually described under the name of *pernio* or *chilblain*, and there are several varieties of form in which they may present themselves, as the erythematous, ulcerated, and gangrenous. These effects may supervene upon slight exposure, and hence they are occasionally met with among our better class of citizens, the parts most liable to suffer being the toes, heel, instep, ears, nose, and fingers. They are usually preceded by slight vesication, and by burning, tingling sensations, as if the surface had been held near the fire. These effects may soon subside, or they may prove a source of annoyance for many months ; in general, however, they are of a transient nature, but the parts, instead of getting completely well, remain weak and congested, and are liable to new attacks of suffering from the slightest causes. Any sudden change in the weather is extremely prone to bring on a paroxysm ; the affected structures become red, or of a dusky purplish hue, swollen, painful, and œdematous ; the epidermis is often raised into little blisters, distended with yellowish, or sanguinolent fluid ; and there are few cases in which itching, sometimes almost insupportable, is not a prominent symptom, the patient feeling as if he could tear the parts to pieces.

Ulcers not unfrequently form, as an effect of frost-bite ; generally preceded by slight vesication, they are superficial, irritable, and indisposed to heal, the discharge being of a thin, ichorous character ; the parts around are red, inflamed, and congested, and the erosive action often spreads over a considerable surface. In some cases it extends very much in depth, and may thus ultimately invade a neighboring joint, bone, tendon, or muscle.

Gangrene is more frequently a primary than a secondary effect of frost-bite ; the affected part is of a dark brownish, or blackish color, cold, insensible, and exquisitely fetid ; in some cases the slough is dry and shrivelled, like a rotten pear, in others, it is moist and expanded. In persons of weak constitution, and in the more remote parts of the body, where the circulation is naturally very feeble and languid, it often spreads to a considerable extent ; but in general its tendency is to limit itself to a small space. When considerable, it may invade all the component tissues of a limb, the soft parts as well as the bones and joints.

Pernio may, as already stated, last for many years, alternately disappearing and recurring under the slightest local and constitutional changes. Atmospheric vicissitudes generally exercise a marked influence upon these attacks, the patient being often a complete barometer ; a combination of cold and moisture is particularly prejudicial. During the dry weather of summer the disease not unfrequently goes off spontaneously, but is sure to return on the approach of winter. In this manner life may be rendered perfectly miserable, especially when the chilblain is seated in the feet, the patient being hardly ever able to walk about with any degree of comfort or satisfaction.

The *treatment* of *pernio* is generally too little regarded by the practitioner, who, knowing that it never endangers life, is too apt to overlook its just claims to his sympathy. Of the various remedies that have been, from time to time, recommended for its relief, those that are of a slightly stimulating

character are most entitled to confidence. The milder forms of the disease may often be promptly relieved by immersion of the part in cold, or ice water, followed by a pretty strong solution of acetate of lead and opium, or, what is preferable, the dilute tincture of iodine, which, on the whole, I have found to be more beneficial than any other article. Sometimes prompt relief follows the application of carded cotton, soap liniment, spirits of camphor, or some other stimulating embrocation.

When blisters form they should immediately be opened, and the affected surface freely touched with solid nitrate of silver, or painted with tincture of iodine. Not unfrequently excellent effects follow the use of the dilute citrine ointment, or ointment of the oxide of zinc. In obstinate cases I have derived great advantage from a blister, retained until thorough vesication was produced.

The gangrenous form of *pernio* must be treated upon general principles. Feter is allayed by the chlorides, and sloughs are removed as they become detached. Amputation is refrained from until there is a well-marked line of demarcation.

In all cases proper attention must be paid to the general health; the diet must be regulated, the bowels evacuated, and the secretions improved and restored. There is reason to believe that great temporary suffering is often induced by neglect of these precautions.

SECT. VII.—MORBID GROWTHS.

The skin is subject to a variety of morbid growths, some of a benign, others of a malignant character. Among the more simple formations belonging to the former class are warts, corns, horny excrescences, and the so-called sebaceous tumor, which, as its name implies, has its seat in the sebaceous follicles, so common in different regions of the cutaneous surface. Fibrous, fibro-cellular, or fibro-plastic growths are also sometimes met with, although they are infrequent; they are never malignant, but are extremely apt to return after extirpation. The most common and interesting development of this description is what is termed the keloid tumor, incidentally referred to in the chapter on the general history of morbid growths. Finally, the skin is occasionally remarkably hypertrophied, either congenitally, or as a result of interstitial deposits.

The number of malignant growths of the cutaneous tissues is quite considerable, and, as they are of frequent occurrence, and often followed by disastrous consequences, it becomes necessary to study them with more than ordinary care and attention. The principal affections, recognized by pathologists, as appertaining to this class of diseases, are scirrhus, melanosis, eiloid, lupus, epithelioma, and the peculiar bark-like formation first described by Dr. Warren under the name of lepid.

1. WARTS OR VERRUCOUS GROWTHS.

Warts are those peculiar excrescences, or prominences, so often seen upon the hands and face of young persons, although the old are by no means exempt from them. They consist essentially of a hypertrophous condition of the papillary structure of the skin, and sometimes occur in such numbers as to constitute a genuine verrucous diathesis. When this is the case, they are not only developed with remarkable rapidity, but are apt to attain an extraordinary size. Of the exciting causes of warts, nothing is known; they often occur in several members of the same family, and instances are observed in which they betray a hereditary tendency.

A wart is a hard, insensible excrescence, generally of a conical shape, more or less movable, and attached by a broad base, although sometimes the reverse is the case, the union being effected by a very narrow pedicle; its surface is rough, fissured or tuberculated, and usually a few shades darker than the adjacent skin; its size seldom exceeds that of a common pea. When cut, it is painful, and bleeds somewhat. Its structure is essentially cellulofibrous. The fluid which follows a section of a body of this kind, has been supposed, but erroneously, to be contagious, or inoculable. A wart on the face, arm, or shoulder sometimes becomes the seat of carcinoma, especially when it is constantly rubbed or irritated.

The *treatment* of warts is very simple. In young persons, in fact, they often disappear spontaneously. The best local remedy is chromic acid, with equal parts of water, applied with a glass brush. It instantly turns the skin black, and forms an eschar, which drops off in six or eight days, leaving a healthy, granulating sore, which soon heals. Tincture of iodine, acetic acid, bichloride of mercury, and sulphate of copper, also, answer an excellent purpose. When a verrucous diathesis exists, recourse must be had to the exhibition of arsenic, or Donovan's solution. Excision is necessary when a wart displays a tendency to malignancy.

2. SEBACEOUS TUMORS.

The sebaceous tumor, essentially consisting of an enlargement of a sebaceous gland with a retention of its secretions, has been described under various names, founded either upon the character of its walls, the fancied nature of its contents, or the kind of structure in which it originates; as encysted, atheromatous, meliceric, steatomatous, and follicular. *Wen* was the familiar appellation by which it was known by the older surgeons. The term *sebaceous*, being expressive of the true situation of this variety of tumor, seems to me to be preferable to any other, and I shall therefore retain it on the present occasion.

The manner in which the sebaceous tumor is formed is easily explained. The first link in the morbid chain is the obstruction of a sebaceous gland, or cutaneous follicle, either in consequence of adhesive inflammation, or the inspissated condition of its own secretion, thereby offering a mechanical impediment to its escape. Being thus forcibly retained, the matter gradually increases in quantity, and as it does so it necessarily presses everywhere upon the walls of the gland, which, in time, expands into a strong sac, fig. 187, varying in size from that of a pea up to that of a small orange. Essentially, then, the tumor is an encysted tumor, consisting of an enlarged or hypertrophied condition of the sebaceous gland, and of an altered state of its own secretion, both the direct and inevitable result of the closure of the natural outlet preventing the evacuation of the affected structure.

The *contents* of the sebaceous tumor are extremely variable, both in color and consistence; in general, they are thick and whitish, looking and feeling very much like a mass of lard or tallow; occasionally they present the appearance and consistence of honey; and cases are met with

Fig. 187.

Sebaceous tumors of the scalp; one at *a* being laid open to show its cyst and contents.

in which they bear a very close resemblance to putty, or a thick mixture of flour and water. Sometimes the contents of a tumor of this kind are thin, almost watery, and exceedingly offensive. At other times, again, short

Fig. 188.

Cyst of a sebaceous tumor, with hairs in its interior.

hairs, very soft, and having well-formed roots, are found in them, as represented in fig. 188.

Pilous matter is most commonly found in sebaceous tumors about the forehead and eyelids. I have repeatedly seen it in these situations, and in several instances in very young subjects. It is not likely that the hairs that are found here are developed in the morbid growth; on the contrary, the probability is that they are intercepted during the process of occlusion of the cutaneous follicle, and that, after they have fallen into the cavity of the cyst, they are capable of attaining a certain deve-

lopment, but ultimately cease to grow, and so become effete matter.

The sebaceous tumor sometimes contains calculous matter, either in part or in whole; consisting of phosphate and carbonate of lime, cemented together by a minute quantity of animal substance. A case has been recorded where the integuments of the buttocks were completely studded with small collections of this description; they occurred in a young lad, and evidently had their seat in the skin-follicles. Similar formations have been observed on the forehead, scalp, nose, shoulders, trunk, and scrotum.

The *cyst* of this variety of tumor, at first very thin, soft, and delicate, becomes, in time, quite thick and dense, often resembling a fibrous membrane; and instances are occasionally met with, although they are rare, in which it is transformed into fibro-cartilage, cartilage, and even bone. In cases of long standing, its thickness is sometimes very remarkable. Externally the cyst is rough, and more or less intimately connected with the surrounding parts by cellular tissue, which is not unfrequently considerably condensed; internally, on the contrary, it is generally smooth and glistening, very much, for example, like the inner surface of the dura mater. Small sacs are sometimes observed in its interior, and I have several times seen indistinct partitions thrown across it, the result, apparently, of plastic, organized deposits.

The sebaceous tumor has but few vessels, and even these are always very small; hence its progress is invariably tardy, and its removal is never attended with any hemorrhage. Little or no pain accompanies its development, and it never manifests any malignant tendency. Sometimes, however, it ulcerates, and becomes the seat of a good deal of local irritation and of a highly disagreeable, offensive discharge. When seated on the scalp, the steady, persistent pressure of such a tumor may occasionally partially indent the osseous tissue, as I have seen in several instances that have fallen under my observation. Although the diseased follicle is originally situated in the substance of the skin, the cyst, as it increases in size, gradually pushes itself beneath it, so that the connection between them is ultimately completely destroyed. Meanwhile, the skin itself becomes attenuated, and often, in great measure, deprived of hair, especially when seated on the scalp, where, particularly in cases of long standing, the surface is often quite bald.

The degree of *mobility* of the morbid growth is extremely variable, depending upon its age and volume, but, above all, upon the amount and laxity of the cellular tissue in the structures in which it is developed. Its shape is for the most part globular; but when it is subjected to considerable pressure, it is not uncommon for it to have a compressed, flattened appearance.

The most common *sites* of the sebaceous tumor are the face, forehead, and scalp. It is also met with on the neck, eyelid, shoulder, back, buttock, and

scrotum. On two occasions I have seen it on the prepuce, the patients being small boys who had been circumcised at the usual period at which that operation is performed according to the rites of the Jewish Church. It is very seldom that the sebaceous tumor is found on the extremities.

The *number* of sebaceous tumors, although usually small, is extremely variable. Sometimes there is only one, but it is not at all uncommon to see as many as five or six on the same person. In one instance, that of a man aged forty, I counted upwards of two hundred, most of them being situated upon the head, face, and neck. Nearly all began when he was quite young, soon after bathing in cold water. They were of the meliceric kind, the contents of many being visible at the enlarged and partially obstructed follicle, where they had concreted, and presented a yellowish, dirty, wax-like appearance. They were of a globular or ovoidal shape, and varied in volume from that of a pea up to that of a hen's egg.

Occasionally these tumors occur in several members of the same family; and now and then they display an evident *hereditary* tendency, as in a case which fell under my observation in 1844, in which the disease existed upon the scalp of a young woman of twenty-seven, and also upon that of her father, a paternal aunt, and her paternal grandmother. The tumors were, respectively, from four to seven in number, and varied in volume from that of a marble to that of a walnut. More recently two other instances of a nearly similar character have come under my notice.

The *diagnosis* of the sebaceous tumor is sufficiently easy. Its chronic march, indolent character, soft, doughy consistence, mobility, and subcutaneous situation, together with the absence of enlargement of the subcutaneous veins, and the normal appearance of the skin, always serve to distinguish it from other morbid growths.

The only *remedy* for this variety of tumor is thorough excision, care being taken that not a particle of the cyst or wall be left behind, otherwise repullulation, to a greater or less extent, will be inevitable. If the tumor be situated upon the scalp, a single longitudinal incision may be made across it, the flaps being dissected off from each side, and the morbid mass lifted out bodily, without exposing its contents. In most other regions, however, the best plan is to lay the tumor open from within outwards, turn out its contents, and then tear away the cyst. When the integuments are diseased, it may be proper to include the altered structures in an elliptical incision. However performed, the operation should never be undertaken without some preparation of the system, as I have repeatedly known it to be followed by erysipelas.

3. MOLLUSCOUS TUMORS.

There is a form of cutaneous tumor, to which, from its fancied resemblance to the knots on the bark of the maple, the term molluscosus has been applied. When fully developed, it is about the size of a ripe currant, which it further resembles by having a central depression upon its surface, caused by the peculiar arrangement of its contents. Their form is variable; some are round or oval, some elongated, and as if compressed, some pedunculated, and some wallet-shaped. In color, they are usually red, reddish-brown, or dusky yellowish; in consistence, soft and spongy.

Molluscosus tumors occur upon various parts of the body, as the face, neck, back, shoulders, nates, and extremities, and often exist in such immense numbers as to constitute a genuine molluscosus diathesis. What is singular is, that they are sometimes met with in several members of the same family; a circumstance which, together with their rapid and consentaneous development, has led to the idea of their being occasionally contagious, or communi-

cable from one person to another by contact. Whether this, however, is really so or not remains to be proved.

The disease, although it has been noticed at a very early period, as in children under five years of age, is most common in adult and elderly subjects. Its progress is frequently very rapid, a large portion of the surface becoming studded with tumors in a few weeks. How the disease is excited we are uninformed, nor is anything known of its predisposing causes. The immediate influence under which it is developed is inflammation of the sebaceous glands, giving rise to a rapid secretion of sebaceous matter, which, becoming too thick to escape at the natural outlets, accumulates in the interior of these reservoirs, pressing asunder their walls, and giving them a lobulated appearance, as is rendered evident on a section of them.

The *contents* of these little tumors consist mainly of epidermic scales, in union with ovoid, oblong, or cuboid cells, heaped together like a pile of eggs, and occupied either by granular matter, oil globules, or a peculiar homogeneous substance, of whose nature we are ignorant.

Left to themselves, molluscos tumors nearly always pass into ulceration, generally beginning at their summits, and gradually progressing until their contents are completely discharged, when the parts usually readily heal; or they are invaded by gangrene, which occasionally extends deeply into the subjacent tissues, and thus leads, in the event of recovery, to disfiguring scars. Finally, cases occur in which the tumors become atrophied, or transformed into little pendulous wart-like excrescences.

The *treatment* of these molluscos formations is best conducted by the topical use of stimulants, of which the most efficacious are tincture of iodine, acid nitrate of mercury, sulphate of copper, chloride of zinc, and chromic acid, all more or less diluted to adapt them to the exigencies of each particular case, or the tolerance of the parts, the object being rather to produce a sorbefacient than an escharotic effect. In general, it will be found that brushing the surface of the tumor over freely once a day with the tincture of iodine will not only promptly arrest its development, but rapidly promote its removal. Laying open the morbid growth, and touching the raw surface slightly with the solid nitrate of silver, is a plan highly recommended by some practitioners. The most expeditious method of all, however, is to cut it away with the knife, or to effect its strangulation with the ligature; but it is obvious that such a procedure can only be adopted with any degree of propriety when the number of tumors is very small.

Constitutional treatment is not to be neglected in this disease. Occasionally the molluscos tumor in great degree, if not entirely, disappears, simply under the influence of a change of air, a judiciously regulated diet, and attention to the bowels and secretions. When the general health is much disordered, the first object should be to amend it by the interposition of suitable remedies, medicinal and hygienic. Cleanliness is of great importance, and must not be overlooked. If there be a scorbutic state of the blood, iron and quinine, with sub-acid drinks and vegetables, will be indicated.

4. MOLES.

Moles are congenital spots, occurring upon various portions of the external surface of the body, usually of a dark, grayish, blackish, tawny, or brownish color, and closely covered with short, thick, almost bristly hairs. They occasionally project somewhat above the surrounding level, but in general this is not the case; they are usually a little harder than the natural skin, and they present themselves in various forms, of which the round and oval are the most common. Some persons seem to be remarkably prone to the formation of moles, and when this is the case it is not uncommon to see a number of

them scattered over different parts of the body. When single, or existing in small numbers, they generally occur on the face, shoulder, neck, or arm. Their size varies from that of a three-cent-piece to that of a dinner-plate.

The color of these spots is due to a redundant deposit of the natural pigment of the mucous network of the skin, with an altered condition of the proper substance of the dermis, and probably also of the cuticle and of the hair follicles.

Long-continued local irritation, such as is caused by friction, pressure, or the want of cleanliness, may occasionally awaken ulceration in these bodies, but in general they remain perfectly stationary and innocuous. A few years ago, I excised a mole from the back part of the arm of an old gentleman, of upwards of eighty, which had been a source of annoyance to him, more or less, for thirty years. It had latterly become ulcerated, had often bled, and was the seat of a very fetid, nasty discharge. It was included in an elliptical incision, the parts healing kindly, and there being no return of the disease.

It is not often that moles become the subjects of surgical interference; it is only, in fact, when they cause serious disfigurement, or when they fall into ulceration, that professional aid is sought. It has been proposed to get rid of them by mild caustic applications, as solutions of ammonia or caustic potassa; but as such a procedure might be followed by the development of keloid, the best plan always is to remove them with the knife, the morbid structures being included in an elliptical incision, the edges of which are afterwards healed, if possible, by the first intention.

5. HYPERTROPHY OF THE SKIN.

Hypertrophy of the skin is now and then observed, chiefly, if not exclusively, as a congenital affection. It is characterized by a soft, pendulous condition of the skin, which hangs off in loose folds from the surface to which it is naturally attached, as if it had been stuck on without any special object. In all other respects, the integument is apparently perfectly normal, there being not the slightest alteration of color, consistence, or structure, at least so far as we are enabled to judge from inspection. The most common sites of hypertrophy of the skin are the nates, scrotum, prepuce, and vulva. The most remarkable example that I have met with occurred on the back of the neck in a female child, upwards of a year old, as the result of a congenital vice; the integument formed a large pendulous mass, of a doughy, inelastic feel, extending from ear to ear, and causing a very unseemly deformity. The child was in other respects well formed, and, with this exception, remarkably beautiful.

When the hypertrophied integument forms an unsightly mass, or when it proves inconvenient by its bulk, the surgeon will be appealed to for advice, and under such circumstances it may become necessary to remove the offending structures. For this purpose, the parts should, if possible, be included in an elliptical incision, care being taken not to cut away so much of the skin as to interfere with reunion. If the tumor be very large, and the patient of tender age, recourse to the knife should be postponed until the constitutional stamina are sufficiently developed to enable the child to bear the shock attendant upon so severe an operation. Special pains should be taken to guard against hemorrhage.

6. ELEPHANTIASIS, OR HYPERTROPHY OF THE SKIN AND CELLULAR TISSUE.

Arabian elephantiasis, Egyptian sarcocoele, or the glandular disease of Barbadoes, as it is variously denominated, although uncommon in this country, deserves passing notice not less on account of the hideous deformity which it

induces than its obstinate and intractable character. The favorite seat of this singular disease is the leg, which often acquires an enormous volume and a most grotesque appearance, causing a striking resemblance to the leg of the elephant, whence its name. It is not, however, confined to this part of the body; on the contrary, it is liable to occur in various organs, particularly

Fig. 189.

Elephantiasis of the leg and foot.

the scrotum, prepuce, and pudendum, which, in consequence, sometimes acquire an enormous bulk. A tumor of this kind, presented to me by Dr. Bozeman, and removed by him from the genital organs of a negro, weighed forty pounds; and Clot-Bey extirpated one, occupying a similar situation, which weighed one hundred and ten pounds. The adjoining cut, fig. 189, affords an illustration of this disease as it manifests itself in the foot and leg.

The disease is met with in both sexes, but much oftener in men than in women; it occurs in various races of men, and frequently begins at an early age, although it is most common in young adults.

In this country and in Europe the affection is very rare, but in certain parts of Asia, Africa, Syria, Arabia, Egypt, and the West Indies, it is extremely prevalent and sometimes observes an endemic tendency.

Of the *causes* of elephantiasis nothing satisfactory is known. The disease is evidently of an inflammatory character, but how this is brought about we are entirely ignorant. It has been supposed that it is owing to an obstruction of the principal veins of the affected parts, impeding the return of blood, and thus creating congestion and irritation, followed by plastic exudation in the interstices of the cutaneous and cellular tissues. From the fact that attacks of erysipelas are not uncommon in the earlier stages of the disease, or, rather, that this affection not unfrequently precedes the outbreak of elephantiasis, it has been imagined that it is essentially dependent upon the disturbance which it occasions in the nutritive and secretory functions of the parts. Others, again, have been led to conclude that the malady essentially consists in an inflammation of the lymphatic vessels, attended with plastic deposits within and around these vessels, whereby their caliber is choked up, and, as a necessary consequence, their contents are prevented from discharging themselves into the thoracic duct. This view is, on the whole, extremely plausible, for it really comprises all the cardinal elements of a consistent theory, which the others certainly do not. That there is, in this disease, serious mechanical obstruction of some kind or other, is unquestionable, and I know of none that would be more likely to produce such a result than compression of the lymphatic vessels. If, then, it is allowable, in the existing state of the science, to frame a doctrine in respect to the origin of an affection so obscure as elephantiasis is acknowledged to be, we may conclude that it is an inflammation of the absorbents, attended with obstruction of their caliber, and deposits of plastic matter, which, becoming gradually organized, is ultimately converted into an analogous fibrous tissue, thereby completely changing the character of the primitive structures, especially the cutaneous and cellular.

If the affected structures be carefully examined by *dissection*, the following

appearances will be observed: The epidermis is very much thickened, rugose, and so firmly adherent as to come off with difficulty. The true skin is of a whitish color, striated in its texture, and very hard and dense, cutting almost like the rind of bacon. In many cases it is from a quarter of an inch to half an inch in thickness. The papillæ are enormously hypertrophied, and of an elongated shape, forming large bodies which stand off prominently from the substance of the true skin. The cellular tissue is completely changed in its character; its areolæ are obliterated, and their place is supplied by a dense, inelastic fibroid substance, exhibiting none of the properties of the original. In elephantiasis of the leg, the muscles, compressed by the new matter, and deprived of activity, are found to be wasted, pale, and in a state of fatty degeneration. The bloodvessels are generally very much enlarged, and hence, when an attempt is made to extirpate the morbid mass, as when it occupies the genital organs, tremendous hemorrhage is to be expected. In some cases, however, the larger veins are obliterated, especially in elephantiasis of the lower extremity. The principal nerves have a white, flattened appearance, and are apparently augmented in size.

Elephantiasis often, if not, indeed, generally, comes on suddenly and unexpectedly, without any apparent local or constitutional cause. At times, however, its development is directly traceable to local injury, as a blow, sprain, or contusion; and in quite a number of cases it has seemingly followed upon the protracted immersion of the parts in cold water, the occupation of the individual compelling him to pursue such a habit. The symptoms are at first of an inflammatory character; the affected surface, red and painful, pits on pressure, and imparts a nodulated, cord-like sensation to the finger; the subcutaneous cellular tissue is hard and infiltrated; and the movements of the diseased structures soon become stiff, awkward, and embarrassed. Sometimes red lines or streaks extend along the course of the lymphatic vessels, as high up as the nearest ganglions, which are themselves more or less tender and swollen. Considerable febrile commotion is generally present, but this soon subsides, and the disease gradually lapses into a chronic state, which often ceases only with the patient's life.

The *diagnosis* of elephantiasis is unmistakable; there is no other affection which bears any resemblance to it. Once seen, it can never be forgotten. The part is not only enlarged, but enormously increased in weight and consistence; it feels heavy and cumbersome, and is as hard, dense, unyielding, and rough as the leg of the animal from the resemblance to which it has derived its name. The surface of the skin, usually much darker than natural, is fissured, grooved, nodulated or tuberculated, and completely deprived of its normal sensibility. Sores occasionally form upon it, and, gradually spreading in diameter and depth, add greatly to the local distress. Sometimes small, hard, shining scabs exist, not unlike those of ichthyosis. The chronic march of the disease, the remarkable deformity of the affected parts, and the peculiar condition of the skin will always prevent it from being confounded with anasarca, the only lesion which bears any resemblance to it.

The disease, once fully established, may remain completely stationary for years, or even during the remainder of life, or it may go on gradually increasing until the affected parts have acquired a volume and a weight many times beyond the natural state. Even under these circumstances, however, the suffering is chiefly of a mechanical character; the general health often continuing good to the last. It is only, in fact, when intractable ulcers form, and there is an abundant discharge of pus, that the constitution is likely to give way under the local drain and irritation. The prognosis is of course most unfavorable in those countries where the disease is endemic; in Europe and the United States, where it occurs only as a sporadic affection, very few die of it.

The *treatment* of elephantiasis is, at best, very unsatisfactory, however early it may be commenced, or however perseveringly and judiciously it may be conducted. Regarding it as essentially consisting in an inflammation of the lymphatic vessels, or of these vessels and the veins, the most rational plan of treatment that suggests itself is the antiphlogistic, of which leeching, blistering, and the application of tincture of iodine are among the more important and reliable means. The object, in the first instance, should be to reduce local action, and thereby prevent subversion of structure. Hence the sooner these remedies are applied the more likely shall we be to obtain resolution. As a sorbefacient, there is no article in the whole *materia medica* that holds out such strong hopes of relief as tincture of iodine, used either pure or variously diluted to suit the exigencies of each particular case. It not only promotes the removal of effused fluids, but produces a powerful revulsive and antiphlogistic action, and should be employed, steadily and persistently, for many months together. The effects of the treatment will be greatly augmented, if, superadded to it, the parts be occasionally scarified, to relieve engorgement, kept at rest in an elevated position, and well bandaged, strapped, or mechanically compressed. Inunction with mild mercurial ointment also sometimes proves beneficial; and, in the earlier stages of the complaint, lotions of acetate of lead, hydrochlorate of ammonia, and of rectified spirits, are worthy of trial, especially when there is much pain, with a tendency to rapid effusion and organization.

Constitutional treatment is not to be disregarded in this disease. It will, in general, greatly assist the action of local remedies if the patient be put under proper restraint in respect to his diet, if he take occasionally a brisk cathartic, and if he be kept pretty constantly under the influence of the saline and antimonial mixture, with a few grains of calomel every night at bedtime, until slight ptyalism is produced. General bleeding might even be advantageously employed at the beginning of the treatment, if there be a robust and plethoric state of the system.

When the malady has attained an extraordinary degree of development, or has gone on for many years progressively increasing, or has remained stationary for a long time, no treatment of which we have at present any knowledge, not even ligation of the principal arteries of the affected tissues, will be likely effectually to eradicate the disease, or, more properly speaking, enable the parts to resume their primitive condition. All topical and general means are, under such circumstances, absolutely unavailing; and the utmost that can reasonably be expected from cutting off the supply of blood to the part is a diminution of its size, not a complete restoration of it to health. Professor Carnochan deserves great credit for the laudable effort which he has made, in several cases of elephantiasis of the leg, to arrest the morbid growth, and ultimately cause its absorption by ligating the femoral artery; but, although his patients, three in number, were, from all accounts, much benefited, it is questionable whether, in any, a complete cure has been effected. In the summer of 1857, I was present at the Philadelphia Hospital, when Dr. Campbell, then surgeon-in-chief, performed an operation of this kind upon a negro, aged about fifty, who had long been afflicted with this complaint in one of his legs; but the result was not at all encouraging. I saw the man occasionally afterwards for many months, and during my last visit to him, more than a year after the operation, the limb had not undergone any material change, either in volume or consistence. Indeed, such a procedure could hardly be expected to eventuate favorably, when we take into consideration the excessive disorganization of the parts and the astonishing enlargement of the branches of the femoral artery. The operation might, if performed early in the disease, and if conjoined with the use of sorbefacients and the bandage,

be worthy of further trial; but I should certainly not feel inclined to recommend its indiscriminate employment.

When the diseased mass is very large, greatly incommoding by its weight and bulk, and entirely unamenable to treatment, the only resource is removal with the knife. If it occupy a limb, amputation will be both a safe and a facile procedure, but if it involve the scrotum, penis, or pudendum, excision may prove not only extremely difficult, but exceedingly perilous, life being endangered, in the first instance, by shock and hemorrhage, and afterwards by pyemia and exhausting suppuration.

7. KELOID TUMORS.

The keloid tumor, so called from its fancied resemblance to a crab, is an affection of the skin, first accurately described by Alibert, in his treatise on cutaneous diseases, in 1810. It is characterized by the existence of hard, semi-elastic, prominent excrescences, of a cylindrical or rounded form, more or less discolored, and the seat of an unpleasant itching sensation. Processes, roots, or branches usually extend from it into the neighboring parts, the whole looking very much like the cicatrice of a burn.

The disease is generally described as being extremely infrequent; but judging from my own experience I am far from thinking that this is the fact. I have notes of at least thirty cases, and many more have come under my observation of which I have neglected to keep a record. It occurs in all classes of society, in both sexes, in nearly all parts of the body, and at almost all periods of life. The youngest case of it that has been under my charge was that of a little girl three years and a half old; on the other hand, I have repeatedly seen it after the age of sixty. A number of my patients were negroes; but whether they are more subject to the disease than whites I am not prepared to affirm, although this is highly probable.

The exciting *causes* of keloid are not always the same. In some cases, though these constitute a marked minority, it arises spontaneously, and is then very liable to show itself in various parts of the body, as if the individual was laboring under a real keloid diathesis. Of this form of the affection I have seen two remarkable examples. In general, keloid succeeds to some local injury, sometimes of a severe, but more commonly of a trivial character, as, for instance, a scratch, puncture, or abrasion. In four of my cases it supervened, respectively, upon the operation of cupping, the application of a blister, the contact of nitric acid, and the cicatrices left by small-pox. In another instance it broke out upon a vaccine scar. In a young lady of seventeen, it was produced by the application of caustic potassa, employed for destroying an enlarged lymphatic ganglion of the neck. In several cases I have known it to follow the use of the knife in the extirpation of tumors. Thus, in an elderly lady from whom I removed the right mammary gland, two years and a half ago, two well-marked keloid growths came on, soon after the operation, at the site of two small incisions made to ease one of the flaps with a view to more accurate approximation; and the occurrence of the disease after the ablation of keloid tumors both at the line of union of the edges of the wound and at the parts transfixed by the pins used in introducing the twisted suture, is familiar to every one who has seen much of this affection. But the most common causes of keloid, so far as my observation and reading extend, are burns and scalds; the great majority of the cases that have come under my notice having been produced in this way.

The period which intervenes between the occurrence of the exciting cause and the actual development of the disease is altogether uncertain; in many cases it is quite short, not exceeding a few weeks, or, at farthest, a few months; on the other hand, however, the time is occasionally much longer.

In several of my cases, the tumors had acquired a large bulk in the space of a single year. Once fairly commenced, the disease generally proceeds with marked rapidity, especially when it is the result of some traumatic cause; the same is also true, at least in some instances, when it arises spontaneously. Thus, in an instance recently under my observation, an immense number of these excrescences appeared spontaneously upon different parts of the body within a few months after the first manifestation of the morbid action.

The peculiar *external characters* of keloid will be readily understood from the annexed drawing, fig. 190, taken from a colored man upwards of fifty

Fig. 190.

Keloid tumors.

years of age, whose body was literally covered with morbid growths of this kind. They were particularly numerous on the neck and trunk, both in front and behind, and also on the shoulders and arms, while the forearms, hands, and lower extremities were entirely exempt from them. In size they ranged from that of a small Lima bean up to that of a sausage, from six to eight inches in length. They were of all shapes; some round or cylindrical, some elongated and flattened, some angular, some crucial, some crab-like or full of processes, roots, or prongs; in short, nature seemed to have exhausted her ingenuity in devising figures for their representation. The surface of nearly all was rough, wrinkled, or puckered. Most of them projected from a line and a half to an inch and a quarter above the surrounding level; some were isolated, others ran into each other, thereby adding still farther to their grotesque appearance. Their consistence varied; most of them were remarkably hard and firm, feeling very much like a mass of fibro-cartilage, with a slight degree of the elasticity inherent in that tissue. In regard to their color, some resembled the natural skin, but the great majority of them

were several shades lighter. The intervening integument was sound up to the very borders of the keloid tumors, which were all distinctly circumscribed, and slightly movable, allowing themselves to be raised up with the thumb and index finger; only a few seemed to be completely tied down.

This remarkable case had commenced early in life, but had for years past been almost stationary. The man was well conditioned when I saw him, and his general health had all along been excellent; the only annoyance which he experienced was an itching or stinging sensation in some of the tumors, which, although at times very severe, especially when he labored under constipation or accidental overheating of the body, left him sufficient comfort for sleep and other enjoyment.

Through the kindness of Dr. Hazard, of this city, I had an opportunity, last summer, of seeing another very interesting case of spontaneous, universal keloid disease, in the person of a young gentleman, aged 18 years, a native of Cuba. Up to twelve months previously, when it first began to show itself, he had always enjoyed excellent health, and, so far as he knew, he was perfectly free from hereditary taint of every description. The tumors were, for the most part, of a rounded or oval shape, not very hard to the touch, movable, vascular, and of a dusky reddish hue. In a few places they existed as distinct ridges, from a line to an inch in width, projecting prominently beyond the level of the surrounding surface. The hands and feet were covered with them, particularly the joints of the fingers and toes; they were also found on the legs, knees, buttocks, right arm, and elbow. They were free from pain, and quite tolerant of manipulation. The general health was somewhat impaired, the youth looking dyspeptic, and laboring under partial paralysis of the left superior extremity.

In white persons the keloid tumor is generally a few shades redder than the adjoining skin; occasionally, indeed, it has a very fiery appearance, and is pervaded by numerous, delicate, superficial vessels, in a state of habitual congestion.

The *site* of the keloid tumor presents nothing of a definite character. When traumatic, it may occur in any part of the body, and the same thing, as we have already seen, may happen in the idiopathic form. It is generally supposed that it is particularly prone to appear on the chest, but, judging from my own observation, I should be inclined to doubt it.

Pathologists have made a distinction between keloid tumors by separating them into two *varieties*, the true and the spurious. The former, it is alleged, arise spontaneously, whereas the latter are always caused by some local injury, such as that already referred to. From my knowledge, however, of this disease, I am satisfied that such a division is altogether arbitrary, and, consequently, without any foundation in nature; the structure in both of the so-called varieties being perfectly identical.

Keloid, although a troublesome, is not a *dangerous* disease, inasmuch as it never degenerates into malignancy. Of all the cases that have come under my notice, not one has exhibited such a tendency. When excised, however, it nearly always returns, and that in a very short time, rising with increased activity, like a phoenix from its ashes; so that the second state is literally much worse than the first. In some cases, the tumors remain completely stationary for a long time; in others, on the contrary, they gradually advance until they have acquired a considerable bulk, when they usually become passive, and so continue for many years. Occasionally, in consequence apparently of prolonged pressure or local irritation, they take on ulcerative action, but such an occurrence is, according to my observation, very unusual.

In regard to their *structure*, keloid formations belong to the class of fibroplastic growths, described in the chapter on tumors. The fibres intersect each other in every possible direction, intercepting cells or spaces occupied

by plastic matter, of a softer nature. A section presents, to the naked eye, a whitish, homogeneous aspect, or, if the mass be very old, very much the appearance of an unripe pear or turnip. It creaks slightly under the knife, and is of a dense, firm consistence, with very little elasticity. Hardly any vessels are perceptible in its interior, but the surface of the growth is usually, as already stated, quite vascular, the vessels passing over it in distinct lines, more or less tortuous and varicose in their arrangement. The minute structure of keloid is well seen in fig. 191, drawn from one of my specimens by Dr. DaCosta.

Fig. 191.

Microscopical characters of keloid.

The *treatment* of keloid is altogether unsatisfactory. So far as I know, there is no remedy which exercises the slightest influence in arresting its progress or promoting its removal. Sorbefacients and alterants of every description, in every form of combination, and in every variety of dose, have been employed, and yet I am not aware of a solitary instance in which their exhibition, however protracted, has been followed by a cure, or even by a tendency towards such a result. The different preparations of iodine, arsenic, chloride of barium, hydrochlorate of ammonia, and other kindred articles, so serviceable in some other morbid growths, have all signally failed in effecting any beneficial changes in this. The excessive itching, burning, or stinging, which is a source of such annoyance when the tumors are large or numerous, is best relieved, according to my experience, by a proper regulation of the diet, an occasional active purgative, the exhibition of the antimonial and saline mixture with Fowler's solution of arsenic, and the frequent use of the tepid bath, either simple, or medicated with soda, potassa, common salt, or bran. Anointing the tumors occasionally with oil or mild pomatum will also prove serviceable. Everything like pressure or local irritation must be carefully guarded against. If ulceration arise, none but the most soothing remedies should be employed.

As to *excision*, my experience is decidedly opposed to it. In the many cases in which I have tried it, signal failure has been the result, the disease always returning at the site of the cicatrice within a short time after. It is only when the tumors act obstructingly, as when they impede the opening of

a natural outlet, or become a source of great disfigurement, that interference should be considered as warrantable. In some cases relief might possibly be afforded by a plastic operation, but on this point I am not able to say anything from personal experience.

8. EILOID.

The eiloid tumor is extremely uncommon, only a few cases having hitherto been met with. It was first described by Dr. John C. Warren, who gave it the present name in consideration of its peculiar coil-like disposition. In its earlier stages it presents the appearance of a small elevation, similar to that occasioned by a burn, which goes on gradually increasing, without pain, heat, redness, or ulceration, until it acquires a large bulk, and sensibly affects the general health. The rolls, in the case of the Boston surgeon, lay in close contact with each other, each being about four inches in length, the whole together looking very much like a triple coil of inflated intestine. The growth seemed to have begun on the right side of the neck by a narrow base. The patient was a negress, about fifteen years of age, whose health had not been good for some time past. The tumor, although removed along with a portion of sound skin, soon returned. When the girl was seen eighteen months afterwards, it occupied the same site, but was not as large as the original one. Being again extirpated, it rapidly reappeared, and soon proved fatal, the patient dying dropsical. Dissection of the body revealed important disease of the liver, water in the splanchnic cavities, and great enlargement of the lymphatic ganglions of the abdomen.

Of the anatomy of eiloid nothing is known. It probably takes its rise in the substance of the dermis, but how, or in what particular part, has not been determined. It is to be regretted that Dr. Warren has failed to inform us whether the secondary growth had the same coil-like appearance as the primary one. The only remedy, of course, for this disease, is early and efficient extirpation, with proper attention afterwards to the general health.

9. LEPOID.

The lepid formation is most generally observed upon the face, nose, and forehead of elderly persons, usually males, of a delicate florid complexion, with a habitual tendency to congestion of the capillary vessels, light eyes, and light, brown, or reddish hair. Although occasionally single, I have more commonly found it to be multiple. In some instances, indeed, quite a number of lepid spots are observed, scattered about in different directions, with intermediate healthy skin. It generally makes its appearance in the form of a small, circumscribed speck, not larger, perhaps, than a mustard seed, and of a dirty, grayish color, which becomes covered with a very rough, brownish crust or scale, resembling the bark of a tree, whence its name. This, falling off, is soon succeeded by another, of the same complexion, form, and consistence. Thus the disease is often kept up for many successive years. At last, however, ulceration sets in, and the dermis exhibits a red, glossy surface, spicular, pitted, or granular, and throwing out a thin, ill-elaborated pus. The skin, upon inspection, is found to be almost of a gristly hardness, its internal surface being studded with numerous little, whitish, rounded bodies, connected together by a dense, grayish substance. The progress of the disease is attended with hardly any pain; but the patient is generally very much annoyed by itching, leading to an irresistible desire to scratch, which always aggravates it.

The nature of lepid is undetermined. Without being able to speak positively, I am strongly inclined to believe that it is merely a variety of lupus

or epithelioma; a supposition deriving plausibility from the circumstance that, although generally disposed to remain long stationary, or to make but little progress, it often ultimately takes on malignant action; pursuing then very much the same course as the milder forms of lupus.

The best remedy for this disease is non-interference. The rough, bark-like scale may occasionally be softened with a little very dilute citrine ointment, or covered with a mixture of two parts of collodion and one of castor oil, to serve as a defence from the air. All irritating applications must be refrained from. If the disease is inclined to spread, the tissues may be destroyed with the Vienna paste, or removed with the knife; but in general it will be safest to eschew all operative interference, as likely to aggravate the case by an early recurrence of the formation, and its more rapid tendency to malignancy.

10. LUPUS.

Under the term lupus are comprehended two varieties of disease, the chief peculiarity of which is a tendency to destructive ulceration of the skin and areolar tissue, or of these and the more deep-seated structures. In point of fact the two affections are identical, the only difference between them being that the one is milder than the other, more tardy in its progress, and less disposed to spread, its ravages being generally limited to the cutaneous textures, or to the parts in which it is originally located. The former of these affections is called the non-exedent, stationary, or serpiginous ulcer; the latter the exedent, eating, or corroding ulcer. It is also known as the canceroid or voracious ulcer. The older surgeons described it under the appellation of *noli me tangere*, in reference to the exquisite sensibility by which it is so often characterized. The term lupus, signifying wolf, is suggestive of the destructive tendency of the affection.

Of the *causes* of lupus, in both of its forms, we have no definite knowledge. In general, it comes on spontaneously, or without any assignable reason, and soon exhibits its peculiar features. Occasionally its origin is apparently referable to some local injury, as a scratch, abrasion, or contusion, or to the irritation of some warty growth. It is commonly supposed that a scrofulous state of the constitution predisposes to its occurrence, and this is probably true, although in a much less degree than has been imagined. My own experience certainly does not warrant the conclusion that the origin of the disease has, in general, any such relation; in most of the cases that have come under my observation, the patients seemed to be peculiarly free from strumous taint, both as it respected the actual state of their own system, and everything like hereditary transmission. Persons of a delicate, ruddy complexion, with light hair, blue eyes, and an unusually active capillary circulation, are most prone to the disease, not only as it regards its frequency, but also the rapidity of its progress and the extent of its ravages. How far a syphilitic taint of the constitution may act as a predisposing cause of lupus is a point that has not been ascertained; unfortunately, it is seldom in the power of the practitioner to obtain a sufficiently accurate account of his cases to enable him to trace, in a satisfactory manner, their various relations.

Lupus may occur in any part of the body, but it will most commonly be found to manifest a peculiar predilection for the nose, cheeks, and eyelids, especially the lower. It is observed in both sexes, and rarely shows itself until after the age of forty. When it attacks the face, it sometimes breaks out simultaneously, or nearly so, at several points. The ulcers, in both varieties of the affection, are usually of an intractable nature, or if, as occasionally happens, they heal at one place, they are sure to spread at another. Their secretions are of an ichorous nature, and their surface is covered by a

brownish, characteristic scab. If reparation take place, the new skin is always very hard, white, irregular, and prone to take on disease from the slightest causes.

1. The *non-exedent lupus*, often described as the serpiginous ulcer of the face, generally begins either as a small, hard, white, shining tubercle, or as a fissure, crack, or excoriation, with indurated edges, and a thin, brownish incrustation. In either case, it soon exhibits its characteristic tendency to spread, not in depth, but circumferentially, for it rarely, at least in its earlier stages, penetrates beyond the substance of the true skin, or even far into it. In fact, it is essentially a superficial ulcer, passing generally from one point to another, but seldom involving the deeper structures, except, perhaps, when it appears on the ala of the nose, where it occasionally evinces a highly erosive disposition. When it affects the eyelids, it may, in time, extend to the fibres of the orbicular muscle, and even to the tarsal cartilage, but in general it remains limited for years to the skin, or skin and areolar tissue. The parts around the ulcer are hard, puckered, tender, and usually somewhat reddish, although very often they retain their normal color. The ulcer is the seat of occasional, darting, stinging, or shooting pain, and of more or less itching, generally much more disagreeable than the pain itself. When the scab, which is usually very thin, and of a brownish, or blackish color, drops off, it is speedily succeeded by another of a similar kind. When the surface is thus exposed, it is occasionally found to be covered by very red, vascular, sensitive granulations, smeared over with thick, yellowish, viscid pus, and disposed to bleed on the slightest touch. The edges of the ulcer are usually steep, jagged, and slightly everted. As the sore spreads in one direction, it often heals in another, leaving a whitish, leucoid, or milky scar, strikingly contrasting with the surrounding parts.

The non-exedent form of lupus is said to be most common in young scrofulous females, but, if this be the fact, my experience has failed to afford me any evidence of it. In most of the cases that have fallen under my observation, and they have been very numerous, it appeared after middle life, in both sexes, with a complexion that was either very florid at the time, or had been so shortly before the attack. My opinion is that writers often confound this affection with the effects of a syphilitic taint of the system, exhibiting itself in the form of one or more superficial, foul, obstinate ulcers, which, when their nature is properly understood, may always be made to disappear promptly under the use of iodide of potassium and bichloride of mercury.

In the *treatment* of this variety of lupus, none but the mildest and most soothing applications should be employed. The one from which I have derived most benefit is the dilute tincture of iodine, which, while it changes the action of the secernent vessels, promotes the removal of effused fluids, and serves as a protective against atmospheric and other injurious impressions. As long as the scab remains on the surface of the ulcer, it should not be disturbed; otherwise it may be covered with a piece of lint, spread with a small quantity of the ointment of the nitrate of mercury, largely diluted with simple cerate. Occasionally a little powdered opium forms a valuable addition. Brushing over the part once every three or four days with a mixture of collodion and glycerine often answers a good purpose. When the ulcer is foul, and has a disposition to spread, it should be touched once or twice, lightly but effectually, with the dilute acid nitrate of mercury. All severe applications must be avoided, as they generally do immense harm.

Along with these topical remedies, special attention must be paid to the state of the general health, which is often not a little disordered. The diet should be light, simple, unirritant, and chiefly, if not exclusively, of a vegetable character, the drinks consisting of water, milk, or weak tea; the bowels and secretions should be regulated with blue mass and ipecacuanha, or blue

mass and colocynth; and if signs of debility exist, as denoted by the state of the countenance, pulse, and strength, tonics should be resorted to, in combination with alterants, of which the best are quinine and iodide of iron, in combination with a minute quantity of bichloride of mercury and arsenious acid. Of late, very favorable mention has been made of the use of the chloride of arsenic in the treatment of this affection, in doses varying from eight to fifteen drops thrice a day, and a number of cases illustrative of its beneficial effects have appeared in the medical journals. Of its efficacy, however, I can say nothing from personal experience. When the vital forces are much impaired, cod-liver oil and milk punch must be pressed into the service.

2. The other variety of lupus, the *exedent*, corroding, or devouring lupus, of authors, belongs unmistakably to the class of affections described by modern pathologists under the name of epithelioma, or cancrroid disease. It is a genuine cancerous development, generally beginning in the form of a hard tubercle, crack, or warty excrescence, and rapidly extending in different directions, both in circumference and depth, until it has occasioned the most frightful ravages, and the most dreadful and disgusting deformity. Thus, it often consumes the whole of the nose, one cheek, the entire lip, the chin, or perhaps the orbit of the eye, and the forehead, the ball of the eye being completely severed from its connections and dropping down into the frightful chasm below. To witness some of these cases is a truly pitiful and shocking sight. The progress of the disease is often remarkably rapid, great mischief being sometimes done in a few months; at other times its march is more slow, or the malady, after having evinced a most destructive tendency, may suddenly stop, with all the appearances of a complete cessation of hostilities. A case has been reported to me where the morbid action, after having destroyed the greater portion of one cheek with the corresponding antrum, has remained in a state of abeyance for the last eight years, although it had been steadily pursuing its course for upwards of fifteen.

The ulcer in this variety of lupus has an excavated appearance, as if it had been punched out of the parts on which it rests; its edges, however, are generally somewhat everted, or everted at one place and slightly overhanging at another, ragged, and often as if worm-eaten; the bottom is foul and covered with unhealthy granulations, or granulations and aplastic lymph; the discharge is ichorous and irritating; and the surface around is indurated, tender, and more or less discolored and œdematous. The pain is generally severe, being of a sharp, biting, darting, or shooting character, and liable to temporary exacerbations from exposure, irregularities of diet, and atmospheric vicissitudes. The general health, at first perhaps entirely sound, becomes seriously affected during the progress of the disease; the appetite and sleep are impaired; the strength declines; marasmus gradually ensues; and the patient, worn out by suffering, finally dies completely exhausted.

The great object in the *treatment* of the corroding form of lupus is to arrest the morbid action, either with the knife, or some suitable escharotic, as the acid nitrate of mercury, or the Vienna paste. In regard to the first of these measures, I must confess I have no great confidence in its efficacy as a means of preventing a recurrence of the disease, since it does not appear to be capable of exerting upon the capillaries in the neighborhood of the affected parts that alterant influence which is necessary to cause a permanent suspension of the specific action upon which the malady originally depended. In most of the cases in which I have employed the knife, the result has been anything but flattering, notwithstanding the most thorough excision and the most careful attention in regard to the after treatment. Indeed, I have often been struck with the apparent avidity, so to speak, with which the disease returns. My opinion, therefore, is that excision, as a general

rule, should give way to escharotics, either such as have been just alluded to, or, what I believe is preferable, in nearly all cases, the actual cautery. The hot iron not only effectually destroys the diseased tissues, but it seems to create a wide spread salutary influence among the surrounding parts, eminently unfavorable to repullulation. Notwithstanding, however, all the care and precaution that can be employed both to get rid of the disease and to oppose its return, it must be confessed that our efforts are generally, in the end, unavailing, the malady usually coming back, and ultimately terminating fatally.

As long as the disease is stationary, it will be best, as a general rule, not to interfere with it in any manner; the scab, if there be any, should be let alone, or, if the surface be exposed, it should be treated with the most soothing and gentle means.

The general health must, in this as in the more simple variety, receive, throughout, proper attention; alterants and tonics will often afford essential service; and the strictest vigilance should be exercised in regard to the diet, bowels, and secretions. Arsenic, bichloride of mercury, and iodide of iron are particularly deserving of trial as constitutional remedies.

11. MELANOSIS.

Melanosis of the skin, fig. 192, is very uncommon, and probably never occurs as a primary disease, being apparently always propagated from the subcutaneous cellular substance, or from some lymphatic ganglion. It nearly always co-exists with melanosis in other parts of the body, and is, therefore, merely an evidence of a general taint of the system. In a case that was under my observation, some years ago, in a man, aged fifty-eight, it involved nearly all the principal organs, and of course finally proved fatal. In another instance which occurred in this city, while I was a pupil of the late Dr. George McClellan, an immense number of melanotic tumors existed in the skin and cellular tissue of the abdomen, varying from the volume of a small pea up to that of a mass the size of a large almond; they were of a firm, fibro-cartilaginous consistence, slightly movable, exquisitely painful, and of a bluish-black color. The remedy, in this case, was excision, a few of the larger tumors being removed at a time; the operation was repeated every ten or twelve days, for several months, by which time, but little progress being made towards a cure, the patient became tired, and positively declined further interference. He finally died completely exhausted by his disease.

When melanosis is confined to the integuments, and occurs as a circumscribed tumor, the proper remedy is early and free excision; but under opposite circumstances, or, when it co-exists in other parts, or is extensively diffused through the cutaneous and areolar tissues, all interference of the kind should be avoided, as likely to accelerate the fatal crisis.

12. SCIRRHUS.

Scirrhus of the cutaneous tissue is also exceedingly uncommon; it is, however, occasionally met with in various parts of the body, particularly the face,

Fig. 192.

Nodule of black cancer in the true skin.

forearms, and hands. It generally begins in the form of a whitish, milky, or leucoid spot, commonly a little elevated above the surrounding level, but now and then apparently somewhat depressed, of a dense, firm consistence, more or less rough, and completely inlaid in the substance of the skin. Large vessels frequently extend across the affected parts, the redness contrasting strikingly with the whiteness of the intervening surface. Movable at first, the tumor gradually contracts adhesions, and, in time, involves the subcutaneous cellular substance. If a section be made, it will be found to be traversed by white lines, and to yield, on pressure, a small quantity of lactescent fluid.

Although the progress of this affection is usually slow, its tendency is ultimately to disintegration and decay, the resulting ulcer having an irregular, jagged appearance, with everted edges, and a foul bottom, the discharge being of a sanious or ichorous nature. More or less pain, of a sharp, lancinating character, generally attends. As the morbid action proceeds, new leucoid spots are often superadded to those already existing; the health gradually gives way, and the patient finally dies exhausted, though commonly not until carcinomatous disease has developed itself in some of the internal organs, particularly the lungs, pleura, and liver. Occasionally the affected parts assume a true encephaloid character, and in this way a tumor of considerable size may ultimately be formed, very tender, vascular, and subject to frequent hemorrhages. Finally, the scirrhus matter sometimes exists as an infiltration, although such an occurrence is very infrequent.

Secondary scirrhus of the integuments is by no means uncommon; it is most frequently seen in carcinoma of the mammary gland and lymphatic ganglions, and generally presents itself in the form of small, hard, shot-like tubercles, firmly and immovably fixed in the substance of the skin. The number of these little bodies is sometimes very great; they are usually quite painful, seldom attain much bulk, and do not often ulcerate, the patient nearly always dying of the primary disease before this event has had time to take place.

The ultimate character of these secondary formations is not well understood; in most cases, especially when of long standing, and of large size, they contain encephaloid matter and true cancer juice. Melanotic substance is sometimes interspersed through them.

Scirrhus of the integuments presents the same unrelenting character as this disease in other parts of the body; extirpation, the only resource in the early stage of the malady, holds out no prospect of permanent relief, and hence all that can generally be done is to palliate the patient's suffering.

SECT. VIII.—INSECTS IN THE SKIN AND CELLULAR TISSUE.

The skin and cellular tissue are liable to be infested by certain insects, which although not poisonous, are capable of inducing serious suffering, especially in persons of a nervous, irritable temperament. I refer more particularly to the chigoe and the Guinea worm.

The *chigoe*, which is very common both in this country, South America, and the West Indies, is a little insect, scarcely half the size of the smallest pin head, which penetrates the skin of the hands and feet, as well as of other exposed parts of the body, for the purpose of sustenance and hatching. It is a species of flea, with a rostrum as long as the body, of a pale-brownish, semi-transparent appearance, with legs of a light lead color, which often deposits its eggs in immense numbers. The first effect is an itching sensation, which is soon followed by heat, redness, and swelling, and, ultimately, by an ugly, irritable, spreading ulcer. If the part, when it has attained this

stage, be carefully examined, it will be found to contain a cyst, about the size of a pea, and of a bluish color, in which the ova live and multiply with astonishing rapidity. When a number of chigoes penetrate the skin together, the suffering produced by them may be so great as to cause violent constitutional disturbance and even death.

The *treatment* consists in picking out the insect and its eggs with a fine needle, care being taken not to rupture the cyst, otherwise the young brood may produce further mischief. Clearance having been effected, the part is well washed with salt water, tobacco juice, or spirits of turpentine, and thoroughly painted with dilute tincture of iodine. The female slaves in the West Indies are said to extract these insects with great dexterity.

The Guinea worm, or little dragon, technically called *filaria medinensis*, also buries itself in the body. It is chiefly met with in hot countries, particularly in Egypt, Arabia, Persia, Abyssinia, and Guinea, the inhabitants of which are often sorely afflicted by it. Of a white color, and of a filiform shape, it has an orbicular mouth, and a slightly pointed tail, its usual length being from five to ten inches, and its thickness that of a small violin string. Its ordinary abode is the subcutaneous cellular tissue of the feet and legs, though it is also found in other parts of the body, as the face, neck, scrotum, hands and arms. It is commonly coiled up circularly, and is inclosed by a distinct cyst, which thus separates it from the surrounding parts. The animal enters the skin when quite young, and gradually increases in size, exciting intolerable itching, inflammation, swelling and suppuration, often attended with fever, and sometimes followed by gangrene. The precise situation of the worm is generally indicated by a sort of boil, or a hard, ridge-like elevation. When ulceration sets in, the head of the creature usually protrudes at the opening, thus confirming the diagnosis of the case.

In the *treatment* of this affection, the proper plan is not to allow the patient to be tormented by the employment of inefficient remedies, but to cut down at once upon the part, and extract the intruder. It is worse than useless to waste time in the application of leeches, liniments, and embrocations, which, so long as the cause of irritation lies buried under the skin, can produce none but the most transient effect. If the tumor is already open, and the head of the animal is protruding, extrusion may be promoted by gentle tractions.

CHAPTER II.

DISEASES AND INJURIES OF THE MUSCLES,
TENDONS, BURSÆ, AND APONEUROSES.

SECT. I.—MUSCLES.

THE muscles are liable to wounds and lacerations, inflammation, atrophy, hypertrophy, and different kinds of transformations, especially the fatty form, which occasionally exists in a very high degree, and over a considerable extent of the body. They are also subject to some of the carcinomatous formations, and to the development of hydatids and serous cysts.

1. *Wounds*.—When a muscle is divided by a sharp instrument, or accidentally ruptured, its fibres immediately retract so as to drag the edges of the wound more or less widely asunder. The extent to which this separation may be carried varies, in general, according to the length and thickness of the muscle, from a few lines to as many inches. In transverse fractures of the patella, the action of the straight muscle of the thigh often draws the superior fragment from three and a half to four inches away from the inferior; and it is reasonable to conclude that fully as extensive a gap would be produced between the ends of this muscle if it were cut in two, or torn asunder. In rupture of the straight muscle of the abdomen, the edges of the subcutaneous wound have repeatedly been found to be separated from an inch and a half to two inches. In the operation for the cure of strabismus, the retraction of the posterior extremity of the divided muscle is seldom less than from four to six lines, and often even considerably more.

The above facts are highly interesting in a practical point of view, inasmuch as they point out the propriety of adopting prompt and energetic measures for effecting and maintaining apposition of the ends of the divided muscle; for observation has shown that the more accurate this is the more speedy and perfect will be the cure. If the edges are brought fully and intimately together, the union will necessarily require but a small quantity of plastic matter for its early and complete consolidation. If, on the other hand, the gap amounts to several inches, either no union will occur, or it will be effected through the intervention of a large quantity of cellulo-fibrous tissue, possessing none of the properties of muscular fibre. Hence the affected structures must always remain proportionably weak and disabled. But this is not the only inconvenience that follows such an accident; in wounds of the abdominal muscles, for example, the gap is sure to give rise to hernia, and it is easy to see that a deficiency of this kind elsewhere would hardly be productive of less serious effects.

2. *Laceration*.—Rupture of the muscles is often produced by very trifling causes, the most common of which are leaping, or jumping across ditches or over fences, lifting heavy weights, or falls from a considerable height, in which the person makes a powerful effort to ward off injury. Cases are upon record of women having lacerated the abdominal muscles during parturition. Injuries of this kind are most likely to happen, other things being equal, when a muscle has undergone the fatty degeneration, which, by rendering its fibres

soft and lacerable, acts as a powerful predisposing cause of rupture. Long continued inactivity of a muscle followed by sudden and violent contraction may be mentioned as another predisposing cause of the accident.

The muscles which are most liable to rupture are the straight muscles of the abdomen, the psoas, deltoid, the two-headed flexor of the arm, the straight femoral, and gastrocnemius.

The place where the rupture usually occurs is near the junction of the fleshy fibres with their tendons; but occasionally a muscle may give way at its middle, or, in fact, at almost any portion of its extent. In twenty-one cases of this affection analyzed by Sédillot, the rupture, in thirteen, took place at the insertion of the fleshy fibres into their tendons, while in the remainder the lesion was seated in the body of the muscle itself. The laceration is sometimes limited to a few fibres; at other times it involves the entire thickness of a muscle, or of a muscle and its aponeurotic envelop. Finally, cases occur in which a number of muscles are ruptured.

The *symptoms* attendant upon this lesion are not always well marked, especially when the affected muscle is deep seated. In general, it may be assumed that the accident has occurred, if, at the moment of some violent bodily exertion, as in leaping a ditch or fence, the individual has heard a distinct noise or snap, like the crack of a whip, feels severe pain in some particular spot, and either falls down, or has but an imperfect use of himself. Upon examining the suffering part, a vacuity will probably be noticed at one point, and an unusual prominence at another, followed by more or less discoloration and tenderness under manipulation. Occasionally the accident is attended with a rather copious hemorrhage, caused by the rupture of an artery of considerable size, as, for instance, the epigastric in laceration of the straight muscle of the abdomen. The pain which follows the injury is often very sharp, and rarely entirely disappears until after the primary effects of the lesion have measurably passed off.

Temporary lameness and inability to move about for some time are, in general, the most serious consequences to be apprehended from this accident, provided it is properly managed immediately after its occurrence. In most cases, a considerable period must necessarily elapse before the reunion of the torn structures will be sufficiently firm to justify their accustomed use. Occasionally violent symptoms have supervened upon the accident; and an instance has been reported of a young man who died from rupture of the psoas muscle, death having been preceded by severe inflammation and infiltration of pus.

The *treatment* of this lesion cannot be the same in all cases, or under all circumstances. Whenever it is practicable, from the superficial situation of the affected muscle, its ends, whether they have been cut or ruptured, should be freely exposed, and then carefully approximated by a sufficient number of stitches to hold them in contact until firm union has been established. For this purpose the threads should be carried nearly through the entire thickness of the muscle, the object being thorough apposition both of the superficial and deep portions of the wound. In case the muscle has been ruptured, the edges of the wound may be so ragged as to require some retrenching before placing them in contact, just as in a lacerated wound of the integuments. If the precaution of stitching the parts be neglected, the results above adverted to will be inevitable, and it is, therefore, impossible to insist too strongly upon the importance of attention to this rule, which is so much neglected by surgeons.

The parts being properly approximated are next placed in an easy, elevated, and relaxed position, splints and bandages being employed for this purpose, if necessary; they are then treated upon general antiphlogistic principles. If the ruptured muscle be deep-seated, our chief reliance must be

upon rest and relaxation, aided by soothing and astringent applications, along with suitable internal remedies, to moderate the resulting inflammation. In lacerations of the muscles of the extremities, important advantage may always be obtained from the use of two rollers, applied in opposite directions, as the ends of the wound may thus not only be more effectually approximated, but the contraction of the fleshy fibres more easily controlled, than in any other manner.

3. *Inflammation*.—Inflammation of the muscles may present itself in two varieties of form, the acute and chronic; both, however, are uncommon, and are chiefly observed as consequences of external injury, as blows, wounds, or contusions, such as we meet with in fractures and dislocations; or as effects of gout and rheumatism. The sheaths of the muscles very frequently, if not generally, participate in the morbid action. When the inflammation is at all severe, considerable effusion of serum and lymph may take place, but it is seldom that the disease runs into suppuration, much less mortification. The latter termination is chiefly met with in erysipelas and carbuncle, in old worn-out subjects, and in persons of different descriptions after violent external injury. It is easily recognized by the dark greenish color of the fleshy fibres, by their softness and lacerability, and by their excessively fetid odor. The parts are detached in ragged shreds, bathed in a thin, sanious, dirty, and offensive fluid.

Acute inflammation of the muscles is characterized by excessive pain, of a sharp, darting character, or by dull, heavy, aching sensations, accompanied with a feeling of soreness, and aggravated by the slightest motion and pressure. In some cases, as when the disease supervenes upon fractures or the amputation of a limb, it is attended by a remarkable twitching or jerking, occasionally amounting to real spasm, which only yields to large doses of anodynes, and hot, soothing applications.

Chronic myositis is not uncommon; like the acute variety, to which it generally succeeds, it is more frequently met with, surgically considered, as a secondary than as a primary affection. When long continued, it is very prone to give rise to fatty degeneration, softening, ulceration, and other changes, which it is often impossible to cure.

4. *Fatty Transformation*.—Fatty degeneration of the muscles is often, if not generally, a result of chronic inflammation, especially when conjoined for any considerable period with steady, persistent inactivity, or want of exercise. Whether inflammation, however, is always necessary to its formation is still a mooted question, although it is highly probable that it is. When thus affected the fleshy fibres assume a pale yellowish, whitish, or slightly reddish color, at the same time that they are unctuous to the touch, and so much softened as to yield under the most trivial force. On pressure, a clear, oily fluid comes out, which greases the finger, is highly inflammable, and is composed of elain, adipocire, and ordinary fat, in variable proportions. These substances are not deposited, as some have conjectured, between the fleshy fibres, but form actually a portion of their constituent principles; their proper tissue being found, when examined microscopically, to be filled with granules, partly interposed between their striæ, and partly replacing them.

The fatty transformation is most common, as well as most marked, in the muscles of the loins, hip, thigh, and leg of old persons affected with paralysis. It is likewise occasionally observed in the heart, and now and then in the muscles around unreduced luxations, large exostoses, and old, deep-seated ulcers. When the change is profound and extensive, it sometimes involves the corresponding tendons and aponeuroses, which, in consequence, lose their polished, satin-like lustre. So far as we know, this disease does not admit of cure.

5. *Ulceration*.—Ulceration of the muscles is an uncommon occurrence; it is chiefly noticed in phagedenic sores of the leg, extending successively through the integuments, cellular tissue, aponeuroses, and, finally, the muscles, which, however, generally resist its encroachments in a very remarkable degree. In some of these cases the fleshy fibres are in a complete state of fatty degeneration, of a whitish color, and so soft as to admit of being scraped away with the greatest facility. When the ulceration is slight, the restorative process usually proceeds kindly, and the breach is soon filled with healthy granulations. No special treatment is required in this disease, apart from the remedies ordinarily employed under such circumstances.

6. *Contraction*.—Another effect of inflammation of the muscles, or of the muscles and their fibrous envelopes, is contraction of their fleshy fibres, leading to marked disorder of their functions, along, perhaps, with severe pain, and even to great deformity, as we so often see in wry neck, consequent upon inflammation of the sterno-cleido-mastoid and splenius muscles, and the muscles of the thigh from the effects of hip-joint disease. In many of these cases the disease is obviously of a gouty or rheumatic character, and, under these circumstances, it often occurs at a very early age, the immediate exciting cause being usually exposure to cold or cold and wet.

In the *treatment* of myositis attended with contraction of the affected muscles, the first object should be to ascertain, if possible, the nature of the exciting cause; as to whether it is the result of rheumatism, gout, scrofula, or syphilis, or of external injury, as a sprain, twist, blow, wound, or contusion; for upon the knowledge thus derived must necessarily depend the character of our remedies, and the chance or otherwise of a cure. I have usually received marked benefit in these cases from the use of the wine of colchicum in combination with a full dose of morphine at bedtime; aided by active purgatives and diaphoretics, especially the warm bath, a well-regulated diet, and the frequent application of Granville's lotion in union with laudanum and soap liniment, thoroughly rubbed upon the affected muscles. The muscular rigidity attendant upon a syphilitic state of the system is best treated with iodide of potassium, either alone, or conjoined with mercury.

In the more subacute or chronic cases of muscular contraction, great benefit may be expected from the use of the hot and cold douche, employed twice a day, and followed, first, by dry friction, then by the application of stimulating liniments, and, finally, thorough shampooing. Frequent motion is also generally of great service; to break up adhesions, and to promote the absorption of effused fluids, upon which the rigidity often mainly depends, as is observed in the shortened and rigid state of the limbs after severe fractures and dislocations.

7. *Atrophy*.—Atrophy of the muscles, of varying degrees, is occasionally observed; it may occur in any of the voluntary muscles, but is most common in those of the shoulder and hip, the deltoid suffering perhaps more frequently than any other individual member. It may depend upon different causes, but generally it is produced by inflammation, palsy, or defective circulation; indeed, whatever has a tendency to impair the function of innervation, retard or diminish the supply of blood, or induce permanent inactivity in a muscle, may be considered as so many causes of the affection. Hence it is found that the lesion is usually associated with paralysis, whether proceeding indirectly from disease of the cerebro-spinal axis, or directly from injury of the nerves distributed to the suffering structures. The muscles around luxated joints, especially those of the hip and shoulder, are frequently atrophied, either simply from the want of use, or, what is more probable, the conjoint influence of inflammation and inactivity. In coxalgia similar effects generally occur, the wasting usually involving all the muscles of the lower

extremity. The fact that gout and rheumatism are frequently productive of atrophy of the muscles is familiar to every practitioner.

The extent to which the wasting of the muscles may proceed is variable. When it exists in a high degree, they may be reduced to mere membranous bands, pale, flaccid, and almost devoid of irritability; in some rare instances their fleshy fibres are completely absorbed, a dense cellular substance being all that is left in their place; or, instead of this, they are found to be softened and transformed into fatty matter.

In the *treatment* of atrophy of the muscles the first object should be to ascertain, if possible, the nature of the exciting cause, by removing which the lesion sometimes rapidly disappears of its own accord, or, at all events, under very simple management. Atrophy dependent upon imperfect supply of blood is often irremediable, and the same is frequently the case when it is caused by gout and rheumatism, or when it is conjoined with the fatty degeneration. The treatment of atrophy dependent upon loss of innervation, constituting what is called wasting palsy, will receive special attention in the chapter on the diseases and injuries of the nerves, where its consideration properly belongs.

Whatever the cause of atrophy of the muscles may be, much may be done, after that cause has been removed, towards effecting restoration by the steady and persistent use of the hot and cold douche, stimulating embrocations, dry frictions, and regular, systematic exercise of the affected structures, educating them, so to speak, and thus gradually qualifying them for the resumption of their appropriate functions.

8. *Tumors*.—Various morbid growths occur in and among the muscles, the principal of which are the hydatid, cystic, melanotic, and encephaloid.

a. It is uncommon to meet with *hydatids* in the muscles; I have myself seen but one case of it. It occurred in 1853, at the surgical clinic of the University of Louisville, in a laboring man, aged twenty-five years, who accidentally discovered a swelling in the substance of the right deltoid muscle six months previously, when it was hardly as large as a hazelnut. At the time of my examination, it was of the volume of an almond with its shell, of a rounded, elongated shape, somewhat movable, and of a firm, fibrous consistence, with a slight degree of elasticity. Within the last few weeks the tumor had become somewhat painful, especially after exercise, and the pressure made in examining it was productive of considerable uneasiness. The skin over it was perfectly healthy. The patient was not aware of anything that could have produced the disease.

The diagnosis of the tumor could not, of course, be determined beforehand; what it resembled most, especially in point of consistence, was an enlarged lymphatic ganglion, but the rarity of such a disease in this situation invalidated this conclusion, and left me in complete doubt as to the true nature of the case. It was too deep-seated for a sebaceous tumor, and it possessed none of the external characters of a fibrous, fibro-plastic, or fatty one.

In performing excision, the knife was carried perpendicularly down over the tumor, in doing which, the point penetrated its interior, an occurrence which was instantly followed by the escape of a small quantity of thin pus, inducing me to think that the tumor, after all, was merely a diseased lymphatic ganglion. On continuing the dissection, however, I soon found that there was a distinct cyst, which, being collapsed, was separated with some difficulty from the fibres of the deltoid muscle, in which it was imbedded. The dissection being completed, a small body, fig. 193, was picked up on the floor, which, on inspection, proved to be a globular hydatid, not more than six lines in diameter, and furnished with a distinct sucker. The cyst was very soft and thin, smooth internally, and filamentous externally.

Fig. 193.

Hydatid.

b. Tumors of a *cystic* character are sometimes met with in and among the muscles. In a case of this kind, which I had an opportunity of seeing in 1856, with Dr. Da Costa, the growth, occupying the upper and outer portion of the thigh, had acquired nearly the volume of an adult head. The patient was a female, aged fifty-eight, and the disease had apparently resulted from a fall down a flight of stairs, in which she struck the limb severely, causing deep ecchymosis and great difficulty in walking. At the end of two months a swelling formed in the situation adverted to, which, gradually increasing, in the course of ten months acquired the size above mentioned, being at the same time the seat of severe darting pains, with considerable discoloration of the integuments. The tumor fluctuated indistinctly, but a puncture with the exploring needle gave vent merely to a few drops of fatty fluid. When removed by Dr. Brinton, it was found to be composed of a very thick, dense, fibrous cyst, filled with a sero-oleaginous fluid. The patient gradually recovered from the effects of the operation, but has been troubled ever since with pain in the limb and difficulty in walking.

c. *Melanosis* sometimes occurs in the muscles, either as an infiltration, or as a distinct tumor, with or without a cyst, of an irregularly spherical shape, firm in consistence, and from the volume of a pea up to that of a foetal head. The morbid product, which generally coexists with similar formations in other parts of the body, is occasionally directly chargeable to external injury; but generally it takes place without any assignable cause.

d. *Encephaloid*, *scirrhous*, and *colloid* of the muscles are very uncommon, so much so, that few practitioners ever meet with them. They obey the same law here as when they occur in other parts of the body. In the interesting case of *colloid* described by Professor J. C. Warren, an immense number of tumors of this kind, varying in size from a pea to that of a small granule, hardly visible without the aid of a microscope, existed in the voluntary muscles, in different regions, especially in those of the thigh and leg.

The probability is that none of these heteroclitic formations are developed in the muscular substance, properly so-called, but that they begin in the interfibrillar tissue, from which, as they increase in size, they gradually encroach upon the fleshy fibres, which they thus displace, alter, or destroy.

SECT. II.—TENDONS.

The tendons, like the muscles, are liable to wounds and lacerations, but, unlike them, they never suffer from malignant formations, excepting secondarily, and then only very rarely. Inflammation of these structures is also very infrequent.

1. *Wounds*.—Tendons, when divided subcutaneously, readily unite through the intervention of plastic matter, without the occurrence of any considerable degree of inflammation. Indeed, the idea is very common at the present day that such wounds are always repaired without inflammation, it being alleged that this process, instead of being necessary for this purpose, is a positive detriment. I cannot subscribe to such a doctrine. If its advocates mean that the inflammation is very slight, or not characterized by the ordinary phenomena, I perfectly agree with them; but if they wish to be understood as affirming that inflammation is entirely absent throughout, from the beginning to the close of the case, it is what I cannot believe, and what is certainly not true.

When a tendon, such, for example, as that of the heel, is cut across subcutaneously, the first thing that is noticed is the retraction of the divided ends, so as to leave a distinct gap between them, often amounting to from an inch and a half to two inches, according to the size of the cord and its

previous tension, or the degree of force employed in stretching the parts with which it is connected. Inflammation, generally of a very slight form, next takes place, and, soon after this is set up, plastic matter is poured out, filling up the space between the two extremities of the tendon, which, at the same time, it serves to connect together. As the abnormal action subsides, nucleated cells form in the interior of the effused matter, and the process of organization thus begun steadily advancing, the new substance is gradually converted into cellulo-fibrous tissue, and this, in its turn, at length into tendinous, which, however, although well calculated to fulfil the purpose for which it is intended, is, like all new tissues, a very imperfect type of the original. The reproductive process generally advances very rapidly, so much so that the person soon acquires an excellent use of the affected parts. It is upon a knowledge of this property in tendon, when subcutaneously divided, to speedy reunion, that is founded the operation of tenotomy, one of the greatest improvements in modern surgery.

When a tendon is divided in an open wound, the two ends rarely reunite at all, owing mainly to two circumstances; the first is, that the ends retract too far to enable us to bring them properly together, and the second, that the wound nearly always suppurates; an occurrence eminently inimical to adhesive action. All the earlier operations of tenotomy that were performed according to this principle, failed in consequence of the violence of the resulting inflammation.

The *treatment* of a divided tendon, then, with an open wound, is very different from that where the wound is subcutaneous. In the latter, the application of a bit of adhesive plaster to the puncture to exclude the entrance of the air, and a little attention to rest and position, make up the whole sum of the surgeon's duty. In the former, on the contrary, the cut ends must be carefully approximated by the silver suture, the rest of the wound being firmly closed; or the limb with which the tendon is connected must be placed in the most thoroughly relaxed position possible, in order to approximate its extremities, and thus afford them an opportunity of reuniting, an occurrence, however, which, I am sure, will rarely take place under any circumstances, however propitious. The experiments of Dr. Levert, of Mobile, performed many years ago, prove that union between the divided ends of a tendon will be much more likely to proceed kindly and satisfactorily, when the parts are held in contact by a metallic suture than by an ordinary one. My opinion is that practitioners have not profited enough by the results of these researches. The recent introduction of silver wire, by Dr. Sims, into our surgical armamentarium, will, no doubt, tend to re-excite attention to them.

The surgeon is sometimes consulted on account of an ununited tendon, with an intervening gap, perhaps, long after the external wound has healed. Under such circumstances, it has been proposed to puncture the retracted extremities subcutaneously, and it has been alleged that such a procedure is not only safe, but generally quite successful. Safe it undoubtedly is, but, as to its being successful, that is an utter impossibility, unless, what seldom happens, the two ends remain in close proximity with each other. The proper remedy is to expose the parts by a free incision, and, having pared the retracted extremities, to unite them with silver wire.

2. *Rupture*.—Tendons are sometimes torn away from their sheaths along with the fleshy fibres into which they are inserted, hanging, perhaps, merely by one extremity; when this is the case, it would be useless to replace them, even if this were practicable, as there would be no likelihood whatever of reunion; on the contrary, severe inflammation and sloughing would be inevitable.

When a tendon is ruptured subcutaneously, a loud snap, like the crack of a whip, is generally heard at the moment of the accident, especially if the

cord be a large one; the part is instantly deprived of its functions, and a well-marked gap, interval, or hollow is perceptible at the site of the injury. More or less inflammation follows, and a long time usually elapses before the patient regains the use of the affected limb. The tendon which is most liable to suffer in this way is that of the heel, its rupture being generally caused by violent muscular exertion, either for some special effect, as in the case of persons on the stage, or for the purpose of saving the body from a fall, as when the individual makes a false step.

The treatment of a subcutaneously ruptured tendon must be conducted by rest and complete relaxation of the affected structures, so as to enable us to bring the divided ends as closely together as possible. To effect this to the best advantage, special apparatus is generally required, as well as the greatest attention and vigilance on the part of the practitioner. The time necessary for obtaining satisfactory union varies, on an average, from six to eight weeks.

3. *Dislocations*.—The tendons are sometimes dislocated, or thrown out of the grooves in which they are naturally situated, in consequence of the laceration of the connecting ligaments, or retaining bands. The accident, which is most apt to befall the tendon of the two-headed flexor of the arm, as it runs along the bicipital groove of the humerus, is generally attended with severe pain at the site of the injury, inability to move the affected limb, and more or less discoloration of the integuments. Considerable swelling often follows, and, if the accident is overlooked, permanent lameness may result. Replacement should be effected as speedily as possible, and it is gratifying to know that this is usually quite easy, provided the true nature of the case is recognized soon after its occurrence.

4. *Hypertrophy*.—Finally, the tendons are occasionally the subjects of hypertrophy, exhibiting an irregular, knotty appearance, which is not only unseemly but sadly productive of discomfort. The affection is most common in gouty, rheumatic, and syphilitic persons, and is usually very readily detected both by touch and sight. The proper remedies are removal of the exciting cause, the exhibition of iodide of potassium, either alone or in union with mercury, and sorbefacient applications.

5. *Thecitis*.—Inflammation of the sheaths of the tendons, technically called thecitis, may originate as an independent affection, or, as not unfrequently happens, it may begin consentaneously with inflammation of the parts which it surrounds and lubricates. In either event, the disease is often of a much more serious character than is generally imagined, nothing short, perhaps, of permanent lameness and deformity being the result. Various causes may give rise to thecitis; thus it is occasionally induced by gout, rheumatism, syphilis, and exposure to cold. On the other hand, it often supervenes upon external injury, as a sprain, blow, puncture, or contusion. In the hand and fingers it is frequently met with as a consequence of dislocation of the wrist-joint, or fracture of the lower extremity of the radius and ulna. In regard to its character, it may be acute or chronic; more generally perhaps the latter than the former. Once fairly established, it is commonly removed with much difficulty, and is liable, as just stated, to be followed by the most disastrous consequences.

The most common sites of thecitis are the sheaths of the tendons of the fingers, the wrist, elbow, feet, ankles, and knees; the disease may occur by itself, or in union with inflammation of the bursae and the lining membrane of the neighboring joints. In thecitis of the hands and fingers it is seldom that the disease exists except in this association, especially when it has been caused by a sprain, dislocation, or fracture of the radio-carpal articulation. Under such circumstances, as I have had frequent occasion to notice, the inflammation is extremely apt to extend to the sheaths of all the tendons, as

well as the joints of the fingers, rendering them stiff, tumid, and exquisitely painful. If the case be neglected, misunderstood, or improperly treated, the whole hand becomes rigid, and the fingers wasted and attenuated, presenting more the appearance of the claws of some of the inferior animals than the organs which represent those parts in the human subject. The pain accompanying this form of thecitis often reaches as high up as the axilla, and I have known it to be so distressing at night as to deprive the patient completely of sleep for days together.

Thecitis, although apparently a trivial disease, assumes a most important character when it invades a number of thecae simultaneously, or successively, and the gravity of the case is greatly augmented if there is at the same time considerable involvement of the neighboring joints, as when the attack takes place in the hands and fingers. Hence no time should be lost, and no pains spared, to get rid of the inflammation before it has produced any serious structural changes, particularly firm and extensive adhesions of the thecae to their tendons. Leeches and tincture of iodine, either alone or in union with saturnine and anodyne fomentations, are the chief topical remedies upon which reliance is to be placed, while the patient is freely purged and restricted in his diet. Venesection and antimony will be necessary if the case prove obstinate. If the disease is found to be associated with a gouty or rheumatic state of the system, wine of colchicum will be of service. In thecitis dependent upon a syphilitic state of the constitution, recourse must be had to iodide of potassium.

If the parts have become stiff in consequence of firm adhesions, the hot and cold douche, followed in immediate succession, along with frictions with sorbefacient liniments, embrocations, or unguents, steady, systematic passive motion twice a day, and the application of the bandage to support the affected structures, will gradually, though in general not under several months, effect restoration. In obstinate cases a mild mercurial course may become necessary, on the same principle that such a plan is occasionally adopted in inflammation of other tissues attended with plastic effusions and morbid adhesions. When the disease is located in the hand, I have generally found it expedient to bandage each finger separately, and to support the member upon a carved splint. In short, in many of these cases nothing but the most zealous and determined perseverance will enable us to effect a cure.

6. *Ganglion*.—A ganglion is a small circumscribed cyst, situated along the course of a tendon, to which it is intimately united. Composed of a

Fig. 194.

Fibroid bodies of a ganglion.

single layer, which rarely exceeds the thickness of the dura mater, it is filled with a thin, yellowish fluid, more or less ropy in its character, and bearing a very strong resemblance, in its general features, to olive oil, the white of an egg, or a solution of gum Arabic. In cases of long standing, the contents of the sac are sometimes nearly entirely solid, consisting of a thick ropy substance, of a dark color, not unlike currant-jelly; of masses, apparently, of semi-organized lymph; or of small bodies, similar, in shape and size, to cucumber seed. In a ganglion of the hand upon which I operated two years ago, I observed the singular looking bodies sketched

in the accompanying cut, fig. 194. They appeared to be in different stages of development, and were evidently merely so many masses of lymph, which had been originally attached to the inner surface of the sac, but had become

separated in consequence of the continual friction of the tendon to which the sac was connected.

The volume of the cyst varies from that of a pea to that of a pigeon's egg; it is of a globular or ovoidal shape, somewhat elastic, perfectly movable, free from pain, and unaccompanied by any discoloration of the skin. A sense of stiffness and of uneasiness, felt chiefly along the course of the tendon on which it is situated, sometimes attends its formation, and induces the patient to apply for advice. I have never known a ganglion to suppurate.

The tumor is most common in the female, and is met with chiefly along the extensor tendons on the back of the hand, wrist, and lower extremity of the forearm. I recollect seeing, some years ago, a case where it was situated over the radial artery, the pulsations of which were so thoroughly imparted to it as to induce the belief, on the part of several physicians who examined it, that it was an aneurism of that vessel. In 1854, I operated before the medical class of the University of Louisville, upon a young woman who had two tumors of this kind, each of the size of a small bird's egg, upon the dorsal surface of the foot.

How this cyst is formed is still a mooted point. From what I have seen of it, I am inclined to regard it merely as a sacculated expansion of the sheath of the tendons, and not, as some pathologists do, as a new formation. From the fact that it is most common in hard working people, it, doubtless, owes its origin to inflammation, although it is seldom directly chargeable to external violence.

The affection sometimes appears at an early age. Not long ago I met with a case in a little girl only eight years old.

The most simple and certain method of treatment consists in rupturing the ganglion, and scattering its contents into the surrounding cellular substance, where they are in general speedily absorbed. I usually perform the operation with the thumb, but, if the cyst is old and very firm, it will be necessary to strike it with a book, or to pierce it previously by a subcutaneous puncture. Evacuation having been effected, a compress inclosing a piece of coin is tied upon the part, to promote the adhesion and obliteration of its cavity, the limb being maintained at rest until the resulting inflammation has subsided. When the ganglion is quite young, a cure may sometimes be procured by the application of iodine and systematic compression; but ordinarily such means are quite futile. Iodine is sometimes employed as an injection, in the same manner as in hydrocele; experience, however, offers nothing in favor of the treatment. When the ordinary means fail, the sac should be cut up as minutely as possible with a delicate bistoury, inserted subcutaneously, the operation being followed up by compression. Both excision and direct incision must be avoided, as likely to endanger the functions of the part.

SECT. III.—SYNOVIAL BURSÆ.

The synovial bursæ, *bursæ mucosæ*, or mucous pouches, exist in considerable numbers in various regions of the body, especially about the joints of the extremities, being small, semi-transparent sacs, occupied by a thin, unctuous fluid. They are for the most part interposed between bone and tendon, tendon and tendon, bone and skin, or tendon and skin, their object being to facilitate motion and ward off pressure. Hence, they are always most conspicuous in those situations which are habitually subjected to friction; and for the same reason they are occasionally developed to meet special contingencies arising from accidental causes, as the pressure of a shoe, crutch, or artificial leg. In club-foot synovial pouches are constantly found upon those parts of the foot which, being partially displaced, are compelled to sustain

the weight of the body. Altogether there are about one hundred and fifty of these sacs in the natural state.

The largest and most important synovial pouches, surgically considered, are situated on the acromion process of the scapula, the space between the hyoid bone and thyroid cartilage, the condyles of the humerus, the olecranon process, the styloid projections of the ulna and radius, the tuberosity of the ischium, the great trochanter, the anterior superior spine of the ilium, the front of the patella, the condyles of the femur, the tuberosity of the tibia, the ankle, the calcaneum, and the heads of the first and fifth metatarsal bones, at their palmar aspect.

The principal diseases of the bursae are inflammation, suppuration, induration and thickening, dropsical accumulations, and the development of fibro-cartilaginous concretions in their interior. It does not seem probable that they are ever the seat of any of the heteroclitite formations; at all events, I have never met with any examples of them.

Inflammation of these sacs may occur either in an acute or a chronic form, the latter being, however, by far the more frequent. The usual cause is inordinate and long-continued friction conjoined with pressure. The disease may also be produced by blows, contusions, wounds, and punctures, and, in persons predisposed to gout, rheumatism, scrofula, and syphilis, by exposure to cold, or the sudden repulsion of the cutaneous perspiration. The housemaid's knee, and the collier's elbow, are examples of inflamed and enlarged bursae produced under the influence of concentrated and protracted pressure; another instance, not less striking, is afforded by the bunion which so frequently forms over the inner surface of the metatarso-phalangeal articulation of the big toe.

1. *Acute inflammation* of the bursae is generally productive of very severe suffering; the pain is tensive, throbbing, persistent, and greatly aggravated by motion, pressure, and dependency; the swelling, which is often considerable, is usually due partly to exterior deposits, partly to an accumulation of synovial fluid, the quantity of which is commonly very much increased; the skin is of a dusky reddish color, and deeply congested; and the functions of the affected structures are greatly impaired, if not completely arrested. Not unfrequently the swelling is of an œdematous or erysipelatous character, pitting readily under pressure, and being the seat of a dull, heavy, prickling sensation. In the more severe forms of acute bursitis, there is usually considerable constitutional involvement, the patient being feverish, thirsty, restless, and troubled with headache, loss of appetite, and other disagreeable symptoms.

Upon cutting into the affected sac, its inner surface is found to be deeply congested, and roughened with lymph, while its cavity is filled with a bloody, serous, or sero-oleaginous fluid, often in considerable quantity, especially if the disease has been of some standing.

Bursitis occasionally passes into *suppuration*, the symptoms, when this is about to occur, suddenly assuming a more severe form, just as when matter is about to be deposited in any other part of the body. The pus, which is usually of a thin, oleaginous character, intermixed with flakes of lymph, may find its way to the surface by ulcerative action, or it may discharge itself into a neighboring joint, although such an event is extremely rare, and is not likely to occur unless the joint has freely participated in the inflammation.

The *treatment* of this disease must be actively antiphlogistic; the part and system are kept perfectly at rest; leeches are applied to the affected surface, followed by anodyne and saturnine fomentations; the bowels, diet, and secretions are duly attended to; and the pain, which is generally severe, is controlled by morphine, or morphine, antimony, and aconite. If matter form, as denoted by an increase of pain and other symptoms, a free and early incision is

made, the edges of the opening being kept asunder by a small tent to prevent reaccumulation. The milder forms of bursitis are generally easily combated by rest, cooling laxatives, and the application of the tincture of iodine, or, what is frequently preferable, a blister, large enough to extend over the affected surface, and retained sufficiently long to produce thorough vesication.

2. *Chronic inflammation* of the bursæ occasionally gives rise to remarkable structural changes, the most common of which is an indurated and hypertrophied condition, the result either of long-continued interstitial deposits, or of the formation of adventitious membranes. However this may be, the walls of the affected sac are sometimes found to be upwards of a quarter of an inch in thickness, and of a dense fibro-cellular consistence, without the slightest trace of its primitive characters. Under these circumstances, the cavity of the pouch is generally very small, filled with altered synovial fluid, and roughened upon its surface, so as to exhibit an appearance not unlike that of a honeycomb. Now and then shreds of lymph are stretched across its interior, dividing it into different compartments. In cases of very long standing, partial ossification of the cyst has been noticed, but such an occurrence is extremely uncommon.

These chronic enlargements of the bursæ are often very obstinate and troublesome, resisting not unfrequently the best directed efforts of the surgeon for their removal. The remedies upon which our chief reliance is to be placed are sorbefacient applications, as iodine and hydrochlorate of ammonia, blisters, mercurial inunctions, and systematic compression. When, these means failing, the tumor is productive of pain and other inconvenience, our only resource is thorough excision, care being taken, especially if a large joint be close by, not to cut too widely away from the morbid mass, lest the synovial membrane of the articulation be inadvertently pierced, or so much injured as to excite violent inflammation.

3. Another result of chronic inflammation of these bodies is an accumulation of their natural secretions, giving rise to what is called *dropsy*, of which one of the best examples is afforded in the so-termed housemaid's knee. The fluid, which varies in quantity from a few drachms to six or eight ounces, according to the size and situation of the affected burse, and the duration of the disease, is generally of a pale straw color, of a slightly unctuous consistence, and of a notably saline taste; now and then it is reddish, or brownish, and remarkably thick and viscid. It is readily coagulable by heat, alcohol, and acids, showing that it is essentially composed of albumen. The presence of the fluid is easily detected by the elastic and fluctuating character of the swelling, and very frequently a distinct friction sound and sensation can be perceived upon handling the tumor; if necessary, an exploring needle is used. The integuments are free from discoloration, there is no enlargement of the subcutaneous veins, and the principal inconvenience experienced by the patient is of a mechanical nature. Now and then there is a good deal of pain, but more generally simply a sense of soreness and stiffness.

The size and shape of the tumor formed by these dropsical collections are subject to great diversity; in general, it does not exceed the volume of an orange, or a goose's egg, but there are cases in which it reaches the bulk of a foetal head, although this is very uncommon. Its shape is generally irregularly rounded or ovoidal, with a compressed, flattened appearance.

Dropsy of the synovial pouches may often be relieved, in its earlier stages, by the diligent application of iodine, astringent and sorbefacient lotions, and, above all, by blisters; conjoined with rest, attention to the bowels, and the use of the bandage. In cases of long standing, however, such treatment is seldom of any permanent advantage, nothing short of a complete and radical change in the action of the secernent vessels answering the purpose. With this view, the water being drawn off with a trocar, the same remedies may be

adopted as in the treatment of hydrocele, that is, injections of stimulating fluids, as tincture of iodine, nitrate of silver, or iodide of iron; or, what I deem better, because more certain, the introduction of a small seton, retained for a period varying from three to six days, according to the amount of the resulting inflammation. In either case, the part is carefully kept at rest, and every precaution used to prevent undue morbid action. When the tumor has become solidified and nearly of its original size, it is an evidence that the seton should be withdrawn. From three to six weeks will usually elapse before a complete cure is effected.

The operation by incision is sometimes practised in these dropsical accumulations; but as it is not only severe, but liable to be followed by violent inflammation, sometimes seriously implicating a neighboring joint, it ought, in my judgment, to be abandoned.

4. Intermixed with the fluid above described, or occurring by themselves, there are occasionally *loose concretions*, of a dense fibrous, fibro-cartilaginous,

Fig. 195.

Fibroid bodies of a synovial bursa.

or cartilaginous consistence, which, from the peculiarity of their appearance, and the troublesome symptoms they occasion, have always been a source of interest with practitioners. They are generally of a light yellowish color, and of a flat oval form, not unlike small melon seeds. Their number is sometimes very remarkable, upwards of fifty having been extracted from a single pouch. The adjoining sketch, fig. 195, affords a good idea of the appearances of these bodies, as they are exposed on dissection, and also of the changes which the bursa has undergone in conse-

quence of their presence. When existing in considerable numbers, a careful examination will rarely fail to detect their true character. The symptoms which they occasion are such as usually attend chronic bursitis.

How are these bodies formed? Two theories have been advanced upon the subject. According to one, they consist essentially of plastic matter, originally poured out in soft amorphous granules or flakes, which, increasing in size and density, are gradually moulded into a determinate shape by the pressure of the surrounding parts, as well as by the friction which they exert upon each other as they are pushed about from place to place in their confined situation. The other explanation is that they are originally connected to the inner surface of the sac, from which they receive temporary support and nourishment; but, finally becoming detached, in consequence of the constant friction to which they are subjected, they present themselves as loose bodies, of the shape and consistence here assigned to them. To my mind, this explanation is the more correct of the two; it is certainly favored by the results of dissection, in which we not unfrequently see some of these bodies still firmly adherent to the inner surface of the affected pouch, and by the analogy which exists between them and the concretions met with in some of

the movable joints, which, there is reason to believe, are always formed in this manner.

The only way to get rid of these bodies is to effect their extrusion by free incision, a tent being afterwards placed in the bottom of the sac, to promote its obliteration.

Bodies, closely resembling small hydatids, have occasionally been found in these pouches. J. Cloquet met with an instance in which there were upwards of one hundred and forty, varying in size from one to three lines in diameter, nearly transparent, and of a lenticular shape. They were situated in a large burse, between the great trochanter and the tendon of the great gluteal muscle.

SECT. IV.—APONEUROSES.

The aponeuroses, considered by themselves, offer very little of interest in a surgical point of view, since their diseases are not only infrequent, but very imperfectly understood. From the intimate relations which they sustain, on the one hand, to the muscles, and, on the other, to the areolar tissue, it is obvious that there can be but few diseases or injuries, of a serious character, of these structures, without more or less mutual involvement. At the same time, it is evident that the aponeuroses, from their peculiar arrangement, must necessarily, in many cases, play a very important part in preventing the extension of morbid action to the muscles which they serve to inclose, just as the periosteum impedes the propagation of disease to bone, and, conversely, from bone to the surrounding textures. This barrier, of course, is often broken in both cases, and then the ravages of the morbid action will be likely to be both rapid and extensive, as we see exemplified in the worst forms of erysipelas, carbuncle, and traumatic inflammation, in which every variety of structure is rudely and indiscriminately assailed by inflammation, not unfrequently terminating, in a few days, in the destruction of an entire limb.

Acute inflammation of the aponeuroses is an uncommon occurrence, and is chiefly observed as a consequence of external injury, or as an effect of erysipelas, carbuncle, and whitlow. It is generally believed that gout and rheumatism are exclusively seated in the fibrous envelops of the muscles, but the probability is that the tendinous, ligamentous, and bursal structures are nearly always implicated along with them, the two diseases sometimes beginning in the former, and sometimes in the latter, but usually ultimately attacking the whole of them.

A bad form of inflammation of the aponeuroses is occasionally produced by punctured wounds, especially when occurring in the palm of the hand and sole of the foot, in persons of broken constitution, dissipated habits, or nervous temperament. The disease soon assumes an erysipelatous disposition, and leads to excessive suffering, both local and constitutional; occasionally it is followed by tetanus.

Inflammation of the aponeuroses manifests but little disposition to pass into suppuration, ulceration, or gangrene.

Chronic inflammation of these membranes is much more common than the acute, and leads to various alterations of structure, as thickening, atrophy, and induration. Sometimes we find them affected with slight ossification, the new substance presenting itself in the form of bony spicules; and I have met with cases where, from longitudinal pressure, they were remarkably attenuated, and pierced with numerous holes, giving them a sieve-like appearance.

I am not aware that the aponeuroses are ever the seat of any of the hete-

roclite formations; dissection, however, has shown that they are occasionally affected by them secondarily.

The *treatment* of aponeurosis must be conducted upon ordinary antiphlogistic principles. Anodynes must be exhibited in full and repeated doses to relieve pain and nervous symptoms; if plethora exists, and the local action is severe, blood must be taken from the arm and by leeches from the affected parts; the bowels must be freely moved; and recourse must be had to the saline and antimonial mixture. Free incisions are made if much tension be present, or the formation of matter be threatened; followed by medicated fomentations and emollient poultices.

Aponeurosis dependent upon a gouty, rheumatic, or syphilitic state of the system, must be managed according to the general principles of treatment laid down for the relief of these affections, by colchicum, iodide of potassium, and mercury, in combination with other suitable means.

CHAPTER III.

DISEASES OF THE LYMPHATIC VESSELS AND GANGLIONS.

THE pathologist can certainly not boast of his knowledge of the diseases of the lymphatic vessels; he knows, it is true, that they are liable to inflammation, but of the manner in which it is produced, and of the effects to which it gives rise, he is, in great measure, ignorant. That these vessels play an important part in various affections is extremely probable; but such are their excessive tenuity and the great delicacy of their structure that no one has yet been able to point out the character and amount of their participation. It has been supposed that at least one form of cutaneous disease, namely, erysipelas, essentially consists in inflammation of the absorbents, and it must be confessed that the opinion, although insusceptible of demonstration, is highly plausible.

SECT. I.—LYMPHATIC VESSELS.

Inflammation of these vessels, technically called *angeioleucitis* or *lymphatitis*, has hitherto been studied to most advantage in connection with external injuries, particularly punctured and poisoned wounds, of which it is by no means an infrequent consequence. Doubtless, the disease is sometimes idiopathic, or dependent upon internal causes, such as give rise to erysipelas and other bad forms of inflammation in the cutaneous and other tissues. When arising as a consequence of an abrasion, or the prick of a needle, as in sewing up a dead body, the affected vessels can be easily traced, as they pass beneath the skin, as small reddish cords, tense, nodulated, and painful to the touch, accompanying the principal veins, and extending as far as the nearest ganglions, in which they appear to terminate. The number of these reddish lines is variable; sometimes there are only two or three, while at other times there are as many as six, ten, or a dozen, forming a kind of band, from half an inch to an inch in width. Whenever the number is considerable, there is always a good deal of concomitant swelling; and the parts, feeling stiff, sore, and tender, readily pit on pressure, owing to the effusion of sero-plastic matter. In the more severe attacks of *angeioleucitis*, as those consequent upon inoculation with putrid or poisonous matter, the tumefaction soon becomes general, spreading rapidly over the whole limb, and the discoloration, losing its striated appearance, so characteristic of the disease in its earlier stages, also assumes a diffusive disposition. Arrived at this point, it is usually impossible to distinguish this affection from ordinary erysipelas, so closely do the two lesions resemble each other.

Occasionally the inflammation seems to take its rise in the deeper layers of vessels, when the discoloration is generally preceded by considerable induration of the subcutaneous areolar tissue, giving the part a kind of brawny sensation; by and by, however, red streaks appear in the skin, and then the disease follows pretty much the same course as when it begins in the superficial vessels.

However originating, the disease nearly always involves the neighboring lymphatic ganglions, causing them to enlarge, and to become tender, red,

and painful. In some of the worst forms of angeioleucitis, the glands manifest signs of being diseased before the absorbents themselves are apparently implicated. Such an occurrence, although uncommon, is occasionally met with in inflammation of these vessels consequent upon dissection wounds.

Angeioleucitis no doubt sometimes passes into suppuration, and, perhaps, even into gangrene; but of these occurrences, as pure, uncomplicated affections, our knowledge is too imperfect to justify us in speaking positively.

The *symptoms* ushering in an attack of angeioleucitis are usually such as are denotive of constitutional depression, following pretty closely upon the injury sustained by the affected vessels. The patient, after having felt indisposed for some hours, seldom more than from twelve to twenty-four, is seized with chilly sensations, accompanied with flushes of heat, a disposition to yawn, headache, pain in different parts of the body, and a dry and contracted state of the skin. Sometimes the attack is ushered in by violent rigors, soon succeeded by high fever, and delirium. If the local affection be at all severe, the symptoms soon assume a typhoid character, the pulse becoming weak and frequent, the surface hot and dry, and the tongue covered with a brownish fur. The local distress, meanwhile, increasing, abscesses form in different portions of the limb, the matter being of a foul, unhealthy character, and disposed to spread extensively among the surrounding structures, in the same manner as in erysipelas and other bad forms of inflammation.

Angeioleucitis may be confounded with other diseases, particularly erysipelas and phlebitis, and the distinction is by no means always so easy as might at first sight appear. In fact, it can only be made out satisfactorily in the earlier stages of the complaint, the principal source of diagnosis being the red striated appearance of the affected surface, reaching from the seat of the injury up to the nearest lymphatic ganglions. In phlebitis, the discoloration is also linear, but the cords are much larger, firmer, more knotty, and more deeply seated; they are also less numerous, and there is not near so much involvement of the lymphatic glands. In erysipelas, the inflammation usually begins as a circumscribed affection, with diffuse, uniform redness, not striated, as in angeioleucitis, or in phlebitis.

In the *treatment* of this disease, the same general principles are to be observed as in the treatment of erysipelas and phlebitis, to which it bears so close a resemblance. The exciting cause being removed, such local and general means are to be employed as may seem to be best adapted to the exigencies of each particular case. Bearing in mind that, if the disease be at all severe, the symptoms will be likely soon to assume a typhoid character, the surgeon will take care not to deplete much, especially with the lancet and purgatives, lest he be instrumental in inducing fatal exhaustion, of which the danger may be already sufficiently great in consequence of the progress of the morbid action. Leeches may be applied along the course of the affected vessels, but not directly over them, if the disease is in its earlier stages, and the patient is robust and in the prime of life. They should be employed in considerable numbers, and be succeeded by warm fomentations, the whole limb being enveloped in flannel cloths wrung out of a strong solution of acetate of lead and opium, and kept constantly wet. The application of iodine will also be found advantageous; also, a long, narrow blister, stretched along the course of the affected vessels, and retained for a sufficient length of time to produce thorough vesication. If matter form, or great tension and throbbing exist, suitable incisions must be made.

The constitutional treatment must be regulated by the character of the general symptoms. Purgatives, to clear out the bowels and correct the secretions; iron, or iron and quinine, to improve the tone of the system and the state of the blood; and anodynes, to allay pain and induce sleep, with a properly regulated diet, will constitute the most reliable and efficient means.

If marked debility arise, brandy, wine, or porter, with nutritious broths, will be required. When the disease proves obstinate, or becomes chronic, a mild mercurial course will be beneficial.

Varicose enlargement of the lymphatic vessels has occasionally been noticed, although the occurrence is extremely uncommon. In a case mentioned by Carswell, of a young man, twenty-six years old, a tumor nearly as large as an orange existed in each groin, for which he had worn a double truss from his boyhood, under the supposition that he had hernia. On dissection, however, each tumor was found to consist of enormously dilated absorbent vessels connected with the inguinal ganglions. When cut into, instead of presenting a solid, compact structure, it had the appearance of a coarse sponge, most of the vessels being from one to three lines in diameter. The same phenomenon was witnessed, only in a more striking degree, in the lymphatics of the pelvic and lumbar regions. The spongy and elastic character of such a swelling ought to prevent any serious error of diagnosis. Hardly any treatment would be necessary in such a case. Excision might prove dangerous, and should not be practised without due deliberation.

SECT. II.—LYMPHATIC GANGLIONS.

The lymphatic ganglions are liable to inflammation, chronic enlargement or hypertrophy, carcinoma, tubercle, earthy degeneration, and fibro-plastic tumors.

Inflammation of these bodies, technically called adenitis, may show itself either as an acute or a chronic affection, and is of such remarkable frequency as to demand special consideration. In whatever form it occurs, it is most common in young children of a strumous predisposition, and is generally brought on by attacks of cold, or by some local irritation implicating the afferent lymphatic vessels. The disease, moreover, may be common or specific, of the latter of which illustrations are afforded in syphilitic bubo, in the bubo of plague, and in the swelling of the lymphatic ganglions of the axilla consequent upon dissection wounds and malignant pustule.

1. *Acute adenitis* is most common in the ganglions of the neck, jaw, and supra-clavicular region; it is also occasionally met with in those of the groin and axilla. The disease may be limited to one of these bodies, or, as is more generally the case, affect a considerable number of them; beginning as a hard, painful knot, exquisitely tender to the touch, and rapidly increasing in size, until, in some instances, it attains the volume of an almond or a pullet's egg. The increase in the size of the tumor is sometimes exceedingly rapid, as we often see in adenitis of the neck from exposure to cold, where a body of this kind, scarcely perceptible in the natural state, may, in the course of a few hours, acquire the size of a filbert or a small marble. As the disease advances, the swelling extends to the connecting areolar tissue, the skin becomes red and inflamed, and the parts pit on pressure. The discoloration is not unfrequently of an erysipelatous character. When the inflammation is fully developed, the local distress is usually very severe, and the constitution actively sympathizes with the suffering textures, the patient being feverish, deprived of appetite and sleep, and affected with constipation.

Dissection shows the affected ganglions to be of a deep reddish or brownish color, infiltrated with sero-plastic fluid, softened, lacerable, or easily crushed with the finger; the cellular tissue around is also abnormally vascular and infiltrated, and, in many cases, it seems to be the principal seat of the morbid action.

Adenitis may end in delitescence or resolution, pass into suppuration, or assume a chronic character. The occurrence of gangrene is very uncommon.

Adenitis sometimes vanishes in a few hours, either spontaneously, or under mild treatment. We often see enlarged and inflamed ganglions of the neck, or at the angle of the jaw, most rapidly disappear under frictions with ammoniated liniment, aided by hot drinks and immersion of the feet in hot water, or simply warming the feet near the fire. When the inflammation is more severe, an active purgative will be necessary, followed by a gentle diaphoretic, as one-fourth of a grain of morphia with one-half that quantity of tartar emetic. The diet must be light, and the part and system must be kept perfectly at rest. If the inflammation threaten to prove troublesome, or to pass into suppuration, leeches and medicated fomentations must be employed. In many cases the dilute tincture of iodine will be beneficial in cutting short the disease.

When adenitis passes into *suppuration*, matter generally begins to form from the fifth to the tenth day, sooner or later, according to circumstances, this event being generally most rapidly excited in young, weakly, or scrofulous children, with an impoverished state of the blood. The pus is not always situated in the enlarged ganglions; in many cases, in fact, it is limited, in great degree, if not entirely, to the neighboring areolar tissue. It is of a light yellowish color verging on greenish, thick, and often very copious; occasionally it is mixed with blood, and with the débris of the affected ganglions. Finally, the matter may occur as an infiltration, or as a distinct abscess.

The occurrence of suppuration is announced by increased heat, pain, redness, and swelling, along with a sense of throbbing, and by high constitutional disturbance, attended by chilly feelings, or even rigors, followed by fever and perspiration.

The *treatment* is strictly antiphlogistic. If the phenomena are clearly denotive of the existence of pus, an early incision is made, free and dependent, to favor thorough evacuation and prevention of reaccumulation. The operation is followed by warm water-dressing or an emollient cataplasm. The use of a tent will occasionally be required to maintain patency of the puncture.

2. *Chronic* adenitis is a very common occurrence; it generally succeeds to the acute variety of the disease, but there are cases in which it is seemingly, although not in reality, a primitive affection. However this may be, its effect is gradually to produce enlargement and induration of the affected bodies, until, in many cases, there is a complete subversion of the natural structures. In the earlier stages of the disease, the gland is of a reddish, brownish, mottled hue, considerably increased in size, and of a firm, fleshy consistence; by

and by, however, it assumes a grayish or whitish aspect, becoming almost homogeneous, and cutting very much like an unripe apple or pear; in some cases it is quite soft and lacerable. When the transformation is very great, the hardness of the gland may be equal to that of scirrhus, with which it is then liable to be confounded. A distinct capsule, composed of dense cellular substance, generally surrounds the enlarged body, which is capable, under such circumstances, of attaining

Fig. 196.

Hypertrophy of the lymphatic glands.

a volume equal to that of a small orange. When a number of such ganglions are agglomerated together, a large tumor is formed, of a hard, firm consist-

ence, more or less adherent to the neighboring parts, and of an irregularly lobulated appearance, as in fig. 196, copied from one of my preparations.

Chronically enlarged or hypertrophied lymphatic ganglions may occur in any part of the body; but they are most commonly met with in the neck, or about the lower jaw. In the internal cavities they are most frequently seen in the mesentery and pelvis, and at the root of the lungs. The effect which these bodies exert upon the structures among which they are situated, is principally of a mechanical character; compressing them, and so interfering more or less with the exercise of their functions. Thus, in the neck they may cause injurious pressure upon the trachea, vessels, and nerves; in the pelvis they may interfere with parturition by preventing the descent of the child's head; while in the lungs they may occasion suffocation by obstructing the entrance of air into the bronchial tubes.

Various causes may give rise to this affection; some of a local, others of a purely constitutional nature. In the neck, it is often occasioned by cold, or by disease of the jaw, teeth, gum, or tonsil; in the groin, by ulceration of the penis; in the axilla, by disorder of the mammary gland; in the mesentery, by irritation of the small bowel. The most efficient general cause is a strumous state of the system; but there is reason to believe that the lesion may be produced by anything that has a tendency to derange the general health, or to impoverish the fluids and solids.

Chronic enlargement of the lymphatic ganglions often continues for years, now advancing, then stationary, and now, perhaps, receding; in general, however, the disease is obstinate, especially when the structure of these bodies has undergone serious organic changes, in which case it is often extremely difficult, if not impossible, to reclaim them by any mode of treatment of which we have any knowledge.

The *treatment* of chronic adenitis is both constitutional and local. In the first place, the exciting cause is looked for, and, if possible, removed; the carious tooth is extracted, the ulcer on the penis healed. The general health is improved by attention to the bowels and secretions, and by a strict observance of the laws of hygiene. When plethora exists, detraction of blood, and the antimonial and saline mixture will be of service; under opposite circumstances, the proper remedies will be a nutritious diet, and alterant tonics, consisting of iodide of iron and quinine, bichloride of mercury, iodide of potassium, and cod-liver oil. When there is no contra-indication, minute doses of mercury in Huxham's tincture of bark will often be highly efficacious, but care should be taken not to carry it to profuse ptyalism. Tartar emetic also, given in small doses, as the tenth or twelfth of a grain, three times a day, will frequently prove eminently beneficial. In most cases a regular system of purgation should be maintained. The German practitioners are fond in this disease of the use of hydrochlorate of ammonia, administered in doses of from five to ten grains three times in the twenty-four hours. The article is a powerful sorbefacient, and is therefore worthy of trial, especially in cases refusing obedience to the more ordinary measures.

Among the more important topical remedies are leeches, and sorbefacient liniments, unguents, and embrocations, assisted by systematic and steady compression. These means must be employed with great caution and judgment, otherwise they will be sure to be productive of harm instead of benefit. All sorbefacient applications should, in the first instance, be of a mild character, their strength being gradually increased as the parts become more tolerant of their impression, and their peculiar effects are rendered more and more apparent. When the enlarged ganglions are favorably situated, compression will often be found a most admirable remedy; it may be applied with the pad of a truss, as in hypertrophy of the inguinal glands, or with a compress and bandage when it affects the glands of the neck, care being

taken not to interfere with respiration. In obstinate cases, the application of a blister occasionally exerts a salutary influence, relieving the enlarged structures of engorgement, and stimulating the absorbent vessels so as to induce them to remove morbid deposits. The electric current has sometimes been advantageously used. Subcutaneous division of the enlarged glands, or comminution with the bistoury, has occasionally been practised, but the effects have not been such as to render a repetition of the operation at all desirable.

Finally, when the disease is intractable, our only resource is removal of the morbid mass, provided it is situated favorably for such a procedure. Such a step, however, should not be lightly taken, as it must often involve serious consequences, on account of the deep situation of the tumor, and its connection with important structures. In the cervical region, for example, the excision of a mass of enlarged and indurated lymphatic ganglions not unfrequently proves a most difficult, embarrassing, bloody, and hazardous operation. Removal, however, will be much facilitated, if the knife be kept close to the enlarged glands. Sometimes the enlarged and disintegrated organ may be pressed out bodily through a small opening in the integuments. When the diseased mass compresses the trachea or great vessels of the neck, and does not admit of removal, relief must be sought by the subcutaneous section of some of the constricting muscles, especially the sterno-cleido-mastoid.

3. *Carcinomatous disease* of the lymphatic ganglions is occasionally met with as a primary affection, more particularly the encephaloid variety. Scirrhus is extremely uncommon; colloid I have never seen here; while of melanosis I have witnessed only a few instances. As a secondary formation, cancerous disease of the lymphatic ganglions is extremely frequent.

Primary *encephaloid* is most common in the lymphatic ganglions of the groin, axilla, and neck; it occurs in both sexes, and at various periods of life, in children and adolescents, as well as in subjects after the age of fifty. In general, the disease arises spontaneously, but in some cases its origin may be distinctly traced to external injury, as a blow or kick. Its progress is usually very rapid, few persons surviving its attack longer than from six to twelve months. Beginning commonly in one of these bodies, as a hard, smooth, semi-elastic swelling, it soon extends to those in its immediate vicinity, thus often involving a whole group of ten, fifteen, or even twenty. In consequence of this arrangement, the tumor has generally a knotty, lobulated surface, and not unfrequently acquires a large bulk, equalling, or even exceeding, that of a fist. Soft and elastic at one point, it is hard and firm at another, while at a third it is occasionally almost of a fluid consistence. As it progresses it contracts firm adhesions to the surrounding parts, the skin becomes attenuated and discolored, and the subcutaneous veins assume that peculiar varicose disposition so common in encephaloid in other parts of the body. By degrees, the morbid mass breaks through its confines, ulcerating and fungating, and destroying life either by hemorrhage or by hectic irritation.

Examined after removal, the morbid mass is found to consist of a soft, brain-like substance, inclosed in thick, strong membranous cysts, representing the original capsules of the affected ganglions, but greatly condensed by the pressure of the contained matter. In addition to these cysts, there is generally a large quantity of filamentous tissue, intersecting the parts in different directions. A grumous looking, semi-organized substance often occurs in these tumors, and there are cases in which they contain serous cysts. In an instance of encephaloid of the axillary ganglions, which I observed in a man fifty-six years of age, there was a cavity of this kind which distinctly

fluctuated under the finger, and gave vent, on being punctured, to upwards of eight ounces of sero-sanguinolent fluid.

The diagnosis of encephaloid of the lymphatic ganglions is easily made; the only affections with which it is liable to be confounded being chronic enlargement and tubercular disease, from both of which it may be distinguished by the history of the case, and the rapid growth and soft consistence of the tumor. In chronic enlargement, the swelling is hard, and often involves a whole chain of ganglions; in tubercular disease the swelling, also very firm, generally manifests a disposition to suppuration, and is nearly always associated with other marks of the tubercular dyscrasia.

The proper remedy is early extirpation, although the disease will be certain to recur, and ere long prove fatal. Such a result will generally occur much sooner in young than in elderly subjects, and it has hence been a question whether they should ever be subjected to operation.

Primary *scirrhus* of the lymphatic ganglions is extremely uncommon; in the few cases in which it has hitherto been observed it occurred in the cervical, inguinal, and axillary regions of elderly persons. The disease is comparatively tardy in its progress, and the tumor, which is distinguished by its great hardness, seldom acquires any considerable bulk. My opinion is, that what is usually considered as *scirrhus* of these bodies is nothing but fibro-plastic disease.

Melanos of the lymphatic ganglions may occur as a primary affection; generally it is associated with melanos in other parts of the body. I have noticed it in a few instances in the lymphatic ganglions of the groin and axilla, which, I believe, are its most frequent seats. It shows itself either as an infiltration, as in fig. 197, from a specimen in my cabinet, or as an irregular tumor, solid, inelastic, and of variable size and shape.

Fig. 197.
Melanos of a lymphatic gland.

Tubercular disease of these bodies is met with chiefly in young subjects, before and soon after the age of puberty; most generally in children. Now and then it occurs in elderly persons, but this is very uncommon. Surgically considered, it is most frequent in the ganglions of the neck and jaw, and may be limited to one of these bodies, or, as is most generally the case, affect a large number of them, either simultaneously or successively. It often co-exists with tubercular disease of the lungs, joints, and other parts. This subject, however, having already been discussed in the chapters on scrofula and tumors, any further remarks respecting it here would be superfluous.

The lymphatic ganglions occasionally undergo the *earthy degeneration*, as in fig. 198, being converted into a soft, whitish substance, not unlike chalk. Such an occurrence is most common in the bronchial and mesenteric ganglions, but is also sometimes seen in those of the neck. Not long ago, I met with a case in which not less than five of the cervical ganglions had become completely ossified; they were of stone-like solidity, of a light brownish color, rounded, and from the size of a pea to that of a hazel-nut. The patient was a middle-aged, strumous female, and the ganglions, which formed a chain along the inner edge of the sterno-cleido-mastoid muscle, on the right side, had been affected from early youth. Their character was obvious to the slightest touch. Excision was easily effected. Such tumors need not be interfered with, unless they become a source of annoyance by their situation.

Fig. 198.
Cretaceous degeneration of the lymphatic glands.

The *fibro-plastic* tumor is sometimes found in these bodies, the proper tissue of which is replaced by a whitish, dense, solid substance, which, to the naked eye, as well as under the microscope, presents all the characteristic features of this morbid growth. The tumor generally occurs in young subjects, after the age of puberty, and is capable of acquiring a bulk varying from that of an orange to that of a fist. It is easily recognized by its firmness, and slow but steady progress, and by the absence of pain and constitutional involvement. The proper remedy is excision.

CHAPTER IV.

DISEASES AND INJURIES OF THE NERVES.

SECT. I.—WOUNDS AND CONTUSIONS.

NERVES, when divided, readily reunite, the connecting medium being plastic matter, which, being effused between and around the severed ends, is gradually solidified, and transformed into an analogous tissue, capable of transmitting the nervous current, although it does not contain any real nerve-substance. In order, however, that the connection shall be satisfactory, it is necessary that the interval between the two extremities be very short, otherwise the plasma will fail to effect the object, and each end will become expanded into a bulbous mass, having all the characteristics of a neuromatous tumor, similar to that which occasionally forms in the stump after amputation, and liable, like it, to become the seat of neuralgia. It is a curious fact that if a nerve be slowly divided with a ligature, the reunion of its extremities will generally be more rapid and complete than when the section is performed with a sharp knife; in the former case there is commonly very little retraction of the ends, whereas, in the latter, they sometimes separate to a considerable distance, thus requiring a large quantity of lymph to fill up the gap.

When a nerve is cut completely across, the parts to which it is distributed are necessarily deprived of their functions, an occurrence which, consequently, serves as a diagnostic sign of the accident. Thus, if the nerve be one of motion, the parts will be paralyzed, while, if it be one of sensation, they will be divested of sensibility. If the division be only partial, the loss of function will, of course, be partial also. In general, the structures beyond the seat of injury feel numb and heavy, with a sense of tingling, prickling, stinging, or burning.

Wounds of the nerves must be treated upon general principles. If there be no serious loss of substance, the divided ends should be as closely approximated as possible by attention to position, and, if necessary, by suture of the neurilemma, the needle and thread used for this purpose being of the most delicate kind. Such a procedure is much better than permitting the extremities to become separated from each other, as they are very apt to do when the suture is neglected, either in consequence of their retraction or of the interposition of other tissues. The operation, if carefully performed, will be free from pain, and, if one of the ends of the ligature be brought out at the nearest point of the common wound, no difficulty can arise in regard to its detachment.

A similar procedure may be adopted when a large nerve has been severed, but has failed to reunite, owing to the great distance at which the ends are separated from each other. An incision being made down to the nerve, the two ends are to be carefully retrenched, and then tacked together by several points of suture, apposition being favored by attention to the position of the parts.

Nerves when *punctured*, pricked, or partially divided, usually occasion severe pain, of a neuralgic character, extending up and down the affected

parts, and attended with muscular weakness, perverted sensation, convulsive movements, and derangement of the general health. Such effects not unfrequently follow the operation of venesection at the bend of the arm, in consequence of injury sustained by one of the subcutaneous nerves. The proper remedy is complete division of the affected filament, either subcutaneously, or, when this is impracticable, by free incision. The operation, however, is not always permanently successful, owing to the deep impression made upon the nervous system, the effect of the lesion eventually becoming general. Besides, the divided extremities of the nerve are very apt to take on diseased action, either by being incorporated in the original cicatrice, or by being expanded into a species of neuroma. When this is the case, the proper procedure will be free excision instead of subcutaneous section.

Severe effects often follow *contusion* of the nerves, the parts to which they are distributed becoming numb, cold, withered, more or less painful, and, ultimately, almost entirely useless. Effects of this kind sometimes succeed to accidents of, apparently, the most trifling character. The nerves, so far as we can form an opinion without the light of dissection, soon become inflamed, and are often irretrievably ruined, being effectually and permanently disqualified for the performance of their functions. It is hardly probable that these effects are due, as has been conjectured, to mere concussion of the nerve-substance; if this were the case, they would be much more transient, as well as less severe. What corroborates the idea that inflammation is deeply concerned in the production of the secondary suffering is the fact that the parts, although seriously crippled at the start, do not evince much derangement until the disease is fully established in all its intensity.

Professor Willard Parker has recently described what he calls *concussion* of the nerves. He considers the accident as similar to concussion of the brain, the nerves receiving a shock eventuating in a sudden suspension of their functions. In the paper which he has published on the subject, in the New York Journal of Medicine for September, 1856, he has related six cases illustrative of the nature of the injury. When the paralysis, which is generally temporary, subsides, the affected nerves are in danger of being assailed by inflammation, which, if it cannot be prevented, must be treated in the usual antiphlogistic manner. A long time frequently elapses before recovery takes place, the nerves remaining weak, irritable, and incapable of performing their proper functions. The limb supplied by the affected nerves is soon fatigued and exhausted by exercise, and is the seat of a dull, aching, tired sensation, which is always aggravated by exertion, especially if carried beyond a given limit; in time, it becomes cold, atrophied, and, in great degree, useless. The general health also suffers, though the disease never proves fatal.

The proper treatment, in the first instance, is rest, absolute and unconditional; and, after the nerves have recovered from the immediate effects of the injury, passive exercise, dry friction, and attention to the general health, which, in the more severe forms of the accident, is always materially, if not seriously, impaired.

Severe pain is often produced by the *compression* of a nerve, without, so far as can be determined, any particular disease of the nerve itself. In aneurism, for example, of the larger arteries the patient often experiences extreme suffering from this cause. The pain, in this case, is either sharp and darting, as in certain forms of neuralgia, or of a burning, tearing, boring, or gnawing character, especially if there be at the same time erosion of the osseous and cartilaginous tissues.

SECT. II.—TETANUS.

The term tetanus is a generic one, employed to denote a peculiar affection of the nerves, characterized by violent contraction of the voluntary muscles, with irregular intervals of partial, though seldom of complete, relaxation. Different names have been devised to designate the disease, according to the nature of the predominant local symptoms occasioned by the affected muscles. Thus, when the muscles of the lower jaw are spasmodically contracted, so as to prevent the patient from opening his mouth, the word *trismus* is employed, or, to use a common expression, the person is said to have locked jaw. When the body is bent forcibly forwards by the action of the abdominal muscles, the affection is denominated *emprostotonos*, and *opisthotonos* when it is drawn backwards by the dorsal muscles. The term *pleurothotonos* is used when the body is drawn to one side. A distinction of much greater importance is that of tetanus into traumatic and idiopathic, acute and chronic. The disease occasionally comes on within a few days after birth, and is then designated as infantile tetanus, the *trismus nascentium* of authors.

In this country, especially in its more temperate latitudes, the surgeon has to deal chiefly with traumatic tetanus, the idiopathic variety being extremely infrequent. Cases of it, however, occasionally occur in the more tropical States of the Union, especially in South Carolina, Georgia, Mississippi, Florida, Louisiana, and Texas; while in the West and East Indies it is sufficiently common. The tetanus of new-born infants occurs chiefly in the southern and southwestern States of North America, in consequence, apparently, of injury sustained in the ligation of the umbilical cord. Infantile tetanus seems to be very common in certain portions of Europe. Thus, it is asserted by Dr. Joseph Clark, that in the year 1782, of 17,550 children born in the Lying-in Hospital of Dublin, 2,944 perished from this cause alone within the first fortnight after birth.

Traumatic tetanus, to which the ensuing remarks are more particularly intended to apply, is not peculiar to any age, to either sex, or to any particular pursuit; on the contrary, it is met with at all periods of life, in females as well as in males, and in all ranks and classes of society, from the most refined and affluent to the most filthy and impoverished. It has been ascertained, however, that the young suffer more frequently than the aged, and that it is particularly liable to occur in persons of a nervous, irritable temperament. Ill health, especially disorder of the digestive apparatus, grief, anxiety of mind, and whatever, in short, has a tendency to depress the energies of the system, powerfully predispose to its development. It is generally stated that men are more prone to traumatic tetanus than women, and the statistics that have been published on the subject would, at first sight, seem to warrant such a conclusion; but it will be found, upon more careful inquiry, that the difference is only apparent, not real, and that it is dependent upon the fact that females are much less obnoxious to the various exciting causes of the disease than the other sex. Blacks and mulattoes are more liable to tetanus than whites. In some portions of the West Indies the disease is almost exclusively confined to the colored population.

Causes.—The causes of traumatic tetanus are, as the term implies, various kinds of external injury, as punctured, lacerated, and contused wounds, burns, scalds, abrasions, compound fractures and dislocations, and surgical operations, as amputations and the excision of tumors. A number of cases have been recorded where tetanus was produced by salivation. Some of the most trivial accidents are, at times, sufficient to produce the disease. Thus, cases have been observed where it followed the application of the scarificator in

cupping, the introduction of a seton, and the extraction of a tooth. Baron Larrey mentions an instance in which it was occasioned by the lodgment of a fish-bone in the fauces. Examples of tetanus, consequent upon the ligation of the iliac, femoral, and carotid arteries, have been recorded by Brodie, Dazille, and Dudley. Many years ago, I met with a case where it supervened upon the injection of a hydrocele, the man dying a few days afterwards. Tetanus has now and then followed upon parturition, and that, too, where the labor was apparently of the most simple nature. The fact is, in persons of a nervous, irritable temperament, any injury, however trifling, or insignificant in itself, may readily induce the disease, especially in hot and damp states of the atmosphere, or during sudden transitions from heat to cold. Exposure to cold draughts, by which the body is suddenly chilled, is, under such circumstances, extremely liable to provoke an attack.

The effect of cold air, when permitted to play directly upon the body, is well illustrated by an occurrence that took place after the battle of Ticonderoga, in 1758. The wounded were exposed the whole night after the action, in open boats upon Lake George, and the consequence was that nine of them died of locked jaw. During our war with Great Britain, most of those wounded by fire-arms on board the frigate Amazon, before Charleston, were attacked with tetanus on the fourteenth day, from a sudden change of very wet and cold weather following a long draught. Wounded soldiers, lying on damp or wet ground, are particularly prone to attacks of this disease.

The injury inducing the disease may be situated upon any part of the body. It was at one time supposed that lesions of the head and face were singularly exempt from tetanus, but more enlarged experience has demonstrated that, although it does not occur with the same relative frequency as when the cause is seated in other regions, yet its invasion after such accidents is by no means uncommon. Injury of the inferior extremity is more prone to be followed by tetanus than a similar affection of the superior extremity; and everybody knows how remarkably liable the disease is to supervene upon wounds involving the tendons and aponeuroses of the hands and feet, especially of the latter. Lesions of the nerves themselves are particularly dangerous in this respect, more especially when they are of a punctured character, or when they are limited to a partial division of their fibres and neurilemma, by a blunt instrument, as a piece of glass or a rusty knife.

The extent of the injury does not, so far as we are able to judge, exert any material influence upon the production of the disease, as it has been known to follow, on the one hand, the most insignificant scratch, and, on the other, the most frightful wound. I believe, in fact, that it may be assumed, as a general principle, that the danger of the occurrence of tetanus is, other things being equal, almost in direct ratio to the diminutive size of a wound. This is certainly true of a majority of the cases that have fallen under my personal observation, an apparently trivial injury, mostly a little puncture, having served as the exciting cause.

Symptoms.—The period which intervenes between the occurrence of the injury and the development of the disease, is liable to considerable variety; but the subject, unfortunately, has not been elucidated by reliable statistics. Enough, however, has been ascertained to prove that it ranges, in the great majority of cases, from four days to a fortnight. In some rare instances, well-marked tetanic symptoms have manifested themselves within several hours after the receipt of the injury, and, on the other hand, cases have occurred where the eruption did not take place under eight or ten weeks. What is remarkable is, that the disease occasionally does not appear until the wound which provokes it is completely closed, owing, doubtless, to some lurking irritation in the nerves of the affected parts.

Although tetanus sometimes comes on suddenly, with hardly any premoni-

tion, yet, in general, the attack is preceded by various anomalous nervous sensations which but too surely announce its approach. The most important and reliable of these precursors are, a sense of *malaise* or universal uneasiness, aching in the muscles, stiffness about the lower jaw, pain in moving the head, and difficulty in protruding the tongue. If there be a wound, it commonly puts on an unhealthy appearance, discharging a thin, sanious fluid, and manifesting no further disposition to heal. After these symptoms, which are often attributed by the patient to the effects of cold, have continued for a variable, but usually a very short, period, others, more bold and decisive in their character, set in, leaving no longer any doubt respecting their true nature. The jaw now becomes firmly locked; the faculty of mastication is completely abolished; attempts at deglutition excite spasm in the throat, with a sense of impending suffocation; and there is an indescribable distress in the precordial region, extending from the ensiform cartilage backwards towards the spine, as if the chest were tightly encircled by a cord. The muscles of the back and abdomen are rigidly contracted, and, in no long time, those of the extremities become similarly affected. When their action is very violent, the spinal muscles may shorten themselves so much as to draw the trunk into a distinct arch, the body resting only upon the occiput and heels, the affection thus constituting the variety of tetanus called *opisthotonos*. The opposite state of this, *emprosthotonos*, is extremely uncommon; for, although the abdominal muscles are usually very firmly contracted, being often as hard as a board, yet it is seldom that they are able to counteract the extensor muscles of the back to such a degree as to bend the head and chest forwards. The disease having reached this stage, may be said to be completely and characteristically established. Frequent spasms now occur, convulsing and agitating the whole frame, and greatly increasing the general suffering. The teeth are firmly clenched; the eyes are fixed in their sockets, and have a wild, unnatural expression; the nostrils are expanded; the corners of the mouth are retracted; the countenance has an old, haggard, and withered look; the respiration is laborious and hurried; and the smallest quantity of fluid is unable to descend the fauces and œsophagus. So great, in fact, generally, is the impediment to deglutition that the very sight of water is a source of suffering. The pain is usually very severe, particularly about the jaw, throat, chest, and spine; while the general sensibility of the surface is so excessive that the slightest breath of air is often sufficient to bring on violent spasms.

Fever is seldom present in traumatic tetanus, even when it has reached its height, although the thirst is generally quite considerable; the pulse, which rarely exceeds eighty, eighty-five or ninety in the minute, is soft and regular, except, perhaps, during the violence of the muscular spasms, when it may be considerably agitated, small and feeble; the tongue, at first moist, becomes gradually dry and brownish; the stomach is extremely torpid; the bowels are generally obstinately constipated; the urine is scanty and high-colored; and the skin is hot and bathed with a copious perspiration, which is occasionally very clammy and offensive, especially towards the latter stages of the disease. The mind is usually unimpaired.

Although such is the most common course of the disease, yet more or less irregularity occasionally arises, giving the symptoms somewhat of an anomalous character. Thus, there may be almost a complete absence of pain; the throat may be free from uneasiness; the respiration may be gasping, or performed with a sort of catch; the eyelids may be half closed; the orbicular muscle of the mouth may be firmly contracted over the teeth; and the extremities may remain completely relaxed. The skin is, occasionally, remarkably hot, the temperature, in some cases, having been found to range as high as 110° of Fahrenheit.

Diagnosis.—The diagnosis of tetanus rarely, if ever, presents any difficulties. In general, the history of the case alone is quite sufficient to determine its real character. The only disease with which it can be confounded is hydrophobia, but the symptoms of the two affections are so very different that none but a most heedless practitioner could possibly commit such an error. The period of latency in hydrophobia is, on an average, not less than a month, while tetanus is usually developed in from four to fourteen days from the infliction of the injury which provokes it. Besides, in rabies there is an absence of locked jaw and of opisthotonos, which constitute such striking features in tetanus.

One of the most valuable diagnostic symptoms of tetanus is the terrible distress in the precordium; it is usually described as of a painful, dragging nature, and is no doubt dependent upon spasmodic contraction of the diaphragm. Coming on early in the disease, it generally continues to its close, and is nearly always attended with opisthotonos, the head and shoulders being drawn, as it were, instinctively backward, to relieve pain and favor the introduction of air into the lungs. In tetanus, the muscular contraction is steady and persistent, though liable to frequent and sudden exacerbations; in hydrophobia it is clonic, occurring paroxysmally, and having distinct intermissions. In tetanus, swallowing is difficult, chiefly by reason of the impossibility of separating the jaws; in rabies, it is dependent upon spasm of the throat and œsophagus; in the former disease, the mind is calm and unaffected; in the latter, it is often powerfully excited, and, at times, even furious.

Prognosis.—The prognosis in traumatic tetanus is extremely unfavorable. In the great majority of cases death occurs from the third to the fifth day; and if we occasionally meet with an instance of recovery, the circumstance is to be regarded only as an exception to a general law of the mortality in this affection. In an experience of thirty-one years, I have seen but two cases where the patient escaped with his life, and then only after a protracted and painful struggle. When the disease has once fairly commenced, the tetanic spasms generally continue to recur, with more or less severity, until they prove fatal. There are no reliable signs which can serve to guide us in regard to the prognosis in this affection. The previous state of the general health, the age of the patient, and the character of the pulse, afford no clue as to the probable issue of the case. The young and the robust fare no better, in this respect, than the old and the infirm. Both alike perish from its attacks. The danger is undoubtedly always, other things being equal, in proportion to the violence and duration of the paroxysms, and it has been found that any tendency to chronicity is generally so much in favor of ultimate recovery; although patients sometimes live for several weeks, and then die from the effects of the malady.

The manner in which death occurs is not well, if at all, understood. In some instances, it is apparently caused by suffocation, from spasm of the muscles of the larynx; occasionally it results from mere exhaustion, life being worn out by the intensity of the suffering; and in a third class of cases, it may probably be induced by convulsions of the heart, interrupting the passage of the blood to the lungs and brain.

Pathology.—It might reasonably be supposed that a disease which is characterized by so much violence during life, would leave some traces of its existence after death; but to show how erroneous such a conclusion is, it is only necessary to refer to the fact that all the dissections that have hitherto been made of persons dead of this affection have utterly failed to throw any satisfactory light upon its pathology and morbid anatomy. Many statements have been reported with reference to these dissections that are entirely without foundation; in fact, in not a few of the cases, natural or accidental ap-

pearances have been confounded with morbid, and lesions have been described which existed only in the imagination of the examiners. From the circumstance that tetanus is essentially a nervous affection, the brain and spinal cord, as well as the nerves emanating from them, and even the great sympathetic, with its plexuses and ganglia, have all been most thoroughly scrutinized in numerous instances, and that, too, by some of the ablest men in the profession, and yet, notwithstanding all this, we are no wiser now in regard to the real lesions of this disease than our forefathers were centuries ago. The whole subject is, in truth, still a mystery. I have myself made several dissections of this kind, and have witnessed others, amounting, perhaps, altogether to eight or ten, without, in a single one, observing any morbid appearances that could justly be ascribed to the effects of the disease. It has been noticed in several instances that the nerves leading from the wound which caused the attack were in a state of inflammation, their substance and neurilemma being congested and discolored.

Of the true pathology of tetanus, then, nothing of a satisfactory nature whatever is known; that it is essentially an affection of the nervous system, or of the nerves of particular muscles, is a circumstance which must be admitted, from the symptoms which characterize it; but in what the peculiar change consists, or to what extent it is carried, are points in the history of the lesion of which we are completely ignorant. I am aware that numerous hypotheses have been framed in explanation of the subject, but the only merit which they possess is their ingenuity; any real value which they may have, it would be difficult to discover.

Treatment.—The treatment of this obstinate, and, unfortunately, too generally fatal, disease, is altogether of an empirical character. That this should be so is not surprising when we remember how completely ignorant we are of its pathology, and the fact that there is hardly an article of the materia medica, of any reputed efficacy, that has not been employed, either singly, or in various forms and modes of combination, for its relief. Although patients occasionally get well of this disease, and that under circumstances apparently the most desperate, yet, when the practitioner comes to analyze his treatment, in the true spirit of philosophy, he is generally compelled to confess his ignorance as to the share which his remedies may have exerted upon the fortunate event, and to acknowledge that accident, rather than his own skill, performed the cure. However this may be, it is certain that the disease sometimes yields to the most insignificant measures, or, rather, that it apparently wears itself out; and that, at other times, it resists the best directed efforts of the ablest and most experienced practitioner. The chances, indeed, of effecting any good, when the disease is fairly established, are very slender in any case, however mild. Hence, whatever is done should be done promptly, and with a view rather to a prophylactic result than to a curative one.

It cannot be expected that, in a work of this kind, I should be able to give even an outline of the more important remedies that have been suggested for the cure of this disease; I shall, therefore, content myself with a brief notice of a few of those which general experience has shown to be the most reliable, or most in consonance with the apparent condition of the part and system.

One of the first and most important indications in every case of traumatic tetanus is the removal, if possible, of the exciting cause, which is, of itself, occasionally sufficient to effect a cure. Thus, if any foreign body remain in the wound, or in contact with the living tissues, the surgeon cannot too speedily extract it, especially if there be already some evidence of approaching disease. Sometimes a vicious cicatrice may keep up the tetanic irritation. Many years ago, I attended, in consultation with the late Dr. Buck, of Louisville, a young girl of fourteen, who had locked jaw from having been accidentally hurt, nearly a month previously, in the right cheek by a small

splinter. Although the substance was immediately extracted, yet the parts continued to be tender, being, at times, even quite painful, and in less than a week tetanus set in. When I saw the case, free use had already been made, without any material benefit, of anodynes and antispasmodics, along with an occasional purgative, and the cheek had been leeches and repeatedly painted with iodine; the girl was pale and feeble, and had lost her appetite. Upon examining the original site of the injury, I found a small circumscribed spot, exquisitely tender under pressure, and of almost fibro-cartilaginous hardness. This being carefully dissected out, no more paroxysms occurred; and in a few days, with the aid of iron and quinine, wine, and a generous diet, complete recovery ensued.

Amputation of the wounded part has occasionally been performed; and, judging from the statistics that have been published upon the subject, there is reason to believe that the operation has now and then proved successful. Nevertheless, there are, I presume, few surgeons who would be found to be so venturesome as to remove a leg or an arm on the approach of such a disease, and none would certainly be foolish enough to attempt the expedient after it is fully established. In the one case, the possibility is that the affection might yield to other and milder means; and, in the other, the disease being no longer one of a local character, but diffused, as it were, through the system, it is difficult to see how amputation, however early performed, could be of any benefit in arresting the morbid action, unless it be upon the principle of substituting a fresh and clean wound for one of an inflamed and irritable character. An interesting case, bearing directly upon this point, fell under my observation, in 1848, in a patient of Dr. Mattingly, of Bardstown, Kentucky. The man, who was fifty years of age, was a stout, healthy farmer, of a nervo-sanguineous temperament, who, about five weeks previously, had the fore and middle fingers of the right hand, between the second and third joints, severely mashed by the passage of the wheel of a wagon, the phalanges being completely comminuted, and supported merely by a few shreds of integument. A physician residing close by where the accident had happened, removed the injured parts with the scissors, and binding up the ill-formed stumps, sent the man home, a distance of thirty-five miles. The parts soon became excessively painful, and at the expiration of the time above specified, well-marked symptoms of tetanus supervened. Five days after this, while the patient was under the influence of chloroform, I removed the mutilated fingers at the metacarpo-phalangeal joints, the whole hand being at the time exquisitely tender and painful, the tongue coated, the pulse hard and accelerated, and the system irritable from the want of sleep. After the operation, the man had tetanic spasms for several days, but they became gradually lighter, shorter, and less frequent, and, in a few weeks, all symptoms of the disease had entirely disappeared.

How far the recovery in this case was due to the amputation of the affected fingers, it would be difficult to determine; but it is reasonable to suppose that the operation was serviceable by ridding the system of a mass of irritation and disease, which, if it had been permitted to continue in operation, might have proved highly detrimental, if not destructive, to the patient.

In regard to the treatment of the *wound* itself, in tetanus, it cannot be doubted that prompt attention to it is a matter of great moment. Our remedies should generally be of the most soothing character, consisting of warm water-dressing, or emollient cataplasms, with a liberal admixture of laudanum, powdered opium, or, what is better than either, sulphate of morphia. If the parts are girded by inflammatory engorgement, or various kinds of deposits, as will be apt to be the case if the wound is of a punctured character, free incisions must be made, the knife being carried thoroughly through the tissues in every direction. A similar method should be adopted when there is

reason for suspecting the lodgment of some foreign body. I cannot approve, in any case, of the practice, at one time so common, and perhaps not yet sufficiently exploded, of pouring irritating fluids into the wound, or of applying escharotics. Such a procedure is only calculated to increase the suffering, and to aggravate the disease.

I have no experience with the section of the *nerves* connected with the injured structures; an operation which is reported to have been several times performed successfully by foreign surgeons. Such a step could only be justified in the case of the smaller nerves, and then, I presume, all the good that would be likely to accrue from it might readily be accomplished by a free division of the affected parts. The section of the larger nerves would be followed by paralysis, which might be permanent.

Attention to the position of the patient's bed is a matter that should not be overlooked in the treatment of this disease. From neglect of this precaution, I have seen several lives lost that might, probably, otherwise have been saved. Exposure of the body to a direct draught is often, of itself, sufficient to bring on an attack of tetanus in a susceptible, nervous person; and, after the attack is fairly established, such an occurrence never fails to aggravate the spasms, rendering them both more frequent and violent. The atmosphere of the room should, moreover, be perfectly dry, experience having shown that moisture is extremely prejudicial in all affections of this description.

The most important *internal remedies* are such, undoubtedly, as are of an anodyne and antispasmodic character, of which opium, tartar emetic, aconite, camphor, assafoetida, and Indian hemp occupy the highest rank. They should be administered in large doses, with a view to an immediate and decided impression upon the general system, and should be given either by themselves or in various states and degrees of combination.

The most eligible preparations of *opium* are the acetated tincture and the salts of morphia, particularly the sulphate. Opium in substance is objectionable, on account of its insolubility, the stomach, under such circumstances, being extremely torpid, and unable to act upon it. For the same reason, a much larger quantity of laudanum and morphia is required to produce their specific effect than in ordinary disease. When the patient is young and robust, or when the spasms are violent and obstinate, the anodyne should be combined with tartrate of antimony and potassa, given in doses sufficiently large to relax the system. The latter remedy is sometimes employed by itself, and several cases have come to my knowledge where it seemed to have effected a complete cure. I am satisfied, however, that its efficacy will always be materially enhanced by a judicious combination of it with morphia. In the use of tartar emetic in this disease, it must not be forgotten that the torpor of the stomach renders it necessary to give it in much larger doses than under ordinary circumstances. If the practitioner were to content himself with the usual quantity, the effects would greatly disappoint him, and the case might, in consequence, proceed rapidly from bad to worse, without receiving any benefit from the remedy.

Aconite is a remedy of great efficacy as a depressant, and may be given as an adjuvant to morphia, or morphia and tartar emetic, in cases of tetanus attended with a robust and plethoric state of the system. It lowers the action of the heart, promotes perspiration, and relieves spasm. *Veratrum viride*, acting in a similar manner, may be used as a substitute.

Camphor and *assafoetida*, administered in large doses, occasionally aid in controlling the spasms in this disease, but they should never be trusted to alone. Their influence, as antispasmodics, is far inferior to that of morphia and tartar emetic.

Indian hemp, soon after its first introduction into practice, received a large share of attention in the treatment of this disease, especially from the East India practitioners, some of whom were at one time disposed to regard it as a specific. Subsequent experience, however, has greatly disappointed these expectations, and in this country very little, if any, confidence is placed in the remedy. I certainly have never derived any appreciable benefit from it in the few cases of tetanus in which I have employed it, although the trials in each were very fair. The preparation which is usually given is the extract, in doses varying from one to two grains, repeated every two hours, or even more frequently, the object being to produce and to maintain narcotism.

Great expectations were entertained, on the introduction of *chloroform*, that at length an effectual remedy had been discovered for the cure of tetanus, and there is no article of modern times which has been so generally employed in the management of this disease. Cases successfully treated by it have been reported by different observers; but how far they were really relieved by this agent is a question which has not been decided. It is certain, however, that it has generally signally failed to cure, although it is usually productive of relief to the spasms, which are a source of so much distress to the patient. It should be administered in the form of inhalation, with an abundance of atmospheric air.

Much comfort is often experienced from the use of the *vapor bath* in the treatment of tetanus; the steam should be conveyed, by means of a tube, from the spout of a tea-kettle, or other suitable apparatus, under the bed-clothes, and may be advantageously medicated with laudanum, or laudanum and chloroform. The remedy possesses no curative agency.

Bloodletting and *mercury*, carried to the effect of salivation, were at one time much vaunted, on account of their supposed efficacy in the treatment of tetanus. They have, however, of late years, been entirely abandoned. The patient is certainly reduced sufficiently soon without venesection; and as to mercury, its use has, as stated elsewhere, been followed, in more cases than one, by the very disease which it was intended to cure, the saliva streaming at the time from the mouth in enormous quantities.

When much exhaustion exists, brandy, wine, and a generous diet are indicated, along with quinine and other corroborants. The profuse and exhausting sweats which so frequently attend the disease are best controlled by aromatic sulphuric acid, and frequent sponging of the surface with a strong solution of alum.

Whatever treatment may be adopted, proper attention should be paid to the bowels, which, as before stated, are generally excessively torpid, and, consequently, difficult to move. When the patient is in a condition to swallow, he may take ten grains of calomel, with double that quantity of jalap, every six hours, until there are free alvine evacuations. If the medicines are slow in their action, their operation may be promoted by the addition of a drop of croton oil, or by means of a stimulating injection, as spirits of turpentine and castor oil. Occasionally, the croton oil may be advantageously rubbed upon the abdomen. Severe purging should be carefully avoided, as, from its irritating and prostrating effects, it cannot fail to aggravate the complaint.

The treatment of tetanus by *counter-irritation* has, I believe, become in great degree obsolete. It was formerly thought, when the disease was supposed to be essentially connected with inflammation of the cerebro-spinal axis, that extensive and rapid vesication of the spine would afford valuable aid in combating the morbid action, and putting a stop to the violent spasms; and examples illustrative of the beneficial effects of this mode of treatment have been published by different observers. The remedy usually selected is either the common blister, caustic potassa, or the actual cautery. The late Dr.

Hartshorne, of this city, was in the habit of employing a solution of potassa, in the proportion of one drachm and a half to two fluid ounces of distilled water. It produces a powerful rubefacient effect, and may be applied by means of a cloth mop to a narrow line of skin, from the occiput to the sacrum. If the hot iron be used, it should be applied transcurrently. I have, however, great doubts in regard to the propriety of any measures of this kind, believing that they frequently aggravate the symptoms instead of relieving them.

When the disease is chronic, and the wound still open, but indisposed to heal, the best plan is to divide the parts freely with the knife, so as to relieve them of engorgement, and invite a more salutary action. It is under such circumstances that the *actual cautery* occasionally answers a good purpose. In a case which occurred some years ago, in the practice of Dr. W. D. Stewart, of Indiana, and the particulars of which he has kindly communicated to me, an immediate stop was put to the paroxysms by this procedure, after various other means had been tried, without any benefit, for nearly a fortnight. No spasms took place after the application, and the patient, a lad nine years of age, made a prompt and perfect recovery. The wound which had provoked the attack was a large, lacerated one, occupying the right side of the scalp, and extending down to the bones.

Anodyne and stimulating *liniments* applied along the spine have sometimes appeared to act beneficially, both in moderating the spasms and in eradicating the disease. Chloroform has of late been used a good deal in this manner, and several cases of its successful employment have been reported in the medical journals; among others, a very interesting one, by Dr. Hinkle, of Marietta, Pennsylvania, of a woman who suffered from tetanus consequent upon the bite of an eel. The treatment was conjoined with purgatives and antispasmodics, as *cannabis Indica*, valerian, and compound sulphuric ether.

Finally, should the patient be so fortunate as to survive the disease, the greatest care must be observed during his convalescence, lest a relapse occur, and destroy him, when he is apparently on the verge of returning health. The clothing should be warm, the diet light but nutritious, the bowels and secretions duly regulated, and exposure to atmospheric vicissitudes sedulously avoided.

SECT. III.—NEURALGIA.

Neuralgia is an affection of the nerves attended with severe, agonizing pain, often paroxysmal in its character, liable to occur in all parts of the body, and generally dependent upon some local irritation, or upon the joint agency of a local and constitutional cause. As it would be out of place in a work of this kind to treat of neuralgia in general, I shall limit my remarks here chiefly to the disease as it manifests itself in certain nerves, particularly those about the face, where the lesion not unfrequently becomes a subject of surgical interference.

Causes.—The causes of neuralgia are various and of the most opposite character. They are predisposing and exciting. Persons of a nervous, irritable temperament are generally supposed, and I believe correctly, to be more prone to the disease than any other class of individuals. Those who are inclined to be rheumatic also frequently suffer from it. It occurs in both sexes, but in what proportion has not been ascertained. In my own practice, which has been unusually extensive in all kinds of neuralgic affections, there has been a decided preponderance of male patients. This may, however, have been merely accidental, as most writers assert that the disease is more common in women than in men. No age is exempt from its attacks, although it is by far most frequent from the twentieth to the fiftieth year. It occurs

in all countries and at all seasons of the year; but is most common in winter and spring in cold northern regions and in districts abounding in malarial exhalations. Cold and damp states of the atmosphere are especially favorable to its production. Like gout and rheumatism, the disease occasionally manifests a hereditary predisposition, and in quite a number of instances I have met with it in several members of the same family.

The exciting causes of neuralgia are of a local and general nature. Among the former, exposure of a nerve to the air, or its compression by some tumor, as an exostosis, or soft growth, is the most common. The most atrocious attacks of this disease are generally witnessed in the branches of the trifacial nerve, in consequence of caries of the teeth, laying open their cavity, and thus allowing the air and other irritating substances to come in contact with the denuded nerve within. Similar effects are often produced by the pressure of a dental exostosis, or by the mere thickening of the periosteum covering the fang of a tooth. Occurrences of a like nature often excite neuralgia in the bones. Sometimes the disease is awakened by the contusion of a nerve, occasioned by a blow, fall, or kick; by the irritation of an old, indurated cicatrice; or by the excitement induced by the presence of a foreign body, as a splinter of wood. In the face, neuralgia has been known to be caused by the lodgment of a piece of dead bone in the nose or antrum. A calculus will occasionally produce the disease in the bladder; so also will worms in the bowels, and the larvæ of insects in the frontal sinus. Neuralgia of the pelvic viscera is often induced by the pressure of a displaced uterus upon the surrounding structures.

A very common exciting cause of neuralgia is exposure to cold while the body is overheated and covered with perspiration. When the predisposition to the disease is very strong, the slightest draught of cold air will often bring on an attack almost instantaneously. Exposure to heat is less injurious, though it is also capable of exciting the disease, especially if it be concentrated for any length of time upon one particular locality, part, or organ.

Attacks of neuralgia are sometimes induced by gastro-intestinal irritation, as the presence of a redundancy of acid, indigestible food, worms, impacted feces, or an overloaded state of the bowels. The disease is not uncommon in dysmenorrhœa and in ulceration of the neck of the uterus, in spinal irritation, and in organic lesion of the brain.

Occasionally the cause is seated in the nerve itself, as when it is inflamed, partially ulcerated, or denuded of its natural coverings. After amputation, the stump often becomes affected with neuralgia in consequence of the extremities of some of the nerves being expanded into neuromatous tumors; and similar effects sometimes supervene upon the division of the nerves in cases of wounds, especially lacerated ones.

Finally, the occurrence of neuralgia, as a consequence of malaria, is familiar to every one. In the southern and southwestern States of the Union, where neuralgia of every form and grade is extremely prevalent, the disease, in the great majority of cases, recognizes no other cause. The attacks, under such circumstances, are generally of a distinctly intermittent type, very similar to those of intermittent fever, recurring once every day or every second day, and, after having continued with great severity for several hours, gradually going off, to reappear about the same period on the next day; each paroxysm being, perhaps, ushered in by chilly sensations, and terminating in more or less profuse perspiration.

Symptoms.—The nature of the pain in neuralgia is not always the same. In one case, it is dull, heavy, and aching; in another, acute and extremely violent; in a third, it resembles the pain produced by thrusting needles into the tissues; in a fourth, it is pungent, smarting, or burning; and in a fifth,

it is sharp and darting, or like an electric shock, running through the parts with the rapidity of lightning.

The pain, whatever its character may be, is generally attended with more or less soreness and tenderness of the affected parts which sometimes pit on pressure, although they are seldom discolored. Finally, the pain may be concentrated, or diffused; that is, it may be strictly localized, or limited to one particular spot, and that perhaps very small; or it may be extended over the greater portion of a nerve, or even over its entire length.

It is important to bear in mind that the pain often breaks out at a point very remote from the one upon which the impression provoking the attack is made. Thus, supra-orbital neuralgia is often produced by disorder of the stomach, or of the stomach and bowels; a carious tooth has been known to give rise to neuralgia of the hip; and spinal irritation not unfrequently occasions neuralgia of the leg, heel, and foot. A very singular case has been reported where a severe attack of neuralgia of the left forearm could always be instantly excited by touching the meatus of the right ear.

Neuralgia is sometimes associated with rheumatism, and it is to this form of the disease that the term rheumatico-neuralgic is generally applied by nosologists. The combination is most generally met with in persons of an arthritic predisposition, usually affects the muscles, especially the intercostal and spinal, and is often exceedingly intractable, rendering the patient miserable for life, and at length wearing him out by the constancy of his pains.

Neuralgia often exists simultaneously in different parts of the body, and when once it is fairly established it is easily excited by the most trivial circumstances. Its progress is variable. In many cases it readily yields to treatment, and not unfrequently disappears spontaneously; on the other hand, it is sometimes a most intractable disease, worrying and fretting the patient, undermining his general health, and disqualifying him for business and enjoyment. In its worst forms the suffering is almost constant; whereas, in the milder, there are not unfrequently long intervals of complete, or nearly complete, exemption from pain. When the affection is contracted early in life, and proves rebellious, it is seldom entirely gotten rid of, whatever means may be adopted for its relief.

Pathology.—The pathology of neuralgia is not understood. It has generally been supposed that it consists in a mere exaltation of the sensibility of the nervous tissue, but if this were so it is hardly supposable that it would be so intractable a disease as it often is. The explanation may probably hold good in those cases in which the disorder is very transient, or of malarial origin. But in other and in the greater number of cases, it is probable that there is some degree of inflammation present, either in the nerve-pulp, or in the neurilemma, or in both, as is proved by the fact that the parts supplied by the affected nerves are generally more or less tender, œdematous, and even somewhat discolored; phenomena which are clearly indicative of an engorged and incited state of the capillary vessels with a tendency to effusion. In other cases, again, it may consist in a mere perversion of the nervous fluid, as when a nerve is compressed by interstitial deposits, or by causes acting upon its periphery, thereby interrupting the current across the seat of the obstruction.

Prognosis.—The prognosis of this disease may be gathered from what has been stated in the preceding paragraphs. It seldom proves fatal. Its course is irregular. It may last for months, years, a lifetime, the patient finally dying of some other disease. The most dangerous form is visceral neuralgia, which sometimes causes death by the constancy and violence of the pains.

Treatment.—The treatment of neuralgia must be deduced, in great degree, from the nature of the exciting cause, which should, therefore, always receive

prompt attention, removing it where this is practicable, or modifying it where it is not, so as to render it as harmless and inoperative as possible. In neuralgia of the face, for example, it will often be found that the cause of the trouble is a carious tooth, upon extracting which the pain instantly vanishes. Neuralgia dependent upon the presence of an old, callous cicatrice, can only be successfully relieved by the excision of the offending tissues. Vermifuge medicines are indicated when it is caused by worms; antacids when it is excited by vitiated secretions of the stomach, and purgatives, when it is occasioned by an overloaded state of the bowels. Thus, it will be perceived that no single remedy, or class of remedies, is adapted to all cases; a fact which strongly suggests, in every instance, the importance of a most thorough and critical examination of the state of the part and system, with a view to the institution of a rational therapeutics.

It must not be expected, however, that the disease will always disappear upon the removal of the exciting cause. Generally, indeed, it will, and that very promptly and effectually; but there are cases where it is inclined to linger, with little or no mitigation, for an indefinite period, the affected parts being seemingly unable to recover their natural functions, either because they have become habituated to the morbid action, or because they have experienced some organic change which no treatment can reach.

The treatment of neuralgia is general and local, except when the cause is obviously of a purely local character, when general means may usually be dispensed with. Purgatives, a proper regulation of the diet, and antineuralgic remedies, as they are named, constitute the more important constitutional measures; while embrocations, leeches, vesicants, the endermic use of morphia, and section of the affected nerves comprise the more efficient and reliable topical agents.

There are few cases of neuralgia which are not benefited by the use of *purgatives*; sometimes, indeed, the disease promptly disappears under a few brisk cathartics. Their exhibition is particularly indicated when there are a coated state of the tongue, disorder of the stomach, a vitiated condition of the secretions, headache, pain and aching in the limbs, or an overloaded state of the bowels. The best articles will be blue mass, colocynth, and jalap, or the compound calomel pill, repeated every other night until there is a decided improvement in the general health. Emetics may often be advantageously exhibited, especially when there is evidence of biliary and gastric derangement. The pain is generally mitigated by their action, and sometimes completely removed the moment they begin to manifest their specific effect.

The *diet* must be plain and simple, easy of digestion, and adapted, in regard to its nutritive qualities, to the exigencies of each particular case. The plethoric will be benefited by abstinence; the pale and anemic, by good living. When the general health is much impaired, tonics, as quinine and iron, a generous diet, wine, brandy, porter, and ale, with exercise in the open air, will be of service. Sometimes a sea voyage, or a residence near the sea shore, is salutary.

There are several articles of the *materia medica* which may be considered as exerting, in some degree, a specific influence over neuralgic affections, and which have hence received the name of antineuralgic remedies. To this class belong quinine, arsenic, strychnine, aconite, and morphia, along with some other anodynes, and the different preparations of iron.

Quinine, the great antiperiodic in intermittent fever, is entitled to the highest rank in the treatment of neuralgia, particularly in that variety in which the paroxysms observe a regular diurnal relapse, with an interval of entire freedom from suffering. It may be administered by itself or in union with an opiate, and a few efficient doses are almost sure to break up the attack promptly and effectually. In my own practice, I seldom give less than ten

grains at a dose, repeated every six or eight hours, until the affection is either vanquished, or the specific effects of the medicine are rendered apparent by the aural and cephalic distress. Some practitioners prefer smaller doses, but experience has shown me that they are less trustworthy, and that, at all events, a much longer time elapses before they put a stop to the disease. Quinine may sometimes be employed with much benefit when the affection is not of malarial origin, but in general its effects are not near so apparent in the former case as in the latter.

In chronic neuralgia, or in acute but obstinate attacks, *arsenious acid* is generally found to be one of our best remedies, given in doses varying from the eighth to the twentieth of a grain, three times a day, in union with an anodyne, or an anodyne and tonic. There are few cases of the disease, however obstinate, that will not be materially benefited by the use of this article, if administered with proper judgment and perseverance. The acid is far preferable, in every respect, as an antiperiodic, to Fowler's solution, being much less liable to cause nausea and anasarca.

With the value of *strychnine*, as an antineuralgic, every practitioner is familiar. I have used it, as such, for many years, and its effects have rarely entirely disappointed my expectations. The dose recommended in the books is much too large. I rarely give more than the twenty-fifth or thirtieth of a grain, and sometimes not even so much as that, thrice in the twenty-four hours. Extract of *nux vomica* is also employed for the same purpose, but is seldom productive of any decided benefit.

Aconite and *Indian hemp* are valuable articles in the treatment of neuralgia, although their efficacy has, I think, been greatly overrated. They may be exhibited in the form of extract, in doses varying from half a grain to a grain every six or eight hours, either alone or conjoined with other articles.

The use of *morphia* is absolutely indispensable in the treatment of neuralgic complaints, not so much as a curative agent, as for the purpose of controlling the excessive pain and inducing sleep. There are cases, however, which are radically cured by the persevering exhibition of this remedy, but then it is generally necessary to give it in large doses, and to sustain its action by carefully watching its effects. Protracted narcotism has occasionally vanquished the disease after all other means had failed, even to afford temporary relief. Several examples of this kind have fallen under my own immediate observation, and others have been mentioned to me by professional friends. For ordinary purposes the dose need not exceed a fourth or a third of a grain, and in chronic or subacute cases, I rarely give more than the tenth, twelfth, or fifteenth of a grain at a time, repeated at suitable intervals.

For many years past I have been in the habit of employing, with very happy effects, in a great variety of cases of neuralgia, a combination of some or all of the above articles, giving them in pill form three or four times in the twenty-four hours. The subjoined will serve as a type of such a formula.¹ It need hardly be added that the effects of the prescription should be carefully watched, as several of the articles are of a potent and even a poisonous character. If the system be anemic, two grains of sulphate of iron or of the valerianate of that salt may be incorporated with each pill. Carbonate of iron I never use, as it has always disappointed my expectations, even when I have administered it in large doses and for a long time, and my experience, in this respect, is, I believe, fully corroborated by the results of the observations of other prac-

Mix, and make xxx pills ; one to be given three or four times a day.

titioners. When the attack depends upon the presence of a redundancy of vitiated gastric acid, the solution of valerianate of ammonia will be found a highly efficient remedy, administered in the dose of a drachm every two or three hours until relief is afforded. Iodide of potassium has been much lauded as an antineuralgic; but although I have used it in many cases, I cannot recall to my mind a solitary one where it seemed to be really of any material service. If it ever does any good in this disease, it is when it partakes of a syphilitic nature.

When the attack is of a rheumatico-neuralgic type, *colchicum* will be required, and will generally act more kindly and promptly than any other article. My invariable plan, however, is to give it in union with a full dose of morphia, as one grain of the salt with one drachm of the wine of colchicum, every night at bedtime, which will be found to be a much better practice than administering these substances in smaller and more frequently repeated quantities.

The *topical remedies* which particularly claim attention on account of their real or imputed virtues are counter-irritants, leeches, morphia, and the steam of hot water, either simple or medicated.

The only counter-irritants that, in my judgment, are at all admissible, in the treatment of this disease, are blisters, ammonia, and iodine. Setons and issues are out of the question, except in deep-seated, obstinate visceral neuralgia, when the latter occasionally prove beneficial, especially if made with the hot iron, directly over the seat of the pain, and if a free and protracted discharge be maintained. The moxa, formerly so much used, has of late years fallen into disrepute. Blisters are particularly valuable in inflammatory neuralgia; they should be retained until the epidermis is well raised, and they are the more desirable because the raw surface thus made may be advantageously employed for the endermic application of morphia. Temporary relief, but nothing more, occasionally follows the use of ammonia in the form of liniment, or of Granville's lotion, frictions with ointment of veratrina, and painting the parts with tincture of iodine. Leeching is sometimes useful, by relieving congestion, and thus removing one cause of compression of the nerve-pulp; the operation being performed as near as possible to the seat of the disease.

The endermic application of morphia has been found highly beneficial in neuralgia, chiefly, however, in mitigating the pain. It may, as already stated, be simply sprinkled upon a blistered surface, be inoculated, or, what I greatly prefer, be injected subcutaneously. In the latter case, some care is necessary in regard to the quantity of the morphia used, as it occasionally evinces its narcotic effects in a very rapid and decisive manner. The operation which, I believe, I was one of the first to perform, but which has since been generalized by Mr. Wood, is executed with a tight syringe, fig. 199, having a

Fig. 199.

very slender nozzle, which is inserted into a small puncture previously made in the skin of the affected parts, the subcutaneous cellular tissue being torn up with a common probe to make room for the reception of a drachm of solution of morphia, holding in suspension from a quarter of a grain to a grain of the salt, according to the exigencies of the case. The operation may be repeated once in the twenty-four hours, or oftener, if deemed neces-

sary. In the ordinary endermic application, the morphia does not penetrate to a sufficient depth; while inoculation is still more uncertain, and is by no means free from pain. I believe that the subcutaneous injection of morphia will be found highly serviceable in many cases, especially when the disease is distinctly localized, and rebellious to other remedies.

Hot applications, particularly moist ones, are generally beneficial in putting a prompt stop to the severity of the pain, especially if they are medicated with laudanum, or some other anodyne preparation. They may be used in the form of cloths wrung out of hot water, and covered over with oiled silk or gutta percha, to prevent evaporation; or in the form of steam conveyed directly to the part by means of a tube connected with a tea-kettle placed over a spirit lamp near the bed.

Section and excision of the affected nerve have often been practised for the cure of neuralgia, with results, however, by no means always satisfactory. Indeed, there is reason to believe, from the facts that have been published upon the subject by various surgeons, that both operations have generally proved unsuccessful; in many cases temporary relief ensued, but in nearly all the disease ultimately recurred with its former violence. I have myself performed a number of these operations, sometimes merely cutting the affected nerve across, and at other times excising a considerable portion of it, but the result has nearly always been unsatisfactory. Surgeons have not hesitated to remove sections of some of the larger nervous trunks, as, for example, the sciatic.

In facial neuralgia, where resection of the affected nerve is more frequently practised than elsewhere, the operation has, within the last few years, been pushed, if the expression be allowable, to an extraordinary extent by several American surgeons, Professor Carnochan having led the way. The results of his cases, three in number, will be found in an interesting paper on the subject in the *American Journal of the Medical Sciences* for January, 1858. The procedure consisted in exsecting the trunk of the second branch of the fifth pair of nerves, beyond the ganglion of Meckel, on account of severe neuralgia of the face. The portion of nerve removed, in two of the cases, was two inches in length, and in the other an inch and three-quarters. The result in all was most gratifying. Should the success of Dr. Carnochan be equally great in the hands of other surgeons, he will have conferred, by the boldness of his operation, an inestimable boon upon a class of patients heretofore considered as almost beyond the reach of relief.

The operation of exposing the second branch of the fifth pair, as performed by Dr. Carnochan, is severe and complicated, and requires, besides chisels and bone-nippers, two trephines, one three-quarters of an inch in diameter, and the other half an inch; the latter being intended for perforating the posterior wall of the antrum. The patient, being placed under the influence of chloroform, is seated upon a chair, with the head resting against the breast of an assistant, who maintains it firmly in this position. The infra-orbital foramen is then laid bare by two incisions, commencing above, near the inner and outer angles of the eye, at the inferior edge of the orbit, and terminating at a sharp point, about an inch below, opposite the furrow on the lower portion of the ala of the nose, the flap thus formed representing the shape of a V. The lip, being now everted, is next detached from the upper jaw, when it is completely divided, along with the cheek, by a vertical incision, extending from the inferior extremity of the V incision through its free border. By dissecting up the two large flaps thus marked out, turning one outward and the other inward, the whole of the front wall of the antrum, together with the trunk of the infra-orbital nerve, is completely laid bare. The crown of the large trephine is now applied immediately below the foramen, and an irregular disk of bone removed, so as to expose the cavity of the antrum. The

lower wall of the infra-orbital canal is cut away with the pliers and chisel, while the posterior wall of the antrum is perforated with the smaller trephine. The trunk of the nerve is then isolated from the other tissues in the sphenomaxillary fossa, and carefully traced beyond the ganglion of Meckel, behind which, close to the round foramen in the sphenoid bone, it is divided from below upwards with a pair of blunt-pointed scissors, curved on the flat. The hemorrhage is slight, and the flow from the branches of the internal maxillary artery, in the sphenomaxillary fossa, is easily controlled by the compressed sponge.

In performing this operation upon the dead subject, I have found it quite easy to obtain a sufficiency of room for exposing the nerve, in its entire length, by carrying a curvilinear incision, from an inch and a quarter to an inch and a half in extent, across the cheek, beginning a short distance below the inner angle of the eye, descending towards the level of the ala of the nose, and terminating a little beyond and below the outer angle of the eye. Whatever plan of incision be adopted, care must be taken not to inflict any unnecessary injury upon the osseous tissues, or to expose the structures of the orbit too freely.

The inferior branch of the fifth pair of nerves may be exposed by perforating the ramus of the lower jaw about three-quarters of an inch behind the large grinder, five-eighths of an inch above the angle of the bone, and an inch and a quarter below the zygomatic process of the temporal bone. A curvilinear incision, with the convexity downwards, is made over the ramus, about two inches in length, and the flap thus made being dissected up, and held out of the way, a disk of bone, half an inch in diameter, is removed with the trephine. The nerve is then hooked up with a blunt tenaculum, and as much as can easily be got at removed with the scissors. Some hemorrhage necessarily follows the division of the dental artery, but this is usually easily arrested by the ligature or by compression.

The inferior dental nerve, at its exit from the jaw, will be found opposite the first bicuspid tooth, midway between the inferior border of the bone and its alveolar margin, and may be easily exposed by raising a semilunar flap of integument, with the convexity looking downwards to the neck. Should it be deemed necessary to follow the nerve into the dental canal, this can be readily done by the use of the trephine.

I do not deem it necessary to give plans and rules for exposing nerves in other parts of the body. Few surgeons, at the present day, will be so rash as to exsect any of the larger trunks of the extremities, and the smaller branches may generally be easily found and divided, or portions of them removed, by attention to the anatomy of the parts concerned.

SECT. IV.—PARALYTIC AFFECTIONS.

1. WASTING PALSY.

A peculiar affection of the muscles, consisting essentially in atrophy and fatty degeneration of their fibres, has recently been described under the name of wasting palsy, from the fact that wasting and loss of power of these structures are its most prominent features. The disease, first accurately delineated by Cruveilhier, has been studied with great care by several European observers, especially Aran, Duchenne, Wachsmuth, Eisenmann, Meryon, and Dr. William Roberts, the latter of whom has embodied all that is known respecting it in an admirable monograph, published at London in 1858. Of the contents of this essay I shall freely avail myself in the ensuing remarks.

Wasting palsy presents itself under two varieties of form, the partial and

general; the first, as the name implies, being limited to particular muscles, or sets of muscles; whereas the other involves nearly all the voluntary muscles, those of mastication and those of the eyeball, including the elevator of the upper lid, being the only ones that escape its ravages. The involuntary muscles, however, remain altogether untouched, even in the worst cases and in the most advanced stages of the disease. Hence, the reason why the general health is usually so perfect amidst this wreck of the active agents of locomotion.

Of the causes of atrophy and palsy of the muscles, our information is too limited to permit us to speak positively. If occasionally their development has been clearly traced to the effects of cold, to rheumatism, or to excessive and long-continued fatigue, such as attends various mechanical pursuits, it is equally certain that, in the great majority of instances, no plausible reason can be assigned for their occurrence. In a few instances, the lesion has appeared to have had a syphilitic or strumous origin.

The time of life at which this disease occurs is variable; it has been noticed in young children, and, on the other hand, occasionally in old subjects; but the most obnoxious period would seem to be between twenty-five and thirty-five. Thus, in eighty-eight cases, analyzed by Dr. Roberts, the average period was thirty years and six months. General atrophy is not limited to any particular age, but attacks indiscriminately children, adults, and old persons; whereas the partial form rarely shows itself before puberty and after fifty. Both sexes are liable to it, but males suffer much oftener than females; although it is impossible to offer any correct data in regard to the relative frequency of the occurrence. The lesion has occasionally been observed in several members of the same family, and also in the offspring of persons who had themselves been its victims, thus exhibiting a sort of hereditary tendency.

The muscles that are most liable to suffer in this affection are those of the extremities, especially the upper. The wasting generally begins at one particular part of a limb, from which it gradually extends to another; but now and then cases are met with in which it attacks several points simultaneously.

It has been noticed that there is usually a tendency in certain muscles to suffer together, as if they were united by a close fellow feeling; thus it has been found that whenever wasting palsy occurs in the muscles of the hand, it is extremely liable to affect those of the forearm also; a similar disposition has been remarked in reference to the muscles of the shoulder and those of the arm. Moreover, experience has shown that when one limb is invaded its fellow of the opposite side is very apt to share the same fate.

The most important *symptoms* of this disease are wasting of the muscles and loss of contractile power, generally coming on in a slow, gradual, and stealthy manner. In the great majority of cases, indeed, the person is unconscious of the mischief that is taking place, until his attention is accidentally directed to the subject by a failure of the power of one of his limbs, especially the hand and foot. "The tailor discovers," says Dr. Roberts, "that he cannot hold his needle; the shoemaker wonders he cannot thrust his awl; the mason finds his hammer, formerly a plaything in his hand, now too heavy for his utmost strength; the gentleman feels an awkwardness in handling his pen, in pulling out his pocket handkerchief, or in putting on his hat. One man discovered his ailment in thrusting on a horse's collar; another, a sportsman, in bringing the fowling-piece to his shoulder." The wasting, at first very slight, progressively increases until the affected muscles are rendered perfectly soft and flaccid, and their substance is so much wasted that they are hardly one-fifth of the natural bulk; they are, in fact, completely withered, as if they had been starved, and deprived of all nervous influence. The loss of power is generally in proportion to the wasted condition of the muscles, proceeding gradually from bad to worse, until the parts

are entirely disabled and useless, no effort of the will being capable of exciting the slightest action.

Besides the above more prominent symptoms, there are others of a minor and subsidiary character. These are fibrillary tremors, cramps and twitches, pain, and a remarkable susceptibility to cold.

Fibrillary tremors, or convulsive twitchings, are very common, especially in the earlier stages of the complaint; they are dependent upon irregular contraction of individual muscular fibres, and are, consequently, always absent when the disease has reached its full development. They generally occur without the consciousness of the patient, and may usually be readily excited by exposure of the affected parts to a current of cold air or water. Cramps are also very frequent; they come on at various intervals, and often constitute a source of real suffering, especially when they are accompanied with pain, which is present in about one-fourth of the cases. The pain may be slight and wandering, severe and fixed, or sharp and neuralgic, shooting about in different directions with the rapidity of lightning. In some instances it occurs in different parts of the muscular system, more or less remote from the seat of the disease, and is then apparently of a rheumatic character. Wasting palsy causes a remarkable sensibility to cold, especially to a cold, humid atmosphere, so that the patient requires an uncommon amount of clothing to keep himself warm and comfortable. Finally, the galvanic excitability of the muscles regularly diminishes with their decay, but is not wholly annihilated until they have completely lost their primitive structure.

It is remarkable that, amidst all this wear and ruin of the muscular system, the general health should uniformly remain unimpaired, even in the worst forms of the disease. The appetite and sleep are excellent; digestion is well performed; the bowels move with their accustomed regularity; and the functions of the kidneys are perfectly normal. The intellect is clear to the last, and the senses retain their wonted vigor. The only trouble which the patient occasionally experiences is difficulty of respiration, from involvement of the diaphragm.

The *progress* of the disease is generally slow, the muscles steadily decaying, until they are at length completely changed in their character; for months and even years they retain some contractile power, and are even susceptible of restoration. General atrophy is always a gradual affection; it seemingly begins in the partial form of the lesion, and is probably merely an aggravated state of it. When the disease has reached this crisis, the patient may be unable to use any of the muscles, excepting, as already mentioned, those of mastication and those of the eye.

The appearances revealed on *dissection* are highly interesting, and characteristic of the disease. The muscles, as might be expected, are wasted in various degrees; some slightly, others very much, and others, again, so completely as to be hardly recognizable, consisting merely of cellulo-fibrous vestiges, with no distinct trace of the original structure. The color of those that still remain is much faded, being pale red, rose, buff, or yellowish, according to the extent of the atrophy; and in all, or nearly all, there are well-marked evidences of granular and fatty degeneration, the former generally preceding the latter, although occasionally they exist independently of each other. Sometimes these changes are confined to one particular part of a muscle, as one-half or two-thirds of its belly, while the other portion retains its natural hue and consistence. Under the microscope, the striped primitive fibres are observed to have vanished, their place being supplied by granular matter and oil globules, and their investing tunic broken down and disintegrated.

The nervous system has been closely scrutinized in many of the reported cases of wasting palsy, but, thus far, nothing of a very satisfactory nature

has been thereby elicited. It appears, however, to be well established that the lesions of the nervous system are of much less frequent occurrence than had been imagined. In some of the cases, indeed, there has been no perceptible change of any kind whatever; in others, there was softening or other disease of the spinal cord, either alone, or in conjunction with atrophy of the roots of the spinal nerves, and of their peripheral branches. In an instance, described by Schneevogt, the great sympathetic with several of its ganglia was extensively wasted and converted into fatty matter.

In what does this disease essentially consist? It was very natural, before our knowledge of the affection was strengthened by the light of dissection, to refer its origin to lesion of the spinal cord, or of the cerebro-spinal axis, such as softening, or chronic inflammation; and from the fact that traces of this description have been observed in several cases, a number of pathologists have been induced to adopt this view. Others, however, maintain, and, as it seems to me, with a better show of reason, that the primordial cause resides in the peripheral nerves, which, becoming affected in a manner that has not yet been determined, undergo atrophy, or atrophy and fatty degeneration, so as to prevent them from conveying a sufficient amount of nervous fluid to the muscles to which they are distributed, and which thus, in their turn, fall into a similar condition. The principal reasons for this conclusion are, first, that in quite a number of the reported cases of this affection the spinal cord was found to be perfectly intact; and, secondly, that, as has been stated elsewhere, the affected muscles sometimes retain, in certain portions of their extent, their natural color and consistence, which could hardly happen if their degeneration depended upon disorganization of the great nervous centres. It may be assumed, then, that wasting palsy is essentially a local disease, originating in some lesion of the nerves of the muscles, and capable, occasionally, of involving the spinal cord secondarily.

The *prognosis* of this affection is generally unfavorable; the partial form is occasionally recovered from, the complete never. In the latter case death, which sometimes does not occur under several years, is usually preceded by great difficulty of respiration, in a paroxysm of which the patient suddenly expires. In partial atrophy, the disabled muscles, after having struggled on for many months, perhaps neither sensibly advancing nor receding, gradually awake from their torpor, and ultimately regain some contractile power, though never their full vigor.

The *treatment* of wasting palsy has hitherto been conducted too much upon empirical principles; a fact, however, which is not surprising when we consider the unsettled views that still prevail in regard to its pathology. If we assume that it is essentially a local affection, unconnected with any lesion of the spinal cord, it must be evident that our remedies should be directed mainly to the seat of the disease. This is accordingly what, I think, should be done. If there is any disorder of the general health, no time should be lost in correcting it. If the lesion can be clearly traced to a syphilitic or strumous taint of the system, as it has been in a few of the reported cases, the proper remedies will be iodide of potassium with bichloride of mercury; or, where a tonic effect is required, potassium with iodide of iron. Gentle purgatives will be useful when there is constipation with derangement of the secretions. The diet must be plain, simple, and unirritant.

The best *local remedy*, in the early stage of the disease, is, I am persuaded, a blister sufficiently large to cover the whole of the affected muscles, and retained long enough to produce thorough vesication. If decided improvement do not follow in a week or ten days, the application should be repeated. I have often obtained excellent effects from this remedy, and can therefore strongly recommend it as worthy of trial. The hot douche, immediately followed by the cold, will also be found serviceable, but to prove efficacious it

should be aided by frictions with some stimulating embrocation, as spirits of camphor, or alcohol and ammonia. The cold douche alone is objectionable, on account of its depressing tendencies. Shampooing will be found useful, and should be practised several times a day. Galvanism has been highly extolled by Duchenne, Meyer, Gros, and others, and there can be no doubt that it has occasionally rendered good service. The current should be passed rapidly over the disabled muscles, taking care to return to each several times during the same sitting; it should be strong in proportion to the obtuseness of the parts, but be gradually diminished as the sensibility augments, otherwise over-stimulation may occur, and thus do harm instead of good. The application may be repeated at first every twenty-four hours, and afterwards twice a day.

Whatever mode of treatment be adopted, it should be combined with gentle exercise of the affected parts, to recall them, as it were, to a sense of their duty. They should, in fact, be re-educated by a system of careful training; but to do this to advantage, the efforts must be steadily and perseveringly continued for many months, if not for several years. If conducted in this way, I should have great hope of ultimate benefit. For some very judicious remarks on this subject, the reader is referred to a paper on paralysis by Dr. Batchelder, of New York, who has made this disease an object of particular study.

2. INFANTILE PALSY.

There is a variety of paralysis which may be briefly mentioned in connection with the preceding; occurring in young children, generally during the period of dentition, and which, in point of obstinacy and incurableness, is, if possible, still more deplorable. It may be called infantile palsy. Its attacks are usually sudden and unaccountable. The child goes to bed in the evening, perhaps to all appearance perfectly well; during the night, however, he becomes feverish and restless, and in the morning, on attempting to walk, he is unable to stand or use his legs. The limbs soon lose their round, plump appearance, the muscles are rendered soft and flaccid, the feet trail the floor, and the surface feels cold and numb, though sensibility is seldom entirely destroyed in any case, however extensive.

The seizure is much more common in the lower extremities than in the upper; very often it is confined to one thigh and one leg, but occasionally both limbs suffer, and now and then all four are involved, the child being perfectly helpless, and in the most pitiable condition. The paralysis is generally complete, but cases occur in which the little sufferer is still able to use certain muscles, although not with anything at all like their natural freedom and strength. When the upper extremity is attacked, the deltoid muscle is very liable to be affected, becoming remarkably soft and wasted, so that the patient finds it impossible to raise the arm or lift the smallest weight.

The cause of this variety of palsy is not always very evident; in general, however, it depends upon disease of the spinal cord, or of the cord and its membranes; probably inflammation, followed by effusion of lymph and serum, or softening of the nervous tissue. However this may be, the idea of such an occurrence is countenanced by the suddenness of the attack, the paralysis of all the muscles, not of a portion of them, as in wasting palsy, properly so termed, and by the remarkable obstinacy of the disease, most persons remaining crippled during the rest of their lives. If occasionally a recovery takes place, it is to be viewed rather as a rare exception than as a general occurrence.

The general health is seldom impaired in infantile palsy; the mind acts with its accustomed vigor, and all the bodily functions are well executed.

As the child advances in years, all the limbs, excepting the disabled ones, increase in size and strength, but the latter remain stationary, or dwindle away still farther, and thus form a striking contrast with the sound.

The *treatment* of infantile palsy must mainly be directed, in the first instance, to the spinal cord, by whose disease it has been provoked. For this purpose leeching, cupping, rubefacients, and blistering should be employed as soon as possible after the occurrence of the paralysis; and these should be followed, if the case is likely to prove obstinate, by a seton, or, what is preferable, because more efficient, by an issue with the actual cautery, applied, as nearly as can be, opposite the seat of the lesion, and made to furnish a copious supply of pus. If anything will reach such a case, it will be active and long-continued counter-irritation. Meanwhile, the muscles themselves must be rubbed and shampooed, and placed upon a course of careful training, as advised under the head of wasting palsy. If the general health is suffering, alterants and tonics are prescribed; the child is carried about in the open air, and special attention is paid to the bowels and secretions. As recovery advances, strychnine may be of service; but no benefit will be likely to accrue from its exhibition in the earlier stages of the complaint. Mercury has been strongly recommended in this disease, given in minute doses several times a day for several successive months; but, although such a plan of treatment is extremely plausible, I cannot say that it has ever been of any material benefit in the large number of cases in which I have employed it.

3. PARTIAL PALSY.

Besides the above forms of palsy there are some others, to which the term partial, transient, or anomalous may be applied, such, for instance, as loss of motion of one side of the face, one eyelid, one side of the tongue, or of the hand, forearm, arm, or shoulder, or even of the entire superior extremity. The subjoined facts will serve as illustrations of its character.

Pressure upon the nerves is liable to be followed by interruption of their functions, at one time temporary, at another permanent. A case recently came under my observation in which a man, aged thirty-five, suffered from partial palsy of the forearm and hand from having rested for two hours with his head upon the limb as he lay asleep upon the floor.

In another case, which came under my notice several years ago temporary paralysis of the left upper extremity was produced by the arm, thrown across the top of a chair, being compressed by the head while the man was asleep. Pressure of the head of a crutch upon the axillary plexus of nerves will occasionally lead to weakness, numbness, and prickling pain in the arm, hand, and fingers. Recently a youth of fifteen was under my charge on account of paralysis of the arm, consequent upon a fall on the shoulder from a railroad car, two months previously. The limb was instantly deprived of motion and sensation, and so continued up to the time of his visit. The head of the humerus had been thrown slightly forwards against the coracoid process, but it exerted no perceptible pressure upon the brachial plexus of nerves.

Paralysis of one side of the face from injury of the portio dura is occasionally met with; more generally the affection is caused by suppression of the cutaneous perspiration, from exposure to cold and wet; and we now and then meet with instances in which it is occasioned by disease of the petrous portion of the temporal bone. The subjoined case affords a good illustration of a very common form of facial palsy.

David Shepard, aged 18 years, blacksmith, of temperate habits, came under my treatment, in 1856, for paralysis of the left side of the face. The attack came on suddenly three days previously, without any apparent cause, soon after eating a moderately hearty dinner. He had been subject to frequent

and severe paroxysms of headache, preceded by dizziness and vertigo. On the day, however, on which he was seized with palsy he had no suffering of this kind; in fact, he had never felt better. His appetite and sleep have always been good, and his bowels regular. The palsy was characterized by inability to move the muscles of the left side of the face, and to close the eyelids, accompanied with a want of sensibility of the integuments. The tongue, when protruded, inclined to the right side, and was deprived of feeling and taste, a lump of sugar, held in the mouth, making no impression on the affected side of the organ. The general health at the time was excellent.

In the *treatment* of these paralytic affections, special attention must be directed to the improvement of the general health, which is often seriously impaired, by the use of purgatives, alterants, and a proper regulation of the diet. In obstinate cases, a mild mercurial course is sometimes serviceable, especially when the lesion is dependent upon organic disease of the brain, or of the cerebro-spinal axis. The principal local remedies are leeches, blisters, stimulating embrocations, the veratria ointment and the hot and cold douches, followed by dry friction. Occasionally electricity proves beneficial.

CHAPTER V.

DISEASES AND INJURIES OF THE ARTERIES.

SECT. I.—WOUNDS AND HEMORRHAGE.

THERE can be no more terrible and appalling sight to a patient and his friends than hemorrhage from a divided artery, especially when the blood is gushing out in a full and angry torrent, threatening every moment to put an end to existence. There is something indescribably sickening and distressing in such a scene, from which every sensitive mind shrinks with dismay and bewilderment. The horror of the scene is increased a hundred-fold, when we are unable to afford the requisite relief. But the sight of blood is not only disagreeable to the common observer; there are few surgeons, however heroic, or well disciplined, who do not, at times, participate in this feeling. If it were not for the frightful hemorrhage which so frequently attends them, operations would be robbed of nearly all their terror, and few men would shrink from their performance. Fortunately, or unfortunately, however—for it is not easy to determine which—this is not the case; the slightest incision is often followed by profuse bleeding, and in the extirpation of tumors, in the removal of limbs, and in various other proceedings, the patient has reason, in many cases, to congratulate himself if he do not perish from the loss of blood. Some of the more serious accidents, as incised, gunshot, and punctured wounds, often prove instantly fatal from hemorrhage; or, if syncope should, luckily, ensue, and thus temporarily arrest the bleeding, death may occur subsequently, but not less certainly, from the same cause. It is for these reasons that hemorrhage has always been a source of so much anxiety to the surgeon, and that its study has engaged so large a share of his attention from the earliest ages of medical science down to the present time. It is, indeed, impossible for him to be too well acquainted with the subject, or too thoroughly prepared to meet its various, trying, and painful emergencies. The reflection, which must often arise, under such circumstances, that possibly all was not done that might have been done, if greater skill had been exercised, is well calculated to overwhelm the sensitive and conscientious surgeon, and to induce a degree of distress which no one, who has not himself experienced it, can possibly appreciate. I do not envy that man his feelings who, through ignorance, inattention, or indecision, allows his patient to perish from loss of blood when he ought to have saved him.

The characteristics of arterial hemorrhage are, first, the scarlet color of the blood, and, secondly, the peculiar manner in which it issues from the injured vessel; it spirts out in jets, synchronously with the contraction of the left ventricle, and not in a steady, continuous stream, as when it comes from a vein. This, however, is true only of the larger arteries; for, when the smaller branches are severed, their contents escape very much like those of a vein, only more forcibly, the fluid even then often projecting to a distance of several feet. When one of the principal trunks is divided, the blood is frequently sent with great violence to the top of the ceiling, or far across the

room, to the horror and dismay of every one present. The consequences of the hemorrhage vary in different cases, and under different circumstances, being by no means always in proportion to the extent of the injury. When proceeding from a large vessel, or a considerable number of small ones, it may prove fatal in a few seconds, or, at most, in a few minutes. In general, however, the case does not progress in this wise; the patient, after having lost a certain quantity of blood, falls into a state of syncope, whereby the heart's action is temporarily enfeebled, and an opportunity is afforded to the blood to coagulate in the wound, and also around and within the artery, at least for a short distance. By and by, however, the system begins to show signs of reaction; color returns to the face, the extremities become warm, and the pulse reappears at the wrist. With these phenomena recurs the danger of hemorrhage; as the heart's action augments, the blood is propelled with increased vigor to every portion of the body, and presently, the temporary clot being washed away, the wound is reopened nearly, if not quite, to its original extent, thus permitting the blood to flow, if not copiously, at least in sufficient quantity to produce further exhaustion. Again fainting occurs, a new plug is formed, and for a time life is once more free from immediate danger; but this truce, like the first, is only of short duration; the same scene is re-enacted a second and a third time, until at last, in consequence of the repeated drain, the heart and the brain are no longer capable of supporting each other in the fearful struggle, and the patient sinks completely exhausted.

A person dying from repeated losses of blood, consequent upon the division of a large vessel, presents a fearful picture. His countenance is ghastly pale; his pupils are widely dilated; he pants and sighs for breath; his ideas are vague and confused; he is sick at the stomach and vomits; the extremities are icy cold; and the whole surface is covered with a profuse, clammy perspiration. The thirst is usually intense and unquenchable, the largest quantity of water failing to satisfy the urgent wants of the system; excessive restlessness and jactitation succeed; the patient calls loudly for cold air: paroxysm after paroxysm of swooning recurs; the pulse has, perhaps, already been long absent from the wrist; the eyes assume a glazed and fixed expression; the respiration grows more and more feeble; and death often steals on so imperceptibly as to render it difficult to determine the precise moment of its occurrence. During all this time, whether it embraces only a few minutes or hours, or whether it extends through several days, there is generally an entire absence of pain, the loss of blood operating as an anæsthetic.

If we inquire into the nature of wounds of the arteries, we shall find that they do not differ, as it respects the weapons with which they are inflicted, from wounds in other tissues. Thus they may be incised, punctured, lacerated, contused, or gunshot, and it would frequently be difficult to determine which class is the worst, or the most certainly and speedily fatal. In regard to their size they present every possible gradation, from the slightest incision to the complete division of the vessel; the wound being either oblique or transverse in the latter case, but of various shapes when the lesion is partial. Occasionally the wound consists of a mere vertical fissure. The different

Fig. 200.

Plan of wounded arteries. *a*. A mere longitudinal slit, extending to an oval space. *b*. A similar wound, in an oblique direction, gaping more. *c*. A less wound transverse, with the proportional gaping great. *d*. A transverse wound of the same size as *a* and *b*, causing a very wide hiatus.

appearances here alluded to are well displayed in fig. 200. The extent and character of the wound necessarily exert, as might be supposed, great influence upon the amount and duration of the hemorrhage, and therefore demand careful study.

When an artery has been completely cut across, there is an instantaneous and impetuous flow of blood, followed immediately by the retraction and contraction of each end of the vessel, as exhibited in fig. 201. The effect of this double action is to diminish the amount and force of the stream, but not to arrest it; instead of this it usually continues until a coagulum has formed upon the orifice of the artery, as well as in the parts immediately around, particularly in the loose cellular tissue constituting its sheath. In this manner a mechanical obstacle is opposed to the effusion of blood, but this would soon be washed away if it were not aided and fortified by the speedy development of a coagulum within the vessel, extending usually as high up as the first large collateral branch. These clots, of which the first bears the name of external, and the other that of internal, fig. 202, are the means which nature employs to put a stop to the hemorrhage; not, however, until, as a general rule, it has proceeded to the extent of causing syncope; a circumstance which is always, as was before intimated, eminently favorable to the coagulation of the blood, and, consequently, also to the formation of the clots now described. But these clots, at this stage of the process, are necessarily very soft, as well as very imperfectly adherent; and hence, in order to guard against their detachment, or, what is tantamount to the same thing, against a recurrence of the hemorrhage, it is imperative that plastic matter should speedily be effused, so that all these parts, clots, vessel, and surrounding structures, may become effectually and permanently soldered together. This accordingly soon happens; for within a few hours after the occurrence of the injury inflammation is enkindled, both in the divided artery and its sheath, and this being followed by a deposit of lymph, the parts in question are more firmly fixed in their respective situations, every day adding to their security and stability. Meanwhile, a process of organization is instituted, the first step of which is the removal of the serous and coloring matters of the clots, thereby rendering them more solid and pale; vessels now show themselves, some of them being probably of new formation, while others, and perhaps the greater number, are derived from the divided artery and its sheath, as well as from the surrounding structures.

The two clots now described are, it will be seen, inseparably blended at the orifice of the divided vessel, and their form and arrangement may not be inaptly compared to a glass stopper, closely fitted into the neck of a decanter. The outer clot is rough and irregular, whereas the internal is perfectly smooth and cylindrical, except its cardiac extremity,

Fig. 201.

Contraction of a divided artery. *a*. The orifice of a dead artery. *b*. The orifice of a living vessel immediately after section.

Fig. 202.

Plan of natural hemostatics, in a cut artery. At *a*, the cut end of the arterial tube; conical, by contraction. At *b*, the arterial sheath, vacated by the retracted artery, and occupied by coagulated blood. At *c*, the coagulum projecting from the orifice of the sheath.

which is nearly always conical, as in fig. 202. The longer the internal coagulum is the less danger is there generally of its premature detachment.

The changes above mentioned as occurring in the two clots are generally the work of time; the gluing process is usually effected rapidly, since its intention is to protect the patient against hemorrhage; but the removal of the serum and coloring matter of the blood, and the conversion of this fluid into solid matter, take place more slowly, and are often not completed under several months.

Fig. 203.

Change in the shape and structure of an artery after ligation.

Finally, if the parts be examined at a still later period, it will be found that both clots have entirely disappeared, and that the injured vessel, as high up as the first large collateral branch, has been transformed into a dense, strong, fibrous cord, fig. 203, similar to that observed in the umbilical arteries of the infant.

Such, then, is the process which nature employs for the purpose of arresting the flow of blood from a divided artery. Taking advantage of the exhausted condition of the system consequent upon the injury and loss of blood, she instinctively forms the two clots, having, first of all, drawn away the vessel from the main wound, as well as caused it to diminish its caliber, and then she goes deliberately to work to fasten these clots just precisely where they are most needed for the purpose. The vessel being thus hermetically sealed, she afterwards busies herself still further in getting rid of these plugs, seeing that they are no longer required, and, finally, completes the labor by converting the now obsolete extremity of the artery into an analogous tissue. These changes, which are both profoundly curious and interesting, bear, it will be perceived, a very close resemblance to those which take place in the callus of a broken bone.

After the ligation of an artery, the supply of blood in the parts beyond the seat of the obstruction is maintained by what is called the collateral circulation, the vessel above communicating freely with that below, as in fig. 204, by its anastomosing branches.

Fig. 204.

Diagram of collateral circulation.

When an artery is divided only partially, whether transversely, obliquely, or longitudinally, an external clot forms, but this is generally so imperfect as to render it altogether incompetent to offer anything like an effectual barrier to the flow of blood. What adds to the difficulty of the case is that the edges of the wound have a constant disposition to gape; and hence, although plastic matter may perhaps be deposited in great abundance, yet it is impossible for the parts to contract permanent and satisfactory adhesions to each

other. Whenever the circulation is conducted with any degree of vigor, the blood as it sweeps along washes off the clot, and appears upon the exterior of the wound; and thus the hemorrhage usually continues, paroxysm after paroxysm recurring in more or less rapid succession, until it proves fatal.

Although such is the course which the case usually pursues when an artery is divided only in a part of its diameter, yet it must not be thence inferred that a very small lesion of this kind may not occasionally be susceptible of spontaneous cure. Such an event, which must, however, at best, be extremely rare, may be supposed to be most likely to occur when the wound is oblique or longitudinal; when the opening in the overlying parts is a mere fissure or canal, offering an imperfect outlet to the contents of the vessel; when the system remains for a long time in a prostrate condition; and when, finally, there is a rapid and abundant deposit of plastic matter in the various structures involved in the injury. I have several times seen small shot wounds of the larger arteries, as the subclavian and femoral, healed in this manner; and there is reason to believe that punctures made accidentally in the brachial, in bleeding at the bend of the arm, are occasionally repaired either by the direct adhesion of their edges, or through the intervention of an external clot. In general, however, all such injuries are followed either by hemorrhage, or aneurism, according to the opportunity, or otherwise, which the blood may have to find its way to the surface.

It is well known that contused and lacerated wounds of the arteries bleed much less freely than incised. The reason of this has already been explained in the chapter on wounds, and need not, therefore, be reproduced here.

But, although nature may, and, indeed, sometimes does, arrest the hemorrhage from a divided artery, yet no sensible surgeon would intrust her with such an office, when it is in his power to get at the seat of the wound; for it is hardly possible to conceive of a case involving one of the larger trunks where her efforts would be likely to be successful, or where, if ultimately triumphant, the patient would not be brought repeatedly to death's door before she could attain her end. It is only in wounds of the internal arteries, as those of the chest and abdomen, and in the aorta and its larger branches, that we must refrain from direct interference, and limit ourselves to the use of general means calculated to keep down vascular action, especially the liberal use of anodynes and sedatives, as opium, aconite, and acetate of lead, the application of ice over the seat of the injury, exposure of the body to cold air, and perfect quietude, both of mind and body. All active exertion must for a long time be avoided, in order that, if a cure should take place, the wound may not be suddenly reopened by the giving way of its edges, in consequence of the imperfect organization of the clots and plasma.

The means employed by art for suppressing hemorrhage are quite numerous, as well as quite diversified in their nature, and will therefore require to be considered somewhat in detail. The most important of these means are: first, the ligature; secondly, compression; thirdly, styptics; and fourthly, torsion. Besides these there are several others of a subordinate character, and upon which, consequently, we shall bestow merely a passing notice.

1. *Ligature.*—Ligatures are composed of various materials, as silk, linen, and soft leather. Of these, the first is the most unexceptionable, and almost the only one now employed by experienced surgeons. It should be round, smooth, well twisted, colorless, and so strong as not to break without considerable effort. For the smaller arteries, as the radial, tibial, and temporal, common sewing silk is well adapted; but for the larger trunks, as the femoral, iliac, and carotid, stay silk, which is a much stouter article, is required. Some practitioners are in the habit of using what is called dentist's silk, no matter what may be the size of the vessel, on the ground that it is much stronger in proportion to its thickness than any other similar substance, and, therefore,

less liable to excite undue irritation. This thread, which is employed in making fishing lines, is rendered very hard and stiff by means of gum, which, however, is easily removed by boiling it for a few minutes in a slightly alkaline solution. Treated in this way, a piece long enough to tie the iliac artery will hardly weigh the twenty-fifth of a grain. I have not had occasion to use this form of silk, having always had reason to be satisfied with the common article. Linen thread makes an excellent ligature; and in case of emergency, a sensible surgeon will not hesitate to take anything that may happen to come in his way. Whatever substance be employed, it is very important that it should be thoroughly waxed, otherwise it will be difficult, if not impracticable, to draw and tie it with the requisite degree of firmness, to say nothing of the greater tendency of the knot to slip. From eight to ten inches is a good average length for a ligature.

Animal ligatures were first introduced to the notice of the profession by Dr. Physick, early in the present century, and they have ever since been occasionally employed by different practitioners, chiefly American. The late Dr. Jameson, of Baltimore, used them nearly altogether for many years, under the belief, founded upon numerous experiments and clinical observations, that they were decidedly superior to all others, their presence never causing any of the irritation which sometimes follows the use of the ordinary substances. The article to which he gave the preference was soft buckskin leather, which he cut into thin, narrow strings, care being taken not to tie them too firmly, lest they should break, and be prematurely detached. Other practitioners have recommended the fibres of the sinew of the deer. The advantage of the animal ligature is that, besides approaching more nearly to the living tissues than any other material, the ends may be cut off close to the knot; its disadvantage, that it soon becomes disintegrated, from the imbibition of the fluids, thereby rendering it liable to separation before it has accomplished the object for which it was applied. This reason is, I conceive, quite sufficient to induce its rejection from practice; for no conscientious surgeon, it seems to me, would ever subject his patient to such a contingency, especially when he has always at hand so reliable a substance as silk.

The wounded artery may be very conveniently drawn out with a pair of spring forceps, seen in fig. 205, an instrument which, indeed, I generally

Fig. 205.

The spring artery-forceps.

prefer, or with a tenaculum, represented in fig. 206. If the vessel be small, it should be seized in its longitudinal axis, but in the horizontal if it be large,

Fig. 206.

Tenaculum.

since in this way we can more effectually occlude its orifice, and thus prevent the loss of blood. It is for this reason, also, that the forceps are generally to be preferred to the tenaculum; the latter instrument, however, possesses

an advantage over the former when the artery is cut off very closely, or when it is desired to include some of the surrounding tissues. Care must be taken not to transfix the coats of the vessel, and then tie the ligature below the

Fig. 207.

Sliding-forceps.

point of perforation, as this might lead to secondary hemorrhage. When no good assistant is at hand, the artery forceps, represented in fig. 207, an

Fig. 208.

Mode of drawing out and isolating an artery.

instrument with broad, serrated extremities, and a movable slide or catch, to close the blades, will be found convenient. The vessel being pulled gently out, as in fig. 208, is carefully isolated from its connections, either with another pair of forceps, the finger, or the knife, or all three together, as may be most expedient. The propriety of excluding from the ligature the smallest nervous filament, as well as the most insignificant vein, and every particle of muscular tissue, must be obvious to the merest tyro, and need not therefore be expatiated upon here. Such a procedure would not only be productive of pain, but would be liable to be followed by suppurative action, and perhaps materially impede the separation of the thread. The ligature is placed immediately above the point of the instrument, whether this be the forceps or tenaculum, and being tied in a single knot, is drawn with sufficient firmness to divide the inner and middle tunics, as in fig. 209, if the artery be one of large size, or even of medium caliber; while in the smaller branches, mere apposition of the opposite surfaces will suffice. In executing this part of the operation, the extremities of the ligature are to be drawn round the fore and middle fingers of each hand, while the thumb is extended upon them nearly as far over as the vessel, in order that the force may be exerted in as gentle and equable a

Fig. 209.

Effects of ligation upon the inner coats of the artery.

manner as possible. Nothing is more unseemly, or more truly abominable, than to see a surgeon or his assistant pull a ligature by fits and jerks, or so violently as to break it in pieces, or, perhaps, lacerate and tear off the artery itself. With a little care and gentleness, a comparatively weak ligature may be thrown round a vessel so as to answer the intention most fully. I deem it my duty to dwell upon this point with some degree of emphasis, because

Fig. 210.

Exterior of an artery after ligation.

it has happened to me to witness quite an unusual number of these Herculean feats with the ligature, the men often pulling as if they had hold of a rope and piece of wood, instead of a delicate thread and artery. Fig. 210 shows the indented appearance of the artery after ligation.

The ligation is completed by making a double knot, when one end is cut off close, and the other is afterwards brought out at the nearest angle of the wound. The knot which is thus made is the reef-knot, fig. 211, in which the ends of the

Fig. 211.

Reef-knot.

Fig. 212.

Surgeon's knot.

thread lie across the artery, in the same manner as in the lips of the wound in the ordinary interrupted suture. The surgeon's knot, fig. 212, is no longer used for the purpose, as, from the manner of making it, it is very irregular, and, consequently, ill adapted to the object. In tying very small vessels, we sometimes use only one knot.

The practice of cutting off both ends of the ligature, and of closing the wound over the injured vessel, first suggested towards the latter part of the last century, by Mr. Haire, of England, and afterwards so warmly lauded by Mr. Lawrence and Mr. Hennen, is now, I believe, universally abandoned, and very justly so, on the ground that the noose, after having performed its duty, creates irritation among the parts with which it lies in contact, leading thus to the development of abscesses, which continue to discharge as long as the foreign substance remains. When the animal ligature is used, this objection does not obtain, as the noose is soon removed by absorption; but then, as was previously observed, this material ought not to be employed, because of its liability to give way before the vessel is completely occluded.

When the arteries are diseased, or abnormally brittle, in consequence of the fibrous, cartilaginous, earthy, or fatty degeneration of their tunics, the ordinary ligature must be dispensed with, and a flat one used in its stead. It may consist of two or more silk threads, carefully waxed, and arranged side by side, or of a piece of soft, narrow braid, and should be drawn so gently around the artery as merely to approximate its serous surfaces. In using the round ligature the object is to divide the inner and middle tunics, as this is most favorable to adhesion; but in this case we aim to preserve their integrity, well knowing that if this be not done the ligature will fall off prematurely, and thus lead to secondary hemorrhage. Cases occur in which the fragility of the arteries is so great as to render them incapable of bearing even this degree of pressure; under such circumstances our only resource is

to surround the vessel with a portion of muscular or aponeurotic substance, and to include the mass in a flat ligature. Such a procedure is much more scientific than the practice, formerly recommended, of tying the artery over a roll of adhesive plaster, an operation which cannot fail to be followed by mischief.

In regard to the propriety of drawing the ligature so firmly as to divide the inner and middle tunics, no doubt is any longer entertained by enlightened practitioners. In the time of Scarpa much disputation prevailed respecting this point in the ligation of arteries, it having been alleged by this distinguished surgeon, on the strength of numerous experiments, that a cure could be effected quite as rapidly, and, in the end, more safely, simply by placing the serous surfaces gently in contact with each other. It was supposed that the part, treated in this way, would unite by direct adhesion, and that, consequently, when the ligature finally became detached, there would be much less risk of hemorrhage than when the vessel is lacerated and contused by the ruder method of procedure above described. Plausible as this theory may, at first sight, appear, it is found to be wholly unreliable in practice, for the very reason which induced Scarpa and his followers to advocate its adoption, the ligature being not only a much longer time in separating, but the two ends of the artery being much less effectually occluded. When it is recollected that a certain degree of inflammation is necessary, after this operation, in order to afford the requisite amount of plasma, for gluing the inner clot to the surface of the vessel, it is reasonable to suppose that it would be much more easily induced by a partial division of the inner and middle tunics than by the mere approximation of the opposite sides of the tube; and this is precisely what the general experience of the profession has at length established in relation to the subject.

When a considerable portion of neighboring tissue is obliged to be included along with the artery, the best instrument for performing the operation is a

Fig. 213.

Tenaculum-needle, armed with a ligature.

sharp tenaculum, with an eye near its point, as seen in fig. 213; a curved needle armed with a ligature; or Physick's artery-forceps, fig. 214.

Fig. 214.

Physick's artery forceps.

An artery is sometimes rendered incapable of bearing the ligature in consequence of the softening of its tunics by inflammation. Such an event, which is often exceedingly perplexing, is most liable to happen in cases of secondary hemorrhage after wounds and amputations. The remedy is to isolate the vessel a short distance beyond its diseased limits, and to ligate it there in the usual manner; or, this being impracticable, to tie the diseased part along

with more or less of the surrounding tissues; or, this also failing, to cut down upon and secure the main trunk of the artery.

In tying an artery in its continuity, whether as a means of arresting hemorrhage, or of curing disease, the ligature is passed around the vessel by means of an aneurism-needle, fig. 215, a kind of blunt tenaculum, with an eye at

Fig. 215.

Aneurism-needle, armed with a ligature.

the free extremity. Special care must be taken, in performing the operation, to disturb the sheath of the artery as little as possible; this structure is intimately connected with the nutrient vessels, and hence the less it is interfered with the less likely will the artery be to soften, ulcerate, or mortify. There is another point of deep interest connected with this operation, and that is the application of two ligatures, with the section of the vessels between them. This operation, which dates as far back as the time of Aetius, was revived by Mr. Abernethy, through whose influence it became for a while quite popular. It was soon found, however, that it was liable to be followed by secondary hemorrhage, owing chiefly to the injury inflicted during its execution, and it has therefore deservedly fallen into desuetude.

It was also in the Aetian operation that some of the surgeons of the last century employed what was termed the *reserve ligature*, intended as a ready resource in sudden emergencies. The cord was placed loosely around the artery, to be tied instantly in the event of hemorrhage, from the premature detachment of the original ligature. Experience, however, which is the only true test in such cases, soon showed that the procedure, instead of answering the design for which it had been intended, had a direct tendency to bring about the mischief, from its liability to produce ulceration of the denuded and tortured vessel. Its evils, indeed, are so palpable that it is extremely probable that it will never be revived by any enlightened surgeon.

When an artery is cut completely across in the continuity of a limb, as, for instance, in a sabre wound of the femoral, it is necessary to use two ligatures, one for the cardiac, and the other for the distal extremity of the vessel. The reason of this is that, however securely the cardiac end may be tied, there will inevitably be more or less hemorrhage from the lower end, unless this be tied also, in consequence of the activity of the recurrent circulation. Every one who has ever had occasion to ligate the brachial artery at the bend of the arm, on account of injury inflicted upon the vessel in bleeding, must have seen that the hemorrhage was only partially controlled by ligating the upper extremity. The blood, under such circumstances, wells up from the lower part of the artery as water bubbles up from the bottom of a spring; it does not issue in jets, or in a saltatory manner, as when it proceeds from the upper orifice, but lazily, and of a dark color, the bleeding resembling that of a vein rather than that of an artery; and thus the hemorrhage goes on, with little or no interruption, until it is arrested by ligature, or until it proves fatal. The flow may, it is true, be temporarily stopped, during an attack of syncope; but even then seldom perfectly, for the reason, apparently, that the vessel here does not possess the same power of contraction and retraction that it does

above, and that, therefore, it is not capable of forming any efficient clot, either external or internal.

The changes which occur in an artery after the application of the ligature are essentially similar to those which occur when the bleeding is arrested spontaneously. The first thing that happens, after such an operation, is the coagulation of the blood within the artery as high up, generally, as the first considerable collateral branch, thus forming what is named the internal clot. The external clot is of course wanting, and this circumstance constitutes the chief point of difference in the two cases. The injured tunics, becoming inflamed, pour out plasma into their own substance, and also upon the free surface of the serous membrane, by which the internal clot becomes firmly and permanently fixed in its situation; the clot next becomes organized, and finally, after an indefinite period, it is completely removed by absorption, the corresponding portion of the artery being converted into a dense, fibro-ligamentous cord.

The changes experienced by the arteries and the blood in their interior, after the application of the ligature, are admirably illustrated in the adjoining sketches. Fig. 216 represents the carotid artery of a dog 48 hours after

Fig. 216.

Fig. 217.

Fig. 218.

deligation. At *a* the coats are cut across; lymph is effused around, and a clot is formed on each side of the ligature. Fig. 217 exhibits the artery 96 hours after the operation. The extremities of the vessel are surrounded by

a mass of plasma, through which the ends of the ligature are seen protruding. Fig. 218 represents the vessel on the twelfth day after the deligation. At *a* the artery is cut open, to show its interior; at *b* numerous vessels are seen coming from the exterior, and coursing onwards to enter the clot at *c*.

The period at which the ligature is detached varies with many circumstances, of which the principal are, the size of the cord and the manner in which it has been tied, the state of the artery, and the amount of the resulting inflammation. A small ligature will, other things being equal, be detached sooner than a large one, and a firm sooner than a loose one; a sound artery will be longer in throwing it off than a diseased one, simply because it has more power of resistance. A ligature upon the brachial artery will generally be detached in about ten days; upon the femoral, in from twelve to fourteen; upon the external iliac, in sixteen; and upon the common iliac, in about twenty-one days. To this rule there are, of course, many exceptions. I recollect the case of a man in the Louisville Marine Hospital, in whom, after an amputation of the leg, the ligature was still firmly adherent to the anterior tibial artery at the end of the fourth month. Dr. Lopez, of Mobile, communicated to me, some years ago, the particulars of a case where the separation was not effected before the end of the eleventh month; and Professor Eve met with one where it did not occur until after the thirteenth month. Such cases constitute, of course, exceptions to the general rule, and it may be fairly assumed that they usually depend either upon the faulty manner in which the operation is performed, or upon the presence of an extraordinary quantity of organized plastic matter, interfering mechanically with the detachment of the thread.

When the ligature is indisposed to come away, gentle traction may be made upon it, repeated once in the twenty-four hours; great care, however, must be exercised in performing the operation, otherwise we may not only inflict severe pain upon the patient, but subject him to the risk of secondary hemorrhage.

The process by which the separation of the ligature is effected is worthy of inquiry. It is generally ascribed to ulcerative action, and this is undoubtedly true; but it is equally true that that portion of the artery immediately embraced by the ligature mortifies, and comes away in the form of a slough. When the cord is drawn very tight, the corresponding part of the artery is strangulated, either at once, or, at any rate, in a few hours; but, in general, the process takes place more tardily, and thus affords the two ends of the vessel time to prepare and fortify themselves for the approaching crisis. If we study the whole subject minutely, it will be found to embrace the following acts: first, the strangulation and death of the vessel at the site of the ligature; secondly, ulceration and the consequent separation of a part of the artery, thus producing a gap in its continuity; thirdly, the adhesion of the clot to the inner surface of the vessel, speedily followed by its organization; and lastly, the absorption of the clot and the transformation of each extremity of the tube into a dense fibrous cord. In addition to these changes, there is occasionally slight suppuration, the matter usually presenting itself in the form of a little abscess.

The discovery of the use of the ligature is due to Ambrose Paré, in the sixteenth century, prior to whose time surgeons were in the habit of stanching hemorrhage with the actual cautery, hot pitch, and all sorts of styptics, of the most cruel and barbarous nature. "For the good of mankind," says this great man, "and the improvement and honor of surgery, I was inspired by God with this good thought." Paré himself fully appreciated the utility of his invention, but his cotemporaries spared no pains to undervalue it, and to revile and persecute its author, subjecting him to the humiliating office of searching the writings of the ancient fathers of medicine for traces of the use

of the ligature as a justification of his practice. Gourmelen, the jealous and malignant President of the College of Physicians of Paris, made himself particularly conspicuous on the occasion, and thus earned an infamous reputation; for the only act by which he is now remembered is his bitter and unrelenting persecution of Paré, rendered immortal by his great achievements.

2. *Acupressure*.—The credit of devising acupressure, as a means of arresting hemorrhage, is due to Professor Simpson, who published an account of it in the *Edinburgh Medical Journal* for January, 1860. Since that period the operation has attracted much attention, having been performed by different surgeons both in Europe and this country with results generally of a highly gratifying character. What its ultimate fate may be, however, time alone can determine. That it is destined entirely to supersede the use of the ligature is not at all likely; on the contrary, indeed, highly improbable, inasmuch as the instrument with which the pressure is made can be applied only in certain regions of the body.

The advantages claimed for this operation over that of the ligature are, first, that it is more easy, simple, and expeditious of execution; secondly, that the acupressure needle does not, like the ligature, provoke irritation, much less suppuration, ulceration, or mortification at the seat of the constriction; thirdly, that the instrument may generally be removed, even when a large sized artery, as, for example, the femoral, is concerned, at the end of the second or third day; fourthly, that the wound will, other things being equal, be more liable to unite by the first intention; and, lastly, that there will be much less risk of the occurrence of erysipelas, pyemia, phlebitis, abscesses, traumatic fever, and secondary hemorrhage.

The only instrument required for this operation is a steel pin, sharp at one end and provided at the other with a glass-head, of a rounded shape, sufficiently stiff to prevent it from bending, perfectly smooth, and coated with silver, zinc, or gold, although this is not at all essential. The length of the pin should vary, according to the caliber of the vessel and the diameter of the limb in which it is situated, from two and a half to six inches. In ordinary cases the lady's bonnet pin, or the pin worn by gentlemen in their shawls, will answer every purpose. In regard to the isolation of the artery from the surrounding structures, the same rules are applicable as in the use of the ligature. There is, however, less danger from the inclusion of the accompanying veins, and hence these vessels may with great propriety be embraced along with the artery in the event of their being disposed to bleed unduly, as they occasionally are in amputations, resections, and the extirpation of large tumors.

In performing the operation, the pin, previously oiled, is passed from without inwards through the skin and thence on through the muscles and other structures down to and underneath the artery, in such a manner as to obliterate completely its caliber by bringing together its opposite surfaces. The instrument is then pushed through the tissues on the other side from within outwards, so that, when the transmission is effected, the extremities shall rest upon the skin, while the middle shall firmly embrace the artery. Should the constriction not be sufficient to arrest the flow of blood, a ligature may be thrown tightly around the pin as in the operation for hare-lip; but this will seldom be necessary, especially if the precaution be taken of inserting the compressor close to the vessel, or at a rather acute angle. The point of compression for the larger vessels should be at least six lines from the open orifice, and about half that distance for those of smaller size. The pin should be left entirely free during the application of the dressings, and in withdrawing it the parts must be well supported in order to avoid the risk of hemorrhage.

The annexed sketches, from Erichsen, will serve to show, at a glance, the

application of acupressure. Fig. 219 exhibits the extremities of the pin as they project through the skin, while fig. 220 displays the manner in which the instrument embraces and constricts the artery. A good idea of it may also be formed by the manner in which the stalk of a flower is fastened to the lapel of a coat by transfixing the cloth with a pin.

Fig. 219.

Acupressure, showing the manner in which the ends of the pin project across the skin.

Fig. 220.

Position of the artery and pin in acupressure.

3. *Compression*.—Although the ligature is the most certain means of arresting hemorrhage, yet cases occur to which it is either not at all adapted, or where, from the great depth and narrowness of the wound, it is impracticable to apply it. It is under such circumstances that compression becomes available; an agent which is often hardly less valuable than ligation itself. It is particularly serviceable when the injured vessel lies upon a bone, as in wounds of the brachial and temporal arteries; in wounds penetrating deep cavities, as the thoracic and abdominal; and, lastly, when the blood issues from a considerable number of small vessels instead of from one large one.

The compression may be temporary or permanent, according to the exigencies of each particular case. When temporary, it is made with the hand,

Fig. 221.

Tourniquet applied to the femoral artery.

finger, tourniquet, or compress and bandage, and is only kept up until the injured artery can be ligated, or secured in some other effectual way. In permanent compression, the application is continued until the vessel is completely obliterated, whether the time be short or long.

Temporary compression becomes necessary chiefly in cases of sudden emergency, as, for example, when an individual is stabbed in the femoral artery, and the surgeon cannot obtain any persons to assist him in tying the vessel. Under such circumstances an attempt is made to arrest the hemorrhage by means of the tourniquet, shown in fig. 221, or by a graduated compress and bandage; the former being placed directly over the course of the artery from which the bleeding proceeds, or, if this be impracticable, over the main trunk of the limb, and the latter directly over the wound as well as for some distance above it, along the track of the vessel. Whichever method be adopted, it is to be borne in mind that the compression, even if it be main-

tained only for a few hours, may become a source not only of excessive pain, but also of mortification, and that, therefore, the greatest possible vigilance should be exercised in its employment.

When the ordinary tourniquet is not at hand, very efficient compression may generally be made by tying a piece of bandage, a cravat, or a handkerchief loosely round the limb, and then twisting it to the requisite extent by means of a stick, fig. 222, or the hilt of a sword, fig. 223, inserted underneath it. This contrivance, usually called the field-tourniquet, because it was

Fig. 222.

Fig. 223.

Field tourniquet; handkerchief and stick.

Field tourniquet; handkerchief and sword.

originally employed on the field of battle, may be resorted to with great advantage when a surgeon is obliged to amputate an extremity without having a sufficient number of intelligent assistants, although it labors under the inconvenience of not always concentrating the pressure upon the spot where it is most needed. For this reason the common tourniquet is always to be preferred.

A very simple and effective tourniquet for field practice was recently introduced by Mr. Tiemann into this country from Prussia, where it is extensively used in the military service, every orderly sergeant being required to carry

Fig. 224.

Prussian field tourniquet.

one in his pocket for ready use. It simply consists, as will be seen in fig. 224, of an oblong square brass ring and of a strong strap, the latter of which,

after having encircled the limb, is passed through the former and secured to the hooks attached to one of its margins. The instrument has no pad.

Compression with the hand may often be advantageously employed for the arrest of accidental hemorrhage, until the surgeon has time to apply the ligature; and it is also occasionally resorted to for the purpose of controlling the circulation in the main artery of a limb during amputation. In the upper extremity it is generally applied to the brachial artery, as it courses along the inner border of the flexor muscle; and in the lower, to the femoral artery as this vessel issues beneath Poupart's ligament, and where, consequently, it lies upon the pubic bone. The annexed drawings, fig. 225 and fig. 226, are illustrative of the subject.

Fig. 225.

Digital compression of the humeral artery.

Fig. 226.

Digital compression of the femoral artery.

In *permanent compression*, the force is applied in one of two ways, that is, either directly or indirectly. The former method is particularly adapted to the suppression of hemorrhage from deep wounds, as in the lateral operation for stone in the bladder; in wounds of the rectum, whether accidental or wilful; in bleeding of the nose and uterus; in the removal of tumors from the maxillary sinus; in the extraction of teeth; in the extirpation of the eye, and, finally, in wounds of the middle artery of the dura mater, as well as in a number of other injuries and operations which will readily suggest themselves to the mind of the reader.

The great objection to this mode of compression is, first, that it is frequently very difficult to prevent it from becoming deranged, and secondly, that it is liable to produce severe pain and inflammation, the latter being generally sufficient to cause profuse suppuration. It should, therefore, I conceive, never be employed with a view of arresting hemorrhage from a large artery, or even from a small deep-seated one, if it be at all practicable to apply the ligature, which is, of course, always the most certain and efficient method; but this objection does not obtain when the blood proceeds from a bleeding cavity, or when it oozes from the bottom of a recent wound. In-

deed, in such a case, compression must be used at all hazards, for there is often no other way by which the flow can be arrested.

The compression may be made with a graduated compress and roller, or by means of sponge, cotton, wool, patent lint, or any other porous substance. Whatever article be employed, the bleeding surface must be previously freed from coagula, so as to enable us to place the compress directly in contact with the orifices of the vessel, as exhibited in fig. 227. When the blood proceeds from a large artery, the circulation must be controlled, during this part of the proceeding, by means of the finger or tourniquet applied some distance above the wound. The compress is then to be thrust gently but firmly into the breach, the

Plan of a graduated compress. *a*. The artery wounded. *b, b*. The graduated compress, arranged so that the apex of the cone is in immediate contact with the arterial orifice, while its mass occupies the general wound, and projects somewhat above the integumental level.

smallest piece being placed directly upon the orifice of the vessel, the next above this, and so on until a sufficient number have been applied, when the operation is completed by bandaging the limb from its distal extremity upwards, care being taken that the compression be made in as equable and uniform a manner as possible. The part is then put at rest, in an elevated position, and action moderated by the use of cold water, anodynes, and other suitable means. The dressings are frequently examined, but not disturbed under four or five days, unless they become displaced, or offensive from the discharges.

When the hemorrhage proceeds from a wound, as, for example, from that made in the lateral operation of lithotomy, the part must be plugged with a sponge, or piece of patent lint, the hollow of which is filled up with similar matter, or raw cotton, an instrument having been previously introduced through the foreign substance for the purpose of conducting off the urine. A like plan is pursued in bleeding of the rectum. In hemorrhage of the uterus, the vagina is plugged, while in epistaxis both nostrils are closed.

In injuries of the bones, we are sometimes obliged to use a plug of soft wood, as a piece of shingle. In compound fracture of the skull, attended with lesion of the middle meningeal artery, running in an osseous canal, such an expedient is often the only one which can be successfully opposed to the hemorrhage. Bleeding of the nutrient artery of the long bones has sometimes to be stopped in a similar manner.

In some cases the tissues of the part whence the hemorrhage proceeds are employed as the compressing agents. In the operation for hare-lip, for example, the simple approximation of the edges of the fissure by the twisted suture effectually arrests the flow of blood from the coronary artery.

The compression is said to be indirect or lateral, when it is applied to the track of the injured vessel, and not to its orifice. It is, in general, a more eligible way of arresting hemorrhage, being free from the objections that have been urged against direct compression, with which, however, it is occasionally combined. The best mode of effecting it is to place a long and rather narrow compress over the course of the artery, extending from the neighborhood of the wound some distance above, and to confine it by means of a roller, commencing at the distal portion of the limb, and carried upwards in such a manner as to afford equable support at every point. In other respects, the treatment is to be conducted as in direct compression. This mode of management is often employed, with the happiest effects, in wounds of the brachial artery, at the bend of the arm, caused by venesection.

4. *Styptics*.—Styptics are remedies which arrest hemorrhage by their direct influence upon the blood, and the arteries furnishing it. They comprise a long and varied catalogue of articles, some of which produce merely an astringent effect; others act apparently mechanically, and others, again, are escharotic, destroying both the vessels and the connecting tissues.

Among the less objectionable styptics are alum, sulphate of copper, and the perchloride of iron, especially the first, which I prefer to every other, when such an agent is called for, and which may be used either in strong solution, or in powder, through the medium of patent lint, applied directly to the bleeding surface, previously freed of coagula. Employed in this manner, it generally produces a powerful astringent effect, causing coagulation of the blood, and marked contraction of the vessels, without necessarily leading to suppuration of the affected structures, which is always the case with most of the other articles of this class. Sulphate of copper may be used in the same manner, or in the form of a stick, held firmly for some minutes upon the oozing surface. Creasote possesses none of the styptic properties which were ascribed to it twenty-five years ago, and is now seldom employed with such a view. The *perchloride of iron* possesses great coagulating powers, but the misfortune is that it creates so much irritation as inevitably to give rise to suppurative inflammation, if not to destruction of the tissues. A similar remark is applicable to the tincture of the chloride of iron. Of matico, I have not made sufficient trial to enable me to form a correct opinion as to its styptic virtues. Judging from what has been said of it by others, we must conclude that it possesses more than ordinary properties of this kind, although further observation is necessary before we can come to a final decision about it.

Within the last few years, the *persulphate of iron* has been highly recommended as a styptic by Mons. Monsel, a pharmacist of Bordeaux. It is applied either in substance, or, what is preferable, in strong solution, and possesses the property of instantaneously coagulating the blood, converting it into a very large, dense clot, which is absolutely insoluble, and which continues to increase and harden for several hours afterwards. What adds greatly to the value of this remedy, is the fact that it is entirely free from causticity. It is particularly adapted to hemorrhage of the nose, mouth, and throat, as well as of other parts of the body where it is impossible to ligate the injured vessels, on account of the great depth at which they are situated. It has also been used for the cure of vascular tumors of the skin and subcutaneous cellular tissue, a solution of the persulphate being injected into them by means of a delicate syringe.

A very convenient and efficient mode of using this salt was recently introduced to the notice of surgeons by Mr. Henry Johnson, of Chester, Pennsylvania. It consists of cotton thoroughly steeped in a saturated solution of the persulphate, and then dried and rolled up for use. Previously to applying it, the wound should be well wiped, when it should be covered with a thick layer, supported by a compress and a roller.

Cold is a powerful styptic, and may be used in various ways. A current of cold air will often promptly and effectually stop capillary hemorrhage, or even hemorrhage produced by the division of a small artery, as is exemplified in operations upon the tonsils and anus, or ano-rectal region, as well as upon other parts of the body. To prove beneficial, the air must have free access to the part, and it may often be usefully directed by means of the fan, which has the additional advantage of rendering it more cool.

Cold water, refrigerating lotions, pounded ice in bladders, or lumps of ice rolled up in cloths and applied to the bleeding surface, or in its immediate vicinity, occasionally promptly arrest hemorrhage. These applications are particularly valuable in deep-seated hemorrhage, or in hemorrhage of the in-

ternal organs and cavities; they must, however, be used with a certain degree of caution, as their protracted continuance may be followed by injurious reaction, and even by mortification of the part. When the wound is situated externally, but too deeply to render the injured vessels accessible to the ligature, the bleeding may often be promptly and effectually checked by a full stream of iced water, directed upon the part, and maintained steadily for some time, from a large syringe.

The *actual cautery* can hardly be considered as a genuine styptic, although it is usually classed under this head. Its effect is not to constrict the vessels, but to destroy them, by producing an eschar, by which the vessels are, for the time, hermetically sealed. Upon the separation of the slough, however, there is frequently a reproduction of the hemorrhage, especially if the wounded vessels are at all large, owing to the imperfect coagulation of their contents. The cases to which the cautery is mainly applicable are those in which the hemorrhage proceeds from a deep and narrow osseous cavity, and in wounds of the tonsils, uterus, and rectum. The instrument, which may be of a conical form, should be heated to a black or slightly red heat, and used in such a manner as not to injure the structures around the seat of the affected vessels. When the artery is very diminutive, we may sometimes attain our object with a hot knitting-needle, a wire, or probe.

5. *Torsion*.—Torsion is an old procedure, reintroduced to the notice of the profession by Thierry, Amussat, Velpeau, and others; at one time pointedly condemned, at another immeasurably lauded; opinion being still at variance, although decidedly preponderating against it. In the enthusiasm of the moment much was said and written in its favor; it was even alleged that the larger arteries might be occluded in this way, and a German surgeon, Dr. Koch, of Munich, actually published some cases of amputation of the thigh, in which he trusted entirely to torsion as a means of preventing hemorrhage. No other practitioner, however, has, I believe, had the hardihood to imitate him, and the operation is now entirely limited to the smallest arterial twigs. The proceeding, which is said to answer most admirably in the inferior animals, serving as a substitute for the ligature, is executed with two pairs of forceps, as shown in fig. 228; a small one for drawing out the artery by

Fig. 228.

Torsion-forceps.

grasping it horizontally, and a long, stout one provided with a slide, and serrated blades, for twisting it in its longitudinal axis; from six to eight turns being required, according to the size of the vessel, to lacerate and bruise its tunics so as to intercept and coagulate its contents. I have rarely found torsion of any service even in the smallest arteries.

General Means.—Whatever mode of procedure be adopted for arresting the bleeding, it is an object of primary importance to place the affected part perfectly at *rest*, in an easy and elevated position; the slightest motion might be injurious, especially where no ligature has been used, and should therefore be sedulously guarded against. Repose of the body is equally necessary

with that of the part, and it is hardly needful to add that mental tranquillity is also of the greatest moment. Cardiac action, too, must be maintained in the most perfect quietude, as any perturbing agency of this kind cannot fail to favor a return of the hemorrhage and exhaust the system. With a view of inducing this result a full anodyne should be administered early in the disease, the dose being repeated from time to time as occasion may seem to require the soothing and sustaining influence of the remedy. Too much stress cannot be laid upon the use of opiates in the management of arterial hemorrhage, and it is surprising that the remedy is not more generally employed than it seems to be. To allow the heart to go riot, or to move and toss about tremulously, as it is so liable to do after serious loss of blood, while we take every local precaution for the suppression of the bleeding, is assuredly a strange inconsistency, and one altogether irreconcilable with experience and common sense.

The *diet* should be perfectly bland, and just sufficient in quantity to supply the wants of the body. To give less might cause irritability of the system; to give more, over-stimulation. The drink must be cold and acidulated, and not taken so freely as to oppress the stomach, which will be sure to happen if the quantity be not carefully restricted, as the thirst is always urgent after the loss of even a comparatively small portion of blood. Lumps of ice, or pounded ice, held in the mouth, and gradually swallowed, often prove most grateful and beneficial. The air of the apartment must be kept perfectly cool; and, in short, every effort must be made to maintain the tranquillity of the circulation.

Secondary Hemorrhage.—Secondary hemorrhage occurs at variable periods; sometimes in a few hours, at other times not under several days or weeks. It is not necessarily preceded by primary hemorrhage, but may come on where the loss of blood in the first instance was perhaps altogether insignificant, and where everything, so far as this event is concerned, gave promise of a most favorable issue. The bleeding often supervenes without any assignable cause, generally suddenly and unexpectedly, and hence it often makes great progress before an opportunity is afforded to arrest it. When proceeding from a large vessel, it may prove fatal in a few minutes, in the same manner as when the bleeding is primary. The scarlet hue of the blood always denotes its source.

The causes of secondary hemorrhage are various, but the most important are the following: 1st. A faulty application of the ligature; 2d. A diseased state of the arteries; 3d. Morbid changes in the clot; 4th. Improper traction upon the ligature; 5th. Tight dressing, or too great dependency of the part; 6th. Want of retraction in the vessels; and 7th. A hemorrhagic diathesis.

1. When a ligature is properly applied it simply divides the inner and middle tunics, leaving the outer intact; this too, however, may be cut, not completely, but partially, and therefore the more insidiously, in consequence of the force used in tightening the ligature; or, the deligation may not have been sufficiently firm, the opposite surfaces being only slightly approximated, and the resulting adhesion, therefore, inadequate to effect hermetic closure of the artery on detachment of the cord; or, lastly, the fault may have existed in the ligature itself, on account of the rottenness of its substance, or the imperfect tightening of the knot. Whatever the cause may be, the proper remedy is more efficient ligation.

2. The hemorrhage may arise from disease of the *artery*, either from undue inflammation, or degeneration of its coats, rendering them incapable of supporting the ligature until the clot has contracted firm adhesions. The mode of procedure is obvious; a more healthy portion of the vessel must be sought for, and the ligation effected with more caution; or, this failing, the hemor-

rhage may be arrested by tying the main trunk of the limb, some distance from the seat of injury.

3. Morbid changes in the *clot*, commencing in a process of softening and disintegration, occasionally occur after ligation, leading to its premature detachment, perhaps several weeks after the operation. Such changes, which are well illustrated by the annexed sketch, fig. 229, from Erichsen, are most frequent in cases of pyemia and diffuse erysipelas, consequent upon some injuries and amputations, eventuating in a tendency to suppurative inflammation. The only remedy, under such circumstances, is the ligation of a healthy portion of the artery.

4. Young and inexperienced surgeons sometimes bring on hemorrhage by improper traction of the *ligature*, with a view to the promotion of its separation; forgetting that they may thus tear the artery, or, at all events, break up important adhesions. Such a procedure cannot, as stated elsewhere, be too severely censured. Re-ligation is obviously the remedy in such a case.

5. *Tight dressing*, causing unequal constriction of the part, or improper dependency, favoring undue afflux of blood, may induce this form of hemorrhage. The result will be most likely to happen when a number of small arteries have been divided, without any attempt having been made to secure them with the ligature. Bleeding having ceased, the dressings are applied, but too firmly, or the part is placed too low, and presently blood begins to appear, issuing, perhaps, with great freedom. The treatment consists in the removal and readjustment of the dressings, with strict attention to posture.

6. Secondary hemorrhage occasionally comes on after operations for the relief of anal, perineal, and other fistules, chronic abscesses, and old ulcers, from an inability of the vessels to *retract* in consequence of the indurated condition of the divided parts. Exposure of the surface to cold air, the application of ice, direct compression, or styptics, constitute the best means of relief. In some cases the actual cautery may be required.

7. Finally, the cause may be a *hemorrhagic diathesis*, an affection which, as will be stated elsewhere, may occur at any period of life, and which it is often found extremely difficult to control by any mode of treatment, however judiciously conducted.

Fig. 229.

Partial absorption of the clot, in the femoral artery, a fortnight after amputation.

SECT. II.—SUBCUTANEOUS HEMORRHAGE.

There is a form of arterial hemorrhage to which, from its situation, the term subcutaneous is very properly applicable. It takes place when, from any cause, an artery is laid freely open, and its contents, instead of escaping externally, are extensively extravasated among the surrounding structures. In ordinary hemorrhage, the blood issues directly from the injured vessel, because the outer wound is sufficiently capacious to admit of its free and unrestrained passage, and the consequence, generally, is that it continues until the patient faints, and the bleeding orifice is closed by coagula. In the variety of hemorrhage, however, under consideration, the opening in the integuments is so small as to prevent the blood from appearing externally, and it therefore accumulates beneath the skin, in the subcutaneous cellular tissue, when the artery lies superficially, or in the subcutaneous and intermuscular

cellular tissue, when it is deep-seated. The accident which usually causes this hemorrhage is a puncture, such as that inflicted in venesection at the bend of the arm, where, in civil practice, it is most commonly met with. It may, however, in consequence of a stab, a bayonet wound, or the laceration occasioned by the sharp end of a broken bone, occur in any part of the body, and is sometimes most profuse, its extent being regulated chiefly by the size of the affected vessel, and the quantity and laxity of the connective substance. In the superior extremity, the extravasated fluid often reaches nearly as high up, on the one hand, as the axilla, and, on the other, as low down as the inferior third of the forearm, extensively separating the muscles from each other by breaking up their cellular connections, and forming a large, ill-shaped, and confused swelling, attended with violent pain, numbness and œdema of the whole limb, and discoloration of the integuments. More or less pulsation is generally present, especially in the earlier stages of the case, and, upon applying the ear over the site of the wound, a well-marked bruit can frequently be recognized, attended occasionally with a peculiar thrill, or a whirring noise, and a vibratory sensation. It is for these reasons that this affection has usually been described by writers as a variety of aneurism; and, as the blood is always widely extravasated, the prefix diffuse is usually added to that term, as particularly expressive of its more important attributes. Strictly speaking, however, there is no aneurism here; there is simply a subcutaneous accumulation of blood, the consequence of external injury, without any dilatation of the vessel, or degeneration of its tunics; and, although there frequently is, as just stated, more or less concomitant pulsation in the part, yet this does not any more entitle it to be regarded as an aneurism than it would if the effused fluid were so much pus or serum.

The blood which is effused in this accident usually promptly coagulates, and, exerting injurious compression upon the parts with which it is in contact, soon excites severe inflammation, which, especially in persons of an irritable constitution, is liable to assume an erysipelatous character, and to terminate in suppuration, ulceration, and even gangrene. The pain is often intense, depriving the patient of appetite and sleep, and making rapid inroads upon the system. I have witnessed cases where, from the excessive distress thus produced, hectic fever soon came on, and life was placed in imminent peril.

The *treatment* of this lesion is precisely similar to that which is necessary when there is an open wound; that is, the artery must be secured promptly and at all hazard, and the coagulated blood thoroughly evacuated. The operation is often one of great embarrassment, owing to the confused and displaced condition of the parts, and the difficulty which is sometimes experienced in finding the injured vessel, which is not unfrequently lost in the midst of the coagulated blood. A large incision is generally required, and two ligatures must be applied, one above and the other below the wound in the vessel, precisely as in ordinary cases, the object being to prevent hemorrhage by the recurrent circulation. As a preliminary step, the brachial artery is compressed in the middle of the arm by the finger or tourniquet, and after the operation is over, the limb is wrapped up in warm water-dressing, medicated with laudanum and acetate of lead, or laudanum and alcohol, to favor the reduction of inflammation.

SECT. III.—COLLATERAL CIRCULATION.

Among the more interesting phenomena that occur after the deligation of the larger arteries, not the least curious and important is the manner in which the circulation is carried on and maintained in the structures beyond the seat

of the ligature. A long time elapsed after the discovery of the ligature before surgeons could be induced to believe that such an operation could be performed in the continuity of a limb without endangering the parts below by gangrene, in consequence of the sudden abstraction of their accustomed supply of blood. Chance gradually led to the correction of this apprehension, which, however, is not without some foundation, as is proved by the fact that the procedure is occasionally followed, even at the present day, in the hands of the most scientific surgeons, by loss of limb and life. Cases had been observed, from time to time, of the obliteration of the largest arterial trunks by fibrinous concretions, and yet it was perfectly certain that the structures in the distal portions of the extremity had retained their normal growth, no difference being discoverable between them and those of the opposite side. Such a result, it was obvious, could only have been brought about by an enlargement of the collateral vessels, thus enabling them to keep up the normal supply of blood, after the obstruction of the main artery. A number of instances had been noticed of complete closure of the aorta, both in its thoracic and abdominal divisions, without any apparent detriment of any kind, either proximate or remote. These facts, the fruits of the cultivation of morbid anatomy, were eminently suggestive, and we accordingly find that they gradually paved the way for some of the most daring feats in surgery. The original trials with the ligature upon the principal arteries in the continuity of the limbs were highly gratifying, as tending to show that, although the distal structures were temporarily deprived of their accustomed supply of blood, yet this occurrence did not sufficiently interfere with their vitality to cause gangrene, the circulation being speedily re-established through the collateral routes. The process employed by nature in effecting this object has been demonstrated, in repeated instances, by dissection of the parts at variable periods after they had been subjected to operation.

The moment a large artery, as, for example, the femoral, is tied, the blood is obliged to seek new channels for its transmission to the distal portion of the limb. For this purpose it passes on in every direction, entering every vessel, both large and small, into which it can find access. This, however, does not occur all at once, but gradually; for as the arteries which are to carry on this collateral circulation, as this arrangement is termed, are comparatively small, some time is necessary to prepare them for the reception and accommodation of the increased flow of blood. In fact, they are compelled to submit to a species of preliminary dilatation, their tonicity being such as rather to resent its encroachment than to yield to its effects. This is the case both with the branches that are detached from the sides of the vessel above the seat of the ligature and with the capillaries of the various tissues entering into the composition of the limb, which, immediately after such an event, always play an important part in maintaining the distal circulation. Hence, for some time after the operation, the quantity of blood below the point of obstruction is necessarily considerably less than in the normal state, as is demonstrated by the cold and pallid state of the integuments, the defective sensibility, and the loss of muscular power, which is occasionally so great as to deprive the patient of motion in the affected member. The diminution of temperature is liable to a good deal of variation, but in general it amounts to several degrees, and hence the surgeon is often obliged to employ artificial heat. Gradually, however, as the circulation increases in vigor, the temperature returns to the natural standard, and in many cases even exceeds it, owing to the enlargement and inordinate activity of the cutaneous capillaries, although such an occurrence is usually of short duration.

An instance occasionally occurs in which there is either no change of temperature at all from this cause, or where it is so very slight as to be hardly perceptible. Such a phenomenon is most apt to happen in old

aneurisms, where, owing to the obstruction in the artery connected with the tumor, the anastomosing vessels have had time to become enlarged prior to the application of the ligature, so that the operation exerts little, if any influence, upon the circulation in the distal portion of the limb, as it necessarily must in recent cases of that disease, and also in wounds of the arteries, in which no such opportunity is afforded for an increase in the size of the collateral channels.

Coincident with this effort on the part of the affected structures to establish the collateral circulation, there is generally a feeling of uneasiness, if not of actual pain, of a burning or tingling character, obviously occasioned by the compression which the enlarged and distended vessels exert upon the neighboring nerves. Usually, however, this effect is of short duration, as the nerves soon accommodate themselves to their new relations. After some time, the parts gradually recover their natural functions, all disagreeable sensations vanish, the muscles increase in vigor, and the process of nutrition proceeds apparently as well as it did prior to the deligation of the vessel.

Although such is the ordinary course of events after the main artery of a limb has been tied, yet important exceptions are occasionally met with. Thus, it now and then happens that the circulation remains extremely languid for an unusual length of time, perhaps for a number of days, if not several weeks, the anastomosing branches being seemingly incapable of enlarging to a sufficient extent to convey an adequate supply of blood to the affected structures; the extremity is, consequently, cold, heavy, numb, and of a reddish or purplish hue, from passive congestion of the capillaries, and is moved with pain and difficulty. A struggle is evidently going on between nature and disease, in which the latter but too often comes off victoriously; the limb either falling into gangrene without the occurrence of reaction, or, reaction taking place, it is overpowered by the resulting inflammation. Finally, cases occur, although, fortunately, very unfrequently, in which the parts remain permanently weak and crippled; the muscles are soft and flaccid, the adipose tissue is absorbed, and the integuments are habitually cold and congested; the circulation having never attained the normal standard after the operation.

It is worthy of notice that gangrene, from defective circulation, is much less liable to occur after the ligation of an artery, in the continuity of a limb, in wounds than in aneurism. This fact, at all events, is clearly deducible from the statistical tables of Dr. Norris, from which it appears that in seventeen cases in which the femoral artery was secured on account of recent injuries and different tumors, gangrene did not occur in a single one, whereas this result was witnessed in thirty-one cases out of two hundred and four in which the operation was performed for the cure of aneurism. May not the cause of this disparity be the compression which the tumor in this disease exerts upon the neighboring structures, thereby obstructing the circulation in the distal portion of the limb, and at the same time seriously embarrassing the functions of the nerves? I presume that this result is very materially influenced by the nature of the wound, necessitating the deligation of the artery. If, for example, the parts are extensively divided transversely, or very obliquely, so as to destroy the continuity of a large number of its more important branches in the immediate vicinity of the wound, gangrene will be much more likely to occur than under opposite circumstances, in which the neighboring vessels being but little injured, the blood will easily find its way into the distal structures, thus affording them the requisite supply not only for the preservation of their vitality but also for the maintenance of their nutrition.

Although the capillaries are greatly instrumental in carrying on the circulation in the distal portion of the limb, immediately after the deligation of its main artery, yet their agency is really merely of a temporary character,

ceasing with the establishment of the collateral circulation, properly so called, as developed by the larger arterial branches in the vicinity of the ligature. These arterial branches are occasionally given off by the affected artery itself, but most commonly they arise from some neighboring trunks. Thus, when the superficial femoral is tied high up, the collateral circulation is established through the agency mainly of the profunda, whose branches inosculate with the articular, which are offsets of the popliteal. In ligation of the brachial, the blood is transmitted to the forearm and hand by the communications naturally existing between the anastomotic and profunda arteries, branches of the affected vessel, and the recurrent branches of the radial and ulnar, in which the brachial terminates. In ligation, on the contrary, of the common carotid, the circulation of the corresponding side of the head and neck is kept up mainly by the communications between the occipital and deep cervical arteries.

It has been noticed, as an interesting physiological fact, that the anastomotic arteries, before they unite with each other, separate into several branches, often as many as three or four, so as to form a kind of circle, as if nature were particularly anxious to guard against any risk that might otherwise occur to the collateral circulation from accident or disease.

However established, the collateral vessels gradually augment in size, until, at length, their united capacity is fully equal to that of the obliterated trunk, as in fig. 230, whatever may have been its size. There are, of course, as already stated, exceptions, but they are, probably, much less frequent than is generally imagined. A highly interesting case, beautifully illustrative of the present topic, occurred, some years ago, in the practice of Dr. Francis West, of this city, by whom the particulars have been published in the second volume of the *Transactions of the College of Physicians of Philadelphia*. The patient, who was a stout, athletic man, aged thirty-two, died suddenly from rupture of an aneurism of the thoracic aorta. On dissection, it was found that this vessel was entirely obliterated, just beyond the remains of the arterial duct, its coats having a constricted appearance, as if they had been embraced by a tightly-drawn ligature. Everywhere else, excepting at the place of aneurism, the aorta was perfectly natural. All the branches of the subclavian arteries were much increased in size; and the internal mammary and epigastric, which served to keep up the connection of the circulation above and below the seat of the stricture, were fully as large as the external iliac, the former having coursed along the walls of the chest in a very tortuous manner. As no tumor was discovered at the seat of the obliteration, Dr. West was unable to determine whether the disease was the result of accident or of a congenital vice. Be this as it may, the case affords an admirable illustration of the manner in which the collateral circulation is carried on after the interruption of the column of blood in such an immense vessel as the aorta.

The collateral circulation is not developed with equal facility at all periods

Fig. 230.

Collateral circulation shown in the thigh. At *a*, the femoral artery has been obliterated by ligature.

of life, or under all circumstances; it is most readily established in young subjects, in whom the arteries, besides being very active, enjoy a high degree of elasticity and pliancy, well adapted for such an enterprise. In old persons, on the contrary, the functional activity of these vessels is often much impaired, many of the small branches are obliterated, and their coats are extremely liable to earthy deposits, converting them into firm, rigid tubes, ill qualified for the discharge of their duties. In many cases, loss of blood, ill-health, or defective vital power, seriously interfere with the development of the collateral circulation.

Finally, the collateral circulation may be too active. Such an event is not likely to happen when the main artery of a limb is tied on account of hemorrhage from a wound, but its occurrence is by no means uncommon in aneurism, and is then apt to be followed by a return of the circulation and pulsation in the tumor, in consequence of the activity of the anastomosing branches, which thus continue to feed the sac, and perhaps effectually oppose the cure.

SECT. IV.—HEMORRHAGIC DIATHESIS.

The hemorrhagic diathesis is that peculiar state of the system in which, generally from some slight traumatic cause, there is a strong tendency to an inordinate discharge of blood. Persons who are laboring under this constitutional infirmity are often placed in imminent jeopardy by the most insignificant scratch, puncture, or incision, which, under ordinary circumstances, would hardly emit more than a few drops of blood. Occasionally the cause of the bleeding is the accidental rupture of some of the smaller vessels of the mucous membrane, as, for example, that of the nose, lungs, rectum, or urinary bladder. The extraction of a tooth is sometimes followed by this form of hemorrhage. I recollect one case in which death was produced in this way; and another where the bleeding, having persisted for nearly four days, gave rise to severe exhaustion and great apprehension respecting the safety of the patient. Many years ago I lost a child, six months old, from hemorrhage consequent upon lancing the gums over the upper central incisors, which were nearly ready to protrude; he was affected at the time with cholera, but previously to that he had always been remarkably healthy. The bleeding commenced in less than twenty-four hours after the operation, and continued, despite all that could be done for his relief, until the end of the fifth day, when he died completely exhausted. A short time before he expired, hemorrhagic spots appeared on different parts of the body, and blood began to be discharged from the bowels. In 1857, I operated for strabismus upon a young gentleman who possessed this peculiarity; the division of the internal straight muscle was followed by an oozing of blood, which continued, nearly constantly, for the greater part of a fortnight, when, the wound being almost healed, the bleeding ceased.

The blood in this variety of hemorrhage oozes from the injured part, as water oozes from a sponge; it does not spirt out in jets, as when it comes from an artery, or in a continuous stream, as when it proceeds from a vein. Its color is neither scarlet nor black, but intermediate between the two; it generally partially coagulates when it is received into a vessel, but rarely does so while it is in contact with the living surface.

This affection has occasionally been noticed in several members of the same family. In a remarkable case, reported by the late Dr. John A. Swett, of New York, it existed in all the children, eighteen in number. All except one had died from this cause, and he was suffering under profuse hemorrhage of the nose and rectum. Twelve sisters died before the age of twelve from

bleeding of the uterus; two of the brothers had fallen victims to traumatic hemorrhage.

Mr. Wardrop gives a curious case in which this peculiarity was hereditary. The patient was a boy, in whom the hemorrhagic tendency displayed itself when he was scarcely two months old. On several occasions, he nearly lost his life from the most insignificant wounds. His brother, twenty-two years old, was frequently afflicted in a similar way. Of his five uncles, not one was free from this predisposition, three died from the division of the frænum of the tongue, and one from the extraction of a tooth; while the other, although he suffered from the same disease, finally died from some other cause. His two aunts exhibited no signs of this diathesis; but, what is singular, all the male branches of their families, excepting one, were thus affected.

A still more remarkable case has been reported by Dr. Hughes, of Kentucky. The predisposition here was associated with a rheumatic diathesis, and was satisfactorily traced as far back as five generations. It was confined exclusively to the male branches of the different families; but the females, nevertheless, invariably transmitted it to their offspring. Many of the individuals died in infancy and childhood, death resulting, in some, from the cut of the lancet; in some, from accidental wounds; in some, from internal hemorrhage; and in two, simply from the application of blisters, the vesicles being filled with blood instead of water.

Of the immediate *causes* of the hemorrhagic diathesis, we are completely ignorant. Whatever they may be, it is evident that they are deeply engrafted in the constitution, as is proved by the fact, first, that it generally shows itself at a very early age; secondly, that it often occurs in several members of the same family; and thirdly, that it is sometimes hereditary. The immediate causes seem to be two: first, a want of coagulating power in the fibrin of the blood; and, secondly, an imperfectly organized state of the capillary vessels, which are the immediate seat of the hemorrhage.

If one were inclined to speculate in regard to the cause of this defective coagulating property of the blood, it would be easy to find it in an insufficient supply of nervous power, upon the presence of which, as is well known, the vitality of this fluid essentially depends. Whatever has the effect of weakening this influence, proportionably interferes with the concretion of the blood, both as it circulates through the body and after its removal by venesection. The fact that the blood remains fluid in those who are suddenly destroyed by lightning, has long been familiar to practitioners. Similar phenomena occur when a person is killed by a blow on the stomach, by prussic acid, the poison of the rattlesnake, excessive bodily fatigue, or violent agitation of the mind. Certain diseases, as Asiatic cholera, plague, and malignant fevers, produce the same effect. It has been satisfactorily ascertained that, when the pneumogastric nerves are tied in animals, the blood loses its property of coagulating, the coloring matter at the same time separating from the fibrin, and assuming an unusually black color.

But in all these cases, the loss of nervous power is sudden, and hence it is easy to perceive how it should influence the coagulation of the blood. In persons laboring under the hemorrhagic diathesis, on the contrary, the blood is generally habitually indisposed to coagulate, so that they are more or less liable to bleeding whenever they experience any injury, however slight. The analogy, then, between these different states of the system is exceedingly remote, and can, indeed, hardly be said to be established. Its force, moreover, is weakened by the fact that the subjects of the hemorrhagic diathesis generally enjoy as good health, and as much vigor of constitution, as those who are free from it. To say that such persons are constantly laboring under a want of nervous fluid, is to affirm that they are imperfectly organized, and deficient in genuine nerve-power; circumstances which, if true, remain to be

proved. I am not aware that any experiments have been made tending to show that the blood in the hemorrhagic diathesis is deficient in fibrin; such observations might be easily instituted, and they could hardly fail to throw important light upon the pathology of this peculiar affection.

The other appreciable element in the pathology of the hemorrhagic diathesis is the want of contractility on the part of the capillary vessels. It has been supposed that this is due to the absence of the middle tunic of these vessels; but such a deficiency must necessarily be a matter of inference rather than of observation, and I am not aware that any one, whose opinion is entitled to much weight, any longer holds such a view. That there is a want of tone in the capillaries is certain, but how this is brought about, or in what it consists, is still a subject of conjecture.

The *prognosis* of this form of hemorrhage is generally not very favorable, particularly when it is of a hereditary nature, in which event it is extremely liable to prove fatal. In the case related by Swett, seventeen out of eighteen members of a family thus affected had perished, and the survivor himself had repeatedly suffered from severe bleeding in different parts of the body. In the case of Hughes, in which the diathesis prevailed in not less than five generations, nearly every individual died from hemorrhage; many of them in infancy and childhood.

In the *treatment* of the hemorrhagic diathesis, two indications are presented: the first is to promote the coagulability of the blood; the second, to increase the contractile power of the capillary vessels. In addition to these, it will be necessary, if a good deal of blood has already been lost when the surgeon is called to the case, to support the system by tonics and a nutritious diet.

The first of these objects is best fulfilled by the judicious use of acetate of lead and opium, the former of which seems to exert a direct influence upon the coagulability of the blood, while the latter affords important aid in controlling the action of the heart, generally rendered turbulent by the bleeding and the patient's mental anxiety. The dose of the salt should vary from half a grain to a grain and a half, every two, three, or four hours, according to the tolerance of the stomach and the amount of hemorrhage, and should contain at least one grain of opium, or its equivalent of acetate of morphia. If heat and dryness of skin exist, a small quantity of antimony or ipecacuanha may be added to each dose, to produce perspiration. Severe depression, however, must be vigilantly guarded against. If there be much cardiac action, tincture of aconite or veratrum viride should be given, its effects upon the system being carefully watched. Whatever else be done, it is of paramount importance, in every case, to control and quiet the heart's action.

To increase the contractility of the capillary vessels, which is the next indication, provided this has not been effected by the acetate of lead, recourse must be had to tonics and nutritious diet. Of the former, one of the best articles, according to my observation, is the tannate of iron, either alone or in union with quinine, in doses varying from two to five grains, administered every two, three, or four hours, in pill form. The diet should be light, non-stimulant, and nourishing, and moderate use should be made of milk punch, toddy, or wine. In general, these measures will be borne, having a tendency rather to quiet the action of the heart than to occasion undue excitement. Tranquillity of mind and body is of paramount importance, and must, therefore, not be neglected.

Purgative medicines will usually prove highly serviceable, both as evacuants, as counter-irritants, and as restorers of the secretions, which are nearly always much disordered in this variety of hemorrhage. Estimating these remedies at their real value, I am satisfied that they are entitled to the highest rank in the treatment of this affection; they must not, however, be

carried too far, otherwise they may induce irritability of the heart, and thus do harm instead of good. If the patient be plethoric, he may take sulphate of magnesia, which is particularly appropriate under such circumstances, on account of its chemical action upon the blood; or, what will generally be better, especially when there is marked derangement of the secretions, a full dose of calomel and compound extract of colocynth.

If the bleeding be attended with fever, or with heat and dryness of the surface, recourse must be had to diaphoretics, as antimony and morphia, or the neutral mixture, aided by tepid ablutions. Coldness of the extremities must be relieved by hot mustard baths.

It need hardly be added, that the sooner these constitutional measures are carried into effect, the more likely will they be to prove efficient in arresting the hemorrhage; the longer the bleeding has lasted, or the greater the amount of blood that has been lost, the more difficult will it be to arrest the disease and prevent its downward tendency. Moreover, a proper plan of treatment having been selected, it should be diligently persisted in until it is capable of exerting its beneficial influence, and not be constantly varied, as is so often the case in the hands of the timid and inexperienced; it being never forgotten that some time must necessarily elapse, in such a case, before the system can be favorably impressed by any measures, however judicious or energetic.

The topical treatment is often of paramount importance. When the hemorrhage proceeds from a wound, the affected structures should, if possible, be included in a firm ligature. For this purpose, the twisted suture may be used; or, if this be impracticable, systematic compression may be made by means of a graduated compress and roller, the surface of the wound having previously been dried, so as to allow the lint to come directly in contact with the bleeding orifices of the divided vessels. The efficacy of the compression will sometimes be increased by the use of a piece of tinder, placed upon the raw surface, or by soaking the lint in a saturated solution of alum. Perchloride and persulphate of iron may also be tried, though their efficacy has been greatly overrated as anti-hemorrhagics. Occasionally, the application of pounded ice will restrain the bleeding more effectually than anything else. Rubbing the wound freely with nitrate of silver or sulphate of copper is sometimes useful. The actual cautery, the Vienna paste, and the different acids, have all been recommended when the hemorrhage resists the more ordinary measures; but the objection to them is that, when the eschar drops off, and frequently even before, the bleeding is apt to recur with increased violence. Finally, when the blood proceeds from the nasal cavity, uterus, or rectum, the most efficient adjuvant will be the tampon.

SECT. V.—DISEASES OF THE ARTERIES.

The arteries are liable to inflammation, acute and chronic, suppuration, softening, ulceration, and various kinds of transformations.

1. ACUTE INFLAMMATION.

Acute arteritis is generally induced by external injury, or by an extension of disease from the adjoining structures. Nevertheless, it occasionally exists as an idiopathic affection, or comes on without any assignable cause, chiefly in persons of a gouty or rheumatic predisposition, from the age of thirty to fifty. Restricted, in the majority of instances, to one or more of the larger trunks, it not unfrequently involves the smaller branches, and sometimes even the capillaries. Occasionally, the disease appears to pervade nearly the whole arterial system.

When arising spontaneously, the disease usually begins in the internal membrane and subserous cellular tissue, from which it gradually spreads to the other tunics; the reverse happening when it is induced by external violence. The anatomical characters of acute arteritis are redness, opacity, rugosity, and softening of the lining membrane, with an engorged, lacerable, and thickened state of the outer and middle coats. When the inflammation is severe, the parietes of the affected artery are generally remarkably pulpy, and so much diminished in consistence as to be easily torn or divided by the ligature. The nutrient vessels are loaded with blood, and often exhibit a real varicose aspect, their ultimate twigs ending apparently in the subserous cellular substance. With regard to the redness of the internal membrane, it is liable to considerable diversity; generally speaking, it occurs in small patches, which are diffused over a considerable extent of surface, and which vary in diameter between that of a split pea and a five-cent piece. In intensity, it ranges from a light pink to a deep scarlet, through numerous intermediate shades of lilac and purple. In some instances the redness is uniform. With this change of color are always associated important alterations of texture. The inner membrane, losing its smoothness and polish, assumes a rough, fleecy aspect, and, owing to the softened state of the subserous cellular tissue, is easily detached from its natural connections. Globules of lymph, either alone or blended with pus, occasionally adhere to its inner surface; and, in the larger arteries, it is not uncommon to meet with well-developed pseudo-membranes, similar, in all respects, to those of the serous textures. The other tunics are also much affected, being moist, tumid, friable, and transformed into a reddish, homogeneous mass, almost devoid of cohesive power. Their elasticity, naturally so great, is partially lost, and in many instances they are freely infiltrated with serosity, sanguinolent fluid, or even pure pus. A common occurrence is the formation of fibrinous concretions, closing up the caliber of the affected vessels.

Suppuration of the arteries is probably more frequent than is commonly imagined. The matter being generally formed upon the inner surface of the vessels, is soon swept away by the circulating current which is, doubtless, the reason why it is not oftener noticed after death. Sometimes, however, it is entangled in the substance of the false membranes, infiltrated into the arterial tissues, or collected into small abscesses between the inner and middle tunics. Arteritis is much less liable to terminate in suppuration than phlebitis, in which respect the one resembles inflammation of the serous membranes, the other of the mucous.

The arteries are almost insusceptible of *gangrene*. Their conservative powers are certainly very great, and hence they often escape destruction in the midst of parts that are perfectly deprived of vitality. In such cases, their outer surface becomes incrustated, at an early period of the disease, with a thin layer of fibrin; and, long before the sloughs begin to separate, the blood coagulates in their interior, thus opposing an effectual barrier to the occurrence of hemorrhage.

Softening of the arteries is a common occurrence, especially in the smaller branches. It is often witnessed in organic diseases of the principal viscera, and is a frequent attendant upon acute inflammation, cancerous affections, and the application of the ligature. The lesion is characterized, as the name indicates, by a diminution of the cohesive power of the vessels, the coats of which are rendered friable, spongy, and inelastic. It is generally accompanied with slight tumefaction, engorgement of the capillary vessels, and effusion of serosity, or sanguinolent fluid into the interstitial cellular tissue.

The *symptoms* of acute arteritis are generally so obscure as to render it extremely difficult to distinguish it, especially when it occurs in the more deep-seated vessels. In the majority of cases, the attack strongly resembles

one of rheumatism. The most reliable phenomena, in a diagnostic point of view, are excessive pain and tenderness along the course of the affected arteries, increased by pressure, cough, and change of posture, and accompanied by violent and tumultuous throbbing, which is sometimes felt over the greater portion of the body, and may often be easily perceived at a considerable distance. The action of the heart is much increased in force and frequency, the pulse is hard, wiry and thrilling, and the system is disturbed by irritative fever, which rapidly assumes an asthenic type. When the disease is at all extensive, the patient soon succumbs under its influence, the immediate cause of death being either exhaustion from the violence of the inflammation, or from the formation of the fibrinous concretions in the larger arteries, thereby arresting the circulation in some of the more important organs.

There are no symptoms denotive of suppuration, ulceration, or softening of the arteries, apart from those of acute or chronic inflammation. The formation of matter would probably be ushered in by rigors, followed by copious sweats, hectic irritation, and excessive prostration, but the occurrence would hardly be of so marked a nature as to serve any diagnostic purpose.

The *treatment* of acute arteritis must be conducted upon general antiphlogistic principles; by the lancet, purgatives, and antimonials, if the patient be young and plethoric, or by a conservative course, if he be weak, decrepit, or exhausted by previous suffering, intemperance, or dissipation. Aconite, veratrum, or colchicum will usually form valuable additions to the other means, especially if they be combined with morphia, which is so necessary to allay pain and quiet the heart's action. If the disease is connected with a rheumatic diathesis, calomel must be given, in full and frequently repeated doses, with a view to early but gentle ptyalism. Colchicum will also prove useful in such a case. The most suitable topical remedies, when the affected arteries are superficial, are leeches, iodine, and saturnine lotions, in union with laudanum.

2. CHRONIC AFFECTIONS.

The most common chronic affections of the arteries are the fibrous, earthy, and atheromatous transformations, which, although of frequent occurrence, are chiefly interesting in relation to the influence which they exert upon the production of spontaneous aneurism. It is for this reason, therefore, that they should be carefully studied. These transformations, notwithstanding that they differ from each other widely in their physical and chemical properties, possess several characters in common, of which the most important are, first, that they are met with almost exclusively in elderly subjects; secondly, that they render the coats of the vessels brittle, and consequently prone to rupture; thirdly, that they nearly always occur in association with each other; and, lastly, that they usually begin in the cellular tissue, between the inner and middle tunics, which, however, in time, commonly participate in the degeneration.

The *fibrous transformation* is characterized by the appearance of small, hard, firm patches beneath the serous layer of the arteries, usually isolated, but sometimes grouped together, of no definite shape, thin, and of a whitish, grayish, or pale yellowish aspect. When the patches are numerous or unusually large, they convert the affected arteries into firm, inelastic tubes. The matter which gives rise to this transformation is originally deposited in the form of fibrin, which gradually assumes the properties here assigned to it.

The *earthy degeneration* is most common in old subjects after the sixtieth year; it usually, however, begins to form as early as the forty-fifth, and cases of it have been observed in very young children. Although it may take place in any of the arteries, it is most generally met with in the aorta and its larger

branches, as the iliac, femoral, popliteal and innominate. What is remarkable, and, in the present state of the science, altogether inexplicable, is, that, while the artery of the thigh is so frequently ossified, the humeral artery is seldom affected. Another fact, not less singular, is that this transformation is comparatively rare in the female; a fact which satisfactorily accounts for the difference in the relative frequency of spontaneous aneurism in the two sexes. We occasionally meet with an instance in which there is a strong ossific diathesis, or tendency to this degeneration, nearly all the arteries in the body being converted into rigid cylinders. The earthy matter is deposited in an amorphous form, and is destitute of bone corpuscles; consisting essentially of phosphate and carbonate of lime, in combination with a small quantity of albumen, which apparently serves as its matrix.

The calcareous matter exists in various forms; sometimes in small grains and nodules, now in scales, plates, and patches, and now in complete rings, which, encircling the vessel, convert it into a firm, rigid, inflexible tube, completely destitute of its natural attributes, as seen in fig. 231. The inevitable effect of these changes, which are always most conspicuous in the inner coat, is to render the artery abnormally brittle, and, therefore, ill able to withstand the pressure of its contents.

Fig. 231.

Deposition of calcareous matter.

The starting point of this deposit is the subserous cellular tissue, whence it gradually extends to the substance of the inner and middle tunics, both of which are sometimes completely transformed by it. It is rare that the outer coat suffers from it; such a change, however, is not impossible, and I have seen specimens in which the deposit was apparently entirely restricted to it. The exciting cause of the calcareous transformation is chronic inflammation. That this is the case is rendered clearly manifest by the fact that it is invariably accompanied by more or less thickening and induration of the arterial tunics, independently of those produced by the deposit itself.

The *atheromatous* deposit, fig. 232, now usually denominated

Fig. 232.

Atheromatous deposits.

the *fatty degeneration*, is, I believe, very rare among our native inhabitants, although it appears to be sufficiently common in our emigrants, especially the Irish and English. In Europe, it is said to be more prevalent in Great Britain than in any other country; a fact which accounts for the remarkable

frequency with which aneurism occurs in that part of the world. However this may be, the deposit always begins in the subserous cellular substance, generally in minute, isolated points, not larger than the head of a pin, of a pale yellowish, whitish, or brownish color, somewhat greasy to the touch, and of a semi-concrete, friable consistence. In time, many of these points, or dots, coalesce, and so form irregular-shaped patches, which, pushing the lining membrane before them, may involve the whole circumference of the tube, and extend several lines or even inches up and down in the direction of its length. Having remained stationary for an indefinite period, the deposit manifests a disposition to softening and disintegration, and is ultimately converted into a curdy, friable, or, more properly speaking, a pap-like substance, possessing, apparently, all the properties of scrofulous pus. At this stage of the disease, the lining membrane is often elevated into small pustules, or little abscesses, which, bursting, discharge their contents into the blood, thus leaving a corresponding number of ragged and irregular ulcers, the base of which is formed by the middle tunic.

The fatty deposit is most common in the aorta, particularly its thoracic portion, near the origin of the great cervical trunks. Its occurrence is almost peculiar to the aged. What the causes are, under whose influence it is developed, has not been ascertained. That it is occasionally connected with imperfect alimentation, and the inordinate use of ardent spirits is unquestionable, but that these circumstances are essential to its production, as some pathologists contend, is what we cannot admit; because the disease, as is well known, has been frequently witnessed in the stoutest and most temperate subjects, a fact which is entirely at variance with such a conclusion.

Under the microscope the atheromatous matter is observed to consist of albuminous and earthy particles, of crystalline plates of cholesterine, of an imperfect fibrous texture, and of oil globules. The amount of fatty substance is frequently so great that it imparts a greasy stain to paper when dried on it by heat. The minute appearances of this deposit are well shown in fig. 233.

In regard to the different transformations now described, there are no remedies, which, so far as is at present known, are capable of exerting any influence over their development. What treatment might accomplish, if their diagnosis could be satisfactorily established, is an interesting problem for future inquiry to solve. To speak of administering remedies for their removal when we are unable to determine the fact of their existence is one of those practical refinements which are more befitting the transcendentalist and the idle speculator than the man of sound sense.

Ulceration, as a consequence of arteritis, whether acute or chronic, is seldom witnessed. Manifesting a peculiar predilection for the larger trunks, it commonly commences in the serous membrane, from which it gradually extends to the middle and outer tunics until it leads to complete perforation. Such a termination, however, is extremely rare. The ulcers, which are very irregular in respect to their form, vary much in their size, number, and general characters. At times they are very small, scarcely exceeding the diameter of a mustard-seed; but they may be as large as a split pea, a five cent piece, or even a guinea, according to the size of the affected tube. Their margins are usually ragged, irregular, and considerably elevated, but seldom injected; their bottom, which is rough and uneven, is commonly formed by the middle

Fig. 233.

tunic, the fibres of which frequently present a shreddy, lacerated appearance. In many instances, the erosions look like so many fissures, cracks, or chaps, with sharp, prominent, and irregular borders. This form of the disease is ordinarily dependent upon the presence of calcareous matter. The number of ulcers is seldom considerable, though in a few rare cases the inner surface of the larger trunks has been found completely checkered with them. When confined to the internal tunic they sometimes admit of cicatrization.

3. INTRA-PARIETAL SEPARATION.

Fig. 234.

The so-called dissecting aneurism. *a*. Semilunar valves; *b*. External vessel laid open in its entire extent, so as to expose the aorta at *c*; *d*. Valvular opening in the coats of the aorta, showing the communication of this vessel with the artificial channel, *b*; the probe *e* passed through the abnormal opening; *f* exhibits the foramina between the aorta and the outer canal.

There is an affection of the arteries, occurring exclusively in old persons, more particularly in women, to which the term *dissecting aneurism* has been applied; it is not, however, in reality, an aneurism at all, but merely a separation of the lamellæ of the middle tunic, as has been satisfactorily established by the investigations of Dr. Pennock, and by an examination by myself of nearly all the reported cases of the disease. A more appropriate name would be *intra-parietal separation*. The lesion, which presents nothing of any practical interest, inasmuch as it is always fatal, is entirely limited to the aorta and the larger trunks more immediately connected with it, and is always dependent upon organic disease of the coats of the arteries, rendering them lacerable, and, consequently, incapable of resisting the impulse of the blood. The manner in which the affection takes place is easily understood. In the natural state the different coats are so intimately connected together that it is almost impossible, even by the nicest dissection, to detach them from each other; but when they are altered by disease,

or by some of the degenerations to which they are so liable, the connecting cellular tissue is rendered soft and friable, and their separation may then be effected with the greatest facility. In this condition, moreover, the tunics themselves are frequently very much changed, so that they are scarcely able to resist the slightest impulse. Now, if under these circumstances the lining membrane gives way, whether from ulceration, erosion, or rupture, the blood will insinuate itself into the accidental opening, which is thus gradually enlarged, at the same time that the fluid is forced on between the layers of the weakened middle tunic, dissecting them from each other as with a knife, and forming thus either a blind pouch or a distinct canal, open at both extremities, or at some intermediate point.

The separation is not of the same extent in all cases. It rarely embraces more than one-fourth, one-half, or two-thirds of the circumference of the tube, while in length it may vary from six, eight, or ten lines to as many inches. Occasionally it reaches nearly from one extremity of the aorta to the other,

being perhaps prolonged at the same time into the carotid, subclavian, and iliac arteries.

4. VARICOSE ENLARGEMENT.

The arteries are liable to a dilated and nodulated condition, similar to that of the veins, and hence very frequently termed varicose enlargement. The affection has also been described under the name of varicose aneurism and of arterial varix. Its general features are well illustrated in fig. 235. The

Fig. 235.

Varicose enlargement.

lesion, which is exceedingly rare, is met with chiefly in the superficial arteries, particularly in those about the head, the forearm, hand, leg, and foot; and consists in a remarkably tortuous, elongated, and convoluted state of these vessels, evidently dependent upon the effects of inflammatory action, as is shown by the fact that their coats are always abnormally thickened, either uniformly, or alternately thickened and attenuated. In elderly subjects it is generally associated with the fibro-cartilaginous, earthy, or fatty degeneration. The dilatation and varicosity sometimes affect an entire artery, but more commonly they are limited to particular portions of it; it may be restricted to one vessel, or occur simultaneously in several. When the diseased artery is superficial, the character of the lesion is rendered sufficiently clear by the tortuous and nodulated course of the vessel beneath the surface; but there are no pathognomonic signs when it is deep-seated.

This affection rarely requires any treatment; for, even when the enlargement is considerable, it is rather an inconvenience than an actual disease. In ordinary cases, the vessels may be supported by the constant use of a well-applied bandage, or of an apparatus constructed upon the principles of the laced stocking. During the forming stage, much may be done in the way of repressing development by astringent and soothing lotions, along with rest and elevation of the parts, and the occasional abstraction of blood, provided the patient be plethoric, in order to moderate the momentum of the circulation. When the disease proves troublesome, by causing pain and functional disorder, the only effectual remedy is ligation of the offending vessels, at the cardiac side of the enlargement.

SECT. VI.—ANEURISM.

An aneurism is a pulsating tumor, occupied by blood, and communicating with an artery deprived, either in part or completely, of its integrity.

The subject of aneurism has been encumbered by too many divisions and subdivisions, and the consequence is that several lesions have been included

under it which do not, properly speaking, appertain to it. The effect of this over-refinement has been to embarrass the study of this disease, and to invest it with difficulties which are altogether foreign to it. The distinction of aneurism into true and false is one of great importance, and should, therefore, be retained. The same may be said in regard to spontaneous and traumatic aneurism. The term dissecting aneurism, introduced by Laennec, and adopted by most modern authors, should be discarded, inasmuch as the affection which it serves to designate has nothing whatever in common with aneurism; it is, in fact, as already stated, merely a separation of the coats of the arteries, without any tumor or symptoms denotive of that lesion. Then, again, as to the term varicose, which I have myself employed, along with others, in my writings, to designate a peculiar form of arterial lesion, it is obviously improper when we come to make a practical application of it. A varicose artery is, in reality, no more an aneurism than a varicose vein; both affections consist essentially in a dilated and tortuous state of these two classes of vessels, and not, like aneurism, in a pulsating tumor, caused by the destruction, partial or complete, of the tunics of an artery. An anastomotic aneurism is a pulsating tumor formed by hypertrophy of the arterial and venous capillaries of a part; critically speaking, therefore, the term aneurism is not applicable to it, and yet, as it has been fully engrafted upon our surgical nomenclature, it is difficult to dispense with it, or to substitute one of a more expressive and appropriate character.

The term true is applied to that species of aneurism in which one or more of the arterial tunics, without being necessarily perfect, form a part of the tumor. A false aneurism, on the contrary, is one in which all the coats have given way, the sac being composed of the surrounding cellular tissue in a state of condensation. It was formerly supposed, chiefly through the influence of the writings of Scarpa, that there was no such disease as a true aneurism, but that in every instance, whatever may be the size, form, or site of the affection, there was a complete absence of the arterial tunics at the situation of the tumor. This opinion, however, has become obsolete, experience having shown that there are cases, although they are confessedly rare, in which the aneurism clearly consists of at least one, if not more, of the coats of the artery from which it springs. Each of these great divisions comprises several varieties, founded principally upon the form and volume of the tumor. Thus, an aneurism is said to be sacculated when it consists of a distinct bag, as so often happens in aneurism of the aorta and the principal branches given off from it; the term cylindroid is used when the swelling affects the artery uni-

formly in its entire circumference, while the tapering tumor is known by the appellation of fusiform. The words circumscribed and diffused refer merely to the dimensions of the aneurism.

The annexed sketches afford a good idea of the arrangement of the tunics of the arteries in the principal varieties of spontaneous aneurism. In fig. 236 the tumor is formed by the expansion of all the coats of the vessel, an extremely rare event; in fig. 237 the middle tunic has given way, the inner and outer being preserved; in fig. 238 the aneurism is formed by the external tunic alone; in fig. 239 the two outer membranes have been ruptured, the inner projecting through the crevice thus left, in the form of a hernia.

Fig. 236.

Fig. 237.

Fig. 238.

Fig. 239.

This variety is very uncommon, but cases of it have been reported by different authors, especially by Haller, Laennec, Dupuytren, and Dubois. It can occur only when the inner coat of the artery has been thickened and fortified by interstitial and surface deposits.

Finally, aneurisms are divided into internal and external, the former expression being used chiefly in reference to the aorta and to the arteries of the viscera, the latter in relation to the vessels of the extremities, the head, and neck. The words spontaneous and traumatic sufficiently explain themselves.

1. LOCALITY, PREVALENCE, AGE, SEX, AND CAUSES.

Spontaneous aneurism does not occur with equal frequency in all parts of the body; on the contrary, there are a number of arteries which are almost entirely exempt from it, or which, at all events, so seldom suffer as to be scarcely entitled to notice. The vessel which is most frequently involved is the aorta; first in its ascending portion, then in the thoracic, and, lastly, in the abdominal. Next in point of liability to the disease are the popliteal artery, the femoral, common carotid, subclavian, innominate, axillary, and external iliac. The arteries of the leg and foot, the hand, forearm, and arm, the face, upper part of the neck, and of the viscera, together with the common and internal iliac, rarely suffer in this wise. Traumatic aneurism may occur in any of the arteries, but is most common in such as are most exposed to external injury.

If we attempt to inquire into the causes which induce spontaneous aneurism more frequently in one artery than in another, we shall be met by difficulties. Several circumstances, however, may be assigned as affording at least a plausible explanation of the circumstance.

1st. It is well known that certain arteries are peculiarly prone to the calcareous and atheromatous degenerations, while others, on the contrary, are almost entirely exempt from them, whatever may be the condition of the rest of the arterial system, or the age of the patient. Now, dissection has shown that those vessels which are most frequently diseased in this way are also those which are most frequently affected with aneurism, and conversely. Spontaneous aneurism of the arm and forearm is among the rarest occurrences, and everybody knows how free their vessels are from the degenerations in question. In the aorta and popliteal artery, on the other hand, they are extremely common, and it is here, as already seen, that spontaneous aneurism is most frequent.

2d. In the next place, some influence is no doubt due, in the production of this difference, to the force with which the blood impinges against the walls of the vessels. Thus, in the aorta, which is more prone to aneurism than any other vessel, the ascending portion, particularly its anterior and right side, suffers more frequently than any other part, and it is here that the blood exerts its greatest force, as it is pumped up from the left ventricle. The popliteal artery, which comes next in the order of involvement, is subjected, in a degree beyond that of any other vessel in the extremities, to a similar influence during the flexed condition of the limb.

3d. It is not improbable that some influence is also due to the weakness which the arteries experience at the origin of their larger branches. The fibres of the middle tunic suffer a species of separation here, in consequence of which they are less capable of withstanding the shock of the blood as it is directed against them. However this may be, experience teaches that aneurism is peculiarly liable to occur at these points.

4th. Another circumstance which may be supposed to favor the production of aneurism is the motion to which the arteries are subjected, especially during sudden and violent efforts. Such an influence must be particularly felt

by the ascending portion of the aorta during bodily and mental excitement, and by the popliteal artery in the various muscular exertions of the lower extremity.

How far any one of these causes alone is capable of producing aneurism is altogether a matter of conjecture. Without degeneration of the arterial tunics, they would probably exert but little influence, while under opposite circumstances it must be very great. Indeed, it is very questionable whether aneurism would be one-twentieth part as common as it is, if the arteries were altogether exempt from the earthy and atheromatous deposits; nay, we may go further, and assert, positively, that if these deposits could be prevented, spontaneous aneurism would almost cease to exist.

The occurrence of aneurism would seem to be influenced by climate or *locality*. The infrequency of the lesion in the inhabitants of the southwestern States of North America, is proverbial. In a practice in Ohio and Kentucky of twenty-three years, in which I witnessed almost every surgical disease incident to the human race, it rarely occurred to me to meet with an example of spontaneous aneurism. My experience, in this respect, is fully sustained by that of Dr. Dudley, of Lexington, whose practice embraced a wide field, which has since been so successfully cultivated by Professor Bush, of Transylvania University. Both these gentlemen assured me, some years ago, that this affection had been extremely rare within the range of their observation. Professor T. G. Richardson, now of New Orleans, superintended, while Demonstrator of Anatomy in the University of Louisville, the dissection of several hundred bodies, and yet he hardly met with an instance of the malady. The testimony of Dr. Bayless, who formerly occupied the same position, is precisely to the same effect. To what this extraordinary immunity is due, we have no means of determining. The population of that region of the United States is a mixed and laborious one, made up from all parts of the civilized world, and pursuing all kinds of occupations, from the most delicate and refined to the most rude and vigorous, and yet a case of spontaneous aneurism, in any class of its citizens, is absolutely an anomaly. My impression is that the disease is equally uncommon in our northern and middle States; but upon this subject it is necessary to speak with some degree of reserve, as we have no positive data to guide us.

In regard to the prevalence of aneurism in our larger towns and cities, our information is also very imperfect. Professor Gibson, formerly of the University of Pennsylvania, asserts that the disease is quite infrequent in Philadelphia, and this I am inclined to believe to be the fact, from the results of my own inquiries. In New York, on the contrary, it would seem, according to the statement of Dr. Mott, to be quite frequent; a circumstance which is, perhaps, not surprising, when we consider the heterogeneous character of the people of that city, and, above all, the extent of its commerce, and the numerous accidents incident to its pursuits. What is remarkable, however, is, that nearly all the cases met with by this distinguished surgeon, during a period of upwards of forty years, occurred among native-born citizens of the United States. In opposition to this fact, however, I have the authority of Dr. John Watson and others, of New York—as communicated to me by Dr. Lente—for stating that the great majority of cases of aneurism in that city, especially in hospital practice, are met with among those of foreign birth. The negroes of that city would also seem to be particularly obnoxious to the disease.

Aneurism is uncommon in the East and West Indies, in the British Provinces of North America, and on the continent of Europe, especially France, Italy, and Germany. In Great Britain, on the contrary, it is sufficiently frequent; more so, perhaps, than in any other part of the globe. According to the report of the registrar-general, it appears that the number of deaths

from aneurism, in England and Wales alone, during a period of five years—namely, from 1838 to 1842—was 593; being an annual average of one in about 131,000 of the inhabitants. The various hospitals of London receive every year a large number of cases of this disease. The people of Ireland are said to suffer more frequently from aneurism than any other race.

The *causes* of aneurism are divisible into predisposing and exciting. Of the former, the most constant, and, therefore, the most important, is a diseased condition of the arterial tissues, usually presenting itself in the form of the earthy and atheromatous degenerations. These degenerations, by rendering the coats of these vessels preternaturally brittle and lacerable, cause them to yield more readily under the impulse of the blood and the various extraneous circumstances which have a tendency to stretch and twist them. I have already expressed the belief that, but for these alterations, spontaneous aneurism would be almost unknown. The influence of age and climate in the production of this disease, is adverted to in the preceding paragraphs. All laborious pursuits, involving sudden and violent muscular exertion, powerfully predispose to its occurrence. Hence, it is more common among sailors, and those who are much accustomed to athletic exercises, than among any other class of individuals. Soldiers suffer much less frequently than was formerly supposed. Men engaged in agricultural pursuits, although their labor is often severe, are, in great measure, free from the disease, owing, doubtless, to the want of liability of their arteries to abnormal deposits. Protracted courses of mercury, a syphilitic taint of the system, and the constant and inordinate use of ardent spirits, are supposed to predispose to the formation of aneurism; but how far, or in what degree, remains to be demonstrated.

The immediate cause of aneurism is rupture of the coats of the arteries, in consequence of severe muscular exertion unduly stretching these vessels; or, as in the case of the aorta and its larger offsets, an inordinate impulse of the blood, during the sudden and violent contraction of the left ventricle of the heart. The vessels, weakened by the degeneration of their tissues, and deprived of their elasticity, readily yield to the forces thus applied, commonly at a particular point, which is afterwards converted into a distinct pulsating tumor, composed generally, in great measure, if not exclusively, of the external tunic of the artery along with more or less of the circumjacent cellular tissue. Sometimes the exciting cause of the disease is ulceration, but such an occurrence is comparatively rare, especially as an affection unconnected with the earthy and atheromatous deposits. This process, as stated in a previous section, should not be confounded with the cracks or fissures which so often follow these deposits, seeing that the latter are usually the result, not of a vital action, as is the case in true ulceration, but of a mere mechanical one, gradually effected under the impulse of the blood, as it rushes over the inner coat of the diseased vessel.

Aneurism occasionally exists simultaneously in several arteries. Thus, it is by no means uncommon for a patient to have one tumor of this kind in the aorta and another in the carotid, subclavian, popliteal, femoral, or external iliac artery. I have seen several instances of the co-existence of popliteal aneurism in the same individual. When the disease affects a considerable number of arteries, it constitutes what is termed the *aneurismal diathesis*; a circumstance which imperatively contraindicates surgical interference, however favorably the external tumor may be situated for operation. Weak, sickly persons, of depraved constitution, and intemperate habits, are the most common subjects of this diathesis. Several remarkable examples of this predisposition to the formation of aneurism are upon record. Pelletan gives one in which the number of tumors was upwards of sixty, and in another, related by J. Cloquet, there were more than two hundred, the patient being

a man fifty years of age. The aneurisms, in this instance, affected nearly all the arteries in the body, but they were most numerous in those of the extremities, the axillary, humeral, radial, ulnar, femoral, popliteal, tibial, and peroneal being all closely studded with them.

It has long been known that the formation of aneurism is influenced, in a remarkable degree, by *age*. Prior to the age of thirty, the disease is extremely rare, and up to the period of puberty it is almost unknown, even in the aorta, which is so much more frequently affected than the other vessels. The greatest number of cases, by far, occur between the thirty-fifth and fiftieth year; a good many cases are also met with during the next decennial period and a half, but after that time the malady is very rare; probably not that the predisposition to it ceases, but because, as it seems to me, in the first place, the number of subjects is comparatively small; and, secondly, because persons at this age are much less exposed to violent muscular and mental excitement than during the meridian of life. That this supposition is true, is rendered highly probable by the fact that the earthy and atheromatous deposits generally exist in greatest abundance in advanced life. The absence of these deposits in young subjects readily explains the non-occurrence of aneurism in children and adolescents. An instance of spontaneous popliteal aneurism in a boy only nine years old occurred in the practice of Mr. Syme, of Edinburgh, in 1844, and is the only case at this early age upon record.

Males suffer from aneurism more frequently than females, but in what precise proportion has not been determined. The question has hitherto engaged but little attention, and it is obvious that it can be decided only by the analysis of a much larger number of cases than have yet been adduced for the purpose. It has been alleged that the relative frequency of carotid aneurism in the two sexes is nearly equal, and the occurrence has been attempted to be accounted for on the supposition that the arteries of the neck of the female are nearly as much exposed to all kinds of violence and muscular exertion as those of the male. Little confidence, however, can be placed in such opinions; for, before we can receive them as true, we must be satisfied that the disease is as common in women as in men, which I am very certain it is not. Mr. Crisp, in his excellent work on the diseases of the arteries, states that of 551 cases of aneurism of all kinds, more than seven-eighths occurred in men.

Having long been impressed with the belief, founded upon numerous dissections, that the difference in the relative frequency of aneurism in the two sexes was due, not to any difference in their occupation, but to the difference in the relative frequency of the earthy and fatty degenerations of the arteries, I was induced to institute special inquiry into the subject, and am gratified to be able to say that my views are fully confirmed by the statements of Dr. D. Hayes Agnew, Dr. C. E. Isaacs, Professor T. G. Richardson, and Professor J. B. S. Jackson. The testimony of these teachers, who are all well known as able and experienced practical anatomists, tends to show, indisputably, that females are much less subject to chronic disease of the arteries of every description than males. Neither their information, however, nor my own, is such as to enable me to determine the relative proportion of these degenerations in the two sexes, in a given number of cases. That it corresponds very closely with the difference in the number of cases of aneurism is what may readily be believed, and what future observation will, no doubt, abundantly verify.

If we assume what is here said to be true, it follows that the opinion which ascribes the greater frequency of spontaneous aneurism in males than in females to their more laborious occupation, their more intemperate habits, and their greater exposure to all kinds of disease, is entirely untenable, and,

therefore, unworthy of confidence. Women, it is true, are not sailors, carpenters, blacksmiths, or hod-carriers, but in many parts of the world they are tillers of the soil, and engaged in almost every variety of pursuit calculated to rupture the arterial tunics if they were in a serious state of disease, such as we so often meet with in the other sex.

2. VARIETIES OF ANEURISM.

True aneurism presents itself under two varieties of form, differing from each other materially in their appearance and mode of formation, although their essential symptoms and effects are usually perfectly similar, if not identical. These two varieties are the tubular and the sacciform, terms which are sufficiently expressive of their general conformation. Each consists of one or more of the arterial tunics, and forms a tumor, which, in time, is capable of exerting the most injurious effects upon the neighboring structures, and of causing the death of the patient.

The *sacciform variety*, fig. 240, is by far the more common of the two. It essentially consists, as the name denotes, in the formation of a pouch, bag, or sac, connected with the side of the affected artery. In the tubular variety the tumor is formed at the expense of the entire circumference of the vessel; in this, on the contrary, it occupies only a limited portion of it. The arteries which are most liable to suffer from sacciform aneurism are the aorta, particularly its thoracic division, the popliteal, femoral, innominate, carotid, and subclavian. The number of tumors is subject to considerable diversity; cases have been reported in which there were so many as to constitute a genuine aneurismal diathesis, nearly all the principal arteries in the body affording several examples of its occurrence. In general, however, there is only one, although others may form during its progress. Thus, it occasionally happens during the march of popliteal aneurism that an aneurism forms in the aorta, the carotid, or in the popliteal artery of the opposite side. The co-existence of aneurism in different parts of the body, and the tendency to its successive development deserve special attention on account of their practical relations; a subject to which allusion will again be made in another part of this chapter.

The sacciform aneurism is capable of assuming a great variety of forms; the most common, however, is the globular, or ovoidal; in rare cases it is conical, elongated, or irregularly flattened, like a shot-pouch. Much diversity also obtains in regard to its dimensions; thus, while in some instances it is hardly the volume of a hazelnut, in others it is as large as the fist, or the head of the patient; in general, however, it does not exceed a hen's egg, or a medium sized orange. The largest aneurisms of this kind are usually found in the aorta and in the popliteal, iliac, and innominate arteries. The attachment of the tumor to the artery is commonly affected by a narrow footstalk; but cases occur in which it takes place by a broad and extended base, and, under such circumstances, it is not unusual for the artery to suffer serious compression during the progress of the disease.

Fig. 240.

Sacculated aneurism. *a.* Artery; *b.* Aneurismal pouch.

The orifice of communication, fig. 241, between the sac and the artery varies in different preparations. When the tumor arises by a narrow foot-

Fig. 241.

Aneurism of the aorta; the greater part of the cyst being filled with clots, and the aperture of communication being small.

stalk the opening is usually proportionably small, with smooth and well-defined margins. When, on the other hand, it is attached by a broad base, the aperture is always much larger, and its edges are also more irregular, sometimes, indeed, quite shreddy and ragged, as if they had been torn. The situation of the orifice is commonly towards the centre of the sac, but it may be at one side, or even at one of its extremities. The form of the opening is extremely variable, and admits of no specific description. In the early stage of the disease, and in nearly all cases where the tumor is small, the orifice is

of a rounded or circular configuration, while in cases of an opposite character it is generally more or less irregular. The internal and middle tunics may terminate abruptly at the margins of the opening of communication, or they may extend into the cavity of the sac, and thus serve to give it a partial lining.

The composition of the sac is easily understood. For the most part it consists simply of the external tunic, the inner and middle having given way either prior to, or during, the development of the disease. The first thing, in fact, that usually happens, in all such cases, is the destruction, by ulceration or some other disorder, first, of the internal, and, soon after, of the middle layer of the artery, leaving thus a kind of crevice, which gradually enlarges under the influence of the impelling column of blood, and thus permits the corresponding portion of the vessel, now of course greatly weakened, to be converted into a pouch. This pouch, usually called the aneurismal sac, is originally, then, composed exclusively of the external coat of the affected vessel, the other strata terminating abruptly at the margin of the opening of communication, neither of them being prolonged into its interior. But this pouch would be very weak, and, consequently, ill adapted to withstand the shock of the blood as it rushes into its interior, if it were not strengthened by adventitious aid, derived from interstitial deposits in the surrounding cellular tissue. We accordingly find that nature, ever on the alert to save the part and system, is prompt in supplying the required relief by setting up inflammation and pouring out plastic matter, both in the substance of the sac and in the neighboring structures, thereby thoroughly gluing them together, at the same time that they are greatly increased in thickness and density, and thus enabled more effectually to resist the effects of the ever-beating, dashing, and tumultuous sanguineous current within. Such aid, then, is wise and needful, and, fortunately, always comes in play at an early stage of the disease, the laceration of the inner and middle tunics of the artery, and the pressure of the blood against the tumor, being sufficient causes of inflammation.

Although the sac is generally composed of the outer tunic alone, cases, nevertheless, occasionally occur where it consists, in the first instance, exclusively of the inner coat, the other two having given way. That such an arrangement is exceedingly infrequent, is proved by the fact that many surgeons of large experience have warmly contested the possibility of its existence. Haller and his cotemporaries, however, met with undoubted cases of it, and, in more recent times, it has been witnessed by Breschet, Dupuytren,

and other observers, who have given particular descriptions of it. One ground for assuming that this form of aneurism cannot occur is, that it has never followed the numerous attempts that have been made to produce it in the inferior animals, by exposing the carotid artery and dissecting off its outer and middle tunics. In every experiment of this kind, the denuded membrane maintained its integrity, and the breach was speedily repaired by a free deposit of plastic matter. There is, however, no analogy between a sound and a diseased artery, and this fact should be borne in mind in the discussion of the subject. When the outer and middle tunics are destroyed by ulceration, as they always must be in such a case, not rapidly, but by slow degrees, it is not difficult to suppose that the inner membrane may, at the injured and weakened part of the vessel, be made to bulge across the opening, in the form of a thin, translucent cyst. Interstitial deposits would soon aid in strengthening the cyst, although ere long, and before it has acquired any considerable bulk, it would be obliged to yield to the resistless impulse of the blood within. Haller designated this form of aneurism by the term *hernia of the inner coat of the arteries*.

Cases in which the sac consists of the outer and inner coats of the artery, the middle having been destroyed, although also exceedingly infrequent, are more common than those in which it consists of the internal tunic alone. Such an arrangement is occasionally observed in aneurism of the carotid, femoral, and popliteal arteries; but, in time, the lining membrane is sure to give way, leaving thus the cyst composed of the outer coat and the surrounding tissues, as in the ordinary form of sacculated aneurism.

The thickness of the sac varies, in different cases and under different circumstances, from the fourth of a line to the fourth of an inch. Its consistence is often remarkably tough, and, in cases of long standing, it is generally composed of several distinct strata, of a grayish, whitish, or drab-colored aspect, consisting of fibres which intersect each other in every conceivable direction. The outer surface of the tumor is rough and shreddy; the internal, on the contrary, is smooth and polished, only, however, as a general rule, in its earlier stages, for in time it also becomes rough, and is finally incrustated with fibrinous matter. Notwithstanding the thickness of the aneurismal sac, and the efforts which nature makes to strengthen it, it gradually dilates, as in fig. 242, under the impulse of the inflowing column of blood, and at length, after the lapse perhaps of several months, manifests a disposition to yield at one or more points, very much as an abscess does, the activity of the absorbent vessels exceeding that of the capillary vessels.

The sacciform aneurism always contains, even at an early period after its formation, *fibrinous concretions*, the presence of which constitutes one of its most interesting and important features, as they are evidently designed, not only to strengthen the tumor, but to aid in its obliteration, and, consequently, in the production of a permanent cure, although such an event is extremely rare. In their arrangement, these clots are always concentric, not unlike the layers of an onion, one being piled upon, and closely connected to, another. Their color and density vary according to the period of their formation, the older being usually of a pale, yellowish appearance, and of a firm, fibrous consistence, while such

Fig. 242.

Sacciform aneurism of the aorta
ready to give way.

as are of a comparatively recent date, exhibit very much the aspect and consistence of a common heart clot. Their thickness ranges from the fourth of a line to that of a sheet of paper; and their number is often immense, thousands existing in a tumor perhaps not larger than an ordinary fist. That these concretions are organized, at least in many cases, is evinced by their intimate adhesion, not only to each other, but also to the inner surface of the sac, by their extraordinary density, and by their yellowish hue, which contrasts most strikingly with that of recently deposited fibrin and coagulated blood. These circumstances show that these lamellæ undergo most important changes after they have been deposited; that absorbent vessels are busily engaged in carrying away the serum and coloring matter of the blood, and in solidifying the fibrin after it has been extricated from the general mass; while the successive development of concretions clearly denotes that the process is as much a vital as a mechanical one. No one, I believe, has yet succeeded in demonstrating any vessels in these strata; but that they are always present, and often in great numbers, in cases of long standing, does not admit of any reasonable doubt. We may look upon these clots, then, as exceedingly interesting structures, capable, after a certain period, of maintaining a kind of independent existence, and whose primary object, in all cases, is to strengthen the aneurismal sac, and, under favorable circumstances, to fill it up, so as to effect a radical cure. What adds to the force of this conclusion is the fact that, when a cure of this description has been effected, the tumor is gradually brought under the influence of the absorbent vessels, by which it ultimately entirely disappears, with the exception, perhaps, of a little nodule, not larger than a pea, and just sufficient to indicate the former site of the disease. It is proper to observe that the recently-formed strata of an aneurismal sac are, in general, very imperfectly, if at all, organized; they are certainly not vascularized and furnished with absorbents.

How are these aneurismal concretions formed? Upon this subject there still exists some contrariety of sentiment. Most pathologists, however, suppose, and very correctly, as I think, that they are deposited from the blood as it sweeps over the inner surface of the sac, during which more or less of its fibrin is disengaged, while the other elements of the fluid are sent forward to mingle with the current in the affected artery. This opinion derives plausibility from the fact that the development of these strata always proceeds most rapidly when there is a comparatively small orifice of communication, with a languid state of the systemic and aneurismal circulation. It has been conjectured that the clots had their origin in an effusion of plastic matter, such as occurs in traumatic injuries and ordinary inflammation; but for such a view I can myself perceive no just ground, as it is impossible to discover the slightest similarity between the two processes. I have stated in the preceding paragraph that the act of formation is both a mechanical and a vital one; mechanical as far as the mere separation of the fibrin from the blood is concerned, and vital as it respects the decolorization, condensation, and intimate adhesion of the concretions.

The *tubular aneurism* is extremely rare; it is observed principally in the aorta, and the branches which are immediately detached from it, especially the innominate, carotid, and iliac, and consists in a uniform dilatation of the vessel, usually composed of all its tunics in varying degrees of alteration. In its shape, the tumor is commonly somewhat spindle-like, and hence it is often described under the name of fusiform aneurism; the term cylindroid has also been applied to it, as its conformation occasionally partakes strongly of that character. The word tubular, however, is more expressive of its appearance, and I therefore adopt it in preference to any other. The annexed drawing, fig. 243, from a specimen in my collection, affords a good idea of this variety of the disease.

The size of the tubular aneurism varies from slight increase of the normal diameter of the vessel to a tumor capable of receiving a large fist. When it occupies the arch of the aorta, it often projects up into the neck so as to form a prominent swelling above the sternum, admitting of satisfactory examination, both by touch and auscultation. The distance between the origins of the carotid arteries is greatly increased, and the aneurism generally encroaches sensibly upon the heart. In nearly every instance its length considerably exceeds its diameter. The dilatation of which it consists seldom terminates abruptly, but is usually lost by insensible degrees in the vessel above and below, thus giving the tumor the appearance of two cones united at their bases. In the smaller arteries, as, for example, the innominate, the aneurism sometimes involves the whole length of the vessel.

Fig. 243.

Tubular aneurism of the aorta. *a.* The aorta, much hypertrophied. *b.* The heart.

The structure of the tubular aneurism is usually made up of all the tunics of the affected artery, in a notable state of alteration, of which hypertrophy constitutes the most striking feature. In two remarkable specimens in my collection, the different tunics are immensely thickened, and increased in strength and density, the effect, evidently, of long-continued interstitial deposits; they both occupied the arch of the aorta, extending as far as the origin of that vessel, and were taken from male subjects upwards of fifty years of age. The lining membrane has lost its white and glossy appearance, and has been replaced by a thick, opaque, and rugose structure, having none of the properties of the original texture. The middle coat is at least ten times as thick as naturally, very strong, elastic, and deprived of its yellowish hue; the outer one is also greatly changed in its appearance, being remarkably strong, thick, and firm. No evidence whatever exists in any of the tunics of the earthy, atheromatous, or fatty degeneration.

From a careful examination of this form of aneurism, it appears to me to consist essentially in a dilatation of the caliber of the artery with hypertrophy of its different tunics. The first step, probably, in its formation is chronic inflammation, causing weakness of the walls of the vessel, and uniform enlargement of its diameter. By and by, however, as the dilatation increases, the coats become strengthened in every direction by interstitial deposits, and it is thus that a tumor is at length formed capable of offering great resistance to the impulse of the blood. It is owing to this superaddition of matter that the tubular aneurism so seldom gives way by rupture, a circumstance in which, as well as in several others, it differs remarkably from the sacciform variety of the disease.

It is not to be supposed, from what precedes, that this form of aneurism always consists of the different tunics of the affected artery; this is unquestionably true in most cases, but we now and then meet with an instance in which the lining membrane, and perhaps, also, the middle layer, are partially

deficient, thus causing irregularity in the dilatation, unless, as occasionally happens, the defect is atoned for by plastic deposits. Indeed, the retention of

Fig. 244.

Aneurism, by dilatation. The abnormal space is almost entirely filled up by fibrin; the arterial canal remaining clear. Spontaneous cure exists in an advanced stage.

all the tunics would seem to be an essential condition to the formation of the true tubular aneurism; if the inner and middle lamellæ be destroyed, even to a small extent, the blood will dilate the vessel unequally, and inevitably give rise to a sacculated tumor. It is in this way that we may explain the occasional coexistence of the two forms of the malady.

The tubular aneurism is remarkable, besides some of the characters already pointed out, for the absence of fibrinous concretions, which are so common in the saciform; and the circumstance may be employed as an additional evidence of the correctness of the view, so long and so generally entertained, that the formation of these substances takes place directly from the circulating fluid, and not as an effect of the deposition of plastic matter, consequent upon inflammation, as some have conjectured. If the development took place in the latter way, it ought to be of frequent, if not of constant occurrence, inasmuch as the inner coat of the affected artery is seldom entirely free from inflammation, and would thus afford a large surface for the effusion of fibrin; but every one who has ever examined a specimen of tubular aneurism, knows how extremely rare it is to find its walls incrustated with anything. In the annexed sketch, fig. 244, from Hodgson, a tubular aneurism is seen occupied by concentric concretions, with a central canal, which preserved the continuity of the vessel, and thus permitted a continuance of the circulation. The stratification appears to have been very perfect.

3. SYMPTOMS OF ANEURISM.

The symptoms of aneurism exhibit, as might be supposed, much diversity, the principal circumstances which influence them being the nature, seat, and age of the tumor. Hence, in order to comprehend the subject thoroughly, it must be studied with special reference to these points.

In spontaneous aneurism, which usually depends upon rupture of the coats of the artery, the patient is often apprised of the commencement of the disease by the occurrence of a sharp pain, not unlike that produced by an electrical shock; he feels as if he had received a smart blow, and perhaps turns round to see who inflicted it. Occasionally, also, he is conscious of something having suddenly given way—he may even have heard a slight noise—and on examining the part a small pulsating tumor is found. Upon being interrogated as to the cause of the accident, he will usually state that it took place while he was engaged in some severe bodily exertion, as leaping, running, lifting, or coughing. But the origin of the disease is not generally

thus marked; in the majority of cases, in fact, the patient has no distinct perception of its occurrence, and he is only apprised of its existence by degrees; not, perhaps, until it has already made serious progress. Such an event will be particularly apt to happen when the lesion consists essentially in a dilated condition of the arterial tunics, unattended with rupture, as it is then often extremely stealthy in its mode of invasion. In traumatic aneurism, on the contrary, the characteristic symptoms ordinarily show themselves immediately after the receipt of the injury of the vessel upon which the disease is situated.

The aneurismal tumor is usually quite small at its commencement, not exceeding, perhaps, the volume of a filbert, a small hickory-nut, or an almond; by degrees, however, it increases in size, and ultimately may acquire a bulk equal to that of a man's fist, or even of an adult's head. In its form it may be globular, elongated, ovoidal, conical, fusiform, or cylindrical; or so irregular as to defy description. However this may be, it is a living, beating tumor, rising and expanding synchronously with the contraction of the left ventricle of the heart. Its pulsations are often perceptible at the distance of a number of feet, especially in strong, plethoric subjects, and are always increased in force and frequency by whatever has a tendency to excite the general circulation. It imparts a distinct impulse to the hand, rising and falling as the blood enters and passes out; it is soft and elastic, and in its earlier stages permits itself to be emptied by steady and uniform pressure. Upon applying the ear to the tumor a peculiar noise is perceived, differing very much in its character and intensity. In general, it is a sort of sawing, rasping, or bellows sound, and so loud as to be heard with great distinctness at a distance of several inches; occasionally it is of a peculiar whizzing, whirring, or purring nature, and cases occur, although they are rare, in which it strongly resembles the buzzing of a fly in a bottle. The immediate cause of the sound is the manner in which the blood rushes into the tumor; its pitch is always greatest, other things being equal, when there is a comparatively small opening of communication, and when the sac, containing but little solid matter, is seated superficially.

The phenomena now described are, in general, susceptible of great modification by pressure applied to the artery above and below the tumor. In the former case, the size of the swelling is notably diminished and all motion and noise disappear; in the latter, it is sensibly augmented, the tumor heaves and rises under the resistance, and the blood, rushing violently against the inner surface of the sac, at each systole of the heart, produces great tumult, with a corresponding increase in the intensity of the different sounds. Considerable changes in the aneurismal sounds are sometimes occasioned by the rugose condition of the margins of the orifice of communication, and by partially detached clots, or projecting filaments, within the sac, intercepting the column of blood, and causing various murmurs and vibrations, together with a tremulous shaking of the tumor, isochronous with its pulsations.

The pain attendant upon aneurism is constant, but subject to variation in its intensity; slight early in the disease, and while the swelling is still small; more severe and harassing as it progresses and encroaches upon the surrounding parts. Diversified in its character, it is generally dull, aching, and throbbing, as if matter were about to form; in some cases it is sharp and darting, in others dull, heavy, or gnawing. Occasionally it is of a neuralgic nature, coming in fits and starts, or, as sometimes happens, in regular paroxysms, once or twice in the twenty-four hours. The immediate causes of the pain are, inflammation of the sac and the pressure of this upon the neighboring structures; hence it is always greatest, as a general rule, in large and old aneurisms, and in those parts of the body which are most abundantly supplied with nerves.

For the same reason that the pressure of the tumor causes pain, the distal parts usually suffer from numbness, and a sense of aching and weariness. Their temperature is diminished; and they are weak and crippled. Great swelling, of an œdematous character, is often present, the result, evidently, of the compression of the veins and lymphatics impeding the return of their contents. As the tumor enlarges, the distal portion of the artery contracts, and conveys less of its wonted supply to the lower parts. Gradually, however, this is compensated for by the collateral vessels, which, naturally existing, augment in size, and, in time, amply atone for the diminished stream in the main trunk. If it were not for this arrangement, the parts would soon shrivel and wither, or, worse, fall a prey to gangrene. Fortunately, such an event can only happen when the aneurism is of extraordinary bulk, or of very rapid development, thereby compressing also the collateral vessels and the principal nerves.

Aneurism of the thoracic aorta, and of the innominate and carotid arteries, is nearly always attended with distressing dyspnœa, severe pain, and palpitation of the heart, which is itself often seriously implicated in the disease, being especially liable to suffer from hypertrophy, softening, and fatty degeneration, along with chronic endocarditis and disorder of the tricuspid and semilunar valves. As the tumor enlarges, the respiratory difficulty rapidly increases, rendering walking painful, and the maintenance of the recumbent posture ultimately impossible. Compression of the trachea may induce asphyxia, and of the œsophagus, inanition. In the abdomen and pelvis, aneurism of the larger arteries, besides causing violent pain, may occasion serious functional disturbance, by interfering with the return of the blood in the vena cava, and thus leading to ascites and anasarca.

4. DIAGNOSIS OF ANEURISM.

Although the symptoms of aneurism are, in general, so well marked as to render it difficult to mistake their import, yet, as the disease may be simulated by other affections, and as doubts may thus arise in the mind of the inquirer concerning its true nature, it is necessary, in every case, however well-characterized it may apparently be, before he comes to a final decision, to institute a faithful examination into its history, progress, and present condition. It has been for the want of proper care in the investigation of this disease that some of the most serious and disgraceful blunders that disfigure the records of surgery have been committed; and, although such errors are now less frequent than they were formerly, owing to the more general use of the exploring needle, and a better acquaintance with pathological anatomy, yet it cannot be denied that what has occurred once may happen again, and that with tenfold effect, as it respects the character of the surgeon, who, to his skill as an operator, is always supposed to unite that of an enlightened diagnostician. The affections with which aneurism is most liable to be confounded are, chronic abscesses, glandular tumors, and encephaloid growths. Attention to the following circumstances will, if carefully remembered, enable the practitioner to avoid error.

1. Aneurism is always, from the first, seated in the direction of one of the larger arteries, whose course may often be distinctly traced by the finger; it is soft and elastic, pulsates more or less violently, is free from pain, and is unattended with discoloration of the integuments. Abscess, on the contrary, begins as a hard swelling, and becomes soft only after it has passed through its different stages; if chronic, matter will form very slowly, and, although it may surround the artery, and thus receive its impulse, yet the peculiar fluctuation of the swelling, and the changes that may be induced in it by pressure and posture, will always suffice to prevent error. In acute abscess,

there is severe pain, pus is poured out rapidly, and there is marked discoloration of the surface, with more or less constitutional disturbance. Glandular lymphatic swellings are most common in the neck, axilla, and groin in children and young persons of a strumous diathesis; they generally advance pretty rapidly, and, after having attained a certain bulk, either remain stationary, or alternately advance and recede; they are usually multiple, and not unfrequently occur simultaneously on both sides of the body. External aneurism, on the contrary, is most common in the popliteal, femoral, innominate, and carotid arteries, in middle-aged and elderly subjects, and, progressing slowly but steadily, never recedes, and rarely exists in more situations than one at the same time. Encephaloid growths occur at all periods of life and in nearly all regions of the body; soon acquire a large bulk; are of varying degrees of consistence, some parts being solid, some soft, and some semi-solid; are attended with great enlargement of the subcutaneous veins; and soon give rise to that pale and sallow state of the features known as the cancerous cachexia. Aneurism, as just stated, advances tardily, is of uniform consistence, especially in its earlier stages, is not accompanied by any enlargement of the subcutaneous veins, and, although the general health may seriously suffer, there is an entire absence of cancerous impress.

2. Aneurism pulsates the moment it is developed; no matter how small it may be, it throbs and heaves isochronously with the action of the heart, and possesses all the characteristic traits that distinguish it in its later stages, although they are perhaps less strongly marked. Abscesses and solid tumors, on the contrary, are seldom affected by the beating of the underlying vessel until they have acquired some bulk, and even then the impulse is often very faint, occurring rather as an undulatory movement than as a distinct shock.

3. In aneurism the tumor is generally firmly fixed, any attempt to grasp and lift it up proving abortive; possibly, it may be pushed gently to one side or the other, but this is all. Moreover, whatever changes may be effected in its relations none can be effected in its pulsations; it throbs and heaves as before. With solid growths this is not so; unless very large, they can be readily isolated from the vessel, and be thus deprived of all impulse, however strong.

4. The pulsation in aneurism is generally uniform, being perceived equally at every point of the circumference of the tumor, which rises and falls synchronously with the systole and diastole of the heart; in abscess and solid growths, on the other hand, it is very irregular, and is usually limited to a particular spot. In aneurism the swelling bounds and recedes under the hand; it feels as if it were alive and panting; in solid tumors the morbid mass rises at each impulse, but there are no expansion and contraction.

5. When an aneurism is firmly and uniformly compressed, it sensibly diminishes in bulk, which, however, recovers itself the moment the hand is removed; in solid growths and abscesses, pressure, however great, produces no such result.

6. In aneurism, the size of the swelling is diminished by pressure upon the cardiac side of the tumor, and increased by pressure upon the distal side. In morbid structures not aneurismal, no change of bulk follows this procedure.

7. The sounds of aneurism are different from those of solid tumors. Both may yield a sawing, bellows, or rasping noise, but in the latter this is never conjoined with the peculiar thrill, or whirring noise, which constitutes so prominent a symptom in the former.

8. Aneurism of the larger arteries ordinarily affords two alternate shocks, one of which corresponds with the diastole of the heart, the other with its systole. These phenomena are never present in solid tumors and abscesses, and are therefore pathognomonic.

Such are the distinguishing characters of aneurism and of the more important diseases with which it is liable to be confounded. It must be obvious, from what has been said respecting them, that mistake can only be avoided by the most rigid and thorough examination, made not once, but repeatedly, in every case of tumor situated along the course of an artery and influenced by its pulsation. Where, after such a pains-taking process, no satisfactory decision can be arrived at, our only resource is to insert a delicate exploring-needle, which, while it can do no possible harm, if it be properly employed, will at once determine the diagnosis.

5. EFFECTS AND TERMINATION.

The effects which aneurism exerts upon the surrounding parts vary according to circumstances, of which the most important are, the situation of the affected vessel, and the size of the tumor. An aneurism of the arch of the aorta will, other things being equal, produce more serious disturbance, both organic and functional, than one of the abdominal portion of that vessel, and an aneurism of the carotid artery than one of the popliteal. It is obvious also that a small tumor will, as a general rule, cause less serious effects than a large one.

The effects which such a disease produces upon the parts with which it is in contact are purely of a mechanical character, eventuating in their displacement, compression, or ulceration, or in all these occurrences combined. An aneurism of the thoracic portion of the aorta must, necessarily, encroach more or less upon the contents of the chest, pushing the heart and lungs out of their natural position, and thereby interfering essentially with the performance of their proper functions. In aneurism of the carotid artery there will be displacement of the trachea, œsophagus, and the great vessels of the neck, along with compression of these parts, and also of the pneumogastric and sympathetic nerves. In popliteal aneurism the part of the limb below the site of the tumor generally suffers from obstructed circulation, as is evinced by the occurrence of anasarca and decrease of temperature, with a feeling of numbness, the result of interruption of the nervous current. When the embarrassment to the flow of blood is very great, or long continued, mortification of the distal portion of the limb is liable to ensue.

When the tumor is situated externally it may produce serious changes in the muscles, which, in many cases, are not only widely separated from each other, but remarkably pale, flattened, and attenuated, exhibiting more the appearance of thin ribbons than of thick, solid, fleshy bodies. The nerves, too, are often very much spread out, the vessels are thrust aside, and the aponeuroses are stretched out like tense sheets. When pressing upon an important joint, the tumor is sure to impede its motion, and may even cause permanent ankylosis, as occasionally happens in aneurism of the popliteal artery.

The effect produced by aneurism upon the osseous tissue is sometimes very remarkable, and is generally most conspicuously displayed in the dorsal portion of the spine. When the disease involves the thoracic aorta, the tumor, which often attains a large size, being crowded into a comparatively small space, is liable to encroach sadly upon the bony walls of the chest, pressing upon and eroding the bodies of the vertebræ behind, as seen in fig. 245, the sternum in front, the ribs at the side, and the clavicle above. There is hardly an osteological cabinet, of any extent, that does not afford striking evidence of the truth of this remark. I have seen specimens where as many as four of the bodies of the dorsal vertebræ were completely absorbed as far as the spinal canal, which, forming the posterior boundary of the tumor, was thus fully exposed to its pulsations. The sternum suffers mostly at its lateral and

upper aspect, but occasionally, as in an instance now under my care, it is perforated at the centre, the movements of the aneurism being distinctly visible at that part. The ribs and their cartilages do not generally participate to any considerable extent in the erosion, and the clavicles are rarely affected, unless the tumor is of great bulk, and projects unusually high up into the neck.

It is not surprising, after what has been said respecting the effects which aneurism is capable of exerting upon the osseous tissue, that the tumor should occasionally cause serious lesion in the soft structures, apart from their mere compression. In its earlier stages, before the swelling has attained any considerable bulk, the inroads are slight, and, consequently, well borne, the parts manifesting no disposition to resent its encroachments; by and by, however, as it progresses, its pressure bears heavily upon the adjacent textures, which, taking on inflammatory action, become matted together by interstitial deposits, which, for a time, thus materially strengthen the aneurismal sac. But this state of things is not destined to last long; gradually the morbid action increases, the superincumbent tissues are more and more expanded, and, at length, ulceration setting in, the integuments yield over the more prominent portion of the sac, followed by destructive hemorrhage.

Fig. 245.

Erosion of the vertebræ from aneurism.

6. SPONTANEOUS CURE.

Unfavorable as the prognosis of aneurism generally is, it is extremely gratifying to know that a cure may occasionally be effected spontaneously, without the intervention of art in any way. That such an event is rare, forming merely an exception to the great law, is unfortunately too true; yet it sometimes occurs under circumstances apparently the most desperate, bidding defiance alike to medical and surgical skill. There are, indeed, few practitioners of enlarged experience, who have not met with cases of this disease in which, contrary to all calculations of the doctrine of chances, the patient made an excellent recovery, after having literally hovered, for days and weeks, over the very verge of the grave; where, in short, everything portended speedy destruction, and yet every vestige of the aneurism ultimately disappeared, the person living for years afterwards in the enjoyment of good health, and in the exercise of his former occupation. How the cure is effected in these cases, our information does not enable us to explain, as an opportunity is seldom afforded of making a dissection of the body after the event has taken place, in consequence of the individual being usually lost sight of. A knowledge, however, of the possibility of such a cure is highly encouraging, and holds out the hope that it may be of more frequent occurrence than has hitherto been imagined.

Although we are not always able to account for the manner in which the patient gets well in this disease, yet observation has demonstrated that it generally occurs in one of five ways, all leading, essentially, to the same result, namely, the formation of clots, by which not only the aneurismal sac is closed up, but also the artery immediately above and below it. When the cure is gradual, the clots are usually arranged concentrically, and exhibit every mark of organization; but the reverse is the case when it is effected suddenly, for

then they are nothing but soft, red blood-masses, similar to what we so often observe after death in the heart and large vessels.

1. The most common way in which the cure takes place is by the gradual filling up of the sac by the formation of clots, thereby ultimately converting it into a firm, solid tumor.

Fig. 246.

An aneurismal tumor obliterated by the deposition and organization of fibrin.

and nearly three inches in diameter, is occupied by hundreds of lamellæ, many of them not thicker than a sheet of paper, of a pale grayish color, closely adherent to each other, concentrically arranged, of a dense, firm texture, and, beyond question, thoroughly organized, even those most recently deposited. At the centre of the tumor, a small irregular cavity exists, which still admitted some blood, as is proved by the fact that the hepatic artery is completely pervious. This mode of reparation is greatly facilitated by the small size of the opening of communication between the artery and the aneurismal sac.

2. Another mode of spontaneous cure is the occurrence of inflammation, followed by the coagulation of the contents of the sac, and the ultimate obliteration of its cavity as well as of the artery in its immediate vicinity. The disease may begin in the tumor itself, or be propagated to it from the circumjacent structures; if it be mild and slow, the cure may be easy and safe, but if it be very active, it may terminate in suppuration, and thus endanger life by hemorrhage, the matter being evacuated along with the clots before the artery is hermetically sealed by an internal coagulum.

3. The reparation occasionally occurs through the intervention of gangrene, either beginning in the tumor itself, or extending to it from the parts immediately around it. The blood coagulates in the sac as it does in an artery in ordinary gangrene, and when the sloughs separate the clots are discharged, the gap being afterwards closed by the granulating process. Such a mode of restoration must necessarily be infrequent, inasmuch as the morbid action by which it is effected generally terminates fatally.

4. The contents of an aneurism are sometimes solidified by the compression of the artery leading to it, caused either by the tumor itself or by some morbid growth in its immediate vicinity. Such a result may follow with nearly equal certainty, whether the pressure be applied to the cardiac or to the distal portion of the vessel.

5. Finally, a very rare mode of spontaneous obliteration may take place, consisting in the detachment of a small clot and its introduction into the distal portion of the artery, thereby more or less completely blocking it up. The blood, being thus checked in its onward flow, soon coagulates, just as it does in artificial compression. It was upon a knowledge of this species of

The most beautiful and perfect specimen of this kind, represented in fig. 246, that I have ever seen, was presented to me, some years ago, by an old pupil, Dr. Shumard, who had removed it from the body of a young steer. What renders it still more interesting, is the circumstance that it was connected with the hepatic artery, which had given way at one side from the rupture, apparently, of its inner and middle tunics. The tumor, which is of a rounded shape,

spontaneous cure that Mr. Fergusson recently attempted to found a new mode of treatment of aneurism by breaking up the contents of the tumor by manipulation, and thus urging them on into the communicating vessel.

When, by any of the above modes, a radical cure is effected, the tumor is gradually brought under the influence of the absorbent vessels, and is ultimately completely obliterated, or, at all events, so far reduced as to leave only a small nodule, indicative of the former site of the disease. The period required for the perfection of these changes varies from three or four weeks to as many months, according to the size of the aneurism and the state of the part and system.

Although an aneurism may, as we have just seen, occasionally get well by the unassisted efforts of nature, yet such an event forms merely an exception to a great law, in conformity to which the disease almost uniformly proves fatal. The period at, and the mode in, which this takes place vary in different cases and under different circumstances, and can, therefore, be pointed out only in a general manner. In aneurism of the aorta, especially in the arch of this vessel, the disease often produces death in less than three months from its commencement; in the innominate its course is also generally rather rapid, and a similar remark applies to aneurism of the primitive iliac; in aneurism, on the contrary, of the carotid, subclavian, axillary, external iliac, femoral, and popliteal arteries, the fatal event is often postponed several months longer. To these statements there are, of course, many exceptions; thus, on the one hand, we occasionally meet with an aneurism which ends fatally in a few weeks, the tumor expanding rapidly, and perhaps bursting quite suddenly during a violent muscular effort; and, on the other hand, the disease may continue, with very little variation, as to size, for a number of years.

There are three distinct modes by which aneurism may cause death: 1. By the injurious compression which the tumor exerts upon the neighboring organs. 2. By the sudden rupture of the sac, and the occurrence of hemorrhage. 3. By the development of inflammation, suppuration, or mortification.

1. Aneurismal tumors of the neck and chest often cause death by compression of the trachea and bronchial tubes, although perhaps not as frequently as has been generally supposed, owing to the wonderful power which these tubes possess of flattening themselves, so as to make room for the entrance of the air into the lungs. Indeed, I am inclined to think, from my knowledge of this subject, that death from direct suffocation, from this cause, is an uncommon event. Great difficulty is often produced by the pressure of the sac upon the pneumogastric and phrenic nerves, and it is extremely probable that life is sometimes destroyed in this way, the more especially if the pressure be conjoined with serious lesion of the air-passages. Finally, death occasionally proceeds from compression of the heart and lungs, interfering with the circulation and respiration; or from compression of the œsophagus, causing inanition. In the abdominal and pelvic cavities, and also in the extremities, the danger from compression is much less, as the structures here are less important to life, as well as more disposed to yield under the encroachment of the tumor.

2. After an aneurismal tumor has attained a certain bulk it is extremely apt to give way, as in fig. 247, either suddenly or gradually, under the impulse of the blood, or under severe muscular exertion. Such an occurrence will be the more likely to happen when the tumor has been of rapid growth, and especially if its interior has not been fortified by the formation of hard, organized clots, so as to increase the thickness and strength of its tunics. It is in this manner that most of the internal aneurisms, which do not cause destruction by mere compression, ultimately terminate, the immediate cause

of death being hemorrhage into some internal and contiguous organ. Thus, in the chest, the tumor usually opens into the trachea, the bronchial tubes, the pleura, pericardium, mediastinum, or œsophagus.

Fig. 247.

Aneurism of the descending aorta, burst, the patient dying suddenly in consequence.

Sometimes a communication is established between the sac and the heart, between it and the pulmonary artery, or, lastly, between it and the vena cava. An aortic aneurism has also been known to burst into the spinal canal, some of the bodies of the vertebrae having previously been destroyed by absorption. In the abdomen, the tumor may break into the peritoneal cavity, or into one of the hollow viscera, as the stomach, intestine, or urinary bladder. In the neck, axilla, groin, and extremities, the aneurism, if permitted to pursue its course, generally finds its way to the surface, very much after the manner of an abscess.

The hemorrhage succeeding to the rupture of an aneurism may be slight, as when the aperture is small or devious, or copious and destructive, as when the opening is large or straight. Most commonly, life is worn out by the frequent recurrence of the bleeding; thus, twenty ounces of blood may be lost to-day, in a week twenty or thirty ounces more, and so on until the patient dies completely exhausted, his condition being, in the meantime, perhaps seriously aggravated by serous effusions into some important cavity. Occasionally the aneurism gives way by a large rent, and the patient expires instantly in consequence of the hemorrhage.

3. More or less inflammation attends all aneurisms; whatever may be their volume or situation, their age, or character, they play the parts of intruders, encroaching upon, compressing, and irritating the surrounding structures, and thus giving rise to various deposits, especially of serum and plasma. It is by means of the latter that, as was previously stated, the sac increases in thickness and density, so as to qualify it the better to bear with impunity the impulse of the inflowing current of blood; without such an occurrence few tumors of this kind would be able to maintain themselves for any length of time, but would soon yield to the resistless pressure from within; in a word, speedy rupture of the sac, and fatal hemorrhage would, in most cases, be inevitable. But, although inflammation is set up for wise and beneficial purposes, the process, unfortunately, is not always kept within the strict limits required to fortify the sac and protect it against early rupture; on the contrary, many circumstances occur to provoke its increase, and to cause it to pass into ulceration, suppuration, and even mortification. Among these circumstances some are of a constitutional, and others of a purely local character; thus, mere plethora and the use of stimulating food and drink may powerfully augment the inflammation, and bring about these untoward results. In general, however, it will be found that the mechanical compression of the tumor, in consequence of the resistance offered to its extension, has more to do with its production than anything else. Sometimes a clot is accidentally detached, and thus becomes a cause of mischief. In external aneurism, the manipulation employed in examining the tumor is occasionally productive of severe inflammation, and similar effects often follow the injudicious use of the affected limb.

Suppuration of the tumor is an infrequent event. A case occurred in 1857, at the Pennsylvania Hospital, in the service of Dr. Pepper, in which

an abscess had formed in connection with an aneurism of the innominate, and killed the patient, a man aged 38, by bursting into the trachea. A report, with a drawing of the case, has been published by Dr. Humphreys, in the Transactions of the Pathological Society of Philadelphia. Ulceration and mortification are more common, and are particularly liable to take place when the tumor is of large size.

Finally, aneurism may prove fatal by exciting inflammation in an important internal organ, as the lung, heart, or pleura. In popliteal aneurism, the pressure of the tumor upon the nerves and arteries below sometimes causes death from mortification of the leg and foot.

TREATMENT.

Notwithstanding the vast amount of attention that has been bestowed upon aneurism, from the earliest periods of medical science down to the present, it may truly be affirmed that there is no subject connected with practical surgery which has been so little understood by the great mass of the profession as this. This circumstance has arisen, it seems to me, not so much from a want of ability on the part of the practitioner to comprehend the nature of this lesion, as from the obscure and imperfect manner in which it is usually discussed in our lecture-rooms and in our systematic treatises. Much difficulty also has grown out of the defective nomenclature of aneurism and of the ambiguity which, until recently, existed in regard to the pathology of this affection, both tending to give rise to erroneous ideas of practice. Light, however, is gradually breaking in upon us; and it is highly probable that the advances of modern science will enable us, ere long, to treat aneurism with as much confidence as any other class of maladies.

Leaving, for the present, out of view the treatment of internal aneurism, as belonging as much to the department of medicine as that of surgery, I shall proceed to consider the various remedies that have been proposed for the cure of the external form of the disease, or, more properly speaking, of those cases of aneurism which are more directly and immediately amenable to the art and science of surgery. In doing this, it will be necessary to bear in mind the divisions of aneurism pointed out in the commencement of the section, as each of them will require corresponding modifications of management.

In the time of Celsus, as well as for a long period subsequently, the treatment of aneurism was conducted in the most cruel and unscientific manner. The only operation which appears to have been known was to lay open the tumor by a bold incision, and, after turning out its contents, to apply the hot iron to the extremities of the affected artery, so as to seal up their mouths. The effect of such a procedure may easily be imagined; upon the separation of the eschar, hemorrhage was sure to take place, and in this way nearly every patient perished, either at the first onset of the bleeding, or by its frequent repetition. This miserable practice continued in vogue until the introduction of the ligature by Ambrose Paré. A different mode of procedure was now adopted, although it can hardly be said to have been much of an improvement upon the one just described. It certainly, however, possessed the advantage of being more scientific, and of being less frequently followed by hemorrhage, notwithstanding it could claim little on the score of simplicity as far as its execution was concerned. It consisted in ligating the artery above and below the tumor, which was then freely opened, thoroughly cleared out, and stuffed with charpie, to promote suppuration and occlusion, the object being to heal the wound from the bottom. Occasionally the more adventurous surgeon took the more speedy route of extirpating the tumor, adopting a plan similar to that which is sometimes pursued at the present

day in treating aneurism at the bend of the arm consequent upon venesection. The result of this operation, too, was often most disastrous; many of the patients died of the effects of inflammation, some of secondary hemorrhage, and not a few of the shock of the amputation performed as a *dernier ressort*, to save them from impending destruction. To prevent these sad occurrences, and afford the sufferer a better chance of recovery, the removal of the limb was often the only operation thought of for his relief.

a. DELIGATION OF THE ARTERY AT THE CARDIAC SIDE OF THE TUMOR.

It is amazing to think that some of the operations above described should have continued in vogue until near the close of the last century. The fact attests, more fully than any other circumstance with which we are acquainted, the low state of surgery up to that period. The merit of performing the first operation for the cure of aneurism upon strictly scientific principles is due to Mr. John Hunter, who flourished in the latter part of that century, and whose labors have shed so much lustre upon the healing art. From having witnessed so many failures from the ordinary procedure, he was led to the conclusion that the cause consisted in the fact that the artery was always diseased for some distance above the aneurism, and that it was, therefore, incapable of becoming sufficiently occluded prior to the detachment of the ligature to prevent hemorrhage. Acting under this conviction, amply confirmed by dissection and observation, he determined, upon the first favorable opportunity, to apply the ligature upon a sound portion of the vessel. While thus revolving the matter in his mind, a man, laboring under popliteal aneurism, was admitted into St. George's Hospital, of which he was then one of the surgeons. The patient was a coachman, forty-five years of age, and the tumor, first perceived three years previously, was not only quite large, but was attended with great swelling of the foot and leg. The operation was executed in December, 1785, the femoral artery being exposed a little below its middle, and surrounded by four ligatures drawn so gently as simply to bring the sides of the vessel together. "The reason for having four ligatures was," as is stated by Sir Everard Home, by whom the case was reported, "to compress such a length of artery as might make up for the want of tightness, it being wished to avoid great pressure on the vessel at any one part. The ends of the ligature were carried directly out of the wound, the sides of which were now brought together and supported by sticking-plaster and a linen roller, that they might unite by the first intention."

It is unnecessary to enter into any details respecting the after-treatment of the case. It will be sufficient for my purpose to state that on the second day after the operation the tumor had lost more than one-third of its original bulk; that the ligatures, some of which came away on the fifteenth day, excited severe inflammation in the artery, as well as in the surrounding parts; and that the man left the hospital on the 8th of July following, in good health, and with no appearance of any tumor in the ham. He subsequently resumed his former occupation as coachman, and died from an attack of remittent fever, fifteen months after the operation. The limb being dissected, the femoral artery was found to be impervious as high up as the profunda, while below the site of the ligatures, as far down as the tumor, it was open, and contained blood, except just where it entered the aneurism, where it had become obliterated. The sac was a little larger than a hen's egg, but more oblong and flattened, and contained a solid coagulum adherent to its internal surface.

I have been induced to give a brief outline of this case for two reasons. In the first place it deserves to be commemorated because it embodies the application of a new principle to the cure of a disease which, until then, was

almost uniformly fatal ; and, secondly, because it will enable us to establish, in a more satisfactory manner than we could otherwise do, the claims of Mr. Hunter to the credit of having originated the operation, which has been so sturdily denied him by the French surgeons, who have, almost with general consent, ascribed it to their countryman, Dominic Anel. I have no disposition to enter into the merits of this dispute, especially at this remote period, when everything relative to it should be fully understood ; I shall, therefore, content myself with a recital of a few of the more prominent and important facts of Anel's operation, for these will be sufficient to show that it differs wholly and entirely from that of Mr. Hunter, and that, so far from involving any new principle, it was merely a simplification of the old procedure.

The case of Anel, to whom surgery is indebted for some of its most valuable improvements, fell accidentally into his hands during a visit which he made to Rome in 1710. His patient was a Catholic priest, who, in consequence of having had the brachial artery pricked in venesection, was affected with an aneurism at the bend of the arm ; the tumor was large, and, being the seat of slight ulceration, seemed to have been on the point of bursting. Having controlled the circulation in the limb by means of the tourniquet, he cut cautiously down upon the artery, and, after separating it from the accompanying nerve, he raised it upon a hook, and tied it as near to the tumor as possible. All pulsation in the tumor instantly ceased, the ligature came away on the eighteenth day, and at the end of a month the friar was able to use his arm quite as well as before the accident.

It will thus be perceived that the operations of the English and French surgeons differed from each other in every particular ; and it is only surprising that there ever should have existed any contrariety of opinion respecting them. The procedure of Anel was executed for the cure of a traumatic aneurism ; the artery was perfectly healthy, and it was tied in as close proximity to the tumor as possible, the Frenchman never supposing that he was about to establish a new principle in operative surgery ; he nowhere alludes to such an intention, and his only object seems to have been to afford his patient, who was suffering great agony, and who might bleed to death at any moment from the sudden bursting of his tumor, prompt relief. The Englishman, on the contrary, had studied the subject with infinite care and attention ; he had made numerous dissections and even performed some experiments upon the inferior animals, as the dog and horse, with a view of ascertaining the condition of the artery in aneurism and its ability to bear the ligature ; and he had clearly perceived that, as the cause of failure of the old operation was that the ligation was always made too near to the tumor, the only safety would be to tie a sound portion of the vessel, even although this should be at a very considerable distance from the aneurism. His object was not to cut off the supply of blood at once, but simply to weaken its passage through the tumor, thereby giving its contents an opportunity of undergoing gradual coagulation, and at the same time preventing the distal parts of the limb from perishing from the sudden stoppage of the circulation. The result of the case above detailed proved the correctness of his reasoning, and established, upon a firm and immutable basis, what is now universally recognized in Great Britain and in this country, as the Hunterian operation for aneurism.

The operation of Hunter has been performed upon almost every artery of the body liable to suffer from aneurism. Even the aorta itself has been repeatedly tied, and, although the cases have all proved fatal, yet the result has been such as to show, most conclusively, that the event has been due much more to the injury inflicted upon the surrounding structures than to the violence done to the circulation by cutting off so great a quantity of blood from its accustomed channels. Great simplicity now characterizes the operation ; a healthy portion of artery is selected, great care is taken, in exposing the

vessel, to disturb its sheath as little as possible, and only one ligature is used, but that is drawn so tightly as to lacerate the inner and middle tunics, when, a double knot being made, one extremity is cut off, and the other is brought out at the nearest point of the wound, which is then treated in the ordinary manner. Cessation of pulsation usually occurs at once upon tightening the ligature, although not necessarily so; sometimes, indeed, several days elapse before it is fully established, but even then it is commonly very much diminished in force, thus paving the way for the formation of clots upon which the cure ultimately depends. The persistence of the circulation, after the main artery of a limb has been ligated, arises from the anastomosing branches continuing to pour their contents into that portion of the vessel which lies between the cord and the sac, as well as into the sac itself, and perhaps also into the distal portion of the artery. When these branches are inordinately large, or numerous, they may keep up such a supply of blood as to compromise effectually the success of the operation.

The operation is generally followed by a slight diminution of temperature in the limb, but this rarely lasts beyond a few hours, when it is succeeded by a marked increase of heat, owing to the augmented activity of the cutaneous circulation, in consequence of the blood being forced principally through the superficial capillaries. Subsequently, however, as the anastomotic branches enlarge, and the circulation becomes equalized, the temperature sinks again, and now perhaps somewhat below the normal standard, the parts really feeling, for the first time, the loss of blood occasioned by the ligation of the artery. In not a few cases the limb retains its temperature after the operation with hardly any variation, as if nothing at all had happened.

Instead of the ordinary silk ligature, Dr. Stone, of New Orleans, in a case of aneurism, in 1859, tied the common iliac artery with a silver wire, simply approximating the sides of the vessel, and leaving the wire in the wound, convinced of its entire harmlessness. The patient died on the twenty-sixth day, but, as no autopsy was made, the disposition of the ligature was not ascertained. At my College Clinic, last June, I secured, in a similar manner, the femoral artery in a case of popliteal aneurism; the patient rapidly recovered without any untoward symptom, and the wire still remains in the thigh, nearly the entire wound having healed by the first intention.

After-treatment.—The treatment after the operation must be conducted with great judgment and attention. The patient being carried to bed, the limb is placed in an easy and relaxed position, but not elevated, lest arterial influx be interfered with; and it is well, especially if there be a diminution of temperature, that it should be enveloped for some time in wadding. Cold applications must be carefully avoided, even if the skin manifest inordinate heat with some degree of swelling, as they could not fail to be prejudicial by lowering the vital powers, and so laying the foundation for mortification. A full anodyne should be administered immediately after the operation, to tranquillize the action of the heart; light diet is to be observed, with cooling drinks; and the temperature of the apartment is not permitted to exceed 65° of Fahrenheit. The bowels must not be opened for several days, and then only by the mildest laxatives, drastic purgatives being particularly objectionable on account of their tendency to cause excitement and throbbing of the arteries; occurrences which would inevitably be injurious after such an operation.

Causes of Failure.—The causes of failure after the Hunterian operation are, first, violent inflammation, followed by mortification; secondly, death of the limb from deficiency of blood; thirdly, secondary hemorrhage, either from premature detachment of the ligature, or rupture of the sac; and, fourthly, maintenance of the circulation by means of a redundant anastomosis. None of these accidents, save the last, and that is a very improbable one, will

be likely to happen if the part and system have been thoroughly prepared for the operation, if the disease has not made too much progress, and, finally, if proper care and judgment be employed in managing the case after the application of the ligature. Deligation of the carotid arteries for the cure of aneurism is liable to be followed by inflammation of the brain and lungs, with softening of the former of these organs and hepatization of the latter. Much of the mortality from the operation is caused by this disease.

No recent statistics of the Hunterian operation, on a large scale, have appeared. The most satisfactory, so far as I know, are those of Mr. Thomas Inman, of Liverpool, published in 1844. His table was made up of all the reliable cases that had been recorded up to that period in the various medical and surgical periodicals.

Name of the artery.	No. of cases.	Deaths.	Proportion.
Innominate artery	6	6	...
Subclavian artery	40	18	1 in 2
Carotid artery	40	11	1 in 4
Abdominal aorta	3	3	...
Common iliac	8	3	1 in 2 $\frac{2}{3}$
Internal iliac	4	2	1 in 2
External iliac	27	9	1 in 3
Femoral	42	7	1 in 6
Total	170	59	1 in 3

b. DELIGATION OF THE ARTERY AT THE DISTAL SIDE OF THE TUMOR.

It is well known that aneurism occasionally occurs so near the trunk as to render it impracticable to perform the Hunterian operation, or that the artery, although accessible at the cardiac side of the tumor, is too much diseased to enable it to support the ligature. Mons. Brasdor, a professor in the old school of surgery at Paris, upwards of seventy years ago, after much reflection upon the subject, arrived at the conclusion that gradual and efficient coagulation of the blood in the aneurism might be produced by placing the cord upon the artery at its distal aspect. He had no opportunity, however, of solving the problem upon the human subject. The merit of this was reserved for Deschamps, although the case upon which he tried it could hardly have been worse for such an undertaking. The patient, besides being old, was worn out by suffering, and the tumor, which occupied the upper part of the thigh, extending to within a short distance of Poupert's ligament, was nearly seventeen inches in circumference. The operation was tedious and difficult, on account of the depth of the artery and the absence of pulsation, but the vessel was at length discovered and effectually secured. Contrary, however, to expectation, the aneurism, which had made marked progress for some time previously, now rapidly increased in volume, and on the fourth day, when it appeared to be on the point of bursting, it was resolved to perform the ordinary operation, notwithstanding the reasons which had just before been urged against its adoption. Two ligatures were applied, but the operation was attended with copious hemorrhage, and the man died in eight hours after.

The operation of Brasdor was next performed by Sir Astley Cooper, in a case of aneurism of the external iliac artery, extending so high up into the abdomen as to render it impossible to place a ligature between it and the heart. The femoral artery was, therefore, tied a short distance below Poupert's ligament, between the epigastric and profunda. The patient did well for some days, when the tumor, which had been gradually diminishing in volume, burst, causing death by hemorrhage.

What the results of these two attempts might have been, if the cases had

been of a more favorable character, is a matter which must, of course, be left to conjecture. It is certain, however, that no attempt was made to repeat the operation until 1825, when, almost forgotten by the profession, it was performed by the late Mr. James Wardrop, of London, in a case of aneurism of the carotid artery. The success was complete. The ligation was followed by an immediate diminution of the tumor, which gradually progressed until, at the end of the fifth week, the neck had nearly regained its natural form; the ligature had dropped off, and the general health was entirely re-established. The patient, a woman, aged seventy-five, continued to be perfectly well three years after the operation.

Having been equally successful in several other cases, Mr. Wardrop was induced to extend the principle of Brasdor's operation to aneurism of the innominate artery. It occurred to him that, by tying one of the branches of this artery, the force of the circulation might be so far diminished in the tumor below as to cause the solidification of its contents; and a favorable opportunity soon after arising, he was not slow in putting his ideas in practice. The patient, a female, aged forty-five, had a pulsating swelling, of the size of a turkey's egg, in the inferior part of the neck, its base being concealed by the sternum, and evidently connected with the innominate artery. For the cure of this disease the right subclavian was tied in July, 1827, with the effect of a gradual amelioration of the distressing symptoms, and the ultimate disappearance of the tumor, its site being occupied merely by an unnatural hardness, the result, probably, of the remains of the aneurism. This was the condition of the patient fourteen months afterwards, at which time the carotid artery still pulsated, although not so vigorously as the left, and the woman was in better health than she had been for a long time.

The procedure now described constitutes what is called Wardrop's operation, although it is in reality, as was before intimated, merely an extension of that of Brasdor; and is only applicable to aneurism of the innominate artery. It has been performed within the last fifteen years in a considerable number of cases, generally by tying the common carotid; but the results have, for

the most part, been unfavorable, owing, as has been alleged, and as is probably the fact, to the occurrence of violent inflammation both in the aneurismal sac and in the vessels in immediate communication with it, terminating fatally in a few days, or, at most, in a few weeks.

Deligation of the artery at the distal side of the sac has hitherto been most disastrous. Thus, of 27 cases, collected by Mr. Erichsen, death speedily occurred in 20, while in the remaining seven, although the patients escaped with their lives, no benefit whatever resulted in regard to the cure of the aneurism.

The annexed cuts afford an illustration of the various methods of ligating arteries for the cure of aneurism, above described.

A glance will serve to show how inefficient such an operation must be when performed according to the plan suggested by Mr. Wardrop.

C. INSTRUMENTAL COMPRESSION.

The treatment of aneurism by compression dates back to a very early period of the profession, and, although the principles upon which it was formerly conducted were far from being scientific, numerous cases have been published illustrative of its efficacy. It is not my design to inquire into the history of the operation, or to seek out its inventor for the purpose of awarding him praise for his ingenuity and enterprise; it is sufficient to state that the compression was originally applied directly to the tumor, or to the tumor and the limb upon which it was situated, either by means of an apparatus specially constructed for the object, or by a compress and roller, extended from the distal portion of the extremity upwards, beyond the seat of the disease. The practice was most frequently employed for the relief of traumatic aneurism, especially that form of it consequent upon injury of the brachial artery, at the bend of the arm, and, although it proved occasionally successful, not a few cases occurred in which it was followed by violent inflammation of the sac and limb, eventuating in ulceration, abscess, or gangrene.

In the latter part of the last century, Vernet, a French military surgeon, conceived the idea of curing aneurism by applying compression upon the artery immediately beyond the tumor, upon the same principle as that upon which Brasdor soon afterwards suggested the use of the ligature. He thought that the operation was particularly adapted to aneurism situated so near to the trunk as to forbid a resort to the ligature, or compression upon the cardiac side of the swelling. It would appear, however, that he practised it only in one instance—upon a man affected with inguinal aneurism—and that so great was the disturbance which it created in the pulsations of the sac, that he was obliged, in a very short time, to abandon it. From the want of success attending the case, ill adapted as it was to test the principles of a new process, no one, it seems, felt afterwards disposed to make further trial of it, and it was accordingly forgotten, or remembered only as an ingenious suggestion.

Compression of the artery above the tumor, or between it and the heart, was first distinctly insisted upon as a remedy for the cure of this disease, by the late Mr. Freer, of England, in his observations on aneurism, published early in the present century. In the work here referred to, he gives particular directions for applying the compression, enjoining that it should be made by enveloping the whole limb with a bandage, and placing upon the vessel, in the most superficial portion of its extent, a small pad, which was then to be screwed down by means of a tourniquet. To render its action more effective, a plate was secured to the opposite side of the limb, which, while it defended the integuments and muscles from injurious constriction, concentrated the force upon the particular point of the artery where it seemed to be most needed. Notwithstanding this precaution, the application of the tourniquet was soon followed by pain and œdema of the extremity, generally so violent as speedily to necessitate its removal. Short, however, as the compression was, it occasionally laid the foundation of a cure, which was afterwards perfected by the steady but cautious use of the ordinary compress and bandage.

Acting upon the suggestions of Freer, Dupuytren and others applied themselves to this mode of curing aneurism, devising useful and ingenious instruments as substitutes for the more clumsy contrivance above described. The French surgeon, in particular, invented a most admirable compressor, at once simple and efficient, which still bears his name, and which he employed successfully in several cases of aneurism of the inferior extremity. The cures, however, that were effected in this way were few compared with the great number of failures, and the consequence was that the treatment never met

with much favor. What added to the dissatisfaction of practitioners was that, in quite a considerable number of cases, it was followed by results highly prejudicial to the limb, if not to both limb and life.

Thus stood the treatment of aneurism by compression, when, in 1843, it was destined to experience a complete revolution in the hands of several eminent surgeons of Dublin, particularly Hutton and Bellingham, the latter of whom, in a short tract upon the subject, was the first to point out, upon correct and scientific principles, the manner in which it acts in curing the disease. Prior to this period, one replete with interest to the progress of surgery and humanity, compression was a very painful and hap-hazard proceeding, conducted without any discrimination and judgment, and, consequently, without any certainty as to its results. The idea was that, in order to succeed, it was necessary that it should be applied firmly and steadily, so as to arrest the circulation, and cause adhesion of the sides of the artery, very much as in the operation of ligation. Hence the poor patient was generally subjected to immense torture, often compelling the speedy discontinuance of the treatment, which, however, notwithstanding this, was occasionally followed by the worst consequences, as manifested in the violent swelling of the affected limb, and perhaps its ultimate loss by gangrene. The procedure was altogether a blind one, and, therefore, just as likely to prove prejudicial as useful. It was employed by one practitioner simply because it had occasionally been employed successfully by another, and not because any one had, as yet, been so fortunate as to lay down any broad and definite rules of action. It was for this reason that it was so long in acquiring the confidence of surgeons; that it was totally abandoned at one time, and resumed, with doubts and misgivings, at another. Its principles were not yet fully developed, or placed upon a just and comprehensive basis. This labor was performed by Dr. Bellingham and his able associates, who thus created a new era in the treatment of aneurism, hardly less brilliant than that of the ligation. What the ultimate fate of this treatment will be time alone can determine; that it is destined to supersede entirely, as some have predicted, the use of the ligature, is extremely questionable, and yet, considering the remarkable success which has attended it, such an occurrence seems not improbable.

Compression, as now conducted, is not only safe, but comparatively free from pain; and, although it is often tedious, yet few cases will ultimately resist its influence. It is more particularly applicable to the cure of popliteal aneurism, in which its greatest triumphs have hitherto been achieved, but it has also been successfully employed in aneurism of the lower part of the femoral artery, and in aneurism of the brachial, particularly at the bend of the arm. It is applied at the site of the Hunterian operation, that is, upon a sound portion of the vessel, at the cardiac side of the tumor, and generally at a considerable distance from it; gently and intermittently, not firmly and persistently, as in the old method; just sufficiently to retard and weaken the circulation in the sac, not to arrest it, and so as to favor the gradual formation of clots; allowing time for the development of the collateral vessels, and the maintenance of the nourishment of the distal portion of the member. Occlusion of the artery at the site of compression is not wished for; on the contrary, it is desirable that the vessel should remain pervious, and retain as many of its normal properties as possible. As the stratification of the sac proceeds; as layer after layer of fibrin is deposited, and becomes firmly cemented to that which preceded it, the hollow pouch is gradually filled up, and usually, along with it, also the upper orifice of the artery. To this rule, however, there are occasional exceptions, the blood continuing to flow from the artery in a direct stream across the sac in a sort of ditch, groove, or narrow channel.

For the purpose of making the compression, various instruments have been devised, one of the most simple and efficient of which is represented in fig. 251; it is a modification of that of Charrière, and was successfully employed by Dr. Gibbons, of this city, in a case of aneurism of the popliteal artery. It consists of a long, wide, concave, steel plate, supporting three semicircles of the same metal, arranged in two segments, which slide upon each other, and are connected each at their free extremity with a screw and pad. The whole construction of the instrument is such as to enable the surgeon to regulate the pressure with the greatest nicety; making it more or less firmly, and at one or more points, or alternately at different points, as circumstances may seem to require.

The annexed drawings, figs. 252, 253, and 254, are added for the purpose of enabling the reader to avail himself of the use of other compressors, if the one here described should prove inadequate.

Fig. 253.

Hoey's clamp.

It will generally be well, if the patient is at all intelligent and trustworthy, to instruct him in the use of the instrument, so that he may regulate the compression, according to its effects; lessening it if it be productive of pain, and conversely.

One important principle in the treatment is to compress the artery against the bone, as a point of support; if the pressure be widely diffused it will only serve to embarrass the venous circulation, and to retard the cure. The preliminary treatment should be the same as in the Hunterian operation; and during the progress of the cure the limb should be kept constantly bandaged from its distal extremity upwards, to support the capillary vessels, and prevent œdema. Strict quietude, both of mind and body, should be observed; the diet should be mild but sufficiently nutritious; and free use

should be made of aconite, opium, and acetate of lead, as suggested under the head of the treatment of internal aneurism. If the case is very pro-

Fig. 254.

Carte's circular compressor.

tracted, and the health is likely to suffer from the consequent confinement, gentle exercise may be permitted in the open air, the instrument being worn several hours in the morning and evening. If any considerable swelling arise in the limb, all treatment must be temporarily suspended, and measures adopted for the relief of the morbid action. To continue the compression under such circumstances would be to jeopard the safety both of the part and patient.

The period at which a cure may reasonably be looked for in this treatment, is subject to much diversity; in some instances compression for a few hours has sufficed to produce this event; in others, and these embrace the greater majority of cases, a number of days are required; occasionally,

several weeks elapse; and cases have been reported where the stratification and obliteration of the sac were not completed under two months. As a general rule, it may be assumed that, other things being equal, the cure will be more rapid in proportion to the smallness of the tumor, the tolerance of the part to compression, and the absence of complications.

The results of the treatment of aneurism by instrumental compression are, on the whole, highly flattering, contrasting most favorably with those of the Hunterian deligation. Thus, of 127 cases of compression, rigidly analyzed by Broca, 116 were successful, or in the proportion of 91 to the 100. Altogether, not more than five or six cases have died from the effects of the operation. On the other hand, the statistics of Dr. Norris, of 188 cases of aneurism of the femoral artery, treated according to the Hunterian principle, show a mortality of 46, or in the ratio nearly of one death to three recoveries. The tables of Mr. Inman, given in a previous page, exhibit a similar result.

Besides its indisputable safety, compression has the advantage, if it fail, that it does not preclude the propriety afterwards of a resort to the ligature.

d. DIGITAL COMPRESSION.

Digital compression for the cure of external aneurism has, during the past few years, attracted some attention, both in this country and abroad, but not in so great a degree as its importance demands. Originally proposed as a distinct measure, in 1846, by Professor Vanzetti, of the University of Padua, it was first successfully employed, a year later, by Professor Knight, of New Haven, in a case of popliteal aneurism, in which he cured his patient in forty hours, the compression having been maintained by assistants.

In a communication in the *North American Medico-Chirurgical Review* for January, 1859, Dr. S. W. Gross has reported the details of a case of femoral aneurism cured by digital compression, and he has accompanied his paper by a statistical report of twenty-two other examples treated by the same method. As this paper gives a more full account of the subject than any other which has fallen under my notice, I shall freely avail myself of its contents.

It is to aneurisms of the extremities that this procedure is mainly, if not

exclusively, applicable, as the compression must be made to bear upon some point of the principal artery of the limb. So far as we have been able to ascertain, the brachial has been compressed in three instances only; once for aneurism of the radial artery near the wrist, and twice for arterio-venous aneurism at the bend of the elbow. In all these cases, the pressure was easily maintained, and the cure was effected in a short time. The femoral artery, at different portions of its course, has been the seat of compression nineteen times for popliteal and femoral aneurisms, of which thirteen cases have been cured. The external iliac has been subjected to the same procedure in two cases of inguinal aneurism; in one the pressure was insupportable, and in the other the assistants became so fatigued that it was discontinued. Moreover, it is very difficult in this situation to keep up the pressure, and such cases should, therefore, be excluded.

It has been shown that digital compression has been successful when mechanical compression was unbearable, or had failed, whether alone or conjoined with other means, interrupted or continued, complete or incomplete; it has even, in several cases, been applied by the patients themselves, and in these instances either a cure was effected, or the tumor was so modified that subsequent ligation, or mechanical compression of the artery always resulted in recovery. In no case has it ever been followed by any bad consequences, as is so apt to happen in ligation.

The pain produced by the pressure of the finger is not greater than that caused by the pad of an instrument; should the point of pressure become tender, flour may be sprinkled upon the surface, or a thin, wet cloth may be interposed between the finger and skin. However this may be, suffering, both local and general, may easily be allayed by the free exhibition of anodynes, which should never be neglected.

Of the twenty-three cases tabulated in the paper of Dr. Gross, fifteen were popliteal, with ten cures, and five failures; four were femoral, with three cures and one failure; two were inguinal, both being unsuccessful; and two were arterio-venous, both of which eventuated favorably. Thus, of the twenty-three cases, fifteen were perfectly successful. Of these fifteen cases, the compression in five was employed independently of other means; in five the digital alternated with mechanical compression; in four cases, apparatus had been abandoned, when digital compression effected a cure; and in one the compression was of a mixed character. Of the failures, in six cases digital compression was employed before other means, and in two after trial by apparatus had been abandoned.

An examination of the facts here detailed will serve to show that digital compression, alternating with the use of apparatus, succeeded in every instance in which it was resorted to, and that, when employed primarily and alone, there were five cures out of seven cases. It seems to me, therefore, that the double method, in which digital and instrumental compression alternate with each other, is the most eligible, not only on account of its having effected cures in every case in which it has been used, but because it is more easy of application, and gives rise to much less inconvenience to the assistants; in fact, the patient himself may sometimes regulate the pressure with perfect success.

The period required for the cure of aneurism by this method is incomparably shorter than by any other known plan of treatment. Thus, of fourteen cases, the shortest time required for a cure was three and a half hours, the longest being seven days, and the average two days and two-thirds. When compared with the cases cured by instrumental compression, the length of time is most striking. In the London hospitals, according to Mr. Hutchinson, the average time for the cure of twenty-six cases of femoral and popliteal aneurism was nineteen days; while Broca found that the mean duration of

treatment in ninety-nine cases was about fifteen days. The greatest objection to digital compression is the difficulty of procuring a sufficient number of competent assistants; but in hospital practice, and in large cities, it will always be possible to do so. Since the publication of Dr. Gross's paper, not less than from fifteen to twenty additional cases of cure by digital compression have been reported.

e. FORCIBLE FLEXION.

This mode of treatment, for the introduction of which the profession is indebted to Mr. E. Hart, of England, is applicable chiefly, if not exclusively, in aneurism of the ham and bend of the arm; possibly cases might arise in which it might be employed with advantage in aneurism of the groin and axilla. The principle of the treatment consists in moderating and retarding the flow of blood in the tumor by bending the leg forcibly upon the thigh, so as to approximate the heel to the buttock, and confining it there by means of a strap, the limb being previously enveloped in a bandage. Care is taken to move the knee occasionally, lest ankylosis should occur. The cure is always tedious, from three to six weeks being generally required for the complete arrest of the pulsation, and in a number of the cases in which this treatment has been pursued it has signally failed; in several, the patient was unwilling to bear the restraint which it imposed, and in one at least it caused the rupture of the sac into the joint, necessitating the ligation of the femoral artery.

It is obvious that this mode of treatment, which commends itself by its great simplicity and freedom from pain, is more likely to succeed in small and recent aneurisms than in large and old, in which it must of necessity be occasionally attended with failure. Indeed, it can hardly be considered as applicable to the latter class of cases, as it might induce rupture of the sac, as in the instance related by Mr. Moore, or be even productive of gangrene of the leg.

f. GALVANO-PUNCTURE.

It would seem that this operation for the radical cure of aneurism was first suggested, in 1832, by Mr. Benjamin Phillips, of London; so far, however, as my information extends, it was not practised by him upon the human subject, and the idea had almost been lost, when, several years ago, it was revived, principally through the agency of Mons. Pétrequin, of Lyons. The operation is founded upon a knowledge of the fact that the galvanic current has the effect, if properly directed, of coagulating the blood as it circulates through the different parts of the body. It is executed by means of two long, slender steel needles, introduced into the aneurismal sac at right angles, and in such a manner as to touch each other, their heads being then connected to the chain of a galvanic battery of moderate tension. The action of the battery is maintained uninterruptedly for a period varying from ten to twenty-five minutes, according to the tolerance of the part, and is usually required to be several times repeated. When the tumor is large the number of needles is increased, and the direction of the current frequently changed, so as to afford a better chance for the formation of clots. As the operation is generally very painful, it is proper that the patient should be placed under the influence of chloroform during its performance. Moreover, as there is danger of seriously charring the integuments, and thus endangering the sac by mortification, the needles should be carefully coated, in a part of their extent, with gum-lac. The success of the procedure is enhanced by compression of the artery above and below the tumor, thereby preventing the clots from being washed away, before an opportunity has been afforded them of becoming consolidated and united with each other and the walls of the aneurism. The after-treatment consists in the application of ice to the part,

in perfect quietude, and in the administration of a full anodyne, to tranquillize the action of the heart and arteries.

Experience has not yet fully determined the value of this mode of treatment. That it is liable to occasional failure is sufficiently evident from the unsuccessful cases that have from time to time been published in England and on the continent of Europe. On the other hand, a considerable number of cases have been reported where its employment was followed by a perfect cure. Of twenty-two cases, collected by Mons. Boinet, in 1851, in which the operation had been practised, nine are stated as having been successful, and thirteen as having been failures. Cases of cure, by this method, of aneurism of the brachial, subclavian, popliteal, and external iliac arteries have been reported by different observers since that period, and, doubtless, others have occurred of which I have no knowledge.

Galvano-puncture is not only painful, but far from being devoid of danger. In some of the reported cases it produced severe inflammation and even supuration of the sac, followed by great swelling of the limb, together with excessive constitutional disturbance threatening the destruction both of the part and system. The operation is, therefore, a hazardous one, and on this account should never be attempted without due consideration of its consequences, especially when the aneurism is large and situated at, or near to, the trunk. Coupling this circumstance with the want of success of the operation, and the severe pain attending its execution, not to say anything of the danger of producing sloughing in the skin and sac by the action of the galvanic fluid as it is being transmitted from the battery to the tumor, it is questionable whether it is worthy of repetition, notwithstanding the high estimate placed upon it by Pétrequin, Burci, and some other surgeons. The force of this conclusion derives additional support from the facts collected by Mons. Boinet, that in seven of the successful cases, above referred to, compression and ice were employed simultaneously, thus creating a just doubt in the mind of the inquirer whether these agents had not as much to do with the cure as galvano-puncture, if, indeed, not more. I am not aware that this operation has ever been performed in this country, and I trust that it may never be undertaken by any one who is not perfectly familiar with the pathology of the disease.

g. INJECTION.

Attempts have been made in modern times to effect the radical cure of aneurism by the injection of certain fluids with a view of favoring the concretion of the blood, the consolidation of the sac, and the obliteration of the affected artery at the seat of the disease. The practice was originally suggested, early in the present century, by Professor Monteggia, of Milan, who proposed the use of solutions of acetate of lead, tannin, and other astringents, as, in his opinion, well adapted to the purpose, although he never, it would seem, performed the operation. His idea was that, by throwing these substances into the sac, so as to bring them fully into contact with the blood within, it might be possible to provoke the rapid formation of coagula, and thus effectually arrest the circulation. He supposed, moreover, that the remedy might occasionally be advantageously combined with Brasdor's operation and with compression of the artery upon the cardiac side of the tumor, applied by means of a tourniquet or some other suitable instrument, very much as it is performed at the present day. The suggestion of the Italian surgeon, however, received little, if any, attention, until within a comparatively recent period, when it became the subject of numerous experiments upon the inferior animals, as the sheep, dog, and horse, principally by the French practitioners, who, after having tried various articles, have at

length been induced to give a decided preference to a concentrated solution of perchloride of iron in water. The fluid is introduced into the sac by means of a small glass syringe, invented by Mons. Pravaz, of Lyons, and represented in fig. 255, a puncture having previously been made with a deli-

Fig. 255.

Pravaz's syringe.

cate trocar and canula, the latter of which is retained in the sac until the injection is completed. The piston of the syringe is moved by means of a screw, so as to enable us to perform the operation more steadily, and without the risk of throwing in more than five or six drops of fluid, that quantity having been found to be quite sufficient for the purpose. As it takes at least half a minute before the blood can be made to coagulate, during which the heart performs not less than thirty-five pulsations, it is necessary to keep the contents of the tumor perfectly quiet, while the injection is progressing, by compression of the artery immediately above and below the aneurism.

The operation is generally productive of severe pain, and as it is liable to be followed by considerable inflammation, it often becomes necessary to make use of antiphlogistic measures, both locally and constitutionally. Its repetition must be governed by circumstances; if everything passes off well, and the sac is promptly solidified, no further interference will, of course, be demanded; but if the reverse be the case, a similar quantity of the solution is thrown in at the end of the third or fourth day, and in the same cautious manner as before. The slightest inflammation of the tumor contraindicates the repetition of the injection.

Since 1853, when Mons. Pravaz first published the results of his experiments on animals, a number of cases have been reported in which injections of the perchloride of iron have been employed in aneurism of different parts of the body, as well as in aneurism of different kinds, as spontaneous, traumatic, and varicose. The arteries upon which the disease occurred were the supra-orbital, carotid, humeral, ulnar, femoral, popliteal, and tibial.

Although a few cures have been effected by this treatment, yet such is the great risk of inflammation, suppuration, and even gangrene, both of the sac and of the surrounding structures, that it is extremely questionable whether any prudent surgeon should repeat it. Of eleven cases, reported by Malgaigne in 1854, it is announced that four had proved fatal, that every one had had bad symptoms, and that only two had been successful. This statement alone, if true, as no doubt it is, is sufficient to condemn the operation as unsafe, and to render its adoption improper in the face of the more unexceptionable methods of ligation and compression. The great desideratum is to discover an article, which, while it shall promptly coagulate the blood, will not cause any severe irritation in the sac and the parts around it. It has been supposed that the acetate of the peroxide of iron might have this effect, but, although at least one successful cure by its use has been reported, yet it has not been tried sufficiently often to enable us to pass any definite judgment respecting its true merits. I should myself have more confidence in the efficacy and safety of the persulphate of iron, generally known as Monsel's salt, than in any other preparation of this metal. It is perfectly destitute, or nearly so, of caustic properties, and is the most prompt and efficient coagulator of the blood of which we have at present any knowledge.

h. MANIPULATION.

Very recently the attention of the profession has been called to a new treatment of aneurism by Mr. Fergusson, of King's College, London. It is termed the method by manipulation. It consists in the forcible squeezing of the tumor, with the intention of breaking up its fibrinous contents in order that some of the fragments thus detached may be carried by the circulation into the distal extremity of the artery, thereby closing its orifice, and so effecting a radical cure. The operation was first performed in 1852, in a case of aneurism of the right subclavian artery, seated partly within and partly on the outside of the scalene muscles, the tumor being about the size of a hen's egg. The sac being emptied of fluid blood, its sides were forcibly rubbed against each other, with the immediate effect of an arrest of pulsation in all the vessels in the limb below. The pulsation, however, returned in about seven hours, and the manipulation was accordingly repeated the next day with a similar result, but it was not until the end of a week that any permanent impression appears to have been made upon the circulation. The tumor now gradually diminished in size, and everything gave evidence of an ultimate cure, when suddenly, seven months afterwards, the patient was seized with violent fever attended with excruciating pain in the part, and died after a few days' illness. Although the axillary artery was found, on dissection, to have been blocked up, the tumor, instead of being obliterated, not only remained hollow, but had extended downwards over the axillary plexus of nerves, the pressure upon which had probably caused the excessive pain which immediately preceded dissolution. In another instance, operated on by the same gentleman, the result was more fortunate, but the cure was not finally effected until towards the end of the second year. Within the last few years several other cases, also successful, have been reported by other surgeons, among whom I may mention Professor Blackman, of the Medical College of Ohio.

In a case of popliteal aneurism recently reported by Mr. Teale, of Leeds, this plan of treatment was successfully conjoined with digital compression. After the latter had been carried on for some time with, apparently, very little effect, a portion of clot was detached, leading at once to the consolidation of the tumor.

I have not had an opportunity of trying Mr. Fergusson's plan of treatment, but it is, I think, extremely questionable whether it ought to be repeated. The great objections to it are, first, the uncertainty of the operation, even when the distal end of the artery has been blocked up; secondly, the tardiness of its progress; and thirdly, the danger that some of the detached clots may find their way into the brain, as in aneurism of the neck, thus causing fatal apoplexy, as has already happened in several cases in which the method has been tried. If employed at all, therefore, it should, in my judgment, be restricted to aneurism of the subclavian, axillary, femoral, and popliteal arteries, in the early stage of the disease, before the tumor has acquired any considerable bulk.

i. VALSALVA'S TREATMENT OF INTERNAL ANEURISM.

Internal aneurisms, inaccessible to the ligature and compression, occasionally recover under a regular and systematic course of treatment designed to promote the coagulation of the blood in the interior of the tumor, by increasing the plastic properties of this fluid, and quieting the action of the heart and arteries. This treatment, which was originally suggested by Valsalva, and which still bears his name, consists in the strict observance of the recum-

bent posture, perfect mental quietude, the occasional abstraction of blood from the arm, and the use, simply, of a sufficiency of food and drink to prevent starvation. When, writes Morgagni, Valsalva had taken away as much blood as was deemed necessary, he diminished the diet "more and more every day, until only half a pound of pudding was taken in the morning, and in the evening half that quantity, and nothing else except water, the weight of which was also regulated, and which he medicated with what is called quince-jelly, or the lapis osteocolla, ground down into a very fine powder. After the patient had been sufficiently reduced by this method, so that he could scarcely raise his head from the bed, to which, by Valsalva's direction, he was confined, the quantity of aliment was day by day increased, until the strength that was necessary to enable him to get up had returned." Most modern writers, in speaking of this method, recommend, as important adjuvants, the internal exhibition of digitalis, acetate of lead, and opium, with a view of insuring more speedily and effectually the ends proposed by Valsalva and his followers; the digitalis being given to diminish the number and force of the pulsations of the heart and arteries, the lead to increase the coagulability of the blood, and the opium to allay pain and nervous irritability.

We have no account of the number of cases of aneurism successfully treated by Valsalva by this method, but that he cured several persons with it is a conjecture warranted by the statements of Morgagni, by whom it was first described. What is still more to be regretted is the fact that we are equally ignorant in regard to the results obtained by others. But, notwithstanding this, it seems to me that the treatment is worthy of more attention than it has hitherto received, especially of late years, when so little has been said and done concerning it. The question, however, arises whether it might not be beneficially modified, so as to render it better adapted to the attainment of the object which it is designed to accomplish. In reflecting upon the subject, some years ago, it occurred to me that, instead of bleeding and starving the patient, upon which so much stress was laid by the Italian practitioner, the end might be more easily and speedily obtained by the abandonment of the lancet altogether, and the substitution of nutritious food, in as dry, concentrated, and non-stimulant a state as possible. If the object be to procure a more plastic and coagulable condition of the blood, to promote the formation of clots, this can certainly be done much more advantageously, as well as in a much shorter time, by such a course than by one of an opposite character. Repeated bleeding and a light farinaceous diet, comprising a little pudding and jelly, taken twice a day, must, unquestionably, render the blood very thin and watery, and therefore less disposed to fibrinization, the very reverse of what is really needed for the cure of aneurism. It would be more in accordance, then, with sound physiology and practice, to refrain from venesection entirely, and to put the patient upon a moderate allowance of food, as a few ounces of equal parts of hashed meat and bread, potato, or rice, at dinner, with a suitable quantity of stale bread, toast, or cracker at breakfast and supper; tea, coffee, and all other drinks, excepting water and lemonade, as well as all kinds of condiments, being scrupulously avoided. The patient should be kept perfectly at rest, in the recumbent posture, with the mind in as tranquil a state as possible, while the system should be steadily maintained under the free use of the tincture of aconite, or of veratrum viride conjoined with acetate of lead and opium, or, what would probably be better, the persulphate of iron. The pulse should be brought down, if practicable, to forty or forty-five beats in the minute, and the chances of success would be all the greater if a prolonged state of somnolency could be maintained, the patient sleeping the greater part of the twenty-four hours. Protracted constipation of the bowels should be aimed at; if purgatives become indis-

pensable, they must be of the mildest character, as all irritating and gripping articles are sure to do harm by exciting the action of the heart and arteries.

The length of time during which this treatment should be continued must vary according to the circumstances of each individual case, and no attempt should, therefore, be made to reduce it to any general principles. It certainly might, with judicious management, be kept up, without detriment, for several consecutive weeks. As the patient emerges from it, he should return, but most gradually and cautiously, to his accustomed diet, except that, for a long time afterwards, it should be free from all stimulants; nor should he, for many months, take any, except the most gentle, exercise. In short, everything should be done calculated to second nature in her efforts to effect the cure thus auspiciously begun, and which, other things being equal, will always be so much the more likely to take place if the aneurism be small and of recent standing.

Since the publication of the first edition of this work, I have had an opportunity of treating three cases of intra-thoracic aneurism according to the plan here sketched; but, although the patients seemed to be materially benefited, as far as their pain was concerned, and the pulse was brought down below fifty, I was not able to satisfy myself whether the progress of the disease was at all retarded. It is proper, however, to add that all the cases were far advanced when they fell into my hands.

j. GENERAL MEDICAL TREATMENT.

Persons affected with aneurism often experience, as stated elsewhere, great pain and other suffering, both from the inflamed condition of the tumor and from the pressure which it exerts upon the surrounding parts. In aneurism of the thoracic portion of the aorta and of the arteries at the root of the neck, the pain and dyspnœa are sometimes excessive, demanding prompt and vigorous measures for their relief. If the patient be plethoric, and the pulsation in the tumor uncommonly active, the loss of twelve, fifteen, or twenty ounces of blood will be useful, but care must be taken not to carry the venesection too far, otherwise injurious reaction may take place, and thus aggravate the suffering. When the tumor is accessible, or situated externally, whether partly or entirely, the blood is often most advantageously abstracted directly from the part by means of leeches, which, even when employed only in small numbers, generally afford immense relief, both as it respects the pain and the difficulty of breathing. Topical depletion is always extremely serviceable in inflamed aneurism, and it is here also that fomentations and refrigerating lotions, simple or medicated, come into play, frequently exerting their happiest influence. Our choice of these remedies must be governed in these, as in other cases, by the tolerance of the part and system. Attention to position and rest must be enjoined, and strictly carried out. The bowels are not neglected, but great care is taken to avoid active purgation, experience having shown that such a procedure always produces undue excitement of the vascular and nervous systems. Anodynes are always well borne in these cases, and should be administered in full doses, either alone or in union with diaphoretics and expectorants, according to the state of the skin and of the respiratory organs. Any complications that may arise during the progress of the disease, whether self-existent or dependent upon the irritation produced by the pressure of the tumor, must be treated upon broad general principles.

FALSE ANEURISM.

A false aneurism consists, as already stated, of a pulsating tumor formed external to the affected artery, and, consequently, without any aid from its

tunics, which are altogether excluded from its composition. A number of affections, of a very opposite character, have been described under this appellation, and the result has been, as might have been anticipated, much confusion. To remedy this evil, I shall limit myself, in the account which I am about to give of the disease, to two varieties of false aneurism, the arterial and arterio-venous, the tumor in each being strictly circumscribed, and connected, in the former, with an artery, and, in the latter, both with an artery and a vein. What is called a diffused aneurism is, in fact, as stated elsewhere, no aneurism at all, but merely an accumulation of blood in the subcutaneous and intermuscular cellular tissue, which, although it may be somewhat condensed around it, yet does not, in reality, in the true meaning of the word, constitute a proper aneurismal sac.

The most common cause of the spurious arterial aneurism is external injury, as a stab or puncture, such, for example, as is so often inflicted in venesection at the bend of the arm, permitting the blood to escape in small quantity into the surrounding cellular substance, which is soon condensed into a firm, circumscribed, pulsating cyst, often not exceeding the volume of a pullet's egg, and of a rounded or ovoidal figure. Similar effects occasionally follow the laceration of an artery, as that of the ham, from the sudden and forcible extension of the leg, from the intrusion of the sharp end of a broken bone, or from ulcerative action.

Sometimes the aneurismal formation is secondary; that is, consequent upon the partial cicatrization of the wound, the interposed or overlying plasma being unable to withstand the impulse of the blood, and so yielding before it. However induced, all the tunics of the artery are at once perforated, and the blood is sent abroad into the circumjacent cellular tissue, in the manner and with the effect just stated.

The sac in this variety of aneurism, formed originally, as has just been remarked, out of the neighboring cellular tissue, is speedily strengthened by the effusion of plastic matter, so that, in time, it often acquires considerable thickness with an extraordinary degree of density. I have seen a number of cases where the cyst, even at an early stage of the disease, was of a very firm, compact, fibroid consistence, and of a white, glistening appearance, its substance being convertible, by dissection, into several distinct strata. The tumor, particularly in cases of long standing, generally contains well organized concretions, arranged in the same concentric manner as in the true sacculated aneurism, and presenting a similar hue and consistence. The course, symptoms, and termination of this disease do not require any special notice, as they do not differ, in any respect, from the ordinary form of the affection.

The *treatment* may be conducted by compression, or, this failing, by ligature. The compression is applied, as in true aneurism, upon the cardiac aspect of the tumor, four, six, or eight inches from it, with the instrument already described, retardation of the circulation and gradual obliteration of the sac being steadily kept in view. If an operation becomes necessary, a free incision is carried across the tumor, and a ligature applied immediately above and below, as in an ordinary wounded artery. The tumor may then be dissected out, or, as some prefer, though I think improperly, it may be left to the influence of the absorbents. As a preliminary step, a tourniquet is cast around the limb to control the circulation in the affected vessel. Although one ligature is occasionally sufficient to effect a cure in this disease, yet I would strongly advise the ligation of the vessel both above and below the swelling, lest trouble should arise on account of the recurrent circulation, and thus lead to the necessity of doing at a subsequent period what ought to have been done in the first instance. The memorable case of Anel affords an excellent illustration of the fact that an aneurism of this kind, espe-

cially when seated at the bend of the arm, may occasionally be cured by a ligature applied just above the tumor.

1. The *arterio-venous* aneurism, originally described under the name of varicose aneurism, consists of a tumor which is situated, as the term implies, between a contiguous artery and vein, so as to admit of a ready interchange of the two kinds of blood. The most common site of the lesion is the bend of the arm, as seen in figs. 256 and 257, where it is generally caused by a puncture in bleeding, in which the overlying vein, usually the median basilic, is completely transfixed along with the superficial wall of the brachial artery. A similar accident may, of course, happen in any other part of the body, from a stab or wound of a contiguous artery and vein, as between the femoral, or between the aorta and vena cava. Sometimes, again, the aneurism forms in consequence of ulceration, beginning in one vessel and gradually extending to the other, and so eventually establishing a communication between them through the intervention of a sac.

In whatever manner the aneurism is formed, the cyst is usually of small size, seldom exceeding, and not often equalling, that of a pullet's egg. It is

Fig. 256.

Varicose aneurism ; external appearance.

composed partly of condensed cellular substance and partly of plastic matter, the latter always greatly predominating, as is shown by its extraordinary thickness as well as density, which closely resembles that of the fibrous tissue. The tumor, although it is seldom the seat of much pain, interferes more or less with the functions of the affected limb. The opening of communication being always very small, the blood rushes into it with a peculiar noise, not unlike that produced by the buzzing of a fly in a paper box, or the purring of a cat. Sometimes it is of a whirring character, similar to the prolonged articulation of the letter R. It is perceived both by the ear and finger, and is so extraordinary that it may be regarded as pathognomonic of the nature of the affection. The sac rarely contains any well-formed fibrinous concretions, and, on laying it open, it is often found to be perfectly smooth and white, like the interior of an artery. Manifesting little disposition to increase, it sometimes remains stationary for years, but seldom, if ever, undergoes spontaneous cure, or terminates in rupture, ulceration, or gangrene.

When the tumor is very small, not exceeding the volume of a filbert or a pigeon's egg, and does not occasion any suffering, interference is neither desirable nor proper; it is merely an inconvenience, and had better be let alone. The reverse, however, is usually the case, and then the same treat-

Fig. 257.

Varicose aneurism ; internal view. a. The artery. b. The vein. c. The intermediate cyst.

ment will be required as in spurious aneurism connected with an artery only; that is, the vessel is tied just above and below the tumor, which is left to undergo absorption, lest its removal should give rise to phlebitis in consequence of the unavoidable injury inflicted upon the affected vein.

When the disease occurs in connection with the aorta and vena cava, operative interference will, of course, be out of the question; nor can anything be hoped for from medical treatment. The case, in fact, is irremediable, and will be sure, in time, to cause death, either by the gradual giving way of the sac, or by exciting violent irritation, pain, and constitutional disorder.

2. *Aneurismal varix*, fig. 258, consists in a direct communication between a contiguous vein and artery, without the intervention of a sac; it differs, therefore, essentially from a varicose aneurism, in which, as has just been seen, there is always a distinct cyst, formed out of the surrounding tissue, along with more or less plasma. The affection is altogether so unlike aneu-

Fig. 258.

Aneurismal varix.

rism, whether true or spurious, that it is surprising it should ever have been included under the same category.

The cause of aneurismal varix—a disease first described by Dr. William Hunter, in 1756—is usually some external injury, such as a puncture, transfixing a vein and piercing the contiguous wall of an underlying artery. Hence, the lesion is most common at the bend of the arm, between the median basilic vein and brachial artery, in consequence of venesection. It may, however, occur between other veins and arteries lying in juxtaposition with one another, either through accident, or from the effects of ulceration commencing in the coats of one vessel and gradually perforating those of the other. The orifice of communication is usually small, and of a circular shape, with well-defined margins, although there is, in this respect, no particular uniformity. The adhesion between the two vessels is generally very firm, as well as of considerable extent, and it is well that it should be so, otherwise there would be constant danger of the connection giving way. Owing to the incessant interchange and commingling of the two kinds of blood, the vessels gradually undergo important changes, the most interesting of which are that the vein assumes the properties of an artery, and the artery those of a vein. The vein, from the impetuous manner in which the arterial blood is sent into it at each stroke of the heart, becomes greatly enlarged both above and below the abnormal opening, at the same time that it acquires an extraordinary degree of density, and pulsates with unusual force. In the arm, where I have met with several instances of this disease, I have found the dilatation of the vein extend, on the one hand, nearly as high up as the axilla, and on the other, as low down as the middle of the forearm. The artery, which now receives black blood, but not in any large quantity, is eventually transformed into a soft, thin, flexuous tube, which, possessing rather the properties of a vein than those of an artery, pulsates but feebly under the finger.

The formation of this disease is generally attended with some degree of pain and swelling, along with interstitial effusions, causing the integuments

to pit slightly on pressure. The parts below the seat of the lesion are imperfectly nourished, and hence they usually feel somewhat cold and numb until the circulation is fully re-established through the agency of the collateral branches. As the blood passes from one vessel into the other it produces a peculiar jarring sensation and a singular whirring noise, not unlike the purring of a cat, which often extends to a great distance along the dilated vein, now performing the vicarious functions of an artery, and which may be regarded as the pathognomonic signs of the disease.

In the cases of this lesion which have fallen under my observation, the inconvenience has been so trifling that I have not considered it proper to resort to operative interference. In one instance the patient had an aneurismal varix on the right arm from venesection performed upwards of fifteen years previously, and, although he was a blacksmith and a hard working man, it did not in the slightest degree interrupt his occupation. When trouble arises so as to render treatment necessary, relief may be attempted by compression of the brachial artery, as in varicose aneurism; this failing, the artery should be exposed by a careful dissection, and a ligature applied both above and below the orifice of communication, all disturbance of the vein being avoided.

SECT. VII.—ANEURISM OF PARTICULAR ARTERIES.

ANEURISM OF THE THORACIC AORTA.

The merest glance at the situation of this vessel is sufficient to impress us with the great importance of its relations, and to show that any deviation from its normal condition, however slight, may be productive of the most frightful consequences.

The disease may exist, 1st, as a fusiform expansion; 2dly, as a dilatation of the coats of the vessel, affecting the greater portion, if not the whole, of its circumference; or, 3dly, as a true, false, or mixed aneurism, properly so called, of variable size and shape, generally connected with the anterior or lateral aspect of the artery, the posterior part being seldom implicated. The ascending portion and arch of the aorta, especially the latter, are by far the most frequent seats of the disease, owing to their vicinity to the heart, which thus imparts to them its impulsive and expansive movements, and to their greater proneness to fatty and other degenerations, rendering their tunics weak and brittle, and consequently liable to laceration. In most cases, the aneurism is of the true species, commencing as a sac-like enlargement, which, as it increases, usually inclines to the right side of the chest, and is capable of acquiring a volume equal to that of a double fist. It soon becomes occupied with organized clots, which occasionally, though very rarely, accumulate to such an extent as to lay the foundation of a spontaneous cure. The opening of communication between the tumor and the artery varies in size from that of a dime to that of a twenty-five cent piece.

The disease, which is more common in men than in women, not unfrequently arises at a comparatively early age, as from twenty-five to thirty, in consequence, apparently, of severe straining and other bodily exertions. Sailors and mechanics are peculiarly liable to it. The astonishing frequency of aneurism of this vessel is shown by the tables of Mr. Crisp, embracing 915 cases, of which 382 affected the thoracic aorta.

The duration of thoracic aneurism varies from a few months to upwards of three years, the average being from nine to twelve months. The tumor usually bursts into the left pleura, pericardium, trachea, bronchial tubes, œsophagus, or posterior mediastinum; sometimes into the heart, lungs, or spinal

canal, and sometimes, again, but also very rarely, externally. Dr. Darrach, of Illinois, has shown by an analysis of twenty-three cases that aneurism of the descending aorta terminates pretty uniformly by rupture, while that of the arch generally ends by exhaustion and irritation, or some concomitant disease of the heart, brain, lung, or kidney. Occasionally the tumor gives way when it is not larger than a pullet's egg.

The *symptoms* of aneurism in this situation are chiefly of a mechanical character, arising from the pressure of the tumor upon the surrounding structures. They consist mainly of pain, cough, dyspnœa, dysphagia, enlargement at the sterno-clavicular region, and of various kinds of sounds, synchronous with the action of the heart.

Pain, from the constancy of its occurrence, is a symptom of great value. It comes on early in the disease, is more severe in sacculated than in fusiform aneurism, and is evidently dependent, at first, or so long as the tumor is comparatively small, upon the pressure which the aneurism exerts upon the spinal and sympathetic nerves, and afterwards upon this cause and upon the erosion and perforation of the tissues, especially the sternum, ribs, and vertebræ. It varies much in degree, character, and situation. In the earlier stages of the disease it is most conspicuous on the left side; it is sharp, lancinating, and intermittent, not unlike the pain of neuralgia, darting about in different directions; at one time into the neck and face, at another through the chest and spine, now along the shoulder and arm, and now through the diaphragm and even the loins. As the tumor enlarges, and erodes, by its pressure, the neighboring structures, the pain becomes more steady, fixed, and severe; it gradually shifts to the right side, and is generally of a burning, gnawing, or boring character.

Cough is also a common symptom; it generally begins early in the disease, and is liable to severe exacerbations, often productive of intense suffering. It is of a crowing, stridulous, or ringing character, and it obviously depends upon the irritation caused by the pressure of the tumor upon the air-passages. Sometimes it is short, spasmodic, and laryngeal.

Dyspnœa is always more or less distressing, especially when the disease has made considerable progress, and is invariably aggravated by severe bodily exertion, as in walking up a hill, or ascending a flight of stairs. It is occasionally extremely violent, although the tumor may not exceed the size of a walnut, owing to the pressure which it exerts upon the trachea, or the trachea and bronchial tubes. During the latter stages of the complaint, the breathing is always so difficult as to prevent the patient from lying down, perhaps for days before he expires.

Dysphagia is seldom present until after the disease has made considerable progress, although it is sure, in the end, to become a prominent symptom; so that, ultimately, the sufferer finds it very difficult to swallow anything either in the form of food or drink.

It is not often that there is any external tumor, except when the aneurism points in front of the chest, as it frequently does in the latter stages, after it has partially destroyed the sternum and the ribs, or the ribs and intercostal cartilages. In the great majority of cases it shows itself on the right side of the chest from three to four inches below the collar bone, as a pulsating swelling, lifting up the integuments synchronously with the contraction of the heart, furnishing a distinct bellows, sawing, or purring sound, and being exquisitely tender on pressure. Occasionally the sac projects into the neck above the fourchette of the sternum, inclining towards the right sterno-clavicular articulation. When this is the case, it must necessarily overlap the innominate, common carotid, and subclavian arteries on the right side, and may even so effectually compress them as to cause their obliteration, although such an event is very unusual.

A distinct aneurismal sound, or purring tremor, is usually perceptible at an early stage of the disease, although it is extremely difficult, if not impossible, always to refer it to its proper source. It is synchronous with the beat of the heart, and gradually becomes more and more faint as the disease advances, in consequence of the progressive filling up of the sac by coagula.

Among the less constant symptoms are, palpitation of the heart, wheezing, panting, or asthmatic respiration, tracheal and bronchial râles, sense of constriction of the chest, œdema and lividity of the face, feebleness and irregularity of the pulse at the wrist, from the pressure of the tumor upon the innominate or subclavian artery, and anasarca of the extremities, especially the inferior. Alteration of the voice is by no means uncommon, and occasionally amounts to complete aphonia. In the more advanced stages of the disease there is also frequently an enlarged and varicose state of the subcutaneous veins over the upper part of the chest, generally towards the right side.

Now, although intra-thoracic aneurism manifests itself by numerous symptoms, yet there is not one that can be considered as absolutely *diagnostic*. It is not surprising, therefore, that the disease should occasionally terminate fatally, without any suspicion as to its true nature. Such an error will be most likely to happen when the tumor is small, or when it bursts into some neighboring canal before it has sensibly encroached upon the walls of the chest. As it increases in volume, its character becomes daily more and more apparent, and all doubt must, of course, vanish when the tumor points externally, although even then a careless practitioner might regard it as an abscess, and, under this supposition, be perhaps even induced to open it, as I have known to be done in two cases, notwithstanding the heaving and pulsating nature of the swelling, and the existence of all the other signs of aneurism. When the aneurism arises from the summit of the aorta, the tumor projects into the root of the neck, and may indeed ascend so high up as to simulate aneurism of the innominate or carotid artery. From this, however, it may in general be readily distinguished by the history of the case, by the impossibility of tracing with the finger the lower boundary of the tumor, by the dulness on percussion of the upper part of the chest, and by the presence of a larger amount of dyspnoea than usually attends cervical aneurism, particularly in its earlier stages.

The auscultatory signs rarely afford any conclusive evidence of intra-thoracic aneurism. Few surgeons are able to discriminate between the sounds of the heart and those of such a tumor, and the difficulty must necessarily be much increased when, as not unfrequently happens, aneurism and cardiac disease co-exist. When the heart is sound, and the aneurism has attained a considerable bulk, the diagnosis will be less ambiguous; but even then it will require a very practised ear to detect the varying shades of difference. The sound of a thoracic aneurism is more like the purring of a cat than the clear murmur attending the first sound of the heart, and its distinctive features are still further defined by the presence of a peculiar tremor or vibratory movement. In the sacculated variety of the affection, it is often impossible to distinguish any abnormal sound whatever; at first, because of the small size of the swelling and subsequently, because the tumor is filled with coagula, impeding, if not preventing, the transmission of sound. In fusiform aneurism, and also in simple but extensive dilatation, the sound characteristic of the disease is generally easily recognized throughout its entire progress.

Dulness on percussion, in a marked degree, can exist only in the event of the tumor being of considerable bulk; a small aneurism may be present, and even prove fatal, without any change of resonance. When there is dulness, it is always most conspicuous at the upper and middle parts of the chest.

Sometimes valuable diagnostic information may be derived from the dis-

placement of the heart by the tumor, its pulsations being perceived in an abnormal position, where there is no evidence of pleuritic effusion or disease of the lung to account for the change.

Among the affections with which aneurism of the thoracic aorta is most liable to be confounded are malignant tumors of the chest, especially enccephaloid, disease of the heart, as hypertrophy and valvular derangement, and aneurism of the innominate, carotid and subclavian arteries. The best security against error will be an attentive consideration of the history of the case, and a thorough study of its progress, time often throwing more light upon the character of the malady than the most elaborate auscultatory explorations.

The *treatment* of intra-thoracic aneurism resolves itself into the adoption of measures calculated to relieve the patient's sufferings rather than to cure his disease, of which there is, in any case, hardly even a remote possibility. If plethora exist, an occasional bleeding cannot fail to ameliorate, at least for a time, the pain and difficulty of breathing. The circulation should be controlled by the cautious exhibition of *veratrum viride*, the diet be light and concentrated, the bowels maintained in a soluble state, and suffering allayed by anodynes. Perfect quietude of mind and body must of course be observed.

ANEURISM OF THE INNOMINATE ARTERY.

The relative frequency of aneurism of the innominate artery does not admit of any definite statement, owing to the great discrepancy in our statistics. Thus, in 179 cases of spontaneous aneurism, excluding those of the aorta, analyzed by Lisfranc, the innominate is mentioned only four times, while the carotid is mentioned seventeen times and the subclavian sixteen. In Mr. Crisp's table of 551 cases, embracing 234 of aneurism of the aorta, the innominate was affected in 20, the carotid in 25, and the subclavian in 23. The disease, as in the other arteries, is much more common in men than in women, and in the laboring than in the higher classes of persons. The greatest number of cases occur between the thirty-fifth and fifty-fifth year. It may exist by itself or be associated with aneurism of the arch of the aorta, the carotid, or subclavian. The extent of involvement varies from the slightest increase of the normal size to an enormous tumor, either tubular, fusiform, or sacculated in its character. Whether every portion of the vessel is equally liable to be affected is uncertain, but observation has shown that the disease is sometimes situated so low down as to become identified with the arch of the aorta, while at other times it is so high up as to extend into the carotid and subclavian. Occasionally, it is limited to the middle of the vessel, each extremity retaining its healthy appearance.

Symptoms.—Aneurism of the innominate artery usually begins as a small tumor at the right sterno-clavicular articulation, between the trachea and the inner edge of the mastoid muscle, immediately above the inner third of the clavicle. In some cases, the patient is conscious of the moment when the accident takes place, there being a feeling as if something had given way while he was shaken by a violent paroxysm of coughing or engaged in lifting a heavy weight. The tumor, at first, is generally very small, probably not exceeding the size of a little almond, of a rounded or ovoidal shape, distinctly circumscribed, and slightly movable on pressing the finger firmly down into the hollow at the top of the sternum. It is not long, however, before it increases in volume; commonly, in fact, it grows rapidly, soon attaining a large bulk, extending upwards into the neck, and laterally towards each side, but especially towards the right, where there is least resistance. As it progresses, it gradually pushes forwards the mastoid muscle, and even the sterno-clavicu-

lar articulation, forming thus a large prominence, beating and throbbing violently beneath the skin. Now and then, upon escaping from the chest, the tumor ascends high up into the neck, perhaps nearly on a level with the larynx, and when this is the case it is not uncommon for it to present a constricted, hourglass-like appearance, as if a cord had been drawn tightly across its middle.

Effects on Neighboring Structures.—The effects which the tumor exerts upon the neighboring parts, fig. 259, are chiefly of a mechanical character, and must be considered with reference, first, to the vessels of the superior extremity, neck, and head; secondly, the trachea and œsophagus; thirdly, the aorta, heart, and vena cava; fourthly, the nerves of the neck and chest; and, lastly, the sternum, clavicle, and ribs.

The pressure of the tumor upon the subclavian has the effect of weakening the force of the circulation at the wrist, and in some cases even of entirely suppressing it. Occasionally, the pulse is extremely irregular, beating not only more feebly than that in the opposite limb, but ceasing to act synchronously with it, the blood hitching and halting, as it were, on its way to the hand. Any tumor may of course produce such an effect, and hence there is nothing characteristic in it. In aneurism of the aorta, the signs of enfeebled circulation are, as a general rule, most strongly marked on the left side, owing to the fact that the tumor, from its proximity to the left subclavian, exerts a more direct and controlling influence upon that vessel than it does upon the right subclavian. The pulsation of the carotid and its branches is sometimes diminished both in innominate and aortic aneurism, but more frequently in the former than in the latter. It is, however, a rare occurrence in either case, and therefore of no diagnostic value.

Compression of the veins at the root of the neck, as the innominate, jugular, and subclavian, but especially the first, by impeding the return of blood to the heart, will occasionally cause *œdema* of the right side of the head, face, and eyelids, and of the corresponding limb, extending as low down as the hand and fingers. The occurrence, however, is uncommon, and it is probable that it may be due, in part, to injury sustained by the right lymphatic duct, situated just behind the tumor.

As the tumor enlarges, it necessarily encroaches more and more upon the trachea, pushing it over towards the left side, and at the same time somewhat backwards. When the displacement is considerable, the patient will breathe with difficulty, and will occasionally be unable to lie down, owing to the mechanical obstruction to the introduction of the air. Should the tumor be situated unusually low, or be of extraordinary size, it may compress and flatten the right bronchial tube. Dyspnoea from both of these causes, however, is less frequent in aneurism of the innominate artery than in aneurism of the arch of the aorta, owing to the fact that, in the latter disease, the tumor enlarges most in a backward direction, its progress forwards being interfered with by the sternum and clavicle. Displacement of the œsophagus

Fig. 259.

Aneurism of the innominate artery, proving fatal by bursting into the trachea.

is sometimes present in both affections, but not as often as has generally been supposed. When existing in a high degree, it may seriously embarrass the function of deglutition, especially the passage of solids.

When the aneurism occupies the inferior portion of the artery, but more especially when it extends downwards into the chest, it follows, as a necessary consequence, that it must press upon the aorta, heart, and vena cava, pushing them out of their natural position, and perhaps seriously diminishing their capacity. The particular effect which such compression must exert cannot always be diagnosticated, but it is reasonable to conclude that it will manifest itself in disordered circulation, especially in tumultuous and confused cardiac action, enfeebled pulse, and more or less dyspnœa. An aortic aneurism will of course be more likely to produce such a state of things than an innominatal.

Pressure of the tumor upon the *nerves* of the neck and chest induces not only pain and cough, but gives rise, in many cases, to severe dyspnœa and dysphagia, the two latter symptoms being not always, by any means, exclusively dependent upon the displacement and flattening of the trachea and œsophagus. On the contrary, they sometimes exist in a very marked and even in an aggravated degree when there is apparently very little, if any, compression of these tubes. We must therefore look for some other explanation of these phenomena, and the most plausible one that suggests itself is that they are due to the compression of the pneumogastric, phrenic, laryngeal, and sympathetic nerves, which are thus disqualified for carrying on their appropriate function, that, namely, of receiving and transmitting, in a regular and harmonious manner, their peculiar influence to the organs to which they are distributed, and in which they play so important a part in the natural state.

The *dyspnœa*, although not a constant symptom, is yet often enough present to render it one of great importance. It varies in degree from the slightest change in the natural respiration to the most frightful embarrassment, in which the patient is almost suffocated, and unable to maintain the recumbent posture. It is of course most severe and distressing when the tumor has acquired an unusual bulk, compressing the pneumogastric and other nerves, and so interrupting their healthy action. It may be constant, or paroxysmal, coming on at irregular intervals, lasting for some time, and then gradually receding, though perhaps at no time wholly absent.

The *dysphagia* is also variable in degree, being at one time very slight, and at another so severe as almost to prevent the patient from swallowing any kind of food, whether solid or fluid. In the more aggravated cases, the difficulty is constant, and the patient finally dies exhausted from starvation. It is a remarkable fact that in almost every case of dysphagia this symptom is preceded by dyspnœa.

The *pain* which accompanies the disease is most severe in the right side, in the situation of the tumor, from which it runs in various directions, particularly along the right side of the neck and head, and the corresponding side of the chest, shoulder, and arm. Occasionally, though rarely, it is also felt keenly on the opposite side. It is generally of a dull, aching, or gnawing character, and is often so excessive as to compel the use of large doses of anodynes for its temporary subjugation.

Cough is occasionally present, probably in one case out of every three or four, but it is less common than in aortic aneurism, and is a symptom of no special value. It is evidently produced by the pressure of the tumor upon the laryngeal nerves, and varies much in frequency and severity in different cases and under different circumstances. From the same cause there is sometimes an altered state of the voice.

When the tumor is very large, and extends outwards and downwards, so as to compress the cervical and brachial plexus of nerves, it may induce par-

tial *paralysis*, as well as, in some cases, partial loss of sensation, in the upper extremity. Such an occurrence, however, is extremely rare, as the sac seldom attains such a magnitude.

There is sometimes marked alteration in the *respiratory sounds*; more frequently, however, in aortic than in innominatal aneurism. The breathing, when affected, is disposed to be stridulous, or wheezing, and this is sometimes the case even when the patient is in the erect posture. The respiratory murmur is seldom affected in innominatal aneurism, obviously because the tumor encroaches but little, if any, upon the lungs; it is only when it extends deep down into the thorax that it is likely to produce such an effect, and then, but not otherwise, there will, also, of necessity, be dulness on percussion of the chest, over the site of the disease. Both these phenomena are more frequent in aortic aneurism, because the tumor in that disease always encroaches more upon the lungs than in the former case.

Finally, the pressure of the tumor occasionally induces serious disease in the neighboring *bones*, as the sternum, clavicle, and first rib, the contiguous portions of which are liable, in the first instance, to be displaced, then to become carious, and ultimately to be wholly absorbed. In some cases there is complete dislocation of the sterno-clavicular joint.

Diagnosis.—After what has just been said, it will be easily understood that the diagnosis of innominatal aneurism must often be extremely difficult, its situation at the root of the neck rendering it liable to be confounded with aneurism of the arch of the aorta, the carotid, and subclavian. Then, again, certain tumors—fatty, fibrous, and encysted—sometimes form at the inferior portion of the cervical region, and receiving an impulse from the innominate, or even from the aorta itself, may thus simulate the disease in question. Finally, I have occasionally encountered great difficulty in determining the diagnosis of disease occurring in this situation in consequence of abnormal pulsation either of this vessel, or of the aorta, apparently dependent upon an anemic condition of the system, or neuralgia of the arteries, and so violent as to communicate a severe shock at every contraction of the left ventricle of the heart to the innominate and its two branches, the carotid and subclavian. The embarrassment, in these cases, is increased if, superadded to the pulsation at the root of the neck, there is an unusual quantity of fat, or some solid growth, and the sharp thrill so common in the arteries of anemic subjects.

On the whole, the most reliable diagnostic signs of aneurism of the innominate are, first, the situation of the tumor at the right sterno-clavicular joint, immediately above the inner third of the clavicle, where it forms a distinct, well-marked prominence; secondly, stoppage of aneurismal beat, thrill, and bellows' sound, by pressure upon the carotid and subclavian; and, thirdly, unnatural weakness of the pulse at the right wrist, with pain and œdema on the corresponding side of the neck, shoulder, and arm. In aortic aneurism, the tumor seldom projects sensibly above the sternum; certainly not before it has attained a considerable bulk, and then it is situated rather in the middle line than on the right side; the arterial pulse, if affected at all, is weakest on the left side, and there also the œdema and pain are most conspicuous; the dyspnœa, dysphagia, cough, stridulous respiration, and change of voice are more frequent than in the innominatal disease; and compression of the carotid and subclavian produces no diminution in the sounds of the tumor.

Prognosis.—The prognosis of brachio-cephalic aneurism is extremely unfavorable. The disease, it is true, may last for a considerable time, but this is very rare; in general, it progresses very rapidly, and soon reaches a fatal crisis, the tumor either opening externally, into the trachea, or into the chest, or else, as is commonly the case, wearing out the patient by constitutional irritation, asphyxia, or inanition. No instance of spontaneous cure has ever been known to occur in this disease.

Treatment.—The treatment of aneurism of the innominate has hitherto been most unsatisfactory. Owing to the short and stunted character of this vessel, and the close proximity of the aneurism to the arch of the aorta, deligation on the Hunterian principle is, of course, altogether impracticable, and hence the only resource is either to treat the disease upon the plan of Val-salva, or to tie the carotid and subclavian at the distal side of the sac, according to the method originally suggested by Brasdor. The treatment of the Italian surgeon holds out but little encouragement, the disease generally going on from bad to worse until it reaches its fatal crisis, despite the most abstemious course of dieting, rest in the recumbent posture, the use of the lancet, and the exhibition of digitalis, opium, and acetate of lead, to promote the formation of clots. With the exception of Mr. Luke's case, there is hardly an instance upon record in which it was followed by any ultimate benefit. Squeezing the tumor, if practicable, would certainly not be justifiable, as the detached clots might, and probably would, fall into the aorta, and thus cause serious, if not fatal, results on the spot, from mechanical obstruction to the circulation. The operation of Brasdor has been performed in a number of cases, which I shall place before the reader in tabular form.

In only one case have the carotid and subclavian arteries been tied simultaneously. The patient died at the end of six days. At the autopsy, the left carotid and right vertebral arteries were found occluded, showing that the circulation of the brain had been carried on by the left vertebral alone. Rossi was the operator.

In three cases, the carotid and subclavian have been successively tied, as recommended by Mr. Fearn, of Derby, England.

No.	Operator.	Sex.	Age.	Carotid ligature.	Subclavian ligature.	REMARKS.
1	Fearn	F.	28	Aug. 30, 1836	Aug. 2, 1838	Died from pleurisy three weeks after second operation. The aneurismal sac was found filled with dense, organized coagula, except a channel the size of the artery for the passage of blood.
2	Wickham	M.	55	Sept. 25, 1839	Dec. 3, 1839	The aneurism increased, and burst with mortal hemorrhage 63 days after the second operation.
3	Malgaigne	M.	—	March, 1845	Oct. 17, 1845	Four days after the operation, the tumor increased rapidly in size, the tumefaction became diffused, and the patient died on the 7th Nov. At the autopsy, the sac could not be dissected; it was confounded with the muscles; in other words, the aneurism was diffused.

In four cases, the subclavian alone has been tied, with a result of three deaths and one recovery.

No.	Operator.	Sex.	Age.	Result.	REMARKS.
1	Dupuytren	M.	40	Death	The subclavian was tied immediately above the clavicle. The tumor diminished, but the pulsations continued. The patient died on the 9th day, from exhaustion following cough and secondary hemorrhage. At the autopsy, aneurism of the subclavian was found, with dilatation of the innominate and aorta.
2	Laugier	M.	57	Death	The vessel was tied immediately above the clavicle. The patient died from asphyxia, one month after the operation. The operator had supposed the case to be one of subclavian aneurism.
3	Wardrop	F.	45	Recovery	The patient, cured of an aneurism occupying the upper part of the innominate, died two years after the operation, of a new aneurism formed above the first, apparently on the same trunk.
4	Blackman	—	—	Death	Tubular aneurism of the innominate and arch of the aorta; left carotid and subclavian obliterated; death on the eighth day from hemorrhage caused by jumping out of bed.

The carotid alone has been tied in eleven cases, of which two were cured, and the rest died.

No.	Operator.	Sex.	Age.	Result.	REMARKS.
1	Evans	M.	30	Re-covered	The tumor still existed, with constant pulsation, at the end of a year. The next year, the sac supplicated, and discharged much pus. At the expiration of nine years, there was no sign of any increase in the affection.
2	Mott	M.	55	Died	After the operation, the tumor was much diminished; but the patient died of asphyxia seven months after the operation.
3	Dohlhoff	F.	—	Died	The aneurism was much improved, but the patient died from the effects of the ligature of the carotid upon the brain. At the autopsy, the aneurism was found occupying the external side of the innominate near its bifurcation; it was as large as the fist, and filled with fibrinous clots.
4	Key	F.	61	Died	The patient died a few hours after the operation from its effect upon the brain. The vertebral arteries were found smaller than natural.
5	Vilardebo	M.	70	Died	The patient was a negro. He died on the twenty-first day after the operation. At the autopsy, two aneurisms were found; one of the inferior extremity of the right primitive carotid, the other of the trunk of the innominate.
6	Fergusson	M.	56	Died	The patient died of pneumonia on the seventh day. The tumor had diminished, and, at the autopsy, was found nearly filled with firm laminated coagula.
7	Hutton	M.	47	Died	The size of the tumor and the pulsations diminished after the operation, but the sac inflamed, supplicated, and opened into the trachea, and the patient died on the sixty-sixth day.
8	Porta	—	—	Died	The patient died forty hours after the application of the ligature. The autopsy showed an arterial dilatation of the innominate and its two branches, without true aneurism.
9	Campbell	M.	48	Died	The tumor began to disappear after the vessel was ligated, but the patient died of pneumonia on the nineteenth day.
10	Morrison	M.	42	Re-covered	The patient recovered from the operation, and died suddenly twenty months afterwards. The cause of death is not given. At the autopsy, the right carotid was found dilated in the form of a sac, and filled with a resisting fibrinous deposit. The brachio-cephalic trunk and curve of the aorta were found larger than usual, and the walls were diseased, but these vessels were not aneurismatic.
11	Wright	M.	70	Died	The patient died on the eighty-eighth day from hemiplegia. The tumor was solidified by fibrin, a canal leading through it to the subclavian. Four abscesses were found in the right hemisphere of the brain.

A careful examination of the above cases affords the following conclusions concerning the deligation of the primitive carotid for the cure of innominate aneurism:—

1. It reduces the volume of the tumor. Thus, in the case of Mr. Evans, of Derby, in 1828, although the aneurism was as large as a walnut, it entirely disappeared in a little upwards of a month. In Dr. Mott's case, in 1829, it was of the size of a pigeon's egg, and disappeared in twenty-six days.

2. The operation leads to fibrinization of the contents of the sac. These changes, which are due, not to arteritis, but to remora of the blood, were well displayed in the cases reported by Mr. Morrison, of Buenos Ayres, in 1834, and of Mr. Fergusson, of London, in 1841. In the former, the innominate artery was reduced to at least one-half its previous bulk; in the latter, the tumor was nearly filled with firm clots.

3. The operation does not involve any *special* risk. In five of the cases it was followed by death, not, apparently, from any agency of the aneurism, but because of the danger which naturally follows the ligation of the common carotid, for whatever purpose. Thus, in the case of Mr. Key, in 1830, the patient died of syncope, produced by coarctation of the left carotid and ver-

tebral arteries. In two other instances, one by Fergusson, in 1841, and the other by Campbell, of Montreal, in 1845, death resulted from pneumonia. In Hutton's case, the cause of death was inflammation and ulceration of the sac, also a very common effect of the operation for carotid aneurism, whether the ligature be placed above or below the tumor. In the interesting case of Professor Wright, of Montreal, in 1855, the patient died of abscesses of the brain, the first example of the kind on record after Brasdor's operation, although severe cerebral symptoms often succeed the ligation of the common carotid for accidents and tumors of the head, eye, and face.

4. The operation has not been productive of a long after-life: chiefly, perhaps, because the cases demanding it were nearly all inherently hopeless, from being associated with organic disease of the aorta, or of this vessel and of the heart. Distinct evidence of this fact existed in at least seven of the cases; in the rest no accurate examination was made. The influence of such complications is shown by the results which followed Brasdor's operation in aneurism of the root of the carotid unmixed with any other lesion. Of five cases of this kind, three completely recovered; one was successful so far as the aneurism was concerned; and in only one was there no improvement.

5. The operation lengthens life if perilled by rupture of the sac, or pressure on the windpipe. In fact, here is its great triumph. In the case of Professor Wright, although the man was in imminent danger before the operation, yet he survived it eighty-eight days. The mean duration of life after deligation of the carotid, under ordinary circumstances, is about four months and a half.

6. The operation has occasionally failed to effect any local improvement. This result followed in three of the cases, in consequence of a want of fibrinization of the contents of the sac.

The facts above stated, deduced mainly from the paper of Professor Wright, in the *Montreal Journal of Medicine*, clearly point, as that gentleman justly remarks, to a division of cases in regard to the applicability of the operation.

1. The most suitable cases are those of uncomplicated innominal aneurism, being akin to the pure carotid form, the sac, which is confined to the part of the vessel near the bifurcation, springing from the left segment of the artery, and not coexisting with degeneration of its tunics or cardiac disease.
2. Those imperatively requiring it are such as entail imminent danger from external rupture of the tumor or from other causes.
3. The most favorable cases are aneurisms proceeding from the left segment of the artery, because then the introduction of blood into the sac is most effectively impeded, as it is derived from the current destined for the vessel which is tied, whereas, when the aneurism is dextro-lateral, the same benefit cannot be afforded, as the supply is furnished by the subclavian. Next to this situation, the most preferable, anatomically, would be the origin of the tumor from the anterior circumference of the vessel.
4. The less advantageous cases are those in which the external tumor extends towards the middle of the clavicle, for this occurrence denotes such an engagement of the subclavian as must effectually counteract any benefit derivable from ligation of the carotid. When the swelling is equal on each side of the innominate, or symmetrical, then the only hope of a certain stasis of blood would be afforded by tying both branches.
5. The cases contra-indicating the operation are those having complications with aortic aneurism, or serious disease of the heart, unless excepted by extreme urgency.

ANEURISM OF THE COMMON CAROTID ARTERY.

Aneurism of the carotid, although less frequent than that of some of the other arteries, especially the popliteal and femoral, has, nevertheless, always

attracted much attention, for the reason, probably, that its exposed situation in the neck has afforded unusual facilities for its observation and study. However this may be, its history is perhaps, on the whole, better understood than that of aneurism of any other artery. The relative frequency of the disease has been placed before the profession by several writers. Thus, in the table compiled by Lisfranc, comprising 179 cases of aneurism, exclusive of those of the aorta, 17 refer to the carotid, the subclavian having been affected in 16, the axillary in 14, the femoral in 26, and the popliteal in 59. In the table of Mr. Crisp, the carotid is stated to have been engaged in 25 cases out of 551, embracing 234 of the aorta, giving thus a considerably larger proportion than that of the French author.

Spontaneous aneurism of the carotid is more frequent in men than in women, but not by any means in the same relative proportion as spontaneous aneurism of the other arteries. Thus, in 34 cases analyzed by Dr. Norris, 27 were males, and 7 females, being in the ratio of nearly four of the former to one of the latter; a ratio which is altogether unequalled by that of any other vessel. An idea formerly prevailed that the disease occurred here with nearly equal frequency in both sexes, but such a conclusion is totally at variance with the facts of the case.

The disease, although occasionally observed at an early *age*, is most common between the thirtieth and the sixtieth year. It occurs with nearly equal frequency on both sides, and, in fact, sometimes exists simultaneously in both arteries. No occupation is exempt from it. One would suppose, from reflecting upon the peculiarity of their pursuits, that acrobats, who are in the habit of making such violent and long-continued use of their necks, often sustaining enormous loads upon their heads, would be particularly prone to carotid aneurism, and yet the disease is hardly known among them.

The *site* of carotid aneurism is variable. Sometimes the tumor is situated very low down in the neck, close to the origin of the vessel; on the other hand, it may be seated high up, near its bifurcation. In the great majority of cases, however, it will be found to be between these two points, at or near the middle of the artery; usually rather above than below.

Symptoms.—The tumor, when first observed, is generally quite small, perhaps not exceeding the size of a filbert, and of an irregularly globular, rounded, or ovoidal shape. The patient, upon being questioned as to the history of the case, usually expresses his ignorance as to the time of its occurrence, though occasionally he is rendered conscious of it by a peculiar stabbing sensation in the neck, or a feeling as if something had suddenly snapped asunder. Commonly the surgeon is not consulted until the tumor has made considerable progress, and acquired the volume of a hen's egg, or of a small orange, the patient, perhaps, having all along supposed that the swelling was merely an enlargement of some of the cervical ganglions. A careful inspection, however, promptly reveals its true character, its pulsation, thrill, and bellows' sound affording unmistakable evidence of its close and intimate arterial connection. Pressure upon the cardiac side of the aneurism, by stopping its circulation, arrests these symptoms, and causes a sensible diminution of the size and consistence of the tumor, while pressure upon its distal side produces an opposite result. As long as it is small, the tumor may readily be moved about, and even raised out of its bed, especially if it be grasped with the thumb and forefinger during the relaxed condition of the sterno-mastoid muscle; as it augments in volume it becomes more fixed in its position, and is eventually rendered almost, if not entirely, stationary.

The symptoms of carotid aneurism are altogether of a mechanical character, being such as arise from the pressure of the tumor upon the neighboring parts; hence, their gravity is generally in proportion to the volume of the morbid growth. In the earlier stages of the disease, there is either no

functional disturbance whatever, or it is so insignificant as not to attract any special attention; by and by, however, as it progresses, the tumor necessarily encroaches more and more upon the delicate and important structures of the neck, thus occasioning congestion of the brain by retarding the return of blood in the jugular vein, numbness, pain, and cough, by compressing the cervical, pneumogastric, and phrenic nerves, and difficulty of respiration, and, perhaps, even of deglutition, by bearing against the trachea and œsophagus. The surface of the swelling, at first perfectly natural, becomes gradually indurated and inflamed, the subcutaneous veins are unusually conspicuous, and the neck is stiff, distorted, and almost immovable. The greatest enlargement of the tumor is generally in the direction of the median plane, as the resistance is much less there than externally, under the edge of the sterno-cleido-mastoid muscle.

Diagnosis.—Notwithstanding that the symptoms of carotid aneurism are usually well-marked, cases, nevertheless, occur in which they are so obscure as to render it extremely difficult to determine the diagnosis, even after the most careful and patient investigation. The affections of the neck which are most liable to be confounded with carotid aneurism, and to render the discrimination doubtful, are diseased lymphatic ganglions, abscesses, encysted tumors, goitre, dilatation of the internal jugular vein, and aneurism of the innominate artery and arch of the aorta.

Enlargement of the *lymphatic ganglions* of the neck is most common in young subjects, before the age of twenty, whereas aneurism of the carotid is rarely met with until after thirty; moreover, it is almost peculiar to scrofulous persons, while aneurism occurs in all classes of individuals, the strumous and the non-strumous. In aneurism the tumor is generally well-defined; its surface is smooth and uniform, and the swelling heaves and throbs, as if it were alive. In glandular enlargement, there is generally a chain of diseased ganglions, either scattered about in different parts of the neck, or stretched along the inner border of the sterno-cleido-mastoid muscle; the tumors feel hard, and may, with a little care, be easily separated, not only from each other, but from the carotid artery, so as to get entirely beyond the reach of its pulsation.

Aneurism of the carotid artery has sometimes been mistaken for *abscess*; the tumor has been punctured, and the patient has speedily perished of hemorrhage. Such an error, of course, implies great carelessness, and could hardly happen at the present day when our means of diagnosis are so much more perfect than formerly. The discrimination must be determined on general principles. If there be an abscess, the history of the case, conjoined with the unnatural heat and redness of the part, the rapid progress of the swelling, the febrile disturbance, and the absence of the characteristic pulsation, thrill, and bellows' sound, will be sufficient to distinguish it from aneurism of the carotid artery.

Encysted tumors, usually containing a serous or sero-sanguinolent fluid, are liable to form at the front and sides of the neck, most generally in connection with the thyroid gland, but sometimes independently of it, in the cellular tissue beneath the muscles. They can usually readily be distinguished by their slow growth and fluctuating feel, the absence of pain and pulsation, and, when they are attached to the thyroid gland, by their obeying the movements of the larynx in the act of deglutition. If, after a careful examination of their history, any doubt exists as to their real nature, the only resource will be the cautious introduction of the exploring needle.

Goitre is liable to be mistaken for carotid aneurism only when it spreads laterally over the neck, so as to overlap the carotid, and receive its pulsation. It is certainly not possible to commit any error of diagnosis in the more ordinary and simple forms of the disease. Confusion is most apt to arise when

aneurism and goitre co-exist, or when, as occasionally happens, the latter disease is developed uncommonly rapidly, and is attended with considerable local distress. Ordinarily, goitre forms in early life, at a period when aneurism is extremely infrequent; its progress is generally tardy, several years elapsing before it attains any material bulk, and is subject to occasional interruptions, and even total suspension, whereas aneurism generally advances rapidly and steadily, the symptoms proceeding from bad to worse, until it attains its crisis. Another important criterion is the fact that goitre is almost peculiar to females, whereas carotid aneurism occurs by far most frequently in men. But the most satisfactory diagnostic signs are, first, that, in goitre, the tumor obeys the movements of the larynx, whereas, in aneurism, it remains stationary, however strong the efforts at deglutition; secondly, that, in the former, the tumor may be drawn away from the vessel, raised up or pushed to one side, while in the latter the vessel follows it, forming, as it does, a part of it; and, lastly, that in goitre the general health rarely suffers, even when the tumor is of large bulk, whereas in aneurism it is always more or less impaired, especially when it has reached such a stage as to be likely to occasion embarrassment in regard to the discrimination between the two affections.

A dilated condition of the internal *jugular vein* may simulate aneurism of the carotid artery. The deception will be more likely to happen if the vein receives a pulsatory movement from the heart or from the carotid, as when the artery is overlapped by the vein. The venous tumor may generally be distinguished by its softness and compressibility, by its situation, which is commonly just above the sternum, and rather behind than in front of the mastoid muscle, and by the circumstance that its motion is more of an undulatory, wave-like, or tremulous character, than shock-like and vibratory, as in aneurism. Superadded to this is the fact that the venous swelling may be readily effaced by pressure applied to its distal extremity, whereas, in aneurism, the pressure, to produce any appreciable effect of this kind at all, must be applied to the cardiac extremity of the tumor, and then it will result only in a diminution, not in complete obliteration.

Finally, a carotid aneurism may be confounded with aneurism of the *brachio-cephalic artery* or of the arch of the aorta, especially if it be situated low down in the neck. When this is the case, the difficulty may be very great, if not insurmountable. The best diagnostic sign with which I am acquainted, and one that will rarely fail us, in such an emergency, is afforded by our ability to insinuate the point of the forefinger between the top of the sternum and the lower extremity of the aneurism, while the head is being bent powerfully forwards, so as to relax as fully as possible the mastoid muscles. If this can be done, the probability is that the tumor is connected with the carotid; otherwise we may conclude that it is formed by the innominate artery, or by the arch of the aorta.

Progress.—The progress of carotid aneurism, although usually rapid, is not so always. The annals of surgery contain several cases where the disease remained almost stationary for a considerable number of years; in one instance as many as fourteen. A spontaneous cure sometimes occurs, but such an event must necessarily be extremely rare. The tumor, if allowed to go on unchecked, eventually—generally at a period varying from three to twelve months—destroys life either by excessive constitutional irritation, hemorrhage, gangrene, pneumonia, or asphyxia. When seized by ulceration, it may burst either externally, or it may open into the pleura, the anterior mediastinum, the trachea, or one of the bronchial tubes.

Treatment.—The treatment of carotid aneurism is generally conducted according to the Hunterian principle of ligating the supplying vessel at the cardiac side of the tumor; and, fortunately, as the disease is ordinarily situated rather high up, this may commonly be done without any very great

difficulty, especially in the earlier stages of the affection, before the swelling has attained much bulk. When the tumor is of great size, or located at the inferior part of the neck, we may be compelled to adopt the method of Brasdor, and tie the carotid on the distal side of the aneurism, trusting that the blood in the tumor, no longer finding an outlet, will gradually coagulate, and so effect its obliteration. The fact is, this artery, owing to the total absence of collateral branches, is peculiarly adapted to this operation, and it is well that it should be so, seeing that, if it were otherwise, we should be obliged to resign many of the more severe cases of carotid aneurism to their fate, without any attempt whatever at surgical interference. It is obvious, from the relations of the vessels and nerves of the neck to the tumor, that compression, now so much employed in the treatment of aneurism of the lower extremity, cannot be brought in play here, the parts being intolerant of the requisite manipulation, to say nothing of the obstruction which it would occasion to the return of the blood in the internal jugular vein, which, being dammed up in the brain and the sinuses of the dura mater, might speedily induce apoplexy, and other serious cerebral symptoms, endangering the patient's life. When the tumor is of extraordinary bulk, rendering ligation of the carotid impracticable at any point, our only hope, faint though it be, is the success of general measures, particularly Valsalva's method, for experience has conclusively proved that no benefit is to be expected from the ligation of the innominate artery, as originally proposed and practised by Dr. Mott. The deligation of the terminal branches of the carotid might be tried with a better prospect of success, but this also would be likely to fail, owing to the numerous offsets of the external carotid, which, unless included in separate ligatures, would continue to transmit the blood from the tumor with sufficient force and activity to maintain its circulation unimpaired, and so inevitably frustrate the intentions of the operation.

When the tumor is unusually voluminous, or even of moderate size, but situated very low down, overlapping and compressing the trachea, the symptoms may be so urgent as to demand the operation of laryngotomy, to save the patient from impending asphyxia. Such an event must, however, be very uncommon.

A very interesting case of carotid aneurism has been related by Dr. Robertson, of Edinburgh, in which he performed an operation after the tumor had burst into the œsophagus. The swelling was situated so low down that he was compelled to ligate the vessel only half an inch above its origin from the innominate artery. Notwithstanding these unfavorable circumstances, the patient made an excellent recovery, the ligature coming away on the seventeenth day.

The operation of tying the carotid is easy enough in ordinary cases, but when the aneurism is large, or the neck very short and fat, it is one of the most difficult and trying undertakings in surgery. The principal accidents likely to attend it are the inclusion of the jugular vein and pneumogastric nerve in the ligature, and the wounding of some of the smaller vessels of the neck, which it is sometimes more difficult to find and secure than the carotid itself.

Mortality and other Effects.—Of the mortality of the operation for carotid aneurism, a tolerably accurate estimate may be formed from the data now before the profession. Of 21 cases mentioned by Mr. Crisp, 10 were successful, and 11 fatal. In 5, the artery was ligated at the distal side of the tumor, and of these, 3 recovered, the other 2 being only somewhat benefited. Of the 11 fatal cases, 5 were lost by hemorrhage, 2 by inflammation of the sac and artery, and 1 by spasm of the glottis, the cause of death in the remaining 3 being doubtful. The table of Dr. Norris contains an analysis of 38 cases, in which the carotid was tied for aneurism, including 4, however,

in which the disease was found, after the operation, not to have been connected with the artery. Of these cases, 22 recovered, and 16 died. The cause of death is mentioned in only 12 of the cases; in 5 it was hemorrhage, in 2 inflammation of the sac, in 2 apoplexy and congestion of the brain, in 1 cerebritis, in 1 spasm of the glottis, and in 1 exhaustion.

In 6 of the 38 cases, the aneurism suppurated, and either burst or was laid open; of these, 4 died and 2 recovered. In one instance the opening in the sac occurred four months, and in another nearly eight months, after the operation. In one fatal case the tumor burst into the pharynx fifteen days after the deligation of the artery, and in another case, which, however, recovered, it had discharged some of its contents into the mouth prior to the operation.

Return of *pulsation* in the tumor, after the operation, was noted in nine of the thirty-eight cases; in one the pulsation never ceased entirely for two months, and in another it continued for upwards of four months.

The detachment of the ligature occurred, in 13 cases, before the twentieth day; in 7, between the twentieth and thirtieth, and in 1 on the thirty-third day. The time, in the remaining cases, was not observed.

In seven of the cases, analyzed by Dr. Norris, there was a mistake in the diagnosis, as was proved on the dissection, for all the patients died. In four, the disease consisted of different kinds of tumors; in two, of aneurisms supposed to be abscesses; and in one, of an aneurism of the vertebral artery. The examples of mistaken diagnosis include the celebrated case of Mr. Liston, of a lad, nine years of age, who had a tumor on the right side of the neck of two months' standing, which, although seated over the carotid, was entirely free from pulsation, except along the track of that vessel. Under the conviction that it was merely an abscess, a bistoury was introduced, the removal of which was followed by a gush of arterial blood to the amount of four ounces. The bleeding being arrested by closing the wound with the twisted suture, the common carotid was tied on the following day, October 21st, close to its origin from the innominate artery. On the 3d of November, the arterial hemorrhage suddenly recurred, but was suppressed by plugging the wound with lint; it, however, again broke forth, and proved fatal on the 5th, that is, fifteen days after the operation. Although the ligature had retained its hold upon the artery, the proximal end of the vessel was found to be quite patulous, no attempt having been made at the formation of a coagulum. The probability is that, as Mr. Liston has suggested, the tumor, in this remarkable case, was originally a scrofulous abscess, a part of the wall of which was formed by the carotid; the latter, becoming ulcerated, finally gave way, and thus sent its contents into the cyst inclosing the matter.

Injury to the internal jugular vein has been a cause of death in several cases of ligation of the carotid. In an instance in which Barovero included this vessel with the artery, the patient died on the sixty-ninth day of gastric fever. Mr. Crisp met with a case where a surgeon tied the internal jugular vein instead of the carotid; the patient was a child, and the error was not discovered until after death.

Very serious cerebral and pulmonic symptoms occasionally follow the ligation of the carotid artery, and are among the principal sources of the mortality from this operation. The effects which the operation produces upon the *brain* have been elucidated both by experiments upon the inferior animals and by observations upon the human subject, and manifest themselves in various ways and at different intervals. Their full importance, however, was not known until after the publication of the researches of Mr. Chevers, of London, in 1845, to whom the profession is greatly indebted for the valuable light which he has thrown upon a subject which, up to that period, had been entirely overlooked. In the one hundred and twenty-five cases analyzed by Dr. Norris, in which the common carotid was tied either for

aneurism, wounds, or erectile tumors, more or less severe cerebral disturbance occurred in thirty. Some of these cases recovered completely, some got well of the operation, but remained afterwards in a crippled condition, and some, perhaps the majority, died, the period of death varying from a few hours to several months.

There is no uniformity either in the character or in the manifestation of the cerebral symptoms. Sometimes they come on immediately, or at all events, within a few hours after the deligation of the vessel; while at other times, and perhaps most generally, they do not appear until the end of several days, weeks, or even months. Their access is usually sudden, but occasionally so gradual and imperceptible as to keep the patient in ignorance of it until it is discovered accidentally. The most frequent symptoms, on the whole, are convulsions and paralysis. The former are sometimes general, but much oftener partial, affecting, for example, one arm, a leg, or one side of the face; in some cases, there are merely spasmodic twitches, or irregular, involuntary movements. The paralysis occasionally exists on the side of the affected artery, but in most cases it occurs on the opposite side, when it sometimes pervades one-half of the body, as in hemiplegia, though generally it is only of limited extent, being confined, perhaps, to the face, tongue, throat, fauces, eyelid, hand, arm, leg, or thigh. Sometimes there is dimness of vision, with or without dilatation of the pupil; a feeling of drowsiness, somnolency, stupor, or coma; dizziness, vertigo, or headache; noise in the ears or partial deafness; delirium, either alone or conjoined with paralysis or convulsions; difficulty of deglutition; dyspnœa; a sense of coldness, or coldness and numbness; and various other symptoms, mostly of an anomalous, nervous character. Occasionally these effects rapidly disappear, but in general they are more or less persistent, and in some cases they remain up to the moment of the death of the patient. In some instances, inflammation of the brain, or of the brain and its envelops, supervenes, either soon after the deligation of the vessel, or at a more or less remote period.

How are these phenomena produced? Are they caused merely by an inadequate supply of blood to the brain, or are they the consequence solely of a loss of equilibrium in the cerebral circulation? To these questions it is of course impossible to return anything like a definite answer. It would seem probable, from the free anastomosis which exists between the branches of the internal carotid arteries, on the one hand, and between these arteries and the vertebral, on the other, that they could not be occasioned by a mere want of blood, inasmuch as these vessels are capable of furnishing the organ with an abundant supply of that material for the purpose of carrying on its healthy functions. Nevertheless, it is not unlikely that unpleasant effects may and do follow the sudden withdrawal of a certain quantity of blood from the brain, resembling those produced by copious bleeding at the arm, or by a smart concussion of the brain. In some instances, it is reasonable to conclude that they are the result of the inclusion of an important nerve; while in another class of cases, as when several weeks or months elapse before their supervention, they would seem to be the direct consequence of inflammation. Under the latter circumstances, dissection reveals softening of the cerebral substance and effusion of serum, or of serum and lymph, in the ventricles and upon the surface of the brain.

The most constant *pulmonary* effects occasioned by the ligation of the carotid artery are cough, bronchitis, and inflammation of the pulmonary tissue. Cough is not only a very frequent occurrence, but often one of great severity, rendering it sometimes extremely difficult to check it. It generally comes on soon after the operation, in fits of a violent spasmodic character, in which the patient is in the deepest distress, looking and acting as if he were about to be suffocated. Its duration is variable; sometimes lasting only a

few hours, while at other times it continues, as a prominent symptom, for days together. When very severe, it may occasion hemorrhage in the wound, by reopening some of the vessels.

It is not easy to determine how this cough is induced. From the fact that it often follows immediately upon the operation, it is not unlikely that it may arise from the inclusion in the ligature of some nervous filament, which thus sets up irritation in the mucous membrane of the air-passages, especially of the larynx and trachea, causing an effect not dissimilar from that awakened by the sudden intromission of a drop of water into the windpipe. That the effect must be somewhat of this character would seem probable, when we reflect upon the spasmodic and uncontrollable nature of the cough which generally characterizes the attack. At other times, the cough may be purely sympathetic, or, what is more likely, may be caused by the compression of the filaments of the tri-splanchnic nerve, which are so abundantly distributed through the coats of the arteries, especially those about the neck and chest.

The effects which the ligation of the carotid exerts upon the bronchia and lungs set in at various periods after the operation, and are denoted by the usual rational and physical signs. On dissection, the mucous membrane of the former is found to be of a reddish color, either uniformly, or in patches, greatly engorged with blood, and covered with pus, or pus and lymph. The lungs are abnormally vascular, loaded with black blood, more or less hepaticized, or solidified at one point and softened at another. Blood and pus are sometimes contained in the anterior mediastinum; the pleura has been known to be the seat of extensive effusions; now and then there are traces of inflammation of the larynx and trachea; and occasionally, though rarely, the examination reveals the existence of pericarditis and endocarditis. When the inflammation of the respiratory organs is at all considerable, the blood drawn during life generally evinces a buffed, if not also a cupped appearance.

Such being the effects which are liable to follow, probably in one case out of every four or five, in the brain and lungs, in consequence of the deligation of the carotid, it is obvious that they should be carefully looked for, in order that proper measures may be adopted for their prompt and efficient removal the moment they arise. Much may be done, in most instances, by way of prevention, by a judicious preparatory course, consisting of venesection, purgatives, light diet, and repose of mind and body, which cannot fail to contribute materially to the protection both of the brain and lungs. The operation having been performed, these organs are most sedulously watched, the least indication that arises being met by appropriate means; and in this way, the case is safely conducted to a favorable issue. If the patient be pale and faint, alcoholic stimulants, cautiously and judiciously administered, will be of service; cough and convulsive symptoms are treated with anodynes and antispasmodics, particularly morphia; and inflammation is controlled by the lancet, leeches, blisters, purgatives, aconite, and antimonials.

ANEURISM OF THE EXTERNAL CAROTID.

Spontaneous aneurism of the external carotid is perhaps still more uncommon than that of the internal carotid; its history, consequently, is involved in obscurity. The situation of the tumor just below the angle of the jaw, its throbbing, pulsatile character, and its gradually increasing volume, would serve to distinguish it from ordinary growths in this portion of the cervical region.

ANEURISM OF THE OPHTHALMIC ARTERY.

Aneurism of this artery is rare, both as a traumatic and as a spontaneous affection. The former is usually caused by severe injury, and is apt to be

followed by excessive enlargement of the structures of the orbit with protrusion of the eye. A number of cases of spontaneous aneurism of this artery are upon record, in only a few of which, however, the nature of the disease has been verified by dissection. Aneurism by anastomosis is also sometimes met with. The progress of aneurism of the ophthalmic artery is usually slow, and the symptoms are always characteristic. The proper remedy is ligation of the common carotid artery as early in the disease as possible, before there is any serious structural change in the parts. Of four cases treated in this way, and recently reported by Mr. Thomas Nunneley, of London, three proved successful, the other having perished from hemorrhage on the sixteenth day. In anastomotic aneurism, a cure has occasionally been effected by injection of perchloride of iron; and lately several cases have been successfully treated by digital compression of the carotid.

ANEURISM OF THE INTERNAL CAROTID.

Aneurism of the internal carotid has been observed only in a few instances, its deep situation at the side of the neck and its exemption from ossific and fatty degeneration serving to protect it from this disease. The diagnosis must necessarily be obscure, and is generally only determined after death. The London and Edinburgh Monthly Journal of Medicine and Surgery, for 1842, contains the particulars of a remarkable case of aneurism of this vessel observed by Mr. Syme. The patient, a woman aged sixty, had had a tumor for about five months in the throat, in the usual situation of abscess of the tonsil. It had attained about the size of a large walnut, exhibited a diffused appearance when viewed through the mouth, and pulsated in a strong and characteristic manner in every portion of its extent. The ligation of the common carotid artery diminished, but did not completely arrest, the throbbing. The woman died in thirty hours after the operation without any assignable cause. Had a less careful surgeon had the management of this case, he might probably have punctured the tumor under the supposition of its being an abscess, and thus instantly hurled his patient out of existence, much to his own discredit and that of the profession.

ANEURISM OF THE VERTEBRAL ARTERY.

Aneurism of this artery, both spontaneous and traumatic, is extremely uncommon, a circumstance no doubt due to the deep situation of this vessel and to its freedom from ossification. In two very interesting cases of this disease, described by Ramaglia, of Naples, and South, of London, the diagnosis was so obscure that the true nature of the disease was not detected until after death. In both the common carotid was tied, without, of course, any benefit. In the former, which was an example of traumatic aneurism, situated behind the left ear, the operator, finding that the deligation did not arrest the pulsation, removed the ligature and treated the case upon general principles, death occurring soon after. In the other instance, in which the carotid artery could be distinctly traced over the tumor, this vessel was also tied under the supposition that it was the seat of the swelling. The tumor, however, rapidly increased, and in a fortnight after caused death by bursting into the trachea. Dissection showed that it was an aneurism of the vertebral artery, situated between the transverse processes of the fourth and fifth cervical vertebræ.

Möbus, a German surgeon, has reported a case of aneurism of the vertebral artery, the result of a wound of the neck, in which a cure was effected by compression and the use of ice.

ANEURISM OF THE SUBCLAVIAN.

Statistics prove that aneurism of the subclavian is nearly as frequent as that of the carotid. In Lisfranc's table the popliteal comes first, then the femoral, next the carotid, and then the subclavian, the latter having suffered in 16 cases out of 179. In the table of Mr. Crisp, comprising 295 cases of external aneurism, the subclavian was engaged in 23, and the carotid in 25. The disease is more frequent in the right artery than in the left, in men than in women, and in the laboring than in the higher classes. The period of life during which most of the cases occur is between the thirtieth and fiftieth years.

The disease may affect any portion of the artery, but is most frequent beyond the scalene muscles, a short distance before it becomes merged in the axillary. The form of the aneurism is generally globular or ovoidal, but cases are observed in which it has a singularly compressed appearance; and, on the other hand, it may be remarkably lobulated, especially when it is very capacious, and extends deeply among the surrounding structures, which thus indent its surface. Its volume is seldom very large, unless it becomes diffuse, when it may attain an enormous magnitude, reaching nearly up to the angle of the jaw, pushing out the clavicle, overlapping the trachea, displacing the scapula, pressing backwards against the ribs and spine, and dipping into the cavity of the chest so as to force down the lung and impede respiration.

As the tumor enlarges, it necessarily encroaches upon and compresses the neighboring parts, causing more or less pain, œdema, difficulty of respiration, dilatation of the veins of the neck, chest, and upper extremity, and a feeling of numbness and sometimes even partial paralysis. Originally small, deep seated, circumscribed, indolent, and movable, it generally steadily augments in volume, approaching, as it does so, nearer and nearer to the surface, loses its defined shape, becomes the seat of incessant pain, and at length contracts firm adhesions to the surrounding structures, identifying itself, as it were, with them. Examined with the ear and hand, it readily imparts to them the peculiar beat, thrill, and bellows' sound so characteristic of aneurism in other regions.

Diagnosis.—The diagnosis of subclavian aneurism is sometimes extremely difficult, and several cases have been reported in which the vessel was ligated where no disease of the kind existed. The affections with which it is most liable to be confounded are aneurism of the innominate artery or arch of the aorta, abscesses, and various kinds of tumors, solid and encysted, benign and malignant. As these lesions are of frequent occurrence in this region, it is impossible for the surgeon to be too cautious in his examination of cases involving questions of diagnosis.

The history of the tumor and its situation at the side of the neck, just above the clavicle, generally afford important data in regard to the diagnosis. If the patient is under thirty years of age, it may almost certainly be assumed that the disease is not spontaneous aneurism, as there are probably not three well-authenticated cases on record in which the subclavian was thus affected at this early period. Aneurism of the innominate is situated lower down, and approaches nearer to the middle line, than aneurism of its subclavian division; and in aneurism of the aorta, the tumor, although it may extend into the neck, rarely projects as far above the clavicle as in the lesion in question; certainly not in its earlier stages, when alone a correct diagnosis can be of any avail in an operative point of view. If the case be seen soon after its commencement, before the tumor has attained any considerable bulk, a very good idea may often be formed as to the precise portion of the artery that is affected by it. Thus, for example, if the aneurism occupies the space imme-

diately exterior to the sterno-cleido-mastoid muscle, and manifests a tendency to extend upwards into the neck, and downwards in the direction of the axilla, it may be assumed that it is seated upon the outer portion of the vessel, beyond the scalene muscles. On the other hand, it may be concluded that it is connected with the inner portion of the artery, if the tumor is placed under cover of the mastoid muscle, and is gradually making its way over towards the median line, thus leaving the inferior triangle of the neck clear. It may be added that in subclavian aneurism the tumor is less liable to encroach upon the windpipe and œsophagus than in innominate and aortic aneurism, and hence there is generally much less cough, dyspnœa, and dysphagia in this than in the other affections. It is only, in fact, when the tumor is of great bulk, or when it happens, from the peculiarity of its position, to exert much pressure upon the pneumogastric, phrenic, and laryngeal nerves, that any serious symptoms of this kind will be likely to arise.

Progress.—Subclavian aneurism is always a serious disease, a spontaneous cure, although possible, as several cases upon record testify, being an extremely rare occurrence. In general, the disease progresses until it attains a certain point of development, when it terminates fatally, either by ulceration and hemorrhage, or by the induction of constitutional irritation. The sac may open externally, a not uncommon event, especially when it is invaded by gangrene; or it may burst into the pleura, lungs, trachea, or œsophagus; in either case, death takes place either instantly or within a short time after the tumor has begun to give way. There are several cases on record in which the aneurism pointed in the axilla and on the shoulder, having completely eroded some of the upper ribs and the body of the scapula, the latter being scooped out so as to form a kind of bed for the accommodation of the sac.

Treatment.—The treatment of subclavian aneurism has hitherto been exceedingly unsatisfactory, and there is no probability, judging from the deep situation and intricate relations of the tumor, that much benefit will ever accrue from any mode of management that may be devised for its relief. The plan of Valsalva, varied in every possible manner, has signally failed in every instance except a few, and no one seems now disposed to place any confidence whatever in its efficacy. Acupuncture and electricity, from which so much benefit had at one time been anticipated, have likewise disappointed expectation. Some time ago a case was reported in which a cure was alleged to have been effected by galvano-puncture, but the example is a solitary one, and the procedure is of too problematical a character to merit serious attention. Of what resource, then, can the surgeon avail himself in this unfortunate class of cases? Ligation of the affected artery is not only difficult, under any circumstances, in consequence of the position of the tumor and the intricacy of its anatomical relations, but is frequently absolutely impracticable on account of the diseased state of the artery, rendering it unable to support the ligature. Shall he adopt the operation of Dr. Mott, and secure the innominate, of which the subclavian, on the right side, is one of the main divisions? Here, again, difficulties meet in every direction, for even if he should be so fortunate as to get his ligature around the vessel, which, however, is by no means always the case, he will find, by consulting the history of the operation, that every instance in which it has been performed has had a fatal termination. Nothing, therefore, is to be gained from that procedure. In short, the Hunterian principle of operation is hardly applicable to any case of subclavian aneurism. On the right side, we are not only obliged to encounter, as just stated, great difficulties in reaching the innominate artery, but in throwing a ligature around the vessel we effectually cut off a large and important supply of blood to the brain, thus greatly enhancing the dangers of the case.

The innominate artery has been tied for the cure of subclavian aneurism in nine cases, the results of which are here subjoined in tabular form.

Ligation of the Innominate Artery.

Opera- tor.	Date.	Age.	Sex.	Disease.	Result.	REMARKS.
Mott	1818	57	M.	Subclavian aneurism	Died on 26th day	Artery tied half an inch below its bifurcation; ligature separated on the 14th day; hemorrhage on the 9th, and again on the 23d day; death on 26th day. Ulceration of the artery, and want of occlusion.
Graefe	1822		M.	Subclavian aneurism	Died on 67th day	Ligature came off on 14th day; death from hemorrhage.
Norman Arendt	1824 1824			Subclavian aneurism	Died on 8th day	Cause of death, inflammation of the aneurismal sac and of the pleura and lungs.
Hall	1830	45	M.	Subclavian aneurism	Died on 5th day	Artery morbidly adherent; dilated, soft, and friable; torn, in the attempt to separate it, at two points, between which the ligature was applied; copious hemorrhage during operation; plugging of the wound; participation of the aorta and carotid in the disease.
Bland	1832	31	M.	Subclavian aneurism	Died on 18th day	Ligature placed around artery near its bifurcation; hemorrhage on the 17th day, proving fatal on the 18th; innominate and carotid closed by solid clots; the subclavian still open.
Lizars	1837	30	M.	Subclavian aneurism	Died on 21st day	Ligature separated on 17th day; pleuritis; death caused by repeated hemorrhages; twenty ounces of coagulated blood at the root of the neck; arteries imperfectly closed.
Hutin	1842	26	M.	Hemorrhage after ligature of subclavian	Died in 12 hours	Tied for secondary hemorrhage, after subclavian had been secured for wound of the axillary.
Cooper	1860	31	M.	Subclavian aneurism	Died on 41st day	Ligature, applied an inch from the aorta, detached on 18th day; patient did well for three weeks, when hemorrhage occurred, and finally caused death.

All the cases in the above table, except one, proved fatal from hemorrhage of the wound, caused by the want of occlusion either of the ligated artery, or of the carotid and subclavian. It will be observed that Graefe's patient survived upwards of two months. I purposely exclude from the table the cases which are usually referred to as having occurred in the practice of Dupuytren and Bujalski, not considering them as sufficiently well authenticated to entitle them to a place in it. I also reject from it several reported cases in which the operation of ligating the innominate artery was commenced but not completed.

Dr. Peixotto, of Portugal, tied the innominate artery in 1851, on account of secondary hemorrhage from the common carotid, which had been ligated three weeks previously. The ligature, however, which was a precautionary one, was not tightened, but applied merely so as to flatten the vessel. The patient made a good recovery. Such an operation can hardly be regarded as a true case of deligation of the innominate artery. The cure was doubtless effected by the ligation of the other vessel.

Mr. Key, of London, in a case of aneurism of the subclavian, found it impracticable to apply a ligature to the innominate, in consequence of the volume of the tumor, and the diseased condition of the latter vessel. The patient was seized soon after the operation with symptoms of pulmonary distress and exhaustion, and died on the twenty-third day.

The operation of ligating the innominate artery is one of no inconsiderable difficulty, even in the dead subject, but in the living the perplexity is greatly

increased by the proximity of the aneurism, by the presence of glandular swellings, and, above all, by the manner in which the parts at the root of the neck are matted together by plastic deposits, rendering it thus exceedingly troublesome to separate them. These embarrassments were experienced in a striking degree by Dr. Hall, of Baltimore; he had great difficulty in isolating the vessel, and, in attempting to do so, tore it at two points, ligating it afterwards between them. Hemorrhage occurred at the time, but was checked by plugging the wound. Another obstacle to successful deligation is disease of the vessel, consisting either in a morbid dilatation, or in a softened and lacerable condition of its coats. Unforeseen difficulties were present in more than one-fourth of the cases in which ligation of the artery has been attempted, compelling the operators to desist, notwithstanding their great dexterity and profound knowledge of the anatomy of the neck.

Mr. Porter, of Dublin, in 1831 attempted to tie this artery on account of aneurism, but was obliged to desist in consequence of its diseased condition. The tumor, nevertheless, gradually disappeared, and the patient, a man forty-seven years of age, finally recovered.

Dr. Hoffman, of New York, in a case of subclavian aneurism in a man, aged sixty-three, cut down upon the innominate artery with the design of applying a ligature to it, should he be unable to ligate the subclavian; but he found the vessel so much enlarged that it was deemed inexpedient to proceed any further, and the patient was accordingly abandoned to his fate. The operation was performed on the 26th of October, 1839, and death occurred on the 19th of January, 1840.

The proposal to ligate the innominate originated with Mr. Allan Burns, from a conviction that the circulation in the head and upper extremity could be maintained without the agency of this vessel, and that it could be easily enough exposed by tracing it downwards towards the aorta, by a careful and patient dissection, the head being at the time bent well back. It remained, however, for Dr. Mott, in 1818, to put the suggestion to the test of experiment upon the living subject; and, although the operation had an unfavorable issue, the man dying, as has already been stated, on the twenty-sixth day, yet we cannot but admire the genius which could plan, and the intrepid skill which could execute, so daring and brilliant a feat. The case was one of subclavian aneurism above the clavicle, and the design had been to apply the thread to the latter vessel, but after exposing it on the tracheal side of the scalene muscle, it was found that its tunics were too much diseased to bear the pressure of the ligature, and he accordingly tied the innominate in its stead.

In a case of subclavian aneurism, Dupuytren tied the axillary artery under the pectoral muscles. Hemorrhage, or, rather, oozing of blood commenced on the fifth day, and the patient died on the ninth.

In another case the same operation was performed by Pétrequin. The tumor continuing to pulsate, the sac was punctured, and eight or nine drops of a solution of the perchloride of iron were injected, the brachio-cephalic trunk being compressed during the injection, and for ten minutes afterwards. The next day all pulsation had ceased in the tumor, but the patient died of hemorrhage at the place of the ligature, twelve days after its application.

Finally, benefit may occasionally arise in subclavian aneurism from *manipulation* of the tumor, as practised by Mr. Fergusson; some of the clots detached in the operation may accidentally find their way into the distal extremity of the vessel, and thus occlude its caliber along with the interior of the aneurismal sac. In a disease so desperate as this is known to be, and in which every expedient hitherto devised has been tried in vain, any suggestion that holds out the least possible chance of relief is worthy of trial.

ANEURISM OF THE AXILLARY ARTERY.

Aneurism of the axillary artery is less frequent than that of the subclavian. In 364 preparations of aneurism in the London museums, examined by Mr. Crisp, including 249 of the aorta, the axillary artery was affected only 8 times. In 551 cases analyzed by him from different sources, including 234 cases of aneurism of the aorta, 18 only were of the axillary artery.

The disease is, out of all proportion, most common in men; it follows upon different occupations, and is most frequently met with between the ages of thirty-five and fifty. In very many of the cases it is of traumatic origin. The volume of the tumor ranges from that of an egg to that of a child's head, the average being that of a goose-egg.

Symptoms.—The symptoms of axillary aneurism are generally so well marked as to render it impossible to mistake their character. When the disease arises spontaneously, or without any assignable cause, it may exist for several months without attracting any particular notice, and the same thing occasionally occurs when it results from external violence, as a blow or strain. Generally, however, the tumor rapidly augments in bulk, and produces such a train of phenomena as to lead at once to its detection. Of these, one of the earliest, and at the same time most unpleasant, is the sense of fatigue or uneasiness in the affected part arising from the pressure on the axillary plexus of nerves. This symptom is usually succeeded in a few weeks, sometimes, indeed, in a few days, by a feeling of pain, which is always in direct ratio to the size of the aneurism, being comparatively slight when it is small, and more or less intense when large. Nor is the pain confined to the site of the disease; in most cases it radiates from it, as from a common centre, in different directions, outwards into the shoulder, downwards along the arm, and upwards into the neck. Pressure, severe coughing, the recumbent posture, and the weight of the limb greatly increase it. Numbness of the shoulder, chest, and arm, is another symptom which generally manifests itself at an early period of the disease, and is never absent when the tumor has acquired considerable magnitude. It is always very distressing to the patient, is greatly aggravated by pressure on the swelling, and commonly extends to the ends of the fingers. Indeed, it is at this point that the sensation in question is often most keenly felt.

The pulsation of the tumor, at first faint and scarcely perceptible, becomes very distinct during the progress of the disease, so that it can not only be felt by the fingers, but seen at a considerable distance; sometimes, indeed, ten or twelve feet from the patient. On applying the ear or stethoscope to the tumor, the blood is found to rush into it with more or less violence, producing a peculiar thrill, or whizzing noise, synchronous with the contraction of the left ventricle of the heart. In the early stage of the disease, the swelling is soft and elastic, and may be readily emptied by pressure; by degrees, however, it becomes firm, tense, and, in great measure, if not entirely, incompressible. In some cases, especially in those attended with great enlargement, there is considerable diminution of the temperature of the affected limb, with indistinctness, if not entire absence, of the pulse at the wrist, more or less cough, dyspnoea, and shortness of breathing. Occasionally the pulse is fully as strong as in the other arm, but irregular or intermittent, losing several strokes in a minute.

In addition to these symptoms, there is always, when the swelling is large, so much displacement of the clavicle as to render it difficult, if not impossible, to distinguish the pulsation of the subclavian artery, the vessel being deeply buried behind and below the bone. In some instances the collar-bone has been found to be considerably imbedded in the tumor, or partially removed by

absorption. Another symptom, which, from its frequency, especially in the latter stages of the disease, requires mention here, is the swelling of the affected limb. This varies in degree in different cases, often extends from the shoulder to the ends of the fingers, and is usually of an œdematous character, pitting under pressure, and becoming aggravated by the dependent position of the part. When thus affected, the muscles lose their contractile power, and the motions of the extremity are proportionably impaired, or entirely annihilated. Sometimes, again, owing to the great magnitude of the tumor, the patient is unable to approximate the limb to the side of the chest. Finally, there is another phenomenon, which, as it is almost invariably present in the latter stages of axillary aneurism, I am disposed to regard as pathognomonic. I allude to the peculiar attitude of the patient, arising from the constant inclination of the head towards the affected side, and the manner in which he supports the corresponding arm; the object of both being evidently to prevent the tension which would otherwise be caused in the tumor. Under these circumstances, too, the countenance wears an anxious and distressed appearance, and, as the system sympathizes with the local affection, there is more or less derangement of the general health.

When the tumor is unusually bulky, it will necessarily greatly encroach upon the clavicle, forcing it upwards into the neck, and at the same time exerting severe pressure upon the subclavian artery, perhaps so much as to render it difficult, if not impossible, to distinguish the pulse at the wrist.

Diagnosis.—Notwithstanding that the symptoms of this disease are usually well-marked, it has sometimes happened that tumors of this description have been opened by ignorant practitioners under the belief that they were abscesses. For such stupidity no apology can be offered. Still, cases occasionally present themselves, though very rarely, in which it is extremely difficult, at first sight, to distinguish between this and other swellings in the armpit or subclavicular region. Enlarged lymphatic ganglions, adipose tumors, or encephaloid growths, for example, if they happen to lie along the course of the axillary artery, might have its pulsation imparted to them, and thus create some doubt in regard to their real character. Under such circumstances, the facility with which the tumor can be elevated or removed from the vessel, the absence of the peculiar whizzing sound, previously alluded to, as being generally present in aneurismal disease, the slight pain and numbness in the part and in the corresponding limb, the continuance of the swelling on the application of pressure to the subclavian artery, and, above all, the history of the case, will generally be sufficient to enable the practitioner to arrive at a correct diagnosis.

In this disease the tumor may be situated either immediately below the clavicle, or in the axilla, properly so called. In the former case, it may not only elevate the clavicle, but extend up into the neck, beneath the bone, as far as the acromial margin of the scalene muscles. In the latter, it has been known to reach some distance down the arm, so as to compress the brachial artery and nerves, and prevent the approximation of the limb to the side.

Treatment.—Axillary aneurism occasionally undergoes spontaneous cure, as in the instances reported by S. Cooper and Breschet. Such an occurrence, however, is extremely uncommon. Most generally the disease, if left to itself, terminates fatally, either by rupture of the sac and exhausting hemorrhage, or by gangrene of the limb. In a few rare cases the tumor destroys life by inducing caries of the ribs and perforation of the pleura, followed by a discharge of its contents into the cavity of the chest. In a case narrated by Mr. Guthrie, it was ascertained, on dissection, that the aneurism had forced its way into the right side of the chest by the destruction of a portion of the first five ribs, and had contracted adhesions to the upper lobe of the lung, into which it had gradually opened and discharged its contents, the man having

spat blood more or less profusely for several weeks prior to his death. In a similar case mentioned by Dr. Neret, of Nancy, an aneurism, about the size of a large chestnut, was seen to communicate with a cavity as large as the head of a new-born infant in the upper part of the left lung. The man had been admitted into the hospital on account of hemoptysis.

The only remedy for axillary aneurism is ligation of the subclavian artery, and it need hardly be said that the sooner this is done the more likely will it be to effect a cure. The operation, however, should not be declined, even although gangrene of the sac has already commenced, provided there is nothing else to forbid it. I am not aware that aneurism of the axillary artery has ever been cured by compression, nor is this surprising when we reflect upon the difficulty of approaching the subclavian under such circumstances, and also the proximity of the axillary plexus of nerves, which could hardly be induced to brook such an attempt for a sufficient length of time to produce any good effect. If the procedure is ever admissible, it will be in those cases where the tumor is uncommonly small, and the subclavian more than ordinarily superficial. The vessel might then be reached and successfully compressed either by the finger, the handle of a key, or the instrument delineated at page 548, figure 165. If the parts were very tender, the patient might be kept gently under the influence of chloroform while the necessary pressure is maintained, just as the obstetrician occasionally blunts the sensibility of the female for many hours together in protracted and painful labor.

Mortality.—Of 27 cases of axillary aneurism, which I analyzed in 1841 in the *Western Journal of Medicine and Surgery*, including one of my own, and for which the subclavian artery was tied, 17 recovered and 10 died, death occurring from the third to the thirtieth day, either from hemorrhage, gangrene of the arm, ulceration of the artery, pericarditis, pleurisy, or pneumonia. In one case it seemed to have been caused by effusion into the brain, and in one, my own, it was consequent upon rupture of the aneurismal sac into the thoracic cavity. In the tables of Dr. Norris, showing the mortality in 69 cases in which the subclavian artery was tied for aneurism, including 9 of wound of the axillary artery and 2 of tumors not aneurismal, though supposed to be so at the time, 36 are stated to have recovered, and 33 to have died.

In three of the cases mentioned in my paper, the subclavian was secured on the tracheal side of the tumor, and all proved fatal. In one of the cases, that of Mr. Colles, the ligature was not tightened till the fourth day after the operation, owing to the supervention of excessive dyspnoea and cardiac oppression.

In my own case, the tumor burst at the end of the twenty-sixth day after the operation, discharging its contents into the right thoracic cavity, and thus causing fatal pleuritis. The patient, a man aged thirty-six years, was suddenly seized with intense pain in the chest, which was particularly severe at the base of the right lung, from which it extended over towards the sternum, on the one hand, and up towards the axilla, on the other. The respiration was hurried, laborious, and fifty-six in the minute; and the pulse, which was quick and tense, rose rapidly to one hundred and forty. Two days after the accident, the patient experienced a sensation near the upper part of the chest, as if a fluid were passing from the pleuritic cavity into that of the aneurismal sac, and, on carefully auscultating the spot, a plashing sound could be distinctly heard at every inspiration, the noise resembling that produced by shaking water in a closed vessel. The respiration in the right lung was now bronchial, and there was extensive dulness on percussion of that side of the chest. It is proper to add that the tumor prior to the operation was about the volume of a large fist, and that the ligature, which

had been placed on the artery on the external side of the scalene muscle, came away on the fourteenth day. The dissection revealed the following facts, the arteries having previously been injected.

The wound made in the operation was completely cicatrized, and the pectoral muscles, although somewhat attenuated, retained their natural appearance. The subclavian artery terminated abruptly at the outer margin of the scalene muscle, where the ligature had been applied, its caliber being closed by a mass of solid fibrin, about one-third of an inch in length, which adhered firmly to the lining membrane, and thus afforded an effectual barrier to the passage of the blood. Between this and the thyroid axis the vessel was occupied by a dark coagulum of blood, which, as it was unadherent, was probably formed only a short time before death. Beyond the seat of the ligature the artery had a rough, ragged appearance, and was sufficiently pervious to admit of the ready passage of a small probe into the aneurismal sac. Superiorly the tumor was overlapped by the brachial plexus of nerves, while in front, at its lower part, was the subclavian vein, which, besides being thrown out of its natural course, was considerably diminished in size. No pus was anywhere discoverable, the parts immediately involved in the operation being intimately consolidated by plastic lymph. The aneurismal tumor, placed immediately below the clavicle, was of a conical form, and about the volume of a moderate-sized orange, being two inches and a quarter in diameter at its base. Its walls varied in thickness at different points from half a line to the eighth of an inch, and its interior communicated by means of an oval aperture, one inch and three-quarters in length by an inch and a half in width, with the pleuritic cavity: it was situated between the first and second ribs, nearly equidistant between the sternum and spine, and was obviously the result of ulcerative absorption, induced by the pressure of the tumor. Both ribs were denuded of their periosteum immediately around the opening, and the serous membrane had a shreddy, ragged aspect. The aneurismal sac contained a few reddish clots arranged in a laminated manner, and closely adherent to its inner surface, especially at the part corresponding with the apex of the tumor.

The right thoracic cavity contained nearly three quarts of bloody-looking serum, intermixed with flakes of lymph and laminated clots, the latter of which were of a reddish-brown color, and had evidently been originally lodged in the aneurismal sac. The pleura exhibited everywhere marks of high inflammation, while the right lung was greatly reduced in volume, from the compression of the effused fluid. The left lung was considerably engorged, and at one or two points almost hepatized. The heart and pericardium were sound. The abdominal viscera presented nothing unusual. None of the arteries appeared to have been affected by disease.

There can be no doubt, from the manner in which this case, which was one of a traumatic character, terminated, that the ulcerative absorption which gave rise to the opening above referred to, and which finally led to the escape of a portion of the contents of the aneurismal sac, commenced prior to the deligation of the artery, having been produced by the violent pulsative action of the tumor. Could such an accident have been foreseen, I should not have hesitated to empty the sac to relieve the parts of pressure, objectionable as such a procedure certainly would be in ordinary cases.

An instance of a character similar to the above occurred in 1823, in the practice of Mr. Bullen, of England, and is related in the twentieth volume of the London Medical Repository. The patient was a man, aged thirty-six years, and the aneurism, which was of nearly five months' standing, also occupied the right side. Eighteen days after the operation, the tumor began to increase in size and to become painful. Very soon evidence of suppuration appeared, and at the end of a week, from six to eight ounces of bloody pus were ejected during a violent paroxysm of coughing, the sac immediately

diminishing one-half in volume. A puncture being made into the swelling, five ounces of a similar fluid were discharged, to the great relief of the patient. It was now apparent that there was a cavity between the first and second ribs, near their sternal extremities, through which the matter had found its way into the lung, and which now readily admitted air from the latter organ, whenever the man coughed, at which time a little also escaped at the artificial opening. By degrees, the discharge of matter ceased, the cough grew less and less, and at the end of three months the recovery was perfect.

Mr. Erichsen, struck with the extraordinary mortality after ligation of the subclavian artery, in the third part of its course, for spontaneous aneurism in the axilla, determined, if possible, to ascertain the cause of death. For this purpose he analyzed 47 cases of the operation, of which 23 recovered, and 24 were fatal. Of the latter 10 perished from inflammation within the chest, 6 of suppuration of the sac, 3 of hemorrhage, 1 of gangrene of the hand and arm, and 1 of general gangrene, the cause of death in 3 not being mentioned.

The ten cases in the first category died of pneumonia, or of this disease and of inflammation of the pleura and pericardium; produced, as Mr. Erichsen suggests, either by an extension of the inflammation of the deep cellular tissue of the neck to the contents of the chest, by the inward pressure of the aneurismal sac, or, lastly, by the injury inflicted during the operation upon the phrenic nerve.

Suppuration of the sac was the immediate cause of death in six cases, and it occurred also in two of the cases that died of inflammation of the chest. Besides these fatal cases there were six of recovery, making thus an aggregate of 14 cases, or a ratio of nearly one in three. The period at which the suppuration set in varied, on an average, from eight days to four weeks.

Hemorrhage proved fatal in three of the cases, and appears to be a frequent cause of death after suppuration of the sac. It may proceed from the distal orifice of the artery opening into the sac, or from one of the large branches in its immediate vicinity, as the subscapular or posterior circumflex.

Gangrene of the hand and arm was the cause of death in one instance only, although the disease occurred also in two others. In Blizard's case, in which there was sloughing of the sac and pericarditis, the gangrene was confined to two fingers; while in Brodie's case it occurred both in the upper and lower extremities, thus showing that it depended, not upon a want of power in the collateral circulation, as in the other examples, but upon some peculiar state of the constitution.

LIGATION OF THE SUBCLAVIAN ARTERY ON ITS TRACHEAL ASPECT.

This vessel is sometimes ligated on the inner side of the scalene muscles. The subjoined table, comprising ten cases, will serve to place the subject in its true light.

No.	Operator.	Sex.	Age.	Result.	REMARKS.
1	Colles	M.	33	Death	In this case there was only a space of three lines between the sac and the bifurcation of the innominate. The patient died of hemorrhage on the fourth day.
2	Mott	F.	21	Death	The patient died on the eighteenth day of hemorrhage.
3	Hayden	F.	57	Death	The patient died on the twelfth day of hemorrhage.
4	O'Reilly	M.	39	Death	The patient died on the thirteenth day of hemorrhage.
5	Partridge	M.	38	Death	The patient died on the fourth day of pericarditis and pleurisy.
6	Liston	M.	—	Death	Patient died of hemorrhage on the thirteenth day.
7	Liston	M.	32	Death	The patient died on the thirty-sixth day of hemorrhage.
8	Auvert	—	—	Death	Fatal hemorrhage on twenty-second day.
9	Auvert	—	—	Death	Fatal hemorrhage on eleventh day.
10	J. K. Rodgers	M.	42	Death	Fatal hemorrhage on the fifteenth day.

The result in all the above cases, except one, has been death by hemorrhage, notwithstanding the undoubted ability and skill of the operators, comprising some of the most illustrious names in surgery. Should this fact not be sufficient to deter practitioners from repeating the operation, or should they continue in their efforts to save life until some one, more fortunate than the rest, shall succeed in finding an exceptional case? The case of the late Dr. J. Kearney Rodgers, of New York, in which the artery was secured on the left side on account of an aneurism, is full of the deepest interest in this respect, as showing that, although the patient finally perished from hemorrhage, yet the ligated vessel was completely closed by an adherent coagulum.

Until the operation of Dr. Rodgers, it was universally regarded as impracticable to ligate the left subclavian artery on the inside of the scalene muscles, such being the intimate relation of the vessel in this situation to the sac of the pleura, the carotid artery, internal jugular vein, pneumogastric nerve, and thoracic duct. It had been thought that, from the severe injury which would necessarily be inflicted upon the surrounding structures during the operation, violent and fatal inflammation must be the speedy and inevitable consequence. At all events, no one had yet been found ingenious enough to devise, and bold enough to execute, such an enterprise. Although it is not likely that the operation will soon be repeated, yet the case in question deserves brief notice here as a matter of surgical history, if nothing more.

The patient was a man, aged forty-two, who, in consequence of lifting a heavy weight, upwards of a month previously, suddenly became the subject of aneurism of the left subclavian artery. At the time of his admission into the New York Hospital, the tumor could be seen above the clavicle, about the size of a small hen's egg, extending outwards towards the shoulder, and inwards towards the sterno-cleido-mastoid muscle, by the outer border of which it was considerably overlapped. The signs of aneurism were well marked in every particular. The operation was performed on the 14th of October, 1845. Two incisions were made; one, three inches and a half in length, along the inner border of the sterno-cleido-mastoid muscle, terminating at the sternum, and dividing the integuments and platysma-myoid muscle; and the other, two inches and a half in length, extending horizontally over the inner extremity of the clavicle, the two meeting at a right angle near the trachea. Several small veins having been ligated, and the flap thus formed dissected up, the sternal portion with half of the clavicular of the mastoid muscle was divided upon a grooved director, a procedure which fully brought into view the sterno-hyoid and omo-hyoid muscles and the deep-seated jugular vein, all covered by the cervical fascia. A part of the aneurismal sac was also in sight, overlapping a considerable portion of the anterior surface of the scalene muscle, upon which the operator could distinctly feel the phrenic nerve. By digging with the handle of the knife and fingers, the deep cervical fascia was now divided close to the inner edge of the scalene muscle, when, after a little search, the subclavian artery was easily discovered as it passed over the first rib, pressure upon this portion readily arresting the pulsation of the tumor. The next step of the operation consisted in passing the ligature around the vessel without injury to the pleura and thoracic duct, but this proved to be one of extreme difficulty, owing to the great narrowness and depth of the wound, the latter nearly equalling the length of the forefinger. This, however, was at length successfully accomplished by means of an aneurismal needle with a movable point, carried from below upwards. The moment the ligature was tied all pulsation in the tumor ceased, and the patient, if not entirely comfortable, made no complaint of any kind.

The wound became somewhat erysipelatous after the operation, but, on the whole, the patient got on well until the 26th of October, when, on changing

his position in bed, hemorrhage supervened, and, continuing to recur at various intervals, destroyed him on the fifteenth day. On dissection, the wound was found to be filled with clotted blood, beneath which the artery had been completely divided by the ligature, which lay loose close by. The stump of the subclavian, between the aorta and the point of ligation, was about an inch and a quarter in length, and thoroughly impervious to air and liquids, its caliber being occupied by a solid and firmly adherent coagulum. The distal extremity of the subclavian contained a soft, imperfect clot, while the vertebral artery, which was given off immediately at the site of the ligature, was almost patulous, and had evidently been the seat of the hemorrhage which caused the patient's death. The aneurismal sac, the size of a small orange, was completely blocked up with coagula. The thoracic duct was uninjured, but the pleura at the bottom of the wound was found to be extensively lacerated, and through the opening thus formed a large quantity of blood had passed into the left cavity of the chest.

In reflecting upon this interesting case, Dr. Rodgers regretted that he had not secured the vertebral artery and also the thyroid axis, believing that this would have effectually prevented the fatal hemorrhage.

ANEURISM OF THE BRACHIAL ARTERY AND ITS BRANCHES.

Spontaneous aneurism of the brachial artery and of its terminal branches, the radial and ulnar, is extremely uncommon, for the reason, adverted to in a previous section, that ossification and fatty degeneration of the coats of these vessels are of such great rarity compared with the same lesions of the femoral and its principal divisions. I have, in fact, never witnessed a single example of the disease, and I am not aware that it has ever been noticed by any one in this country. Cases of the disease, however, are mentioned by foreign authorities, among others by Desault, Palletta, Flajani, Pelletan, and Scarpa. Spontaneous aneurism of the ulnar and radial arteries are spoken of by several writers, but in so vague a manner as to render it difficult to determine whether the disease depended upon degeneration of the coats of the vessels, or merely upon laceration by external injury.

All these arteries are subject to traumatic aneurism; the brachial, however, is much more frequently involved than the radial and ulnar, and one of the most common causes of the occurrence is venesection at the bend of the arm, the puncture of the lancet establishing a communication between the vein and the artery, thus giving rise to what is called an arterio-venous aneurism. Or, instead of this, the instrument may almost completely sever the artery, and so induce a diffused aneurism, not opening into the vein, but diffusing its contents, up and down, over a large portion of the inner and fore part of the limb. Some of these latter cases are occasionally very formidable, requiring great judgment and skill for their successful management.

Arterio-venous aneurism may sometimes be cured by systematic compression of the brachial artery, at a distance of five or six inches from the seat of the disease; but in general the most expeditious plan is to lay open the sac, turn out its contents, and tie the artery above and below, the inferior ligature being necessary to prevent hemorrhage from the recurrent branches.

Wound of the brachial artery, without communication with a vein, should be treated, if the case can be reached soon after its occurrence, by compression; but if there be extensive extravasation of blood, constituting what is usually, but improperly, called a diffuse aneurism, the vessel must be exposed at the site of injury, and ligated at its cardiac and distal extremities.

Aneurisms and wounds of the ulnar and radial arteries must be treated upon the same general principles as those of the brachial artery, and do not, therefore, require any special mention. Compression can rarely be rendered

available, except at the wrist, and even here it will usually be found to be unsatisfactory, on account of the difficulty of maintaining it in a firm and steady manner. Hence, the proper way is always to ligate the affected vessel at once, not waiting until the parts have become obscured by the extravasated blood. As both arteries are very deep-seated in the upper and middle portions of their extent, rendering it very difficult to expose them, it has been proposed, when they are wounded in these situations, to ligate the brachial; but the objection to this procedure is that, while the cardiac extremity of the affected vessel will thus be closed, the distal one will remain patent, and thus admit of a continuance of the hemorrhage by the recurrent circulation.

Wounds of the arteries of the hand, especially of the palmar arch, are best managed by free incisions and the application of two ligatures. It is great folly, under such circumstances, nay, it is positively worse than folly, to tamper with the comfort and welfare of the patient by the use of compression, either direct or indirect, if the vessel be of any considerable size. Only precious time is wasted; the bleeding will return whenever the mechanical support is taken off, and in this way the patient may lose quarts of blood before the hemorrhage is finally arrested, as I have known to happen in more instances than one. The ligation of the radial and ulnar arteries will be equally unavailing, for blood will still be sent to the wound by the interosseous branch, and, even if this also were secured, still the probability is that the bleeding would go on, especially if some time had elapsed since the occurrence of the accident, owing to the communication of the anastomosing vessels. We now and then read of cases in which the brachial artery has been tied for the arrest of hemorrhage of the palmar arch. Can there be anything more absurd than such a procedure, or that shows a greater degree of ignorance of the anatomy of the hand? The advice of John Bell, in his *Principles of Surgery*, in regard to the treatment of wounded arteries in general, cannot be too strongly enforced here: "Meet the danger boldly, and don't be afraid to look your enemy in the face."

A curious case of aneurism under the ball of the right thumb has been related by Mr. Pilcher, as having occurred in a goldsmith from the repeated though slight blows inflicted with his hammer in the exercise of his trade. The disease speedily disappeared after ligation of the radial and ulnar arteries at the wrist.

ANEURISM OF THE COMMON ILIAC ARTERY.

The history of aneurism of this vessel remains to be developed. Nothing short, in fact, of a careful analysis of the various recorded cases of it can place it in its true light. That the disease is extremely uncommon in its occurrence is a circumstance which has long been familiar to surgeons. The table of Mr. Crisp supplies only two cases of aneurism of this artery in 551 cases of the lesion as it shows itself in different portions of the arterial system. Both occurred in males. In one, the tumor was seated on the right side; the patient was a sailor, exposed to hard labor in whale-fishing; the aorta was tied by Dr. Murray, of the Cape of Good Hope, but the man died twenty-three hours after the operation. In the other case, the aneurism, also seated on the right side, was of a fusiform shape, and communicated with the common iliac vein. No operation was performed.

The following table exhibits the results of five cases in which the abdominal aorta has been tied for aneurism of the common iliac.

No.	Operator.	Date.	Sex.	Age.	Result.	REMARKS.
1	Cooper	1817	M.	38	Died in 40 hours	The operation was performed for aneurism of the left iliac artery. The tumor being of enormous size, extending four inches above and four inches below Poupart's ligament; the thread was applied three-quarters of an inch above the bifurcation of the aorta. The sac contained an immense quantity of clotted blood.
2	James	1829	M.	44	Died in 3½ hours	There was an external iliac aneurism, for which the femoral was ligated. Increasing in size, 33 days afterwards the aorta was tied. The ligature was applied eleven lines above the bifurcation of the vessel, and five below the mesenteric artery.
3	Murray	1834	M.	33	Died in 23 hours	There was an extensive aneurism of the right external iliac, the tumor reaching as high as the umbilicus, and more than half way across the lower part of the abdomen. Mortification of the limb was rapidly approaching when the operation was performed. The aorta was tied about four lines above its bifurcation.
4	Monteiro	1842	M.	31	Died in 10 days	A large tumor occupied the lower part of the abdomen and upper part of the thigh. It was a spurious aneurism of the femoral artery, caused by the bursting of that vessel. The patient died, at the expiration of ten days, of secondary hemorrhage, from a small opening in the vessel corresponding with the knot of the ligature, which had been applied four lines above the point of bifurcation.
5	South	1856	M.	28	Died in 43 hours	The aneurism occupied the external and common iliac, and was of immense size. The ligature was applied a little above the bifurcation of the aorta.

It will be perceived from the above table that the five cases in which the abdominal aorta has been tied, all terminated fatally; a result which might assuredly have been foreseen by the distinguished surgeons who performed the operation. Questionable as the propriety of such an operation is, I should, I confess, be strongly tempted to perform it if my patient were placed in circumstances precluding all hope of relief from any other source. That this was the feeling which prompted Sir Astley Cooper, in 1817, to undertake it, and which has since induced others to imitate his example, is more than probable, and our only regret is that their efforts have not been crowned with success. What the effect might have been if the cases had been of a more favorable nature prior to surgical interference is, of course, merely a matter of conjecture, but it is perfectly evident, from their history, that they were all in as desperate a condition as they could well have been at the time. The tumor, in every instance, was of enormous volume, almost, in fact, ready to burst; in Mr. Murray's patient there was, besides, incipient gangrene of the lower extremity. In the case of Mr. James, an error of diagnosis had been committed, which led, improperly, as was afterwards proved, to ligation of the femoral artery, thereby causing the patient not only much suffering but the loss of much valuable time, upwards of four weeks having elapsed between the two operations.

In performing the operation, the peritoneum was divided in two of the cases, and left intact in three; in one instance, it was opened to the extent of nearly four inches. Such a procedure would probably of itself have been a cause of death, had the patient survived the immediate effects of the deligation of the vessel.

The case of Dr. Monteiro, the most successful of all, is replete with interest, as it establishes the fact that the circulation may go on in the lower extremities, after the flow of blood in the abdominal aorta has been completely arrested by the ligature. The patient survived the deligation ten days, when he died of secondary hemorrhage, caused by a small aperture in

the side of the vessel corresponding with the knot in the thread. The dissection showed that the peritoneum, which had not been cut in the operation, was perfectly free from inflammation. The aorta had been ligated four lines above its bifurcation, and an inch below the inferior mesenteric artery. The aneurism, which was a false one, had originated in a rupture of the upper extremity of the femoral artery, from which the blood had made its way upwards, underneath Poupart's ligament, through the intermuscular cellular tissue, into the iliac fossa, and thence on behind the peritoneum along the posterior part of the abdomen, as high up as the diaphragm and liver. The common and external iliac arteries were involved in the tumor, and were in an inflamed and friable condition. The external wound had nearly healed.

It is worthy of remark that the pulsation in the tumor ceased immediately on tying the ligature, but returned slightly on the third day, and became more marked on the fourth. Hemorrhage supervened the day before death. The operation was followed by coldness of the lower extremities, but in four hours afterwards this had passed off, and the temperature was now a little above the natural point. No paralysis was present at any time in the limbs.

ANEURISM OF THE INTERNAL ILIAC.

Aneurism of the internal iliac, gluteal, and sciatic arteries is very uncommon, and their history has not been studied with sufficient care to enable us to present anything like a satisfactory account of them. Owing to the deep situation of the former of these vessels, the diagnosis of aneurism occupying its course would necessarily be attended with considerable difficulty, and should not be declared without a good deal of reserve and circumspection. Aneurism of the sciatic and gluteal arteries is more frequently traumatic than spontaneous. In fat, muscular subjects the disease is generally difficult of recognition, and hence it is not surprising that solid growths have sometimes been mistaken for it. Mr. Guthrie once tied the internal iliac artery for a tumor which he had taken to be aneurismal, but which, after death, was found to be of an encephaloid character, the deception having been caused by the circumstance of the tumor having received a distinct impulse from the artery. I have not met with aneurism of the pudic artery, and am not aware that the disease has ever been observed in this country. Mr. Erichsen states that the only instance of the kind with which he is acquainted is exhibited in a preparation in the Museum of the College of Surgeons at London.

Aneurism of the gluteal and sciatic arteries may be treated by ligating the internal iliac, or exposing the sac by a free incision, turning out its contents, and tying the vessel above and below. Such a proceeding would, unquestionably, be very bloody, but by far less hazardous in the end than deligation of the internal iliac.

The *gluteal* artery has been tied at least twice in this country for the cure of aneurism; once by Dr. Davidge, of Baltimore, and once by Dr. George McClellan. The tumors being of great bulk, the incisions were obliged to be unusually large, and the loss of blood was very profuse. Notwithstanding this, however, both patients made an excellent recovery.

ANEURISM OF THE EXTERNAL ILIAC.

Aneurism of the external iliac is a rare affection. In the table of Mr. Crisp, the most elaborate hitherto furnished, it occurs only 9 times in 551 cases, while the femoral is mentioned 66 times, and the popliteal 137 times. In 364 specimens of aneurism contained in the London museums, the same writer found the external iliac affected in 7 cases, the femoral in 12, and the popliteal in 50. The nine cases analyzed by Mr. Crisp all occurred in males:

two, between twenty and thirty; four, between thirty and forty; one, at forty, and one at fifty-six, the age of the other not being given. The disease is most common in hard working persons. One of the worst cases of it that I have ever seen occurred in a priest.

The tumor in this disease may be seated at any part of the artery, but in general it will be found rather low down, and, as it progresses, it manifests a tendency to pass underneath Poupart's ligament into the upper part of the thigh. It usually rapidly augments in size, and is capable of attaining a large bulk, encroaching upon the iliac fossa and the pelvic cavity, lifting up the peritoneum, and pressing forward the structures in the inguino-femoral region, so as to give rise to great deformity in this situation. The pulsation, thrill, and bellows' sound are usually very distinct. If the patient be very thin, compression of the abdominal aorta will arrest the movements of the tumor, and diminish its volume, thus serving to distinguish it from other affections. The diagnosis is, nevertheless, not always so easy as might at first appear. Several cases have been reported where the common iliac artery was ligated on account of morbid growths, supposed to be aneurismal, which afterwards proved to be of a malignant character. On the other hand, a tumor really aneurismal has occasionally been confounded with one altogether of a different character. Such a mistake is most likely to happen when the aneurism is partially solidified by the coagulation of its contents, thereby preventing the perception of pulsation. It is only necessary to allude to the possibility of such an occurrence in order to put the practitioner upon his guard in the investigation of his cases.

When an aneurism of the external iliac artery has attained a considerable bulk, the patient walks with extreme difficulty, and is unable to flex the thigh upon the pelvis. The whole limb is enlarged and œdematous from the obstruction to the return of the venous blood, while the pressure of the tumor upon the femoral nerves keeps up constant pain, with a sense of numbness and stiffness in the parts below, generally extending as far down as the foot and toes.

Aneurism of the external iliac artery, if left to itself, proves fatal in one of three ways, by rupture and hemorrhage, gangrene of the sac or limb, or constitutional irritation. A spontaneous cure now and then occurs, but the circumstance is extremely rare, and, therefore, does not deserve to be taken into the account in our therapeutic considerations.

The only remedy hitherto employed in the *treatment* of this disease was deligation of the artery leading to the tumor; the external iliac, when the aneurism was situated low down, so as to leave a sufficiency of the superior portion of the vessel intact, and therefore in a suitable condition for the reception of the ligature; or, when the reverse was the case, the common iliac, one of the most formidable operations in surgery. I believe, however, that it will be found that the tumor may generally be promptly obliterated, especially in its earlier stages, by compression of the iliac as it passes over the brim of the pelvis; and, although I am not aware that this practice has ever been adopted, yet I am the more inclined to regard it as feasible, from the fact that the external iliac does not give off any branches, in any portion of its course, so as to offer any barrier to the process of solidification of the contents of the sac. The epigastric and circumflex iliac arise just above Poupart's ligament, and could not, therefore, in any wise interfere with the cure. If a case of aneurism of the external iliac should be presented to me, I should certainly give this mode of treatment a fair trial, and should feel very sanguine of success. Digital compression would of course be preferable to any other, on account of the greater facility of its application.

The result of the ligation of the artery leading to and feeding the tumor, has, on the whole, been rather encouraging. In the nine cases mentioned in

Mr. Crisp's table, the common iliac was tied in two, one recovering, and the other perishing of hemorrhage on the eighth day. In four cases the external iliac was ligated, and all got well. In one instance both the femoral artery and the abdominal aorta were tied, but the man died a few hours after the last operation. One case was cured spontaneously, and another recovered under compression.

Within the last few years the treatment of inguinal aneurism by digital compression has been tried. Of four cases thus managed, only one—a patient of Dr. Nichols, of New Orleans—was cured. The thumb was pressed against the neck of the sac for thirty hours, by which time the pulsation had stopped, but, as a matter of precaution, it was continued for ten hours longer.

ANEURISM OF THE FEMORAL ARTERY.

Aneurism of the femoral artery is very common, although less so than that of the popliteal. In Mr. Crisp's cases, 551 in number, 66 relate to the femoral artery, of which 61 occurred in males, thus showing that the disease is very rare in women. The period of life at which it is most frequently met with is from thirty to fifty. As in the other arteries, aneurism of the femoral is most common in the laboring classes, particularly in those persons who are subject to severe muscular exertion of the lower extremities, causing a sudden strain upon the vessel. Instances have been observed in which each femoral artery was simultaneously affected with aneurism, and it occasionally happens that the same vessel has two such tumors connected with it.

The femoral artery is not equally subject to aneurism in all parts of its extent. The superior third suffers more frequently than the rest of the vessel, and external aneurism occurs here much oftener than in any other artery, except the popliteal. Sailors are said to be particularly liable to the disease in this situation, owing, as Mr. Crisp supposes, to the violent flexion and extension of the thigh which they are obliged to make in mounting the rigging and performing other labors on ship-board. I have never seen an instance of spontaneous aneurism in the lower third of the thigh, and general experience concurs in declaring that such an occurrence is extremely uncommon. In some of the published cases, the disease is described as having been femoro-popliteal, a term evidently intended to convey the idea that the lesion involved both the terminal portion of the femoral and the incipient portion of the popliteal.

Diagnosis.—The diagnosis of femoral aneurism, although generally easy, is sometimes involved in so much obscurity as to cause not a little perplexity. This is more especially the case when the tumor is seated along the middle or lower third of the thigh, where the artery is tightly bound down by the muscles and aponeuroses. Abscesses and various morbid growths, solid, semi-solid, or fluid, and malignant and non-malignant, are the affections with which it is most liable to be confounded; and it behooves the surgeon, in every case of doubt, to institute the most careful and thorough examination before he expresses an opinion in regard to its character, or permits himself to engage in any operative procedures for its relief. The best diagnostic, unquestionably, is the effect which compression of the femoral artery exerts upon the tumor, when it is situated some distance below Poupart's ligament, or of the ileo-femoral, when it occupies the superior part of the thigh. If the tumor be aneurismal, the compression will not only arrest its pulsation, thrill, and bellows' sound, but, while it is being kept up, it will enable the surgeon to squeeze out its contents, and thus greatly diminish its volume, circumstances which cannot possibly occur when the swelling is of a non-aneurismal character, whatever may be its structure or consistence. The exploring needle is only to be used in cases not admitting of discrimination

by the method here suggested, and then it should be so fine as not to cause hemorrhage or excite inflammation.

The femoral artery, in the upper portion of its extent, is sometimes protruded forward by a *synovial bursæ*, situated behind the psoas muscle, just below Poupart's ligament, especially when the pouch is inflamed and much distended, in which case it will probably receive an impulse from the vessel, so as to cause the swelling to simulate aneurism. The proper way to determine the diagnosis is to flex the thigh upon the pelvis, a procedure which, by taking off the tension of the muscle, puts a stop to the pulsation of the tumor, and thus reveals the true nature of the disease.

A number of *lymphatic ganglions* lie in the upper part of the thigh, immediately upon and around the femoral artery. Enlargement of these glands has been mistaken for aneurism, and, conversely, aneurism for enlargement of the glands; but the history of the case and a careful examination of the parts will generally promptly clear up the diagnosis.

Psoas abscess occasionally points below Poupart's ligament, and might be mistaken, by a careless observer, for aneurism of this vessel, or of the external iliac. The best diagnostic signs are the want of pulsation, the soft and fluctuating character of the swelling, the absence of discoloration of the skin, and our ability to efface the swelling almost entirely, when the patient lies on his back with the thigh and pelvis a good deal elevated. Moreover, if there is pus, a drop will be sure to follow the withdrawal of the exploring needle.

Progress.—The course of the aneurism is variable. When it is situated high up, it is liable, in its progress, to extend upwards, and to project at length beneath Poupart's ligament into the pelvic cavity. When, on the other hand, it involves the inferior portion of the artery, it may pass down into the ham, and so simulate popliteal aneurism. The swelling usually increases rather rapidly, and, in time, often spreads over a large space, diffusing itself, in fact, widely, in consequence of the giving way of the two inner tunics of the artery. When this is the case, the limb below the seat of the tumor becomes greatly enlarged and oedematous, from obstruction to the return of the venous blood, and the patient constantly complains of stiffness, pain, and numbness in it, extending generally as low down as the feet and toes. In the more advanced stages of the disease, progression becomes difficult and finally impracticable, the whole limb feeling like a dead, heavy mass. A spontaneous cure occasionally occurs; but most commonly the disease goes on from bad to worse, until life is destroyed by gangrene, excessive suppuration, hemorrhage, or constitutional irritation.

Treatment.—The treatment of aneurism of the femoral artery may, I think, generally be successfully conducted by compression, especially now that our means of applying and regulating it are so much better understood than formerly. The compression may be made either with the finger or by means of one of the numerous mechanical contrivances now before the profession. In the case of a negress, aged thirty-two, who was under the joint care of my son and myself, last summer, on account of a large aneurism of the upper third of the femoral artery, the assistants succeeded in effecting complete solidification of the contents of the sac in forty-six hours, by digital compression alone. The tumor progressed most favorably, and in less than three weeks after the operation, the woman was able to walk about the house. In this case, referred to in a previous section, there was not more than an inch of space between the aneurismal sac and Poupart's ligament, in consequence of which the compression was obliged to be applied to the iliac artery as it passed over the brim of the pelvis. Several instances of an equally gratifying termination have followed this treatment in the hands of other surgeons.

When compression is inapplicable, the only resource of course is deligation

of the artery which supplies the tumor with blood. The operation is easily done at Scarpa's triangle when the aneurism occupies the middle or lower third of the femoral artery, or even when it extends up to the inferior portion of this space, provided the coats of the vessel are sufficiently sound to bear the pressure of the ligature. When this is not the case, or when the tumor is situated high up, near Poupart's ligament, or projects beneath it partly into the pelvic cavity, the proper remedy will be ligation of the external iliac, an operation which, although not devoid of risk, has now been performed so often and so successfully as to be justly ranked among the established resources of surgery.

Mortality.—In Mr. Crisp's 66 cases, above referred to, the external iliac alone was tied in 43, and in two others both this artery and the femoral; 36 of the patients recovering, and 10 dying. Of the latter, three perished from hemorrhage, four from gangrene of the sac or limb, one from tetanus, one from exhaustion, and one without any apparent cause. In 12 of the cases the femoral artery alone was tied, with a result of 9 cures to 3 deaths. Amputation was successfully employed in five cases; in two, the tumor was obliterated by compression, and in one the disease spontaneously disappeared.

In the table of Dr. Norris, comprising 118 cases of ligation of the external iliac artery, of which, however, 97 only relate to aneurism, 85 recovered, and 33 died, three of the former having undergone amputation of the limb in consequence of gangrene. In 4 of the 97 cases of aneurism, the disease existed simultaneously both in the thigh and in the ham, and in 3 of these the operation succeeded in curing both tumors. A return of pulsation in the sac took place in 9 cases, and hemorrhage in 14, of which 7 proved fatal, and 7 recovered. In 10 cases the tumor suppurated after the operation, although they all ultimately did well. Gangrene of the limb occurred in 16 cases out of the 118, of which 12 died. In two instances the peritoneum was wounded, but both patients recovered.

Finally, a number of cases of femoral aneurism have been recorded in which a cure was effected simply by refrigerant applications to the tumor, aided by steady compression with the bandage, strict recumbency, and an abstemious regimen. This treatment has occasionally succeeded both in the spontaneous and traumatic form of the disease.

ANEURISM OF THE POPLITEAL ARTERY.

The extraordinary frequency of aneurism of the popliteal artery has long been familiar to pathologists and surgeons. With the exception of the thoracic portion of the aorta, there is no artery in the body which is so often the subject of this disease. The table of Mr. Crisp, already so frequently referred to, comprises an analysis of 551 cases of spontaneous aneurism, of which 137 occurred in the vessel under consideration, the thoracic aorta suffering 175 times. Three circumstances seem to serve to establish this extraordinary liability to aneurism on the part of this artery; one is its extreme proneness to ossific and fatty degeneration, another, the curve which it forms behind the knee, and the third, the frequent, sudden, and forcible extension to which it is so constantly exposed in the various movements of the lower extremity.

Age and Sex.—Popliteal aneurism occasionally occurs at a comparatively early age, a number of cases having been observed in which it took place before the twenty-fifth year. Mr. Syme has related one in a child of seven years. The great majority of instances, however, are met with between thirty and fifty. Both sides seem to suffer nearly in an equal degree, and both are occasionally affected simultaneously, or successively, as I have myself wit-

nessed in several individuals. The disease is almost peculiar to men. In Mr. Crisp's cases, 137 in number, 133 occurred in males, and only 4 in females. No occupation is exempt from aneurism of the popliteal artery, but the statistics which have been published upon the subject conclusively show that the laboring classes, especially soldiers, sailors, bargemen, and porters, who are in the constant habit of making long-continued and violent exertions of the muscles of the lower extremities, are more obnoxious to it than any other. The idea, first broached by Morgagni, that postilions and coachmen are particularly prone to popliteal aneurism, has been proved to be erroneous.

Diagnosis.—Aneurism of the popliteal artery is probably produced in most cases by a sudden and violent sprain or twist of this vessel while its coats are in a state of osseous degeneration, and consequently deprived of their elasticity, by which they are prevented from following the various movements of the leg with their accustomed freedom, a sudden rupture being thus induced, of which the patient is himself often made conscious, either by his feeling, or by a kind of snapping noise. The tumor, being at first quite small, generally escapes attention until it has acquired a considerable bulk, as, from the great depth at which the artery is situated, and the unyielding nature of the parts in the ham, it takes some time for it to reach the level of the surrounding surface, or to exhibit to the eye the characters of a distinct swelling. A careful examination, however, will always enable us, even at an early period, to arrive at a satisfactory conclusion respecting the nature of the case, except, perhaps, in very fat subjects. The tumor will be found to throb synchronously with the artery in the groin, and, by grasping it firmly between the thumb and finger, it may readily be pushed about in the hollow between the tendons of the flexor muscles, feeling like an elastic, circumscribed knob, which is easily diminished by pressure, but immediately regains its former size when the pressure is removed. As the disease progresses, the sac increases in volume, and encroaches more and more upon the popliteal space, pushing aside the soft parts, compressing the popliteal vein and nerve, and interfering seriously with the movements of the limb. The leg is habitually bent at an obtuse angle with the thigh, and all efforts to straighten it prove abortive; it is the seat of constant aching pains, with a sense of numbness or tingling; its temperature is notably diminished, and its subcutaneous cellular tissue, owing to the obstruction to the return of the venous blood, is loaded with serum, or serum and lymph, giving the surface a glossy, shining appearance, and causing it to pit under pressure. The ear and the hand readily detect the characteristic thrill and bellows' sound.

Aneurism of the popliteal region is liable to be confounded with other tumors, and we read of cases in which the sac was laid open under the impression that the disease was not arterial. The lesions for which it is most apt to be mistaken are abscesses, solid and fatty growths, and synovial bursae.

Abscess of the ham is of very uncommon occurrence, and is in general easily distinguished by the history of the case, its inflammatory character, by the absence of pulsation, by the presence of fluctuation, especially when the matter is considerable in quantity, and by our inability to produce any change in the volume of the swelling by compression of the femoral artery high up in the thigh. When any doubt exists, a small exploring-needle, carefully inserted into the tumor, will readily determine the diagnosis.

Solid growths, of various kinds, benign and malignant, are liable to form in the popliteal region, and might be mistaken for aneurism, especially by a careless and inexperienced surgeon. The fact that such tumors are usually stealthy in their origin, tardy in their development, firm in their consistence,

and free from pulsation, will always readily distinguish them from aneurism of the popliteal artery.

A *synovial bursæ* is occasionally developed in this space, but the occurrence is rare, and it would be difficult to imagine how such a growth as this should ever be confounded with an aneurism in this region. In the Louisville Medical Review, a case of this affection is reported by Dr. S. W. Gross, in which the largest tumor of this description that I have ever seen, occurring in a man, aged twenty-nine years, was readily diagnosticated by the exploring-needle, although its history—especially the absence of pain and pulsation, its non-interference with the patient's occupation, and the preservation of the natural appearance of the leg below the knee—had been sufficiently denotive of its true nature without any expedient of this sort.

Progress.—Aneurism of the popliteal artery may remain circumscribed for a considerable length of time; but, in general, it becomes soon diffused, and by its pressure upon the surrounding structures causes not only great pain and swelling in the leg below the knee, but a tendency to mortification by cutting off the nervous and vascular supplies. Such a termination, in fact, is almost inevitable if the case be permitted to proceed unchecked. Sometimes a spontaneous cure occurs, probably in consequence of the pressure of the tumor upon the artery, thereby arresting the circulation in the sac. Professor Pancoast, some years ago, had a case of popliteal aneurism upon which he had intended to operate the next day; but when he got to his patient's room, he found that all pulsation in the tumor had ceased, and the man gradually recovered without any farther trouble. Occasionally the tumor opens into the knee-joint.

Treatment.—The treatment of popliteal aneurism was, until recently, usually conducted by deligation of the femoral artery in the superior third of the thigh, according to the method of Hunter, first practised in 1785. Since 1840 numerous instances have been cured by compression, and so gratifying has been the result of this procedure that the old operation is likely, before long, to become almost obsolete. In a case recently communicated to me by Professor Blackman, of Cincinnati, that gentleman succeeded in arresting completely the pulsation in a popliteal aneurism by digital compression for two hours, after the failure of various other methods.

Forced flexion, described at page 754, is particularly applicable to aneurism of the ham, and always deserves a fair trial provided the tumor is not so large as to encroach seriously upon the structures of the joint or to threaten to burst into its interior.

Mortality.—The mortality from the operation for popliteal aneurism by the Hunterian method would seem to be variable. In the table of Dr. Norris, comprising a list of 188 cases of aneurism for which the femoral artery was tied, 142 were cured, and 46 died. It is proper, however, to add that the ligation in 33 of the cases was performed for other purposes than aneurism of the popliteal artery. The table of Mr. Crisp furnishes 110 cases, operated upon by the Hunterian method, of which 91 recovered completely, 7 required amputation after the use of the ligature, and 12 died. Of the 11 cases of double popliteal aneurism comprised in it, all were cured; 10 by ligature, and one by compression. The greatest cause of the mortality after the ligation of the femoral artery is gangrene of the leg.

Traumatic aneurism of the ham is unusual. Cases have occurred where it was occasioned by a sabre wound, a musket ball, or the sharp end of a piece of bone in fracture of the femur above the condyles. A few cases are also recorded of arterio-venous aneurism in this situation, in consequence of ulceration establishing an interchange of blood between the popliteal artery and vein.

ANEURISM OF THE ARTERIES OF THE LEG AND FOOT.

Spontaneous aneurism of the arteries of the leg is almost unknown. The traumatic form of the disease, however, is occasionally met with, and there are few cases in surgery more difficult to manage, especially when the lesion involves the posterior tibial artery, owing to the great depth at which this vessel is situated, and the confused condition of the parts in consequence of the extravasated blood. The proper remedy, of course, is free exposure of the affected vessel, removal of the coagula, and ligation of both ends. To accomplish this to the best advantage, often involves great coolness on the part of the operator, and an unusual amount of anatomical knowledge and dexterity. During the operation, the iliac artery should be compressed at the brim of the pelvis, or a tourniquet be applied round the upper part of the thigh. Without such precaution, the hemorrhage might be frightfully profuse.

Injuries of the arteries of the foot are often followed by troublesome hemorrhage, which may eventually become quite exhausting. Cases of this kind are, more than almost any other in surgery, a stumbling-block to men ignorant of surgical anatomy, and it is not going too far to say that they are also, at times, exceedingly perplexing to the educated practitioner, annoying, fretting, and worrying him until his patience is nearly exhausted. The arrangement of the arteries in the sole of the foot is very similar to that of the palm of the hand; the anastomosis between the plantar arteries is very extensive, and hence when these vessels are wounded it often becomes extremely difficult to arrest the flow of blood permanently without the use of the knife and ligature. It might be supposed, at first sight, that well-regulated, systematic compression would put an effectual stop, in most cases, to the hemorrhage, but this, it is well known, is not the fact. It arrests the bleeding temporarily, and that is all. If an occasional exception occurs, it is an exception merely, nothing more. The rule is that the plantar arteries, when divided, will continue to bleed until they are secured by ligature. Why, then, not ligate them at once, without waiting until the patient is blanched and exhausted by the loss of blood, in the vain hope that compression may eventually stop it? That this is the proper course of procedure, is unquestionable; the only objection to it is the extensive wound which we may be obliged to make in order to bring the bleeding vessel fully into view, so as to enable us to apply the ligature. Still, as this must generally be done, sooner or later, in every case, we cannot too strongly insist upon its being done as early as possible after the infliction of the injury. In making the necessary incisions, care must, of course, be taken not to disturb any important structures; and in every instance the golden rule must be observed, to tie each end of the bleeding vessel, lest the hemorrhage should continue through the recurrent branches.

It has been proposed in these cases to cut down upon and tie the principal arteries of the leg, and we read of instances in which even the great trunk of the thigh was ligated for such a purpose. Such a procedure cannot be too strongly condemned, as being contrary both to common sense, anatomical knowledge, and sound experience. The experiment of tying both the tibial arteries has been tried again and again under such circumstances, and the almost invariable effect has been complete failure; as might, indeed, have been anticipated from a careful study of the disposition of the arteries of the foot.

Notwithstanding the somewhat pointed manner in which I have here spoken against compression in hemorrhage of the plantar arteries, it is but proper to add that I have seen this very method occasionally put a most prompt and

effectual stop to the flow of blood. I recollect distinctly the case of a little girl, which came under my observation many years ago, where I succeeded, by a single dressing, in arresting an exhausting and daily recurring hemorrhage of upwards of a month's duration. A graduated compress placed over the orifice of the bleeding vessel, and confined by a roller extending from the toes upwards, aided by elevation of the leg and cold applications, constituted, as it always should when such a procedure is adopted, the means employed on the occasion.

Sometimes we may advantageously resort to the expedient of compressing the anterior and posterior tibial arteries by means of two corks, placed directly over the vessels, opposite the malleoli, and bound down firmly by a suitable bandage, passed around the foot and leg in the form of a figure 8. The corks should each be wrapped up in a bit of patent lint, and should be at least three-quarters of an inch in length, and of proportionate thickness and breadth, otherwise it will be difficult to make them retain their proper position. When the compression is obliged to be made with great firmness, it may be well, in order to defend the soft parts, to extend a piece of sheet-lead across the limb under the bandage.

SECT. VIII.—OPERATIONS ON THE ARTERIES.

LIGATION OF THE INNOMINATE OR BRACHIO-CEPHALIC.

Although the innominate may easily be exposed on the dead subject, as was shown by Dr. George McClellan as early as 1820, by a linear incision carried vertically down in front of the trachea, without dividing any of the cervical muscles, yet I believe that such a plan would be ill suited to the purpose when there is a large tumor pressing upon and displacing the parts which environ this vessel. The operator must have ample room, and it will not, I presume, materially affect the issue of the case whether a little more or a little less tissue is cut. The plan suggested by Dr. Mott, in his celebrated case, is, on the whole, it seems to me, the one best adapted for obtaining ready access to this artery, and is that which I should myself follow if I were called upon to secure the innominate for the cure of aneurism. The incision resembles, in outline, the shape of the letter L, the horizontal limb corresponding with the upper border of the clavicle and sternum, and the vertical with the inner margin of the sterno-cleido-mastoid muscle, each being about three inches in length. The lower incision extends as far inwards as the centre of the trachea. The triangular flap thus mapped off, embracing the skin and platysma-myoid, being dissected up, the sterno-cleido-mastoid, sterno-hyoid, and sterno-thyroid muscles are respectively separated upon a director from their inferior connections and turned out of the way. A layer of the deep cervical fascia is now cautiously pinched up and divided, when, by a little scratching with the finger-nail, the handle of the scalpel, or the end of a probe, the carotid will be brought into view a few lines above the top of the sternum, accompanied by the jugular vein and pneumogastric nerve. Taking this vessel as his guide, the surgeon can easily trace the course of the innominate downwards towards the heart, and isolate it from its associate vein. The ligature, when the case admits of it, should be applied about the middle of the vessel, the needle being carried around it from left to right and from behind forwards.

In performing this operation, it should be remembered that this artery is only about sixteen lines in length; that it rests upon the trachea, which it crosses somewhat obliquely at the base of the neck; that the middle thyroid veins, and sometimes the middle thyroid artery, run along its inner side;

and that on the right side, and on a plane anterior to it, is the innominate vein, the two vessels being intimately united together by cellular substance, and in close relation behind with the pneumogastric and phrenic nerves, the latter lying external to the former. The top of the pleura is a little inferior and external to the artery, and might, unless great caution is used, be easily wounded. The middle thyroid artery is sometimes given off by the innominate on its tracheal aspect, and should be looked for in isolating the vessel, as its division might be followed by annoying hemorrhage.

LIGATION OF THE COMMON CAROTID.

To Mr. Abernethy is usually, but erroneously, ascribed the merit of having first tied the common carotid. From some remarks of Hebenstreit, it appears pretty certain that the operation had been performed some time previously by a surgeon during the extirpation of a scirrhus tumor of the neck, in which he accidentally divided this vessel, and immediately surrounded it with a ligature, the patient soon recovering. The English surgeon did not ligate the artery until 1798; the case was one of wound of the internal carotid, and the man died in thirty hours. The first operation that was performed upon it for carotid aneurism was by Sir Astley Cooper, in 1805, and was unsuccessful, the case terminating fatally on the nineteenth day. Three years subsequently, he ligated the vessel again, and now with a happy result.

There are two points of the neck at which the common carotid may be tied, the place of election being regulated by the circumstances of the particular case. These are the upper and inferior cervical regions, and it will be well, in every instance before the operation is begun, to recall to mind the more important anatomical relations of the parts, otherwise serious blunders may arise, such, for example, as tying the omo-hyoid muscle or jugular vein instead of the artery, or including along with the artery the vessel just named, or some important nerve, as the pneumogastric, sympathetic, or laryngeal. As the artery proceeds upwards, it is overlapped by the sterno-mastoid, sterno-hyoid, and sterno-thyroid muscles, and crossed by the omo-hyoid towards its superior extremity. Running down in front of its sheath is the descending branch of the ninth pair of nerves, a little, thread-like filament, easily recognized by its whitish appearance, while within the sheath are, on the external side of the artery, the internal jugular vein, and behind and between them the pneumogastric nerve, the sympathetic and recurrent nerves being posterior to the sheath. These relations are very intimate, and hence the most cautious procedure is necessary in isolating the parts previously to the application of the ligature. The embarrassment is often immensely increased by the manner in which the artery is overlapped by the jugular vein, which occasionally, though less frequently than is generally supposed, swells out enormously during every effort at expiration, so as to obscure the vessel and render its ligation extremely difficult. The best way of remedying this is to request an assistant to compress the vein both at the upper and lower angle of the wound, the blood having been previously pressed out of it.

The common carotid, on the right side, is sometimes absent, its place being supplied by two trunks, which, arising separately from the arch of the aorta, ascend along the neck, assuming the office of the external and internal carotid. When this arrangement exists, which, however, is extremely rare, the order of origin of the branches of the aorta is as follows: the right subclavian, right external carotid, right internal carotid, left common carotid, and left subclavian. It should also be borne in mind that the common carotid may, on the one hand, bifurcate very low down, not perhaps reaching as high up as the inferior border of the thyroid cartilage, and, on the other hand, it may not separate into its terminal divisions until it gets to the angle of the jaw.

Lastly, it may be crossed in front by the inferior thyroid artery, lie upon the vertebral artery as this vessel passes along the spine, and include in its sheath the descending branch of the ninth pair of nerves.

In ligating the carotid, the patient should be recumbent, with the head inclined to the opposite side, and well supported by pillows, the shoulders being at the same time somewhat raised, in order to place the neck in a proper horizontal position. If he do not desire to take chloroform, he may sit on a chair, the head resting against the breast of an assistant.

In the lower part of the neck the artery may be exposed by making an incision, from two and a half to three inches in length, along the inner border of the sterno-cleido-mastoid muscle, commencing just above the clavicle. The skin and platysma-myoid muscle being divided, a portion of the cervical fascia is pinched up with the forceps, and opened transversely to an extent large enough to admit a grooved director, upon which the membrane is then slit up and down nearly to the length of the outer incision. Two retractors are now inserted into the wound, one being used to draw the sterno-cleido-mastoid muscle outward, and the other to draw the sterno-thyroid inwards towards the trachea. The sheath of the artery being thus exposed, a little piece of it is now raised with the forceps, and divided horizontally, when, the director being introduced, it is slit open so as to denude the artery to a small extent, and enable the operator to isolate it from the jugular vein and the pneumogastric nerve, the ligature being passed from without inwards. Generally a small subcutaneous vein will be found passing along the line of incision, communicating above with the facial vein, and below with the thyroid plexus. This must, of course, be carefully avoided.

The artery being more easy of access in the superior part of the neck than the inferior, this point should always be selected, when this is in our power, for ligating it. To expose the vessel in this situation, an incision should be carried along the inner margin of the sterno-cleido-mastoid muscle, commencing a little below the cricoid cartilage, and reaching nearly as high up as the angle of the jaw. Embracing the integuments, platysma-myoid muscle, and cervical fascia, it will thus conduct the operator at once down to the

sheath of the vessel, which is then to be opened in the same cautious manner as in the previous case; and the artery being separated gently from the accompanying structures is ligated by passing the needle round it from without inwards, so as effectually to exclude the jugular vein. The omo-hyoid muscle which crosses this part of the carotid must be held aside with a hook.

The annexed cut, fig. 260, represents the common carotid as being exposed by a long incision, with a view of showing where it is crossed by the omo-hyoid muscle.

When access to the common carotid, in the inferior part of the neck, is rendered difficult on account of the low

Fig. 260.

Ligation of the common carotid.

situation of the tumor, the best plan is to divide the sterno-hyoid and sterno-thyroid muscles, either alone, or jointly with the inner portion of the sterno-mastoid, so as to enlarge the space between the aneurism and the sternum. By observing this precaution, Mr. Porter, of Dublin, was enabled, in one case, to ligate the vessel successfully within the eighth of an inch of the innominate; and examples of a similar character have occurred in the practice of other surgeons.

The carotid is sometimes tied at a very early age. I recollect a case in which I assisted Dr. McClellan, where that excellent and brilliant operator secured this vessel in a child only five months old, on account of an immense nevus of the upper part of the face. I remember, also, that the descending branch of the ninth pair of nerves was divided on the occasion, as it interfered with the passage of the ligature. No untoward symptoms of any kind occurred; the tumor diminished somewhat after the operation, but in less than a month it was larger than ever.

Ligation of the common carotid is occasionally required on account of wounds of the neck involving the external carotid or some of its branches. The operation is often embarrassing in consequence of the confused condition of the parts from the extravasation of blood, and is, moreover, not always successful, owing to the establishment of a return current through the internal carotid into the external carotid. Hence secondary hemorrhage, sometimes of a very profuse character, is liable to ensue, necessitating further proceeding, and that, perhaps, at a time when the wound is in a high state of inflammation. In order to avoid all this, Dr. Gurdon Buck has proposed the simultaneous ligation of the common and internal carotid arteries, and, in the *New York Medical Times* for November, 1855, he has given the particulars of a case in which the operation was followed by the most gratifying results.

The common carotid artery has been repeatedly secured for wounds, epilepsy, and erectile and other tumors, as well as for the purpose of restraining hemorrhage in operations upon and about the jaw, face, and neck. The statistics of these operations present points of much interest, and they have been placed in a very clear light by the tables of Dr. Norris. In 30 cases in which the artery was tied on account of wounds, 15 recovered, and 15 died; in 16 cases in which it was ligated previously to, or at the time of the extirpation of tumors of the jaw, face, or neck, 8 died; in 6 in which it was tied for the cure of epilepsy, all recovered from the effects of the deligation, although in 2 both vessels were secured; and in 42 cases in which it was tied for the cure of erectile tumors and various growths of the diploë, orbit, neck, jaw, and maxillary sinus, 20 were cured, 13 died, and 9 recovered from the effects of the operation without being materially benefited. In upwards of 20 of the 94 cases, more or less severe cerebral symptoms followed the operation.

Dr. James R. Wood, in 1857, published the details of 39 cases in which the primitive carotid was secured by different surgeons of the city of New York for various affections, as secondary hemorrhage, malignant growths, benign tumors, epilepsy, and aneurism of the branches of the carotid, with a loss of only six. Of these six cases, only five were dissected. The cause of death in two was found to be softening of the brain, in one inflammation of the jugular vein, in one pericarditis with abscess in the lung and liver, and in one exhaustion.

A number of cases have been reported in which both these vessels have been tied, either simultaneously or after a variable interval. The following table affords a summary view of nearly all the examples of this kind that have yet occurred.

Operator.	Date.	Age.	Sex.	Disease.	Interval.	Result.	REMARKS.
Macgill	1823	Adult	F.	Tumors of both orbits		Improved	Vision destroyed before operation, and eyes presenting a mass of disease.
Mussey	1827		M.	Anastomotic aneurism of scalp	12 days	Failed	Pulsation returned in tumor, which was excised three weeks after second operation.
Mussey		28		Ditto	28 days	Recovered	
Müller	1831	4½		Erectile tumor	4½ mo.	Recovered	
Preston	1831	51	M.	Epilepsy	84 days	Failed	Fits had existed for six years, and had latterly been attended with palsy on one side.
Preston				Epilepsy	1 mo.	Failed	Convulsions the day after each operation. No material relief.
Kuhl	1834	53	M.	Aneurism of the occiput	72 days		The second operation was performed during a profuse hemorrhage of the scalp. The first operation was followed by syncope and convulsions.
Mott				Disease of parotid	15 min.	Died in 48 hrs.	
Mott				Malignant polypi	Several months	Recovered?	
Ellis	1844			Secondary hemorrhage	4½ days	Recovered	
J. M. Warren	1845	23		Erectile tumor	33 days	Failed	Tumor occupied the mouth, face, and neck. Subsequent excision of the diseased structures, followed by cure.
Hamilton		18		Epilepsy	6 mo.	Recovered	
Robert			F.	Aneurism	8 mo.	Recovered	
Blackman			M.	Disease of antrum	21 days	Recovered	
W. Parker	1854	42	M.	Malignant disease of nose & orbit	32 days	Died	
G. C. E. Weber	1857	20	M.	Epilepsy	17 days	Improved but not cured	Disease had existed five years; had no attack for seven days after first operation. No cerebral disturbance after either operation.

Of the above cases, 16 in number, 14 recovered from the effects of the operation, and 2 died. In Dr. Mott's case, where both vessels were tied almost simultaneously, coma soon supervened, and the man died in forty-eight hours. In the case of Dr. Ellis, of Michigan, the second deligation was performed at an interval of four days and a half, on account of secondary hemorrhage consequent upon a gunshot wound, and no unpleasant symptoms followed, the patient making an excellent recovery. In Dr. Mussey's case twelve days intervened between the two operations, neither of which was succeeded by any accident. To Dr. Macgill, of Maryland, belongs the credit of being the first to tie both carotid arteries on the same subject.

LIGATION OF THE EXTERNAL CAROTID AND ITS BRANCHES.

The external carotid, extending from the superior border of the thyroid cartilage to the neck of the lower jaw, is situated just above its origin, in the triangular space formed by the omo-hyoid muscle below, the digastric above, and the sterno-mastoid externally, immediately beneath the integuments and platysma-myoid; but it soon sinks deeper in, passing up under cover of the stylo-hyoid and digastric muscles, and is finally buried in the substance of the parotid gland. It is accompanied by two veins, and is crossed near its commencement by the hypoglossal nerve, and, in various parts of its course, by branches of the external jugular and other veins. The glosso-pharyngeal

nerve is interposed between this artery and the internal carotid, while the superior laryngeal nerve lies under both.

Deligation of the external carotid is seldom required for anything else than wounds and vascular growths about the face and head. The vessel is often opened in attempts at suicide, though less frequently than is generally imagined; for persons intent upon self-destruction usually bend the neck so far back as to place the artery beyond the reach of the knife. Some of its branches are, however, commonly injured under such circumstances, especially the superior thyroid and lingual, and the hemorrhage thus produced may be promptly fatal. A ligature may be readily placed round the external carotid, in the first part of its course, by carrying an incision, about two inches and a half in length, along the inner edge of the sterno-mastoid muscle, commencing opposite the middle of the thyroid cartilage, and terminating at the angle of the jaw. The trunk of the common carotid will guide the finger to its external division. The incision should be made with great care, lest violence be done to some of the numerous offsets of the vessel. The artery, as it lies beneath the digastric and stylo-hyoid, is exposed with difficulty; the incision must be proportionably large, and the muscles just mentioned must be well depressed with the retractor.

The principal branches of this artery, requiring surgical consideration, are the superior thyroid, lingual, facial, occipital, and temporal.

The *superior thyroid artery* is, as already stated, much exposed to injury in attempts at suicide, and may, under such circumstances, be easily traced simply by following the wound. If it becomes necessary to ligate it, as is sometimes the case in hypertrophy of the thyroid gland, with a view to diminish the supply of blood, it may be laid bare by making an incision across the upper part of the neck, obliquely downwards and outwards from the side of the hyoid bone to the edge of the sterno-mastoid muscle.

The *lingual artery* may be exposed in the same manner as the thyroid, near which it takes its origin; its situation, however, is very deep, and its relations are so complicated that it is generally better to secure the external or common carotid.

If the operation should be deemed necessary, it may be performed as follows, according to the plan laid down by Mr. Skey.

"The head of the patient being placed horizontally, and the neck lengthened by raising the chin, an incision of about twelve lines in length should be made immediately behind the corner of this bone, the outline of which should be distinctly ascertained before proceeding to the operation: the incision should be directed downwards and forwards. The skin and platysma being divided, the fascia is exposed, which should be also divided to the length of the external wound. The facial vein, often of considerable size, may be brought into view at the upper part of the wound, in its course downwards to the internal jugular, and should be drawn outwards. The remaining parts should be torn, rather than cut asunder, passing transversely inwards, nearly parallel to the upper edge of the cornu of the os hyoides, when the artery will be exposed. In

Fig. 261.

Ligation of the lingual artery.

passing the needle behind it, care must be taken to avoid the superior laryngeal nerve, which descends nearly at right angles behind the artery."

The *facial artery* is frequently concerned in operations about the neck, face, and lips, and may be easily compressed with the finger as it passes over the jaw. If divided, it should immediately be secured. When its ligation becomes necessary, in case there is no wound, its pulsation will point out the proper situation for the incision. When it is desired to secure it just above its origin, the incision should be made as in the operation upon the lingual, its approach being facilitated by drawing the digastric strongly upwards. The vessel is most easily exposed and tied where it lies over the jaw, as in fig. 262.

Fig. 262.

Ligation of the facial artery.

The *occipital artery* sometimes requires ligating on account of wounds, but its depth in the lower part of its extent is such as to protect it generally from injury involving the cervical region. On the back of the head, however, it is not unfrequently laid open, and usually bleeds very freely. It may be exposed just above its origin by carrying an incision along the inner border of the sterno-mastoid muscle, in the angle formed by it and the digastric, the latter of which must be well drawn down. It is in intimate relation here with the hypoglossal nerve, which hooks round it as it passes forwards towards its destination. The artery, after emerging from the splenius muscle, on the back of the head, fig. 263, is superficial, its course beneath the scalp being denoted by its pulsation.

Fig. 263.

Ligation of the occipital artery.

Fig. 264.

Ligation of the temporal artery.

The *temporal artery* is occasionally wounded, and may be secured immediately above the zygoma, by a short vertical incision, fig. 264, embracing the temporal aponeurosis, immediately beneath which it is situated. Lower down, the depth at which it lies is too great to justify an attempt at ligation. Should it be divided in this portion of its extent, the best plan is to tie the external carotid.

The anterior branch of this vessel is the one always selected in arteriotomy, when it is wished to practise depletion on account of affections of the

brain or the brain and its membranes. After a sufficient amount of blood has escaped, the artery is cut across, and a graduated compress applied. If this precaution be neglected, a false aneurism will form.

The *internal maxillary artery* is sometimes wounded in consequence of a thrust with a sharp knife or dirk. The necessary result, of course, is a copious hemorrhage, for the arrest of which the only remedy is ligation of the external carotid; compression, it is true, now and then succeeds, but the only reliable means is the ligature. When the vessel is wounded in the extirpation of the jaw, it may sometimes be seized and tied; when this is impracticable, the bleeding may generally be stopped with the hot iron, or with the tampon, wet with a saturated solution of alum and tannin, or covered with persulphate of iron.

LIGATION OF THE VERTEBRAL ARTERY.

The vertebral artery is the largest branch of the subclavian, and, of course, bleeds profusely when divided, as it occasionally is in wounds of the neck. Taking the opening as the guide, the vessel should be traced to the seat of injury, and a ligature applied to each extremity. The dissection necessary for its exposure should be conducted with the greatest caution, on account of the important and complex relations which the vertebral sustains to the surrounding parts.

LIGATION OF THE SUBCLAVIAN ARTERY.

The point which is usually selected for tying the subclavian artery is just external to the scalene muscle, in what is considered as the third course of the vessel. One single incision will generally be found to be sufficient for the free exposure of the artery, and this may be strictly horizontal or more or less curvilinear, according to the fancy of the operator. It is only when the tumor is so bulky as to cause great malposition of the shoulder, forcing the collar-bone high up into the neck, that two incisions can really be required, the one extending along the upper border of the clavicle and the other vertically upwards, parallel with the outer edge of the sterno-cleido-mastoid muscle.

Previously to commencing the operation, the patient should be placed in the horizontal position upon a narrow table, with his head and chest moderately elevated, and the face slightly inclined towards the sound side. An assistant taking hold of the hand, keeps the affected limb close to the trunk, at the same time that he pulls down the shoulder as much as possible, in order to draw the clavicle away, as it were, from the subclavian artery as it passes from the scalene muscle towards the first rib. The surgeon, standing by the side of the patient, above the shoulder, stretches the integuments of the neck upon the upper part of the chest with the fingers of the left hand, while with the other he makes an incision, about two inches and a half in length, di-

Fig. 265.

Ligation of the subclavian artery, in its outer third.

rectly along the middle of the clavicle, commencing at the sternal origin of the mastoid muscle and terminating near the anterior margin of the trapezius. In this manner he divides the skin, the superficial fascia, and the platysma-myoid. Letting go his hold with his left hand, the parts will be found instantly to resume their natural situation, leaving thus the incision on a level with the superior border of the clavicle. The next step of the operation consists in detaching from this bone the deep cervical fascia, or rather aponeurosis, which may readily be accomplished by a few gentle strokes of the handle of the scalpel instead of the point of the instrument, which would greatly endanger the surrounding vessels and nerves. The external jugular vein will be found close to the outer edge of the mastoid muscle, and should be held out of the way with a blunt hook. The supra-scapular artery will also generally appear, at this stage of the proceeding, just above and behind the clavicle, or partially covered by it, and should be treated in a similar manner; or, if it be divided, it should immediately be tied. The omo-hyoid lies at the outside of the incision, bound down by a process of the cervical aponeurosis, which should next be torn through with the knife. Taking the anterior scalene muscle for his guide, the operator feels for the tubercle of the first rib, a little to the outside of which the artery will be found pulsating, more or less distinctly, and where it may in general be easily secured by passing the needle from before backwards and from below upwards. Before tightening the ligature, it should be ascertained that it controls the circulation of the aneurismal sac, and, above all, that it does not include any of the cords of the axillary plexus of nerves, a circumstance which has happened in several of the cases in which this operation has been performed. It should be stated that whenever the clavicular origin of the mastoid muscle is unusually broad, as it not unfrequently is, it should be divided upon a grooved director. By pursuing this course, I am convinced that our approach to the vessel will, in the majority of cases, be greatly facilitated. Particularly will this be the case when the design is to apply the ligature behind the scalene muscle.

In this manner, the subclavian may, in the generality of cases, be easily reached without much waste of blood or loss of time. In some instances, however, the operation is rendered extremely difficult, tedious, and embarrassing, owing either to the magnitude of the tumor and the consequent elevation of the clavicle, the diseased state of the artery, an unusual course of the vessels of the neck, or, even when these follow their natural direction, the swollen and distended condition of the subclavian vein, some irregularity on the part of the omo-hyoid, an enlarged condition of the cervical lymphatic ganglions, or, finally, the great condensation of the parts from the effusion of plastic lymph. A few remarks on each of these topics must suffice.

1. The *elevation of the clavicle* is generally in direct proportion to the size of the tumor. Sometimes, however, even when the swelling is comparatively diminutive, this bone is situated much higher up than usual, owing to the peculiar conformation of the individual. In either case, the difficulty of finding the vessel will be much increased. In one instance, where the elevation was produced by the enormous development of the disease, Sir Astley Cooper was forced to abandon the operation altogether. When such a contingency arises, which, on the whole, must be extremely rare, instead of giving up the case in despair, as was done by the English surgeon, the best plan, it seems to me, would be to divide the anterior scalene muscle, so as to enable us to apply the ligature somewhat nearer the heart, or even on the tracheal side of that muscle.

2. The operation is occasionally rendered more or less intricate and embarrassing by the *diseased state of the artery*. In this case, although the vessel may be easily enough approached, it is impossible to apply the ligature at

the usual situation. To divide the scalene muscle, or to cut down along its inner margin, for the purpose of securing the vessel at one or other of these points, is here our only resource. The brachial plexus of nerves may also be so much in the way of the operator as to render this course necessary, as happened on one occasion to Dupuytren.

3. The *cervical vessels*, both arterial and venous, are almost constantly in the way of the operator, even when they follow their usual route. This is particularly true of the external jugular vein and of the supra-scapular artery. The former of these vessels, commencing at the angle of the jaw, passes vertically down the neck under cover of the platysma-myoid. In the early stage of its course, it rests upon the sterno-mastoid; afterwards it gets to the outer border of this muscle, and finally, at the inferior part of the neck, sinks behind it, to terminate in the subclavian vein near its junction with the internal jugular. Just before it disembogues, which it sometimes does by several distinct trunks, it receives two pretty large branches, the supra-scapular and transverse cervical, which traverse the neck in a horizontal direction from without inwards, parallel with the arteries of that name. These arteries, as well as their accompanying veins, lie deeply at the root of the neck, especially the supra-scapular, which is frequently concealed for some distance by the clavicle, on a line with which it runs to reach the root of the coracoid process; it is generally a branch of the thyroid axis, and rests at first upon the anterior scalene muscle, crossing as it passes outwards the subclavian artery. The course of the transverse cervical artery is nearly similar, but it is usually situated somewhat higher up; it is also considerably smaller, and is most frequently derived immediately from the subclavian.

Now, in attempting to reach the subclavian, it is almost impossible to avoid wounding some of the vessels above mentioned. The external jugular vein is particularly in danger, and can scarcely escape without the utmost coolness and dexterity on the part of the operator. As soon as it is recognized it should be separated from the surrounding structures by a few gentle strokes with the handle of the scalpel, and drawn to the outer side of the wound. This plan is undoubtedly always the best and safest when it can be adopted; however, it sometimes happens that the vessel is so much in our way as not only greatly to embarrass our progress, but absolutely put a stop to it. In this case, it must be cut across, or, what is preferable, tied with two fine ligatures, and divided between them. By pursuing this method, we not only avoid a troublesome hemorrhage, but effectually prevent the introduction of air into the lower portion of the vessel, an occurrence which should always be guarded against. The supra-scapular artery, if in the way, should be carefully drawn aside, or, if it be wounded, immediately secured. Any bleeding vessels, indeed, no matter whether arterial or venous, provided they pour out a sufficient amount of blood to interfere with the operation, should at once be tied, though no more ligatures should be retained than are absolutely necessary.

4. The inordinate *swelling of the subclavian vein* is another source of embarrassment which is occasionally experienced in operations of this kind. This vessel is usually situated somewhat below and superficially to the artery, being separated from it by the anterior scalene muscle, upon which it lies. Commencing at the inferior margin of the first rib, where it is continuous with the axillary, it passes horizontally inwards until it joins the internal jugular vein, within a few lines of the sterno-clavicular articulation. In this course, in which it is almost entirely concealed by the clavicle, it receives the small branches which accompany the different offsets of the artery as well as the external jugular, which last enters it, as before stated, nearly opposite the centre of the bone, but sometimes more internally. After the division of the cervical aponeurosis in the lower part of the neck, the operator will occa-

sionally observe this vessel alternately to swell and subside, owing not so much, as some have supposed, to the natural flow of the current within it as to the reflux caused by the action of the right auricle, aided by the hurried and agitated state of the respiratory movements. The difficulty thus occasioned is not only annoying, but sometimes so embarrassing as to render it almost impossible even to see the artery, much less to separate and tie it. To remedy this, it has been suggested that the operation should be suspended for a moment, and the patient placed in the semi-erect posture to allow him to make several full and easy inspirations, after which, it is said, the tension of the vein will be diminished, and the regurgitation of the blood cease. The surest and most expeditious plan, however, is to hold the vessel out of the way by means of a broad blunt hook, or copper spatula, carried down behind the clavicle. In this manner the vein may be effectually compressed to the extent of half an inch, or more, if necessary, and the artery fairly brought into view.

5. The *omo-hyoid* muscle, instead of forming a triangular space, as it usually does, with the scalene muscle and the clavicle, may run parallel with, and just above, that bone, or even entirely below it. In either case, should it be productive of inconvenience to the operator, he should pass a director under and divide it. Such a proceeding, however, can seldom be called for, as, by laying open its sheath, the muscle may generally be drawn out of our reach.

6. The *lymphatic ganglions*, at the inferior part of the neck, may be so much enlarged as to interfere seriously with the different stages of the operation. When this is found to be the case, instead of trying to save these bodies, they should be carefully dissected out, as we shall thus not only expedite our arrival at the artery, but, what is a matter of no little importance, greatly facilitate the healing of the parts after the vessel is tied.

7. Finally, considerable embarrassment may arise from the *condensed and indurated* state of the parts, caused by the effusion of plastic lymph. This may always be looked for when the disease is of long standing, or when the tumor is so large as to excite severe inflammation in the deep-seated structures immediately above the clavicle, thereby obscuring the nerves and vessels.

If, from the above causes, it be sometimes difficult to denude the artery, to convey a ligature around it will often be found to be much more so. Indeed, this generally constitutes the most annoying and embarrassing step of the operation. To facilitate this procedure, various mechanical contrivances have been resorted to, some of them so complicated in their character as to be well calculated to enhance instead of diminishing the difficulty. Under ordinary circumstances, every indication may be fulfilled with the common aneurismal-needle, or even with a common eyed-probe. Whatever mechanical contrivance be employed, the ligature, as a general rule, should be passed from before backwards and from below upwards, as it will be found much easier in this way to prevent injury to the subclavian vein, while there will be no danger whatever of including any of the cords of the brachial plexus of nerves. Owing to the great depth of the wound, not a little difficulty is sometimes experienced in tightening the knot. In this case the ingenious instrument invented by Dr. Hosack, of New York, will be found very useful. By holding the first knot firm it enables the surgeon to tie a second or third with the utmost facility.

Notwithstanding the assistance to be derived from the different instruments that have been invented for that purpose, such has been the difficulty, in some instances, of conveying the ligature around the artery as to lead not only to great delay, but almost to an abandonment of the operation. It has been suggested, under these circumstances, to saw through the clavicle, and to this proposal I can see no objection, provided the shoulder is so much elevated as to offer an almost insurmountable barrier to the passage of the

ligature. By this practice, although a compound fracture of the clavicle would be superadded, yet this would be of the most simple kind, while the operation, instead of occupying from one to two hours, as has repeatedly happened heretofore, could be completed in a comparatively short time; the vessel could be much more effectually secured, the risk of wounding the subclavian vein and other parts would be greatly diminished, and the patient would have a much better chance for recovery.

The arteries which are more particularly concerned in maintaining the collateral circulation after the ligation of this vessel, are the supra-scapular, transverse cervical, internal mammary, long thoracic, circumflex, and subscapular, the first three being branches of the subclavian, the other three of the axillary. The thoracic artery frequently arises from the aneurismal sac, and is therefore liable to be obliterated for some distance in the progress of the disease.

The subclavian artery has been tied several times in the second course of its extent, but the procedure is very difficult, as well as replete with danger, owing to the proximity of numerous important structures, especially the phrenic nerve, jugular vein, pleura, and thyroid axis. The external incisions are similar to those employed for exposing the artery in the other parts of its extent; as soon as the anterior scalene muscle is fully brought into view, a grooved director is carried behind it, and its lower attachment carefully severed from the clavicle, the phrenic nerve having previously been placed beyond the reach of the knife. The top of the pleura, lying close by, must not be wounded in passing the needle. It will thus be perceived that the operation is one of excessive delicacy, requiring consummate anatomical knowledge and skill for its successful execution. The greatest objection, however, to its performance is that the subclavian is obliged to be tied so close to the superior intercostal and deep cervical branches; a circumstance which must necessarily materially interfere with, if not wholly prevent, the formation of a firm and adherent clot.

The subclavian is occasionally tied for wounds of the axillary artery. In the table of Dr. Norris, comprising 69 cases of operations upon this vessel, 9 were performed for this purpose, and of these, 6 proved fatal. Mr. Guthrie, in his *Treatise on the Diseases and Injuries of the Arteries*, refers to 22 cases in which the subclavian was ligated for a similar object, 11 times above the clavicle, and 11 times below. Of the former cases, 9 recovered, and 2 died; death in one being caused by the bursting of an internal aneurism, and in the other, by gangrene after amputation at the shoulder-joint. Of the 11 cases in which the artery was tied below the clavicle, 6 recovered, and 5 perished, three from gangrene of the limb, one from exhaustion, and one from hemorrhage.

LIGATION OF THE AXILLARY.

The axillary artery requires ligation chiefly on account of penetrating wounds, or its accidental laceration during the reduction of ancient dislocations. Of the latter occurrence, quite a number of cases have been reported by surgical writers. There are two regions where the vessel may be secured, either just below the clavicle, or in the hollow of the axilla. In the intermediate point, the vessel is so deeply situated, and in such intricate relations, as to render its approach a task of much difficulty.

The artery in the first of these regions is very deep seated, and hence it has been advised, instead of tying it, to ligate the subclavian in the third stage of its course. Cases, however, occur, in which it is desirable to secure it soon after its origin, and this can generally be done without any difficulty, provided the surgeon is sufficiently cool and deliberate, and has a thorough knowledge of the anatomy of the parts. The patient being placed in a half-

sitting posture, with the arm slightly abducted, an incision is carried along the inferior border of the clavicle, through the skin and platysma-myoid, commencing one inch from the sternum, and extending to within a short distance of the deltoid muscle, care being taken to avoid the cephalic vein, as it lies in the groove between the latter and the great pectoral. The next step consists in dividing the fibres of the great pectoral to the full extent of the external wound. The small pectoral is now seen at the lower portion of the wound, and should be relaxed by bringing the arm close to the trunk. A retractor being inserted, and the divided structures well depressed, the artery will be found at a short distance below the clavicle invested by a dense fascia, which must be carefully scraped through before the vessel can be fairly exposed to view. The accompanying vein, which often swells suddenly out during expiration, lies below and in front of it, while the brachial plexus is behind, except one of its branches, which is above and in contact with it. The anterior thoracic artery, one of the offsets of the axillary, is also on its anterior surface. The needle is passed from within outwards, in order to exclude the vein. As difficulty is sometimes experienced in distinguishing the artery from the cords of the axillary plexus of nerves, it will be well, before tightening the thread, to ascertain what effect its application has upon

Fig. 266.

Ligation of the axillary, in its inferior division.

the pulse at the wrist, or in the aneurismal sac. The costo-coracoid ligament sometimes requires division in this operation.

To expose the artery in its inferior section, fig. 266, the arm should be abducted and supinated, and an incision, nearly three inches in length, made through the axilla, close to the border of the broad dorsal muscle. The cellular and aponeurotic structures being next divided, the median nerve and axillary vein will be brought into view, the

two roots of the former embracing the artery on each side, and the latter running along its anterior surface. Cautiously separating these parts with the finger, or the forceps and director, and turning them in opposite directions, the artery is exposed, and tied by passing the ligature from within outwards.

LIGATION OF THE BRACHIAL.

The brachial artery, in consequence of wounds and various kinds of traumatic aneurisms, requires to be ligated more frequently than any other artery in the body. Extending from the lower border of the axilla, on a level with the tendon of the teres muscle, to nearly one inch below the bend of the elbow, it is overlapped above by the coraco-brachial muscle, and in the middle by the two-headed flexor, while inferiorly it is completely covered by a reflexion of the brachial aponeurosis. Its whole course, however, is comparatively superficial, so that it is easy to feel its pulsations in the greater portion of its extent. In attempting to secure the artery high up, near its origin, an incision, two inches and a half in length, should be made along

the inner margin of the coraco-brachial muscle, the arm being extended and supinated. The artery, accompanied by its two veins, will be found lying here between the median and ulnar nerves, the former being on its outer side, and the latter on the inner. If the artery be sought for at the middle of the arm, the best guide to its seat will be the internal edge of the two-headed flexor muscle. The median nerve, in this part of the course of the artery, usually lies on the inside and in front of the vessel. At the bend of the arm, the brachial is readily exposed by dividing the brachial aponeurosis in a line with the ulnar border of the tendon of the two-headed flexor muscle. In none of these operations is it necessary to divide any muscular fibres.

Schemes for tying the brachial, radial, and ulnar arteries, are depicted in fig. 267.

In operating upon the brachial artery, it should be borne in mind that this vessel is subject to certain varieties, which may serve both to perplex the surgeon, and mar the result of the undertaking. The most frequent of these anomalies is the high division of the artery into the radial and ulnar, which, on reaching the elbow, either pursue their usual course, or, as is more generally the case, the former proceeds superficially down the forearm, while the latter becomes deep seated; or their course may be reversed, the radial following its ordinary route while the ulnar descends immediately under the skin. Several instances have been

Fig. 267.

Ligation of the brachial, radial, and ulnar arteries; also of the palmar vessels.

Fig. 268.

Double brachial artery.

met with in which the brachial divided high up into two branches, which subsequently united again into a single trunk, as in fig. 268, which afterwards bifurcated regularly into the radial and ulnar.

LIGATION OF THE RADIAL AND ULNAR.

The radial artery, whose course along the forearm is indicated by a line drawn from the middle of the bend of the elbow to the forepart of the styloid process of the radius, may be tied near its origin, at its middle, and at its inferior extremity. When the design is to ligate it above, or in the first of these situations, it may be approached by an incision, about three inches in length, parallel to the inner border of the long supinator muscle, between which and the round pronator the vessel will be found, accompanied by its two veins, the radial branch of the musculo-spiral nerve lying at its outer side and some distance from it. Care is taken not to wound the basilic vein. In the middle third of the forearm, the artery lies between the long supinator and flexor muscle of the carpus, the spiral nerve descending close along its radial border. In the inferior portion of its extent, the artery is comparatively superficial; its pulsation is very distinct in the greater part of its length, and therefore serves as a ready guide to its course.

The ulnar artery is sometimes divided in the upper part of its extent by a knife or ball, and in this event it may generally be easily found by taking the wound as our guide, enlarging it, if necessary, and tying the vessel at each extremity. When a false aneurism exists in this situation, it is usually recommended to ligate the brachial, but I am satisfied that it would be more safe, in every instance, to tie the ulnar soon after its origin, by cutting boldly through the thick muscular mass at the upper third of the forearm, as we could thus effectually guard against hemorrhage from the recurrent circulation. In the middle of the limb the artery lies along the radial border of the ulnar flexor of the carpus, which should therefore be taken as a guide to the knife, and be carefully separated from the common flexor of the fingers. The ulnar nerve here lies on the inner side of the vessel. Near the wrist the artery is generally found with facility, its situation being indicated by its pulsation.

LIGATION OF THE ABDOMINAL AORTA.

Ligation of the abdominal aorta may be required on account of a wound, either of itself or of the common iliac, and in that event the best plan would probably be to enlarge the external opening to an extent sufficient to encircle the vessel with the thread. In ligating the vessel for aneurism, the patient should lie on his right side, and care should be taken to avoid injury to the peritoneum, which can be easily done by adopting the procedure of Dr. Murray, since followed by Monteiro and South, of making a curvilinear incision, with the convexity towards the vertebræ, from an inch above the anterior superior spinous process of the ilium to the cartilage of the tenth rib. It should be fully six inches in length, and should extend, in the first instance, merely through the common integuments. The various underlying structures should then be severally divided until the peritoneum is brought into view, which is cautiously peeled off from the iliac and psoas muscles with the hand a short distance beyond the contemplated point of ligation. The separation of the aorta from its accompanying vein on the right side, and the filaments of the sympathetic nerve in front, constitutes one of the greatest difficulties of the operation, but is generally best effected with a long director, slightly sharp at the extremity, and the nail of the index finger. The ligature should be passed round the artery from left to right, and from behind forwards, about one inch above its bifurcation into the common iliacs.

LIGATION OF THE COMMON ILIAC.

The common iliac artery was first ligated by Dr. William Gibson, of this city, in 1812, in a case of gunshot wound, his patient surviving the operation thirteen days, death being caused by peritoneal inflammation and secondary hemorrhage. Subsequently to this, namely, in 1827, it was tied, for the first time under such circumstances, for aneurism of the external iliac, by Dr. Mott; the ligature came away on the nineteenth day, and in less than two months the man was entirely well, and is, I believe, still living.

This artery has probably been secured altogether nearly forty times. The most extended and reliable statistics of the operation that have yet appeared are those of Dr. Stephen Smith, of New York, who has arranged his cases under four distinct heads, as they relate, first, to the arrest of hemorrhage; secondly, to the cure of aneurism; thirdly, to the starvation of pulsating tumors; and lastly, to the ligation of the vessels, as a means of avoiding hemorrhage during the removal of morbid growths. Two of the tables of Dr. Smith are so interesting and instructive that I shall take the liberty of transcribing them. His paper will be found at length, in the American Journal of the Medical Sciences for July, 1860.

GROUP I.—*Eleven Cases of Ligation for the Arrest of Hemorrhage.*

No.	Operator.	Sex.	Age.	Side.	Disease or accident.	Result.	Date of death.	Cause of death.
1	Gibson	M.	38	L.	Gunshot wound of external iliac artery	Died	15th day	Hemorrhage
2	Liston	M.	8	R.	Hemorrhage after amputation of thigh	Died	24 hours	Exhaustion
3	Garviso	Hemorrhage from bursting of aneurism	Died	4 hours	Exhaustion
4	Pirogoff	M.	...	R.	Hemorrhage after ligation of external iliac	Died	14th day	Hemorrhage
5	Deguisse	M.	42	R.	Hemorrhage after ligation of the external iliac	Cured		
6	Post	M.	20	L.	Hemorrhage from an incision into an aneurism	Died	24 hours	Exhaustion
7	Uhde	M.	26	L.	Rupture of internal iliac in applying ligature	Died	4th day	Peritonitis
8	Edwards	M.	27	R.	Rupture of an aneurism of external iliac	Died	25th day	Hemorrhage
9	Holt	M.	24	R.	Hemorrhage from opening a gluteal aneurism	Died	3d day	Exhaustion
10	Parker	M.	20	R.	Hemorrhage from a stab in the groin	Died	10 hours	Exhaustion
11	Buck	M.	40	L.	Hemorrhage after ligation of external iliac	Died	17th day	Hemorrhage

Of the above cases, 10 were fatal, and 1 recovered, being a mortality of nearly 91 per cent. The average period of death was eight days, the cause in 5 being immediate exhaustion, in 4 secondary hemorrhage, and in 1 peritonitis.

GROUP II.—*Fifteen Cases of Ligation for the Cure of Aneurism.*

No.	Operator.	Sex.	Age.	Seat of aneurism.	Result.	Date of death.	Cause of death.
1	Mott	M.	33	Right external iliac	Cured		
2	Crampton	M.	30	Right external iliac	Died	10th day	Hemorrhage
3	Stevens	M.	...	Right external iliac	Died	2d day	
4	Salomon	M.	38	Left external iliac	Cured		
5	Syme	M.	31	Right external iliac	Died	4th day	Gangrene of leg
6	Peace	M.	36	Right external iliac	Cured		
7	Hey	M.	41	Left external iliac	Cured		
8	Garviso	External iliac	Cured		
9	Lyon	M.	53	Left external iliac	Died	50 hours	Exhaustion
10	Jones	M.	34	Right external iliac	Died	15th day	Erysipelas
11	Wedderburn	M.	25	Left fem., ext. iliac	Died	4th day	Gangrene
12	Van Buren	M.	46	Right external iliac	Died	4th day	Suppuration of sac
13	Stephen Smith	M.	33	Right external iliac	Died	48th day	Hemorrhage
14	Stone	M.	36	Left external iliac	Died	26th day	Dysentery
15	Goldsmith	M.	40	Left external iliac	Died	5th day	Exhaustion

Of the cases comprised in this table, all, except one, were males. The aneurism was located on the right side in 8, and on the left in 6, the seat in one not being given. The mortality was $66\frac{2}{3}$ per cent.

In the third group, Dr. Smith gives 4 cases, in which this vessel was tied by Guthrie, Stanley, Moore, and Meier, on account of pulsating tumors supposed to be aneurismal, but which proved to be malignant. All the patients, except one, died.

The fourth group comprises 2 cases, in one of which the artery was tied by Bushe, for an anastomotic aneurism, in a child six weeks old; and in the other by Chassaignac, in a man, aged 49, to prevent hemorrhage. Both patients died.

Of the above 32 cases, 27 were males, and 3 females, the sex in 2 not being given. The ages varied from six weeks to fifty-nine years, 22 of the cases occurring between the twentieth and fiftieth years. In 17 cases the right common iliac was tied, and in 13 the left. Of the whole number 25 died and 7 recovered, being a mortality of about $78\frac{1}{2}$ per cent. The average period of the separation of the ligature in 12 cases was nearly twenty-three days, the minimum being eight days, and the maximum thirty-six days. In 9 cases the peritoneum was wounded during the operation, and all these, excepting one, died. In 9 cases in which anæsthetics were used, and in 9 in which they were not used, all perished. It would thus seem that the ligation of this artery is one of the most unsuccessful operations in surgery.

The tables of Dr. Smith do not include the case by the late Dr. Luzenberg, of New Orleans, in which the primitive iliac artery was successfully tied in 1846. Dr. Hammond, of San Francisco, also ligated this vessel, but with a fatal issue, in 1861, on account of an aneurism of the gluteal artery, death occurring on the twenty-fourth day.

From numerous trials upon the dead subject, Dr. Smith advises, as the easiest and safest method of approaching the vessel, that an incision be made extending from near the anterior extremity of the eleventh rib to within a very few lines of the internal ring, with a sharp curve inward of one inch. It will thus pass about an inch and a half within the anterior superior spinous process of the ilium, and be about seven inches in length. The curve at the lower extremity of the wound will allow the most perfect freedom in the elevation of the peritoneum, and the complete exposure of the artery.

Ligation of the common iliac, fig. 269, is far from being an easy operation,

especially in case of aneurism, attended with a large tumor and morbid adhesions of the peritoneum. The patient lying on his back, with the thighs somewhat relaxed, a slightly curvilinear incision is made along the lower part of the abdomen, about half an inch above Poupart's ligament, commencing at the external ring and passing upwards and outwards a short distance beyond the anterior superior spinous process of the ilium, its length varying from five to seven inches, according to the exigencies of the particular case. The operator should, in every instance, give himself an abundance of room. The first cut extends merely through the skin and superficial fascia. The other structures, beginning with the aponeurosis of the external oblique muscle, are then severally divided upon the director down to the peritoneum, more and more caution being observed in proportion as we approach the deeper parts. The serous membrane is now gently and slowly detached, by means of the finger, from the aneurism and other textures, as high up as the necessities of the case may demand. The artery being thus denuded, is next isolated from the accompanying vein, and the thread deposited by passing the needle from within outwards, above the middle of the vessel. The different steps of the operation will be greatly facilitated if the patient have previously taken an active cathartic, to unload the bowels. Care must be taken not to wound the spermatic cord.

The primitive iliac arteries extend from the cartilage between the fourth and fifth vertebræ to the sacro-iliac symphysis, diverging from each other as they descend at a somewhat acute angle, their point of commencement being nearly opposite the umbilicus. Each rests on the spine and psoas muscle, and is crossed anteriorly, at its bifurcation, by the ureter. On the right side, the accompanying vein lies, above, behind and external to it, while, lower down, a portion of the vein appears on the inner side; on the left side, the vein passes along the inner side of the artery, both vessels lying under cover of the sigmoid flexure of the colon. Neither artery presents any anomalies of importance in a surgical point of view.

LIGATION OF THE INTERNAL ILIAC.

The ligation of the internal iliac has now been practised in seven cases, the operation having been first performed by Dr. Stevens, of Santa Cruz, in 1812, upon a negress, on account of a spontaneous aneurism of the gluteal artery, nearly of the volume of a child's head. Of these cases four recovered, and three died, a result which may well create surprise when we take into consideration the great depth at which this vessel is situated, the injury that must necessarily be inflicted upon the surrounding parts in exposing it, and the exceedingly unfavorable character of most of the cases themselves prior to the operation. The artery, moreover, is very short and disproportionably large, being generally less than two inches in length; it is, besides, in intimate relation with various important structures, thus rendering it extremely difficult of access. Thus, it lies on the internal iliac vein, which, however,

Fig. 269.

Ligation of the common iliac.

on the right side projects from underneath it over its outer edge; it is crossed above by the ureter, and is overhung by the bladder, while that on the left side lies immediately behind the rectum. Close by are the sacro-lumbar and obturator nerves, the latter, along with the external iliac vein, running in the angle which separates the internal from the external iliac artery.

The manner of exposing the artery is the same as in ligating the common iliac. Dr. White, of Hudson, who tied this vessel successfully in 1827, for gluteal aneurism, made a semi-circular incision on the side of the abdomen, with its convexity to the ilium, seven inches in length, commencing two inches to the left of the umbilicus, and terminating close to the external ring. It is not necessary, however, I conceive, to carry the incision so far inwards, as the object can be just as well attained by the other process, and with less risk of bad consequences. The peritoneum is carefully raised with the fingers; and it is worthy of notice that the membrane, as it is being peeled off, invariably carries with it the ureter, thus placing this duct completely beyond the reach of the ligature. The fascia investing the artery is scraped away with the nail or handle of the scalpel, and, taking the precaution of avoiding the external iliac vein, which lies in the angle between the internal and external iliac arteries, the ligature is deposited by passing the needle from within outwards.

When the internal iliac artery is very short, or the pelvis unusually small, so as to render the ligation of the vessel very difficult, it would be more prudent to secure the common trunk; the procedure would be attended with less violence to the parts, and with less risk of peritonitis and secondary hemorrhage.

LIGATION OF THE GLUTEAL.

The gluteal artery has been repeatedly ligated on account of hemorrhage and traumatic aneurism, as, for example, in the famous case of Mr. John Bell, where, to use his own hyperbolic language, the incision was upwards of a foot and a half in length. In exposing the vessel for the relief of hemorrhage, the surgeon is necessarily obliged to take the external wound as his guide, enlarging it, if possible, in the direction of the muscular fibres, and giving himself an abundance of room, especially if the artery be divided just as it emerges from the sacro-sciatic notch. It must be remembered that the vessel is accompanied by a vein and nerve, which must be carefully excluded from the ligature. If the artery be cut off close, it may be necessary to pass the thread with a curved needle, and to include in the noose some of the surrounding tissues, as it will probably be impracticable to raise it with the tenaculum.

In case of traumatic aneurism of this artery, most writers recommend the ligation of the internal iliac; but, when we remember the difficulties and dangers of this operation, and the probable occurrence of peritoneal inflammation and of secondary hemorrhage, it seems to me that it would be better, in every respect, to cut down upon and tie the gluteal itself. The operation will of course be bloody and formidable, but skill, boldness, and promptness may accomplish much, even in a case like this, especially when everything is well ordered beforehand, and the assistants are properly instructed in their respective duties. The incision, made in the direction of a line extending from the posterior superior spinous process of the ilium to a point midway between the tuberosity of the ischium and the great trochanter, must be at least eight inches in length, and should be carried at one stroke down into the aneurismal sac, the contents of which should then be turned out, and the artery instantly secured, as it lies towards the upper part of the wound.

LIGATION OF THE SCIATIC ARTERY.

The sciatic artery is also liable to be injured, either by sharp-pointed bodies penetrating the gluteal region, or by falls upon the buttock in which the vessel is laid open by a splinter of bone round which it passes as it proceeds forwards. It is situated under the great gluteal muscle, at first posterior and then internal to the great sciatic nerve, and winds round the spinous process of the ischium, near its root, behind the muscles which are inserted into the intertrochanteric line of the femur. It may be exposed by making a similar incision, as in the preceding case, but about an inch and a quarter lower down. When the operator is in doubt as to which artery is implicated, whether the sciatic or gluteal, the incision should be made as nearly as possible in the intermediate space.

The sciatic artery has been tied, in at least one instance, for an aneurism seated upon its own trunk, Dr. Dugas, of Georgia, being the operator. Owing, however, to secondary hemorrhage, caused, apparently, by the patient's own imprudence, the common iliac had to be secured at the end of a week, when the man was almost moribund from the loss of blood. Death occurred four days afterwards.

LIGATION OF THE EXTERNAL ILIAC.

Ligation of the external iliac artery was first practised by Mr. Abernethy, in 1796, in a case of aneurism of the femoral artery, which he had previously tied at the distal side of the tumor; but severe hemorrhage coming on some time after, he found it necessary to apply a ligature above the swelling. The operation, however, failed; and it was not until 1806, after two other attempts, that his efforts were finally crowned with success. In this country it was first performed by Dr. Dorsey, of this city, in 1811, in a case of inguinal aneurism.

There are several methods in vogue for exposing this artery and encircling it with a ligature, each of which has its advantages and disadvantages, although the results have perhaps not essentially varied in any. That of Abernethy, slightly modified, is perhaps the most unexceptionable. It consists in making a curvilinear incision, with the convexity downwards, along the inferior portion of the abdomen, commencing about an inch and a half above Poupart's ligament, just outside of the external ring, and terminating on a level with the anterior superior spine of the ilium, about two inches on the inner side of this process. Its length should be from three inches and a half to four inches, according to the size of the tumor, and the stature of the patient. The first cut, extending through the skin and superficial fascia, will probably divide a few little arteries that should be tied before proceeding any farther. The aponeurosis of the external oblique muscle is now in sight, and should be divided upon the director; then the muscle itself; and afterwards each, in regular succession, of the overlying structures, until the transverse fascia is exposed. This membrane will readily be recognized by its opaque, whitish appearance; and a small hole being scratched through it with the nail or scalpel, is next slit open to the full extent of the outer wound. The next step, and one of the most delicate of all, consists in gently and cautiously detaching the peritoneum from its connections in the iliac fossa; an operation which is often attended with considerable difficulty on account of the morbid adhesions. The iliac artery will now be felt pulsating at the bottom of the wound, having the anterior crural nerve at its outer side, and on a somewhat deeper plane, and the iliac vein at first behind, but afterwards, near Poupart's ligament, internal to it. The sheath covering the artery

being now scratched through in front over a sound portion of the vessel, the instrument bearing the ligature is gradually insinuated around it from its inner side, this procedure being found best to avoid injury to the vein.

There are several circumstances worthy of attention in connection with the ligation of the external iliac. In the first place, the ligature should, if possible, be placed round the vessel about its middle, which will be nearly two inches above Poupart's ligament, the artery being usually from three inches and a half to four inches in length. If the ligature be applied low down, near to the origin of the epigastric artery, there may not be sufficient room for the formation of a coagulum, and the patient may perish of secondary hemorrhage, as happened in one case to B  clard.

Secondly, care must be taken not to wound the peritoneum. I have witnessed several instances in which it was separated with immense difficulty, in consequence of the great firmness with which it adhered to the aneurismal sac, from the effects of plastic deposits. In a case which occurred in the practice of Dr. Post, of New York, the membrane was so much thickened and altered by disease that he found it quite impossible to detach it, but was obliged to make an opening into it in order to admit his ligature.

Thirdly, no little difficulty is occasionally experienced in separating the artery from its accompanying vein, owing to their naturally firm union, which is no doubt often increased by disease. The object is most easily attained with the nail or a probe, slightly sharpened at the extremity.

Fourthly, should the external iliac be found to be too much diseased, or the tumor so large as to overlap the greater portion of the artery, as it may do when the sac extends upwards beneath Poupart's ligament, it will be easy to ligate the common trunk simply by enlarging the wound, especially at its upper angle.

Fifthly, the operation will be greatly facilitated if the patient's bladder and bowels be well evacuated a short time previously.

Lastly, the wound made in the operation should in this, as in the ligation of the other pelvic arteries, be sewed up carefully from the bottom, by carrying the needle close down to the peritoneum; in other words, the muscular and integumental lips should be tacked together separately, the object being the production of firm union, so that there may be no risk of hernia when the patient begins to sit up and walk about.

After the ligation of the external iliac, the collateral circulation is maintained chiefly by the anastomosing branches of the gluteal, sciatic, obturator, and pudic arteries, with the circumflex and deep branches of the femoral.

LIGATION OF THE EPIGASTRIC AND CIRCUMFLEX ARTERIES.

The *epigastric artery* is occasionally wounded, either accidentally or in operating for hernia, tapping the abdomen, or ligating the iliac. The vessel, although small, may give rise to fatal hemorrhage, the more readily as the bleeding is generally insidious and deep seated, and it should, therefore, be secured without delay. To do this, an incision, about two inches in length, is made just above, and parallel to, Poupart's ligament, in a line corresponding with its centre, cautiously dividing the parts until the artery is reached, as it lies between the transverse fascia and peritoneum. It is accompanied by two veins, which must be carefully excluded from the ligature. The artery arises on the inner side of the external iliac, about three lines above Poupart's ligament, and ascends inwards just within the inner border of the internal ring, where the deferent duct hooks round it on its way to the abdominal canal. Should the vessel be cut off close to the external iliac, it might become necessary to cast the thread around this artery instead of the epigastric.

The *circumflex iliac* artery, given off by the external iliac, usually a little lower than the epigastric, is sometimes wounded, and may, from its large size, cause embarrassing, if not fatal, hemorrhage. It may be secured, in the first part of its course, in the same manner, very nearly, as the epigastric, the incision being made close to, and parallel with, Poupart's ligament, its centre being opposite the internal ring. Further out, it may be exposed by dividing the tendon of the external oblique muscle within half an inch of the margin of the ilium, where it is firmly bound down by the transverse fascia.

LIGATION OF THE FEMORAL.

The common femoral artery begins on a level with Poupart's ligament, and terminates from an inch and a half to two inches below in the superficial and deep femoral, the former being its direct continuation. The vessel, in all this course, is perfectly superficial, being covered merely by the skin, superficial fascia, and aponeurosis; it is involved, however, in a number of lymphatic ganglions, which, when they become enlarged, may receive the pulsation of the artery, and so simulate aneurism. The femoral vein lies on the inside of the vessel, in the same sheath, and great care is required in separating it previously to passing the ligature. The femoral nerve lies external to the artery, and is therefore not endangered in the operation. Exposure of the artery is easily effected by a vertical incision two inches in length; the needle should be conveyed from within outwards.

Ligation of the superficial femoral artery is often necessary on account of wounds involving its continuity, and, until a comparatively recent period, it was also frequently practised for the cure of popliteal aneurism. If the artery be severed by a cut, or pierced by a sharp-pointed body, it is evident that it should be secured at the site of injury, the wound being, if necessary, enlarged, and a ligature applied to each extremity of the vessel.

In case of aneurism, the femoral artery may be tied at two points of its extent, namely, at the superior and middle, the former being, however, by far the more eligible, as the vessel here is comparatively superficial, and therefore easy of access. Its course along the thigh is indicated by a line extending from a quarter of an inch within the centre of Poupart's ligament to the inner margin of the patella. In the upper third of the limb, it lies immediately beneath the common integuments and the femoral aponeurosis, its pulsation being easily felt as it runs along the inner margin of the sartorius muscle. This space is from four to five inches in length, and is of a triangular shape, its base being formed by Poupart's ligament above, and its apex by the convergence of the sartorius and adductor muscles below. The femoral vein runs along the inner border of the artery, and is inclosed in the same sheath; the connection between them is very firm and intimate, and it therefore requires great caution to effect their separation. The femoral nerve lies on the outside of the artery.

To expose the artery in this part of its course, an incision should be made along the inner border of the sartorius muscle, beginning about two inches and a half below Poupart's ligament, and extending obliquely downwards to the lower extremity of the triangle through the skin and superficial fascia. A portion of the aponeurosis is now pinched up with the forceps, and a horizontal opening made in it just large enough to admit the point of the probe, upon which the sheath of the vessel is then carefully divided for the space of about nine lines. The artery is now separated from the vein in the usual manner, but with extreme caution, and the ligature passed from within outwards, close to the former vessel. Injury to the vein would be a serious calamity, as the patient might perish from phlebitis. The occurrence is usually denoted by a gush of black blood upon drawing out the thread. Pressure

will readily arrest the flow, and the vessel must on no account be tied. A little nerve occasionally runs down in front of the artery; should this be the case, it must be drawn out of the way.

The femoral artery, in its middle course, as seen in fig. 270, is deep seated, lying under cover of the sartorius muscle, which must, consequently, be

Fig. 270.

Ligation of the femoral artery in its middle course.

turned to one side in the act of exposing it. The corresponding vein will be found external to the artery. In some instances it is double, and then the artery runs between the two vessels, closely hugged by them. In operating upon the superior portion of this space, just below the triangle above described, the incision should be made along the inner edge of the sartorius, which is then everted so as to afford free access to the vessel as it lies beneath the aponeurosis. If, on the other hand, the lower site be selected, the cut should be made on the outside of the muscle; but no one will be likely to do this if he can avoid it, as the operation will be both tedious and difficult, and possesses no advantages whatever over the more common procedure.

The femoral artery is subject to certain anomalies which should not be forgotten when we undertake its ligation, as they might seriously affect the result. The most important of these anomalies are the following: First, the high division of the artery, the vessel separating a short distance below Poupart's ligament into two branches, which go to form the posterior tibial and peroneal. Secondly, the artery may be double, the

supernumerary one giving off the branches usually furnished by the profunda. Thirdly, it may consist of two equal trunks which afterwards unite to form the popliteal. Sir Charles Bell found this curious anomaly in a negro upon whom he operated for popliteal aneurism, the two vessels coalescing as they entered the ham. In this case the blood in the sac had in a great measure coagulated, notwithstanding that the circulation through it had been maintained by the artery, which had not been excluded from the ligature. A similar instance occurred to Sir Astley Cooper. An abscess formed in the sac, after the detachment of the ligature, and the patient died of hemorrhage. The dissection showed that a large branch had been given off by the femoral artery above the point of ligation, and had again united with that vessel just before it terminated in the popliteal, thereby feeding the tumor, and preventing its obliteration. A case of the entire absence of the superficial femoral artery has been recorded by Manec, its place having been supplied by the sciatic which passed down along the back of the limb to become the popliteal.

Compression of the femoral artery is often necessary on account of hemorrhage, either of this vessel itself, or of some of its branches. It is also frequently employed for the purpose of controlling the circulation of the limb in amputations of the thigh and leg; and latterly, it has been much resorted

to for the cure of popliteal aneurism, having, in many cases, superseded the use of the ligature. When the object is to arrest the flow of blood, or stanch hemorrhage, the most suitable point for its application is the margin of the pubic bone, which is separated from the artery only by the pectineal muscle, and upon which, consequently, the pressure may be made with great efficiency. The best instrument for the purpose is the thumb of a stout assistant, or the handle of a large key, resting upon a small, thick pad. The more concentrated the pressure is, the more efficacious it will be in stopping the bleeding, and in preventing injury to the accompanying vein and nerves, circumstances that must not be overlooked in such a procedure. If the force be applied with the thumb, it may often be maintained for several successive days without detriment to the parts.

The other situations at which the artery may be compressed are the upper part of the thigh, just below Poupart's ligament, and those portions of the limb where the vessel may be pressed against the shaft of the femur, by directing the instrument outwards and backwards. When the compression is designed to be permanent, as in the treatment of popliteal aneurism, it should be frequently varied, making it now at this point, and then at that, as it may be painful or otherwise; and it is, moreover, of great importance, under these circumstances, that the instrument with which it is applied should not completely encircle the extremity, lest it impede the return of the blood in the veins, and thus occasion swelling and other mischief.

LIGATION OF THE DEEP FEMORAL.

The deep femoral artery has been known to be the seat of spontaneous aneurism, but the occurrence is extremely rare, and very difficult of diagnosis. The profound situation of the tumor, underneath the muscles at the anterior and inner part of the thigh, will usually serve to throw some light upon its character; but the only reliable sign is the continuance of pulsation, thrill, and bellows' sound, with somewhat of an augmented intensity, in the swelling, when firm pressure is made upon the superficial femoral, about two inches below Poupart's ligament, so as to direct the blood with increased force into the deep vessel. The proper remedy, in such a case, as well as in traumatic aneurism, would be ligation either of the affected artery, or of the common femoral, an inch below its origin, where it is felt beating immediately beneath the skin and aponeurosis. The application of the ligature to this vessel is sometimes required on account of hemorrhage.

The deep femoral is usually given off by the common femoral, from an inch and a half to two inches below Poupart's ligament; but it is sometimes detached considerably higher up, and occasionally it is furnished by the external iliac or by the femoral, immediately after the commencement of this vessel. The artery, soon after its origin, passes inwards, behind the superficial trunk, and gradually places itself under cover of the long adductor muscle, between which and the great adductor it afterwards descends towards the femur, near which it pierces the latter muscle, and finally disappears on the posterior part of the thigh. When this vessel is injured, the wound will, of course, serve as our readiest guide to it; and in that event, two ligatures will always be necessary to put an effectual stop to the hemorrhage. In case of aneurism, the artery may easily be exposed, near its origin, by an incision similar to that which is made in ligating the common femoral, or the superficial femoral, in the superior portion of its extent, beginning an inch below Poupart's ligament, and descending obliquely in the direction of the inner border of the sartorius muscle. The deep trunk may then be readily traced to the requisite extent, and should be encircled a few lines below the origin of its two circumflex branches.

LIGATION OF THE POPLITEAL.

The popliteal artery being situated deeply in the cavity of the ham, in close relation with numerous important structures, is very difficult of access, especially in fat subjects. Fortunately it is seldom necessary to attempt its deligation, as wounds and traumatic aneurism here are of extremely infrequent occurrence. The artery is in intimate connection by its outer and posterior surface with the popliteal vein, from which it is not always easily detached. Sometimes the vein is double, and then the artery lies between the two trunks, closely and firmly embraced by them. The popliteal nerve is separated from the vessels by a thick layer of fat; superiorly it lies exterior to the artery, but as it descends towards the leg it gradually winds round it to place itself along its internal border.

There are two points at which the popliteal artery may, if necessary, be exposed for the application of the ligature; these are its superior third and its inferior third. The middle portion of the artery is never interfered with,

Fig. 271.

Ligation of the popliteal at its upper and lower parts. *a.* The popliteal vein. *b.* The popliteal artery. *c.* The posterior saphenous vein. The popliteal nerve, on the outside of the artery, has been accidentally omitted in the diagram.

on account of its great depth, its near proximity to the knee-joint, the unyielding character of its lateral boundaries, and its intimate connection with the accompanying vein and nerve.

The artery may be ligated in the upper third of its extent, where it is more accessible than anywhere else, by carrying a vertical incision along the outer border of the semi-membranous muscle, for about three inches, extending down as far as the popliteal nerve. The muscle is then drawn inwards and the nerve outwards, when, by the cautious use of the forceps and handle of the knife, the vein and artery will be easily found, and must be gently and carefully separated from each other, the needle being passed from without inwards.

Exposure of the artery, in the lower third of its extent, may be effected by a vertical incision between the heads of the gastrocnemius muscle. Care is taken not to injure the posterior saphenous vein and nerve, which lie close by, but to draw them, along with the popliteal nerve, away from the knife. The artery will be found to be deeply

imbedded in the ham, partially concealed by the popliteal vein, but projecting somewhat to its outer side. In our attempts to expose the popliteal artery, care must be taken not to make too free a use of the knife, for fear of wounding the articular branches which are given off at a right angle, and which might, if injured, cause embarrassing hemorrhage.

LIGATION OF THE ANTERIOR TIBIAL.

The anterior tibial artery may require to be tied on account of hemorrhage or traumatic aneurism, and the best plan always is to take the external wound as our guide to the seat of the injury. The vessel, whose course is indicated

by a line drawn from the head of the fibula to the base of the great toe, may be secured at three different points.

The artery, in the superior third of its extent, lies underneath and between the anterior tibial and common extensor muscles, and may be exposed by a vertical incision, four inches in length, carried down in the direction of the line just mentioned. The skin and superficial fascia being divided, the aponeurosis is to be slit open upon a director to the full extent of the outer wound; the two muscles are then to be separated from each other along their raphe, and the artery, which lies in close contact with the interosseous ligament, is surrounded with the ligature, care being taken not to injure the accompanying veins. The anterior tibial nerve is exterior to the vessels.

In the middle third of the leg, the relations of the vessel are essentially the same as in the upper, except that the long extensor of the toe is interposed between the anterior tibial and common extensor. The artery is still deep-seated, and a long incision is required for its full exposure. A branch of the peroneal nerve sometimes attaches itself to the artery here, and must be drawn away before passing the ligature.

In the inferior third of the limb, the artery lies on the tibia, between the tendons of the common extensor of the foot and the proper extensor of the great toe, the latter overlapping it on the inside. The vessel here is, therefore, comparatively easy of access.

The *dorsal artery* of the foot, the continuation of the anterior tibial, may be easily tied in any portion of its extent, as it runs down across the instep, its course being indicated by a line extending from the centre of the ankle-joint to the posterior extremity of the first interosseous space. It lies under cover of the integuments and aponeurosis, and may readily be exposed by carrying the knife along the outer border of the tendon of the long extensor muscle of the great toe.

LIGATION OF THE POSTERIOR TIBIAL.

The posterior tibial artery occasionally requires ligation on account of wounds, and, if the operation be performed high up, the task is one of the most arduous and perplexing that a surgeon can be called upon to execute. It has fallen to my lot to tie it in this situation in two instances, and the difficulties in both were very great, having been increased tenfold by the confused condition of the parts, in consequence of the large quantity of extravasated blood. In one of these cases the artery had been laid open by a pistol ball, and in the other by a dirk-knife; the hemorrhage in both was profuse, and could only be effectually controlled by the ligature.

The situation of this artery is very deep; its course is at first obliquely inwards, and then vertical, being indicated by a line extending from the

Fig. 272.

Ligation of the anterior tibial, at various parts. The wounds are supposed to be held asunder. The ligature is under the vessel.

inferior border of the popliteal muscle to the fossa between the heel-bone and the inner ankle. It is covered in the superior two-thirds of its extent by the gastrocnemial, soleal, and plantar muscles, but during the remaining portion it lies immediately below the integuments, except at its commencement, where it is slightly overlapped by the tendo Achillis. It is accompanied and embraced by two veins, one being on each side of it. The attendant nerve lies internal to it in the upper part of the leg, but as it descends it crosses the artery superficially, and places itself along its outer margin. It is not without interest to know that the posterior tibial is sometimes double.

The artery may be exposed and tied in the upper and middle portions of its extent in one of two ways. The first consists in detaching the gastrocnemial muscle for about four inches along the inner border of the tibia, and

Fig. 273.

Ligation of the posterior tibial, at various parts. The wounds are held asunder, and the ligature is under the vessel.

cutting across the inner head of the soleal, by reflecting which we come directly down to the posterior layer of the aponeurosis of the leg, the free division of which brings the vessel at once fully into view. Care must be taken to avoid the internal saphenous vein, which runs close along the line of incision. In the other method, which was suggested by Mr. Guthrie, the artery is laid bare by a long, vertical cut, extending through the centre of the muscles of the calf. Its advantages are, first, that the artery being more directly approached, is more effectually under our control, and, secondly, that there is less danger of bagging, if blood and pus are poured out. The length of the incision need not exceed that in the other operation, and the hemorrhage is generally insignificant.

The posterior tibial sometimes requires ligation in the lower portion of its extent, between the heel and ankle. Taking its pulsation for his guide, the surgeon makes an incision, about two inches long, directly along its track, which is nearly midway between the two points here indicated. The direction of the incision should be somewhat curvilinear, with the concavity towards the inner malleolus. The artery here lies beneath three aponeurotic layers, which must be successively divided upon the director, when the needle is passed under the vessel from behind forwards, care being

taken not to include the accompanying veins and nerve.

In consequence of the superficial situation of this artery in the lower portion of its extent, a convenient point is afforded between the inner malleolus and the tendo Achillis for the application of pressure in the treatment of hemorrhage of the sole of the foot. The effect may be greatly increased if the circulation be also arrested in the anterior tibial, as may readily be done by placing a compress over it, just above the joint. A bandage is then extended from the toes upwards as far as the ankle, round which it is to be passed in the form of the figure 8, until the bleeding is completely arrested.

Sometimes a metallic arch may be advantageously stretched across the front of the joint, one end resting upon each compress, the object being to ward off injurious pressure.

The two *plantar arteries* begin opposite the two heads of the abductor muscle of the great toe, being the terminal branches of the posterior tibial; they are deep seated, and, when injured, are often a source of troublesome and annoying hemorrhage, owing to the remarkable freedom of their anastomoses. All precepts for exposing and tying these vessels, founded upon their anatomical relations, are useless. The best plan is to be guided by the external wound, and to provide an abundance of room with the knife, always taking care to cut in the direction of the length of the foot.

LIGATION OF THE PERONEAL.

The peroneal artery, after running a short distance, passes obliquely downwards and outwards to reach the fibula, along which it descends until it arrives near the outer malleolus, where it divides into its two terminal branches. It may be secured, in the upper portion of its extent, by making an incision, long and vertical, through the bellies of the gastrocnemial and soleal muscles; and inferiorly, as it runs along between the outer malleolus and tendo Achillis, by a cut at least two inches and a half in length, directed upwards and outwards towards the fibula. The vessel here rests upon the interosseous ligament, under cover of the long flexor of the great toe, which must be detached as far as may be necessary from the bone, and drawn outwards.

CHAPTER VI.

INJURIES AND DISEASES OF THE VEINS.

THE affections of the veins requiring to be noticed under this head are, wounds, hemorrhage, inflammation, varicosity, the formation of phlebolites, and the introduction of air.

SECT. I.—WOUNDS.

Of wounds of the veins not much need here be said, as they rarely exhibit any difficulty in regard to their treatment, or much danger in respect to their termination. Like wounds of the arteries, they may be produced by various weapons, and are, therefore, distinguished by different names, as incised, punctured, lacerated, contused, and gunshot. They are always followed by more or less hemorrhage, according to the size of their caliber, the blood issuing from them in a continuous stream, of a dark, purple color. When the division is complete, there is hardly any retraction, or annular constriction, and hence the bleeding often progresses until it proves fatal, especially if the vessel be large and superficial, as in wounds of the jugular and femoral, fainting not materially favoring the formation of a clot. Partial wounds, of whatever direction, will also bleed copiously, if they are at all extensive, and no mechanical obstacle is offered to the flow of blood. If the incision is small, exhibiting the character rather of a puncture than of a cut, the bleeding, after having continued for some time, will gradually cease, in consequence of the formation of a minute, but gradually increasing, clot upon the edges of the wound. These phenomena may often be witnessed in ordinary venesection at the bend of the arm, the clot adverted to constituting one of the impediments to the flow of the blood, and occasionally compelling the operator to open another vein. In gunshot wounds, severing a large vein, the hemorrhage frequently proves as suddenly fatal, or nearly so, as in corresponding lesions of an artery; or, life being preserved by the narrow state of the wound, or the valve-like disposition of its walls, the blood may be extensively, and perhaps most prejudicially, infiltrated into the intermuscular and subcutaneous cellular tissue.

The chief danger from wounds of the veins arises from loss of blood and inflammation of their tunics. The latter occurrence is occasionally observed as a consequence of the operation of bleeding at the arm with a foul or blunt lancet. In ordinary cases, however, there is but little risk of this kind, the parts readily uniting by adhesive action, since there is no impediment to this process from the sanguineous current, as there is, under similar circumstances, in an artery; all is calm and quiet within, and hence the most extensive wounds are often repaired in an almost incredibly short time.

The *treatment* of a wounded vein is generally very simple, merely by compress and bandage, and attention to position. If seated superficially, we have only to bring the edges of the breach together in the usual manner, and the hemorrhage will generally cease at once, without any direct application to the vein itself. In the operation of bleeding, the only dressing commonly

employed, after the necessary quantity of blood has been evacuated, and the edges of the puncture have been approximated, is a small compress, placed immediately over the part, and confined by means of a bandage; the slight inflammation which follows furnishes the requisite amount of plasma, and in less than twenty-four hours the union is generally so firm as to render it difficult to break it. The rule with all good surgeons is never to tie a vein, in any case, or under any circumstances, if it can possibly be avoided; not that such an operation involves any special difficulty, but because of its liability to be followed by severe inflammation, of a diffusive, erysipelatous character, tending to extend into the larger trunks and thence on towards the heart. Cases, nevertheless, occasionally occur, as in wounds and operations about the neck, axilla, groin, and thigh, where, from the extensive character of the lesion, and the impossibility of arresting the hemorrhage by compression, the ligature must be employed at all hazard; and it is gratifying to know that, although such a procedure is perhaps never entirely free from danger, yet it has often been crowned with the most complete success.

Rest is of great moment after wounds of the veins; it should be absolute, for the slightest motion may break up the adhesions, and thus endanger the part by inflammation. Exclusion of the atmosphere is also very desirable, and may be secured by compress and bandage alone, or by these means, aided by collodion.

SECT. II.—DISEASES OF THE VEINS.

Inflammation of the veins, technically called phlebitis, is occasionally an idiopathic affection; most commonly, however, it arises from injury, inflicted either directly upon these vessels, or indirectly through other structures. It frequently follows upon severe accidents and surgical operations, and, when this is the case, it is apt to give rise to pyemia, or multiple abscess, a disease which, as stated elsewhere, nearly always proves fatal. Phlebitis is a much more common affection than arteritis, and differs from this lesion still further in its liability to terminate in suppuration, which arteritis seldom does, the ordinary product of the latter being plastic matter, not pus. Another peculiarity of phlebitis is its tendency to extend along the vessels towards the heart, thus greatly increasing its dangers. Recent researches, however, render it probable that this tendency is much less frequent than was formerly imagined. The affection is sometimes confined to one vein; but, in general, it involves a considerable number, either simultaneously or successively. In the former case, it is said to be circumscribed; in the latter, diffused. Finally, it may be acute or chronic.

1. ACUTE PHLEBITIS.

The symptoms of acute phlebitis are not always well marked. When the affected vessels are superficial, their course is generally indicated by the existence of a corresponding number of red lines, which, on applying the finger, feel like hard, rigid cords, exquisitely sensitive to the touch, and reaching from the seat of the injury up the limb as far as the eye can follow them. The discoloration, which varies from a faint, rosy tint to deep red, or even purple, according to the intensity of the morbid action, gradually diffuses itself over the surrounding surface, and eventually exhibits all the characters which distinguish that of erysipelas. Considerable swelling usually attends, not unfrequently pitting on pressure. The pain is of a sharp, smarting, or burning nature, and is generally so severe as to deprive the patient effectually of appetite and sleep.

The constitution always deeply sympathizes in phlebitis, even when of comparatively limited extent. The disease is often, if not generally, ushered in by chilly sensations, if not actual rigors, alternating with flushes of heat; the pulse is frequent, quick, and irritable; the skin hot and dry; the stomach nauseated and otherwise disordered; the bowels costive; the urine scanty and high-colored. If the patient was in ill health immediately prior to the

attack, the symptoms will usually be of an adynamic character from the beginning; or, if not, they will soon become so. Excessive prostration, delirium, an icterode state of the countenance, gastric irritability, and great restlessness are usually prominent symptoms in every severe case of phlebitis.

The *anatomical characters* of acute phlebitis are swelling, opacity, and pulpiness of the internal membrane of the veins, with uniform redness, varying from light pink to deep florid. The middle and outer coats soon become profoundly injected, and their proper substance, although at first preternaturally soft and humid, is at length rendered so dense and firm that the vein feels like a hard, contracted cord. The cavity of the inflamed vessel is filled with clotted blood, as seen in fig. 274, sometimes blended with pus or lymph, and in many cases it is lined by a false membrane, susceptible, under certain circumstances, of organization. Instances occur in which the pus is infiltrated into the substance of the vein, or collected into small abscesses beneath the serous lining. The pus of phlebitis is generally an imperfectly elaborated fluid, containing a large quantity of plastic matter, and comparatively few characteristic globules.

Acute phlebitis is always a dangerous, and often a fatal, disease, few persons recovering when the morbid action is well established, or extensively diffused. This remark is true both of the traumatic and idiopathic forms of the disease; also of external and internal phlebitis, or

of inflammation of the superficial and deep-seated veins. The pus formed in the affected vessels, commingling with the blood, soon poisons the system, and thus renders the heart, brain, and spinal cord unfit for the performance of their functions.

The *treatment* of phlebitis cannot be conducted with too much caution. When the disease is situated superficially, an attempt should be made, by leeches, blisters, iodine, and nitrate of silver, to circumscribe the morbid action, and thus prevent the formation of pus. Such a result, however, is not to be expected when the disease involves the internal or deeper veins, where the inflammation often makes great, if not irreparable, progress before the surgeon is aware of its true character, and where, consequently, treatment of every kind is of little or no avail. All lowering measures are generally inadmissible, even when the patient is comparatively young and plethoric; debility, great and marked, is sure to arise, and to call imperatively for the use of tonics and stimulants. Purgatives are exhibited to clear out the bowels and correct the secretions; and mercury is given in frequent and liberal doses with a view to early and decisive constitutional impression, the best form being calomel, or calomel and blue mass. The addition of morphia will be required for the threefold purpose of preventing undue purgation, allaying pain, and inducing sleep. The best stimulants are milk punch, quinine, and iron, especially the tincture of the chloride.

If abscesses form, their contents must be evacuated by early and free

Fig. 274.

Phlebitis; a section of the femoral vein, occupied principally by fibrous clots.

incisions ; the internal organs must be diligently watched, and any complications that may arise must be met by appropriate measures.

2. CHRONIC AFFECTIONS.

The characters of chronic inflammation of the veins differ considerably from those of the acute form. The coats of the vessels are usually so much thickened, hypertrophied, and indurated as to preserve, when cut across, their cylindrical figure, like an artery. The redness is of a brownish tint, interspersed with numerous shades of gray, violet, or purple ; and the inner membrane, which is rough and shrivelled, can easily be raised in large opaque shreds. In some instances, the vein is dilated, or contracted, obstructed with clotted blood, lined by lymph, or filled with pus.

The disease sometimes passes into *ulceration*, but the occurrence is much less frequent than in the arteries. Commencing most commonly at one or more points of the inner membrane, it gradually extends to the other tunics, which it sometimes completely erodes. The immediate effect of this accident is an effusion of blood, which may be so great as to produce fatal results. The ulcers, which affect various forms, are occasionally quite numerous, and spread over a large extent of surface.

Chronic phlebitis is observed chiefly in the veins of the inferior extremity, and in those of the spermatic cord and of the ano-rectal region, as a complication of hemorrhoids. The principal symptoms are pains, of a sharp, pricking, or dull aching character, tenderness on pressure, and a sense of fulness or distension at the seat of the disease. The treatment is gently antiphlogistic, removal of the exciting cause constituting an object of primary importance.

There are certain states of the system in which the veins attain a very great size, and, consequently, carry an inordinate amount of blood. This *hypertrophy*, for so may it be termed, is very conspicuous in chronic affections of the joints, and in various kinds of tumors, both vascular and malignant. It is always conjoined with hypertrophy of the arteries, and forms one of the most serious obstacles to the cure of certain diseases.

Obliteration of the veins is by no means uncommon, and is almost always the result of inflammation. Sometimes it is caused by the pressure of a tumor forcing the sides of the vessel closely in contact, and so converting it into a dense, ligamentous cord. The largest veins are sometimes thus obliterated. Such a condition is extremely apt to be followed by dropsical effusions and other ill effects inimical to health and life.

Loose concretions, *phlebolites* or vein-stones, as they are termed, varying in size from a currant to a pea, are occasionally found in the interior of these tubes. Commonly of a yellowish, brownish, or bluish color, they are of a hard and brittle consistence, and of an oblong, oval, or spherical form, with a smooth, even surface. When divided, they are found to be made up of several thin but distinct lamellæ, disposed concentrically around a small delicate nucleus, frequently consisting of fibrin. The number of these concretions is extremely variable ; occasionally as many as ten, twenty, or even thirty are observed. They are generally met with in the smaller veins ; more frequently, perhaps, in the spermatic, uterine, vaginal, vesical, hemorrhoidal, and splenic, than in any other. In the saphenous and its branches, they often exist in connection with varicose enlargement. Their composition is principally phosphate and carbonate of lime, with a small amount of animal matter, probably albumen, and a trace of oxide of iron.

SECT. III.—VARIX.

A varicose and dilated state of the veins is by no means uncommon, especially in the lower classes of working people, and in mechanics whose avocation compels them to maintain habitually the erect position. The veins which are most liable to suffer in this respect are those of the inferior extremity and of the spermatic cord, but those of the abdomen, scrotum, vulva, trunk, and face are also occasionally implicated, while those of the superior extremity are almost exempt from the disease. Of the deep-seated veins, those most frequently affected are the jugular, azygos, subclavian, and hemorrhoidal. I have met with quite a number of cases where there was apparently a varicose diathesis, almost all the principal veins in the body being abnormally tortuous and dilated.

Age seems to exert a remarkable predisposition to this disease. Thus, varicose enlargement of the spermatic veins is most common in young men soon after the age of puberty; while, in the inferior extremity, the greater number of cases occur after the thirtieth year. In the hemorrhoidal veins, the malady is most frequent in elderly subjects.

The veins, in this disease, are preternaturally large, tortuous, knotty, and convoluted, or as if they were folded upon themselves, being augmented both in diameter and length, and observing a singularly serpentine course as they proceed to their place of destination. Their coats are hard, dense, and elastic, rolling under the finger like fine cords; with, here and there, a portion that retains its normal characters, or that is uncommonly thin and expanded, as if it were ready to give way under the slightest exertion. In cases of long standing, they frequently offer a good deal of resistance to the knife, perhaps even emitting a sort of grating noise. On being laid open, they are found to be rough and irregularly sacculated, strong bands being sometimes stretched

across their interior, which divide the tube into small cells, occupied by coagulated blood, phlebolites, or fibrinous concretions, in a state of organization. In the advanced stages of the disease, many of the valves are broken down, if not completely destroyed, while in recent cases they are simply thickened, indurated, displaced, or ruptured. These changes, which are generally most conspicuous in the internal saphenous vein and its branches, are obviously brought about by chronic inflammation, or by repeated attacks of the acute form of that disease, and often lead to great and irreparable mischief. Occasionally, the affected vessels are converted into dense, rigid, and impervious cords, altogether disqualified for the discharge of their functions.

The state of the vessels here described is well depicted in fig. 275, taken from a patient of mine, a stout, robust laboring man, upwards of fifty years of age. The enlargement, which was much greater than I ever saw it before, was

Fig. 275.

Varix of the leg.

principally situated on the inner surface of the limb, and was associated with similar disease of the veins of the scrotum, penis, and abdomen.

The disease in question may be caused in various ways. In the inferior extremities of pregnant females, it is generally induced by the pressure of the distended uterus, creating a mechanical impediment to the return of the blood in the iliac veins, and, indirectly, in the saphenous. Wearing tight garters, drawers, or stockings, may also occasion the disease, and a similar effect is brought about by the habitual maintenance of the erect posture. Hence, the disease is very common in persons who are compelled to stand much. Varix of the hemorrhoidal veins generally depends upon habitual distension of the rectum and frequent straining in defecation. The causes of varicocele are still imperfectly understood, although there is reason to believe that the disease is most commonly developed under the influence of onanism, and other mechanical obstruction calculated to weaken the spermatic veins.

A natural predisposition to varicose enlargement occasionally exists in certain individuals; the veins seem to be unusually large and feeble, and to become tortuous and dilated under the most trifling obstacles to the onward movement of their contents. When this is the case, the disease often occurs simultaneously in different parts of the body, superficial as well as deep.

The *effects* of varicose veins vary according to the situation of the malady. In the legs, the pressure of the enlarged and distended vessels is always productive of a good deal of pain, of a pricking or stinging nature, of tumefaction of the skin and cellular tissue, and of more or less tenderness along the track of the affected veins. In the more aggravated cases, ulceration of the integuments is apt to take place, commencing usually at one particular spot on the inner surface of the limb, and gradually progressing until a large sore is established, called, from this circumstance, the varicose ulcer, which it is always difficult to heal, and which occasionally extends into the enlarged veins, thus causing copious, if not fatal, hemorrhage. In the spermatic veins, the disease may give rise to atrophy of the testicle, and to distressing neuralgic pains; while in the hemorrhoidal it leads to the formation of piles, and other disagreeable symptoms.

Although the development of varix is generally slow, yet cases occasionally occur in which it progresses very rapidly. During the latter months of utero-gestation, the veins of the feet, legs, and thighs often attain an enormous bulk in a few weeks, and I have seen repeated instances of a similar kind in the spermatic and hemorrhoidal veins. In the inferior extremity, the disease, after having gone on for some time, often remains stationary for an indefinite period, neither perceptibly advancing nor receding. In some instances, it undergoes a sort of spontaneous cure; that is, inflammation is set up in the affected veins, and, this being followed by the formation of fibrinous concretions, their caliber is ultimately rendered completely impervious, thus compelling the blood to seek other channels. Instead of this favorable result, the inflammation sometimes leads to erysipelas, abscess, and even death. Varicocele never proves fatal, nor does varix of the hemorrhoidal veins, although both are, at times, a source of severe suffering.

Treatment.—The treatment of varix resolves itself into palliative and radical. The former consists, as the term implies, of the removal of the exciting cause of the disease, and the adoption of such remedies as are calculated to relieve the part and system of suffering without positively curing the malady. In varicocele, onanism must be interdicted; in varix of the hemorrhoidal veins, straining and constipation must be counteracted; and in varicose enlargement of the veins of the lower extremity, all sources of constriction must be removed, together with whatever else has a tendency to weaken, irritate, and inflame the diseased structures, and thereby occasion further enlargement. Giving artificial support to the affected veins often

has a good effect. Hence the use of the suspensory bag in varicocele, and of the laced-stockings in varix of the saphenous veins. In every form of the lesion, great benefit accrues from attention to the general health, and from the occasional administration of an active purgative, which, by clearing out the bowels, thus affords a freer passage of the blood in the diseased veins towards the heart. If the patient be very plethoric, he may sometimes advantageously lose blood. In varix of the legs, nothing commonly affords more prompt and satisfactory relief than a good bleeding at the arm; and the same remedy must be called into requisition, along with astringent and anodyne lotions and perfect rest of the parts, when the veins are unusually tender and painful from an accidental access of inflammation.

For the *radical cure* of this disease numerous operations have been devised, a few only of the more important of which need be noticed here, as the rest have either fallen into merited neglect, or are too dangerous to justify their repetition. Besides, the claims of these different operations will more naturally come to be considered when we speak of the several varieties of varix, as varicocele and hemorrhoids. There are really but two operations which, according to my experience, should ever be resorted to for the permanent relief of this disease; these are the ligature and the caustic issue; and if we apply these remedies to individual forms of the lesion, we shall find that the former is exclusively adapted to varicocele and hemorrhoids, and the latter to varix of the feet, legs, and thighs. Both procedures are extremely simple, but, simple though they be, they should never be employed without a thorough and protracted preparation of the part and system; and I deem this the more necessary, because, in the great majority of cases upon which we are obliged to operate, the disease is rather an inconvenience than a serious evil, threatening loss of limb and life. I will not pretend to assert that there are no cases of varix where an operation is not absolutely necessary; to do this would be absurd; what I mean to say is simply this, that no man, however skilful or experienced, should endanger his patient's life by rushing headlong into measures which, if injudiciously used, may lead to the worst results. The preliminary treatment should be mild but of longer duration than in ordinary diseases; the object is to remove any irritation that may exist in the affected veins, to soothe and calm them, in order that they may be the better prepared to withstand the rude assault about to be made upon them. To accomplish this object the patient must be subjected to light diet, to a course of gentle purgation, and to almost absolute rest in the recumbent or semi-erect posture, for at least a fortnight. This is the more important if he be plethoric, intemperate, or very excitable. When it is remembered how intolerant the veins are of injury, and how resentful they are of surgical interference, such precautions cannot be considered as idle.

The operation with the ligature is either direct, as in piles, or subcutaneous, as in varicocele, and in either case it is as safe as it is effectual. The principle on which it operates is that of strangulation, by which the enlarged vessels are converted into a slough, which is subsequently detached by ulcerative action. For this purpose it is necessary to draw the cord with great firmness, so as to produce the result in question in the shortest possible period, as well as with the least suffering. When the ligation is direct, as in hemorrhoids, it is always necessary to encircle the base of the tumor, or tie it as near as practicable to its point of attachment to the bowel. When the base is unusually large, it is sometimes transfixes with a needle armed with a double ligature, one of which is then drawn around each half of the morbid growth, the object being its more effectual strangulation. The subcutaneous operation is particularly applicable to varicocele, to which, in my judgment, it ought to be exclusively limited. It is performed by means of a stout spear-pointed needle and a strong ligature, introduced in such a manner as to avoid

the spermatic cord, the instrument making only two punctures, one in front of the scrotum and the other behind, by retracing its steps after it has effected transfixion. The ends of the cord are then firmly tied in the usual manner, the pressure being increased from day to day until the ligature is detached.

In operating upon the veins of the inferior extremities, I am persuaded that the safest plan is the establishment of a series of issues, made with the Vienna paste, the proper mode of applying which will claim special attention in the section on varix in the second volume.

The *after-treatment* is not to be disregarded in these operations. The great danger is a bad form of erysipelas, connected, doubtless, with phlebitis, its tendency being to diffuse itself extensively over the system, and to give rise to typhoid symptoms. I have not myself, however, witnessed any such effects in any of my cases, and I am inclined to ascribe my good fortune more to the pains which I have always taken to prepare my patients than to any particular skill in performing the operation or in conducting the after-treatment, though no one could be more careful about this than I am. If everything goes on well, little else will be necessary than strict attention to the diet and quietude of the part and system, with an occasional purgative; if erysipelas supervene, calomel, opium, and quinine will be indicated, along with milk punch, and the application of iodine, astringents, and emollient cataplasms.

SECT. IV.—INTRODUCTION OF AIR.

A fatal, though, fortunately, not a common accident, incident to certain operations, is the spontaneous introduction of air into the veins. It is most frequent in operations about the neck, face, and axilla, and was first noticed, as a distinct occurrence, in 1818, by Mons. Beauchesne, in exsecting a tumor from the neck of a young man, in which it was necessary to disarticulate and raise the clavicle. At the moment of effecting this, the patient became faint, and, exclaiming that he was dying, expired in less than half an hour afterwards. The examination of the body revealed the existence of an aperture in the internal jugular vein, at its junction with the subclavian, through which the air, causing the fatal result, had doubtless entered the circulation. Shortly after this, the accident happened to Dr. Mott and Dr. Stevens, as well as to several European surgeons, so that, in due time, the attention of the profession became fully aroused to the nature and importance of the subject.

The disastrous effects of the introduction of air into the venous circulation were known, long ago, to Wepfer, Vander-Heyden, and other physiologists; but they were lost sight of, in great measure, until attention was recalled to the subject by the experiments of Bichat, Nysten, and Magendie, who showed that a very small quantity of this fluid, suddenly injected into the jugular vein of dogs and other animals was sufficient, in most cases, to cause death almost instantaneously. On the other hand, it has been found that a large quantity, as, for example, several cubic inches, will not destroy life, if it be introduced slowly, the air, in this case, combining with the blood in such a manner as to prevent it from producing any serious mechanical inconvenience. Upon dissection, air is readily discovered in the cavities of the heart, as well as in other parts of the circulatory apparatus, thus accounting satisfactorily for the fatal event.

The *symptoms* which characterize the entry of air into the venous system are essentially those of cerebral apoplexy. The patient is generally seized, suddenly and unexpectedly, in the midst of the operation, with a sense of faintness, or a horrible feeling of terror, oppression, and exhaustion, inducing him to believe, and perhaps to exclaim, that he is dying. The countenance, in a moment, assumes a dark, livid hue, the body is agitated with

convulsive movements, the breathing is slow, difficult, and stertorous, the muscles are completely relaxed, the pulse is feeble and almost imperceptible, the pupils are dilated, and the individual is wholly unconscious. In short, he dies in a state of profound coma, like a person in a fit of apoplexy. On applying the ear to the cardiac region, the action of the heart is found to be excessively oppressed, the organ struggling powerfully to overcome the mechanical obstruction caused by the admixture of the gaseous and sanguineous fluids, which, swept slowly and heavily along over the fleshy and tendinous columns, occasions a loud, churning noise, synchronous with the contraction of the left ventricle, and at the same time a peculiar thrill, or vibratory sensation, perceptible by the hand as it rests upon the chest.

Such are the effects which are usually observed when air has been introduced suddenly, even in small quantity, into the venous circulation; and there is a strong probability that they will steadily increase in severity until they prove fatal, despite the most judicious and energetic measures that may be employed to counteract them. The period at which death occurs varies from a few minutes to several hours; in some cases life is destroyed almost with the rapidity of lightning, and in most cases in from twenty to forty-five or fifty minutes. The fatal event, if not instantaneous, is always preceded by a rapid reduction of the temperature, and a diffusion of the lividity over the whole body, the surface being of a leaden hue, as in death from asphyxia. Cases have been noticed where, after the symptoms had continued for some time in a very bad form, the purplish appearance of the cheeks was suddenly replaced by a reddish tinge, affording evidence, although generally of a deceptive character, of speedy reanimation and ultimate recovery.

The immediate cause of death, in this accident, has been variously explained; indeed, it is remarkable what little coincidence of opinion there is upon the subject among writers. From the fact that air has occasionally been found in the right cavities of the heart, after surgical operations in man, and in animals after experiments, it has been assumed that it was the inability of this organ to contract upon its contents, and thus send a sufficient quantity of blood to the lungs and brain for the due performance of their functions. Others have maintained that the primary trouble is in the pulmonary tissues. Thus, Mr. Erichsen supposes that it depends upon the manner in which the air and blood are beaten up together in the right cavities of the heart into a spumous fluid, which is unable to pass through the lungs, thus depriving the brain and spinal cord of their due supply of blood, and inducing fatal syncope, usually attended with convulsions. In opposition to this view, it may be stated that, if air be injected in considerable quantity into the carotid artery of an animal, all the phenomena of apoplexy, such as stertorous breathing, loss of sensibility, and spasmodic rigidity of the muscles, will instantly be produced, and soon occasion death from obstruction of the cerebral circulation. Whatever of truth these different explanations may embody, it is evident that the secondary effect of the presence of the gaseous fluid, that which really causes the fatal termination, is the want of a sufficient quantity of oxygenated blood in the great tripod of life, the heart, lungs, and brain.

If the patient survive, the transition to health is seldom instantaneous; on the contrary, several hours generally elapse before he recovers his consciousness and strength. In a case mentioned by Dr. Warren, the man, after having lain in a state of insensibility for two hours and a half, awoke as if from a profound sleep, still breathing, however, like an apoplectic. The night was passed without any accident, and, on the following morning, he was as well as usual, except that he had a headache and some soreness in the chest. Sometimes the patient recovers from the immediate consequences of the accident, but dies afterwards from pneumonia, produced, probably, by the irritating effects which the fluid exerts upon the pulmonary capillaries,

and through them upon the air-vesicles. Such an occurrence, however, is infrequent.

The local phenomena accompanying the introduction of air into the veins are of great interest, particularly in their diagnostic relations. In general, there is some noise, or sound, so loud and distinct as to be plainly perceived by the operator and his assistants, and which, occurring in combination with the sudden distress of the patient, is of the utmost value as a means of discrimination. In some cases, the sound is of a hissing nature, like that arising from air rushing into a narrow and exhausted receiver; in some, it is bubbling, clucking, or lapping; in some, gurgling, sucking, or licking. The immediate causes of these variations are, the size, shape, and situation of the opening in the injured vein, the quantity of blood in the wound, and the volume of the vessel and the relation which it bears to the surrounding parts. Whatever may be the nature of the sound, or the degree of its intensity, it cannot, when once heard, be forgotten, and is always clearly characteristic of the accident. In addition to this phenomenon, there is occasionally, but by no means constantly, an appearance of bubbles of air about the wound in the vein, especially if it be somewhat deep seated.

The veins through which air is usually spontaneously admitted in surgical operations are those about the neck, particularly the external and internal jugular and their immediate branches. It may also enter by the veins of the face, the axilla, and the chest. Thus, in one of Dr. Mott's cases, it passed in through the facial vein during the extirpation of an enlarged parotid gland. Dr. Warren met with an instance in which it was introduced by the subscapular vein; Clemot saw it enter by the veins of the chest; and Delpech had a case where it gained admission by the axillary vein. In operations on the trachea, and in the removal of tumors from the anterior part of the neck, the veins lying in this region might easily be wounded so as to let in air.

The reason why the veins in the localities here enumerated are alone subject to this accident is that they are under the influence of a suction action during inspiration, owing to a tendency to the formation of a vacuum within the chest during the expansion of the lungs. This action is naturally limited to the veins at the root of the neck, and it is here, therefore, that air is most liable to be introduced spontaneously; it may, however, as has already been stated, pass in through the veins of the face, axilla, and thorax, but that it may do so it is necessary that these vessels should be found in the condition of rigid tubes, or in a state of canalization, as it has been termed; for if they are merely collapsed, flattened conduits, it is evident that the air will not be able to enter them, however freely they may be punctured. There are various circumstances which may induce this accidental canalization of a vein, of which the principal are the adhesion of its walls to the parts through which it passes, and the manner in which it is held during the operation, rendering it open-mouthed and gaping when divided. Sometimes the introduction takes place in a perfectly healthy vessel at a considerable distance from the root of the neck, in consequence of the tension into which it is thrown by the position of the head and arm, as happened in one of Warren's cases, where the air was admitted by the subscapular vein. The probability of this occurrence is much increased when operations are performed upon the neck, face, and axilla, for the removal of large tumors, especially such as are of a glandular nature, including veins of considerable size. In injury of the jugular veins the accident will be most likely to happen if the wound be made just above the clavicle, where the suction action is naturally strongest. Air thrown into veins in remote parts of the body will destroy life as promptly and effectually as when it enters in the localities above alluded to, and the only reason why the accident does not occur in them is that the vessels are not under the immediate influence of the respiratory organs, as they are about the neck and

chest. Legallois witnessed three cases of instant death in female animals from the introduction of air into the inferior vena cava and heart by the uterine veins.

Treatment.—The treatment of this accident is preventive and curative. For the former, different plans have been suggested, most of which may occasionally be adopted with advantage. In the first place, the operator should remember where, and under what circumstances, such an occurrence is most likely to happen; for, being thus put upon his guard, he will be more cautious in the movements of his knife, and thereby, in all probability, altogether avoid the much dreaded mischief. Secondly, when he is about to begin his incisions, he should request an intelligent assistant to compress at the root of the neck any veins that may be within reach, and, consequently, in danger of being injured in the early stage of the procedure. In conducting the deep dissection, he should make careful use of the handle of the scalpel, as well as of his fingers, to detach the morbid structures, or to separate the sound, as the case may be, and if he finds that any veins are included within them, so as to require to be severed, he should secure them at once with the ligature at the cardiac side of the tumor. Sometimes a temporary ligature may be proper to be removed, or tied, after the completion of the operation, according to the exigencies of the case. It has been recommended that, when we are compelled to divide any of the vessels about the neck, the patient should be desired previously to make a full inspiration; such a procedure, however, would hardly be safe unless the vessel should become instantly collapsed, and remain so afterwards. Thirdly, in operating in the different regions under consideration, care must be taken to avoid those positions of the head and arm which are calculated to produce tension and canalization of the veins. Fourthly, it having been found that the entrance of the air into the veins can be prevented in the inferior animals by compressing the chest and abdomen, Mr. Erichsen strongly insists upon the propriety of swathing the body as tightly as the comfort of the patient will admit, with a view of compelling respiration solely by the diaphragm. Not having any experience with this plan, I am not able to give any decided opinion respecting it; but I should be disinclined, on principle, to adopt it, especially if the patient required the use of an anæsthetic during the operation. Lastly, should the accident happen, notwithstanding every possible precaution, as indicated by the occurrence of the peculiar hissing, clucking, lapping, or gurgling noise, previously mentioned, or by the appearance of bubbles about the wound in the vein, compression must instantly be applied, and all further proceeding abandoned until the trouble is effectually remedied.

To recover a patient from the effects of this accident, various methods of treatment have been proposed, some of which are, to say the least, anything but philosophical. The idea of sucking out the air from the injured vein, a plan proposed by some French surgeon, by the introduction of a suitable instrument, such as a silver canula or catheter, amounts to little less than a positive absurdity; for, independently of the difficulty and tediousness of such an operation, it would be far more likely to be followed by an additional introduction of air than the abstraction of that which has been already admitted. But, even granting, for the sake of argument, that a tube could readily be passed into the vein without the risk of letting in more air, it would not be practicable to remove the fluid from the lungs, which it must necessarily reach within a few seconds after the occurrence of the accident. Once admitted, no skill can dislodge it, either by this or any other means. When the patient is plethoric, and has lost but little blood during the operation, it has been recommended to open the temporal artery, on the ground that it might have the effect of removing cerebral and pulmonary congestion, and thus favor the restoration of the circulation. The utter futility of such

a procedure must be apparent, when it is recollected that this congestion depends, not merely upon an imperfectly aerated blood, but upon the presence of a spumous fluid, which the capillaries are incapable of propelling onward. The same remarks are applicable to the section of the right jugular vein, which, it has been alleged, might prove beneficial by unloading the corresponding cavities of the heart.

What, then, since the above modes of treatment are unavailing, is to be done for the restoration of the patient? Are there any means upon which we can place any reliance with a fair prospect of success? So far as I know, there are not, and hence our chief, if not sole, dependence must be upon the adoption of such means as may be best adapted to support the system under the terrible depression under which it is laboring. With this view, the treatment should be conducted very much upon the same principles as in syncope from loss of blood, or asphyxia from drowning. The patient is laid at once recumbent, with the head and shoulders lower even than the rest of the body, and, if the circulation be still going on, firm pressure is immediately applied to the axillary and femoral arteries, for the purpose of allowing as free an access of blood to the heart and brain as possible. Sinapisms of the most powerful kind are applied to the extremities, the precordial region, and the spine, in its whole length, and the body is wrapped up in blankets, wrung out of hot water, at the same time that cold air is freely admitted to the nose and mouth. If the patient is able to swallow, he must be made to take brandy and ammonia, otherwise these fluids must be promptly injected into the rectum. Finally, as a *dernier resort*, artificial respiration should be established, by means of a tube, introduced through the glottis, or through an opening in the larynx, and steadily and faithfully maintained, if necessary, until some time after all signs of breathing and circulation have disappeared.

CHAPTER VII.

AFFECTIONS OF THE CAPILLARIES.

THE capillaries are liable to enlargement, consisting of a species of hypertrophy of their tunics, with more or less dilatation of their caliber. The disease may be limited to the arterial capillaries alone, to the venous capillaries alone, or it may involve both classes of vessels, constituting thus a kind of compound affection. However this may be, the consequence of the enlargement is the formation of a distinct tumor, which may eventually acquire a large bulk, and seriously compromise the safety of the patient, especially when it is of an arterial character. In many cases, if, indeed, not in all, the disease is congenital, having, perhaps, already made considerable progress at birth.

SECT. I.—ARTERIAL TUMORS.

The only arterial tumor, properly so-called, that can be recognized, in a practical sense, is that which was originally so ably and graphically described by John Bell, of Edinburgh, under the name of aneurism by anastomosis. His account of the disease is by far the most clear and elaborate that has yet appeared, and it is remarkable that hardly anything of importance has been added to it by subsequent observers, either as it respects its anatomy, etiology, or mode of treatment. The only error which the Scotch surgeon committed was the assertion that the lesion was peculiar to adults, and that it was a perfect aneurism.

The most common sites of the arterial tumor are the scalp, lip, nose, orbit, eyelid, cheek, and chin; it may, however, occur in any part of the body, and I have repeatedly met with it upon the shoulder, trunk, fingers, and foot. Some years ago, I removed a considerable tumor of this kind from the big toe of a young man of twenty-two. I have also seen examples of the disease in

the vulva of young girls. The texture in which it is usually situated is the cellular, especially the subcutaneous and submucous; I do not recollect ever to have seen it anywhere else, though its occasional occurrence has been noticed in the liver, spleen, and kidney.

This tumor is essentially composed of a network of arteries and veins, closely connected together by cellular or cellulo-fibrous tissue, as exhibited in fig. 276. It is, in fact, originally nothing but a species of hypertrophy of the capillary vessels, commencing in a little speck, perhaps, not larger than the head of a pin, and going on gradually enlarging until, at length, it acquires an enormous volume. The arte-

Anastomotic aneurism.

ries, which are free from the earthy and fatty degeneration, have a singularly convoluted arrangement, and, in cases of long standing, or of extraordinary bulk, some of them are often as large as a small goose quill; their walls are disproportionately thin and diaphanous, and from being pressed out laterally into short, blind pouches, it is very common for them to have a sacculated

appearance. This increase in the caliber of the arteries is not limited to the tumor, but always extends some distance beyond its proper boundaries, as can readily be ascertained by a careful examination with the finger; in fact, it is sometimes easily detected with the naked eye. The general disposition of the veins is similar to that of the arteries; they are, however, usually less capacious, relatively considered, and hence the blood returns with less facility than in parts naturally constituted.

The tissue by which the vessels are connected together is, in the first instance, nothing but ordinary cellular substance, naturally existing in the part where the tumor is developed; it is perfectly soft, spongy, and extensible. In time, however, it necessarily undergoes important changes, brought about by the pressure exerted upon it by the impetuosity of the inflowing blood, and by its temporary sojourn in the midst of the morbid mass. Hence it is that, while in some situations it exists most sparingly, so much so, indeed, as to be hardly demonstrable, in others it is preternaturally abundant, and truly cellulo-fibrous.

Such are the grosser elements of this form of tumor. Examined more minutely, it is found to consist of a kind of areolar structure, the cells of which, varying in size from that of the smallest pin's head to that of a pea, freely communicate with each other, not unlike those of a sponge, by means of lateral pores. These cells, which exhibit every diversity of shape, are formed apparently by the ampullar expansions of the coats of the arteries, and bear, in their general character, a considerable resemblance to those of the erectile organs, as the penis and clitoris. In old tumors of this description, some of the sacs occasionally become closed, thus assuming, as it were, an independent existence. The cause of this occurrence is probably inflammation, leading either to direct adhesion of the contiguous surfaces of the arteries, or to the formation of coagula. The contents of these cysts are either serous, sero-sanguinolent, or sanguineous. In the latter case they are generally solid.

Finally, the arterial tumor has no distinct, separate envelop; the only covering which it has is derived from the superincumbent structures, as the skin or mucous membrane, which, in time, become atrophied by the incessant beating of the blood beneath, and ultimately give way by ulcerative action. In general, the surface of the tumor is of a reddish scarlet hue, with, here and there, a purple spot, and so transparent as to allow many of the enlarged vessels to be seen through it. Occasionally a few granules of adipose matter overlie the tumor, or are dispersed through its substance.

It will thus be perceived that this tumor is in reality not a true aneurism, preceded and accompanied by the fibrous, earthy, or atheromatous degeneration, but simply an abnormal dilatation of the capillary arteries, involving, in time, the larger arteries in their immediate vicinity, and attended by a corresponding but less developed state of the capillary and adjacent veins. It consists, in fact, clearly and distinctly, in a hypertrophied condition of these vessels; or, in other words, as was previously remarked, in a gradual evolution and growth of arteries and veins from tubules that are imperceptible by the naked eye to vessels of extraordinary size. There is no addition of new vessels, but the whole tumor is formed out of those which naturally exist in the part, enlarged in every direction, in length as well as in diameter, under the pressure of the increased and ever-present afflux of blood. The coats of the vessels are not, it is true, as thick and firm as those of arteries and veins, properly so-called, usually are, but the aggregate capacity is so much greater than what the part naturally possesses that it must be regarded as a product of supernutrition, and nothing else.

The origin of the arterial tumor is often ascribed to the effects of external violence, as a blow or fall, and that it may occasionally be so excited is highly

probable; in general, however, it arises without any assignable cause, as a nevus, or mother-mark. Indeed, I am inclined to think that the affection is nearly always congenital, even in those cases in which it is said to have begun in the adult. This may be accounted for on the assumption that the nevus was originally so exceedingly minute as to have entirely escaped attention, until it began to assume an active character. However this may be, the starting-point of the disease is usually a little reddish speck, not larger than the head of a small pin, perfectly free from pain, and seated just beneath the skin, or partly in the skin and partly in the subcutaneous cellular tissue. Its growth is generally very gradual, so that a number of months, and perhaps even several years, may elapse before it attains the volume of a pigeon's egg. Occasionally, however, it increases with great rapidity, and soon acquires a frightful bulk. Of this occurrence I had a striking illustration, not long ago, in a female child, thirteen months old. At birth a reddish spot, as large as a dime, was observed at the centre of the left cheek. At the end of five weeks it had nearly doubled its dimensions; a quack now applied some caustic substance, eventuating in a large slough. The sore, which was the seat of occasional hemorrhage, healed in a little more than two months, leaving an unseemly scar, upwards of two inches in diameter, with red, spongy edges. A year after the use of the escharotic, when I first saw the child, the tumor was of immense volume, horribly disfiguring the features, and occupying the whole of the left side of the face, extending forwards to the nose and mouth, upwards to the eyelid and temple, backwards behind the ear, and downwards into the neck, its antero-posterior diameter being eight inches and a half, and the vertical six. The tumor, of a bluish color, was of a soft, spongy consistence, and sensibly increased whenever the child cried, laughed, sneezed, or coughed. At its lower and back part it had a peculiar aneurismal thrill and bruit, synchronous with the action of the heart. During the last few months the inside of the cheek had become much enlarged, and now presented a knotty feel and bluish appearance. The upper jaw, along its alveolar process, was of unusual size, evidently from the same cause, and was beginning to encroach seriously upon the mouth. The swelling was free from pain, and there was no disorder of the general health.

In general, however, the tumor proceeds more slowly, and it is not uncommon to meet with cases, in which, after having made some progress, it remains for a while stationary. When it begins as a nevus, it is not unusual for it to continue as a little reddish spot for several years, when, its activity being aroused, how or why we know not, it grows with unwonted vigor, and soon attains a large bulk. The tumor has generally an irregular outline, and rarely projects more than six or eight lines beyond the level of the surrounding parts. It is soft and compressible, the finger sinking into it as it would into a wet sponge, but the moment the pressure is removed it immediately regains its former situation. Its color varies in different cases; when it occurs in the skin, or skin and cellular tissue, it is generally of a reddish hue, inclining to scarlet, especially in its earlier stages; but in old cases, and when it lies beneath mucous membrane, it is more commonly of a bluish or purplish color. It beats and throbs synchronously with the contraction of the left ventricle of the heart, and imparts a peculiar aneurismal thrill to the finger. Its movements are often perceptible at a considerable distance, and are always sensibly augmented under the influence of mental emotion. When of considerable volume, the tumor may produce severe pain and other inconvenience by its pressure, but in most cases there are but little local suffering and constitutional disorder.

Such a tumor sometimes ulcerates and sloughs, causing more or less hemorrhage, and ultimately perhaps death. Some years ago, I saw a female child, aged ten months, who had a congenital arterial nevus upon the right

shoulder and arm, which gradually extended down towards the elbow; it was of a dark purple color, and of a soft, spongy consistence, throbbing and beating violently. The general health was good, but after some time ulcers began to form on different parts of the tumor, which now became very painful and inflamed; in a few weeks more gangrene set in, and, gradually progressing, soon destroyed the little patient. The hemorrhage which succeeds the ulceration of this tumor, although sometimes very profuse, seldom proves fatal; after the bleeding has continued for some time, the blood coagulates upon the abraded surface, and thus affords the vessels an opportunity of preventing further effusion. In the female, the hemorrhage is occasionally vicarious of the menstrual flux; the tumor becomes full and tense at the return of each period, and, giving way at the top, allows the blood to drain off, without serious injury to the part or system. It has been asserted that such a growth may degenerate, changing its primitive character, and assuming one of a worse kind, as the medullary or melanotic. Without altogether denying the possibility of such an occurrence, I have never seen any cases in my own practice to justify the conclusion.

Treatment.—The treatment of this form of tumor may be conducted by excision, escharotics, strangulation, injections, starvation, and, lastly, by amputation, as when the disease occupies one of the extremities. Besides these methods, there are several others of a more doubtful and less trustworthy character, which will be briefly noticed in their proper place.

a. Excision is chiefly adapted to small arterial tumors, before they have acquired much functional activity, or given rise to any marked enlargement of the neighboring arteries. The operation is then perfectly safe, easy of execution, and likely to be entirely successful. But if we wait until the tumor has attained a large bulk, beating and throbbing violently at every pulsation of the heart, as if it were ready to burst, the attempt, besides proving one of immense difficulty, may be attended with so copious a hemorrhage as to cause speedy exhaustion; we have then a formidable enemy to deal with, and we may consider ourselves happy if we do not let our patient perish from the loss of blood, gushing forth, as it will, in torrents, at every stroke of the knife. In such a case the prudent surgeon weighs well, before he begins his perilous operation, the chances of his success; he measures every inch of the unexplored territory, and equips himself thoroughly, at every point, for the trials and perplexities of his portentous undertaking.

When excision is determined upon, the rule of practice is, as John Bell long ago so correctly observed, not to cut into the tumor, but around it, and yet not so widely around it as to include an unnecessary quantity of sound tissue. The operation is performed rapidly, the finger of a good assistant quickly following the knife in order to compress any important artery that may be divided, until the whole mass is completely extirpated; and it will be wise, if practicable, always to arrest the circulation in the main artery leading to the tumor before we begin our incisions. Removal being effected, upon the principle here enjoined, the ligature may often be entirely dispensed with, all bleeding ceasing the moment the operation is over; or as soon as the edges of the wound are thoroughly approximated by the twisted suture, a mode of dressing peculiarly adapted to this form of disease, on account of the hemostatic influence exerted by its compression.

b. Small arterial tumors may often be readily destroyed by *escharotics*, of which I have found the Vienna paste to be preferable to any other, used as in making an ordinary issue. The paste is retained for fifteen minutes, being spread out sufficiently to cover the whole of the affected surface; the application is followed up by an emollient poultice, and when the slough is detached the sore is treated upon general principles. When the tumor is very

large, and so situated as not to involve any important structures, interference with which might prove prejudicial, it may be attacked, either simultaneously or successively, at several points of its extent, for the purpose of converting the whole mass into an eschar. For obvious reasons the caustic should not be used upon those parts of the body which are habitually exposed, as the face and neck.

c. Strangulation may be effected by transfixing the base of the tumor with one or more needles, and then drawing a ligature firmly around them, so as

Fig. 277.

Erectile tumor. The integument, uninvolved, has been reflected by flaps. Transfixion is being completed, previous to deligation. *a.* The larger ligature, in the act of being pulled through. It fills the aperture of puncture, preventing bleeding; and, besides, bears a stronger strain in the tying.

to cut off at once, and effectually, its sanguineous supply. Or, instead of this, a stout double thread may be conveyed beneath and around it by means of a spear-pointed needle, provided with an eye, one cord being tied upon one side of the swelling, and the other upon the opposite side. If the integument be sound, the ligation is preceded by its careful division and reflection, as in fig. 277, in order that, when the morbid growth has been removed, it may be replaced, and thus serve to protect the parts from an unseemly cicatrice.

When the tumor is so flat and elongated as not to admit of inclusion by the quadruple ligature, recourse may be had to the ingenious expedient of Erichsen, which combines the great advantage of thorough strangulation with a small ultimate cicatrice, it being unnecessary to embrace an undue quantity of integument for the eradi-

cation of the disease. The operation is performed in the following manner:—"A long triangular needle is threaded on the middle of a whip-cord, about three yards in length; one half of this is stained black with ink, the other half is left uncolored. The needle is inserted through a fold of the sound skin, about a quarter of an inch from one end of the tumor, and transversely to the axis of the same. It is then carried through, until a double tail, at least six inches in length, is left hanging from the point at which it entered; it is next carried across the base of the tumor, entering and passing out beyond its lateral limits, so as to leave, as shown in fig. 278, a series of double loops about nine inches in length on each side. Every one of these loops should be made about three-quarters of an inch apart, including that space of the tumor, and the last loop should be brought out through a fold of healthy integument beyond the tumor. In this way we have a series of double loops, one white, and the other black, on each side, as in fig. 278. All the white loops should now be cut on one side, and the black loops on the other, leaving hanging ends of thread of corresponding colors.

Fig. 278.

Fig. 279.

Erichsen's mode of ligating vascular tumors.

"The tumor may now be strangulated by drawing down and knotting firmly each pair of white threads on one side and each pair of black ones on the other. In this way the tumor is divided into segments, each of which is strangulated, by a noose and a knot: by black nooses and white knots on one side, by white nooses and black knots on the other, as in fig. 279."

d. Starvation may be attempted in one of two ways; either by tying the arteries which immediately feed the tumor, or else by occluding the main vessels which lead to the parts where the tumor is located. Of these two methods, preference should always, if possible, be given to the former, on account of its having a more direct and controlling influence upon the arrest of the morbid growth; when the swelling is very large, the two plans may sometimes be advantageously combined. Ligation of the arteries in the immediate vicinity of the tumor should be performed at several points at once, otherwise but little impression will be likely to follow; and care is taken, in performing the operation, not to interfere with the proper substance of the tumor, lest embarrassing hemorrhage ensue.

Deligation of the main artery leading to the parts upon which the morbid growth is situated has hitherto been practised chiefly upon the common carotid, in aneurism by anastomosis of the orbit, face, and scalp. The success has been variable, but, in the main, not very flattering, and yet I conceive that the procedure may be very proper when no other treatment is available. The misfortune, perhaps, is, that it is always employed as a *dernier resort*, and it is, therefore, not surprising that it should have so often failed. Dr. Mott, many years ago, tied the common carotid artery on account of a large arterial tumor, involving both orbits, the nose, and part of the forehead, in a child only three months old; the mass gradually diminished in size, and became so much consolidated as to lead to the belief that it might afterwards be extirpated, if such a measure should be deemed expedient. The final result of the case has not been reported. In 1828, I assisted Dr. George McClellan in taking up the right common carotid for the cure of an aneurism of the corresponding side of the face and orbit, in a child five months old. The operation seemed to arrest the growth of the tumor for a fortnight, but, at the end of that time, its activity was again aroused, and it went on gradually and steadily increasing until it caused death by hemorrhage and constitutional irritation. Dr. Mussey, Dr. J. Mason Warren, and others, both of this country and of Europe, have tied both carotids for the cure of this disease. The first of these surgeons applied the second ligature, after an interval of twelve days, without the occurrence of any untoward symptoms.

In the case of Dr. Warren, a little upwards of a month elapsed between the first and second operations; no unpleasant effects supervened, and the patient, a man aged twenty-three years, made a rapid recovery, although the arterial tumor was of enormous size, involving the mouth, face, and neck. Professor Kuhl, of Leipsic, tied the left carotid in a man of fifty-three, and, in forty-one days afterwards, the right carotid, on account of an extensive arterial disease of the scalp. The patient recovered, but not without considerable cerebral disturbance and repeated hemorrhages from the tumor. In tying two such large arteries for the cure of this affection, it is important to allow a sufficient period to intervene between the two operations for the dilatation of the collateral vessels which supply the brain, so as to enable this organ to obtain the requisite supply of blood for the proper execution of its functions. Several cases, it is true, have lately been published, in which the ligation was performed after a very brief interval, without any serious detriment to the cerebral circulation, yet this fact does not invalidate the necessity of this precaution in the class of maladies in question.

Mr. Oliver Pemberton, in a paper in the *London Lancet*, for May, 1860, has adduced some valuable statistics upon this subject. Of 35 cases in which the ligature was applied to the principal trunk of the artery leading to the tumor, 14 were cured, 10 died, 9 were unsuccessful, and in 2 the result was imperfectly given. In 6 of these 35 cases the operation was performed for vascular growths of the orbit, and, of these, 5 were cured. In 10 other cases in which the branches of the main artery were ligated, not one was permanently relieved.

e. Of the various *injections* that have been used for the relief of this tumor, the principal are nitric acid, creasote, iodine, and perchloride of iron, introduced in small quantity, either pure or diluted, with a delicate syringe, similar to that spoken of under the head of aneurism. These fluids are all more or less irritating, while several of them are capable of exciting high inflammation; hence it is hardly necessary to add that they should be employed with the greatest possible care and gentleness. At least one case is upon record, where a drop of nitric acid, injected into a small arterial growth of a child, caused death by convulsions.

The only really unobjectionable injection, for the cure of this disease, is a strong solution of persulphate of iron, a few drops of which may be deposited in different parts of the tumor, by means of a delicate syringe, the nozzle of which, introduced subcutaneously, is moved about in such a manner as to break up the coats of some of the capillary vessels. Coagulation occurs almost instantaneously, and in the course of from five to ten days, the whole growth drops off in the form of a slough, leaving a sore which gradually heals by granulation. By means of this salt, which is now rapidly coming into use as a hemostatic, I am satisfied that any case of arterial or venous tumor, unless very bulky, may be promptly and effectually cured.

f. Finally, among the subordinate and less certain remedies may be mentioned the use of heated needles, the seton, vaccination, and compression.

The introduction of *heated needles* into the midst of the morbid growth was strongly recommended, some years ago, by several American surgeons, who followed up the suggestion by the publication of a number of cases illustrative of its efficacy. On the strength of these reports, I was induced to make trial of the remedy in a number of instances which fell into my hands shortly afterwards, but such was my disappointment that I soon abandoned it altogether. My opinion is that few practitioners now employ it, or have any particular confidence in its efficacy. In performing the operation, which is adapted only to very small arterial tumors, a number of slender, sharp-pointed needles, generally as many as three, four, or five, inserted into a wooden handle, and heated red, are thrust into different parts of the morbid

growth, where they are retained until they become cool, when they are withdrawn, the introduction being repeated every three or four days, the object being to provoke an effusion of plasma. Besides the pain attending this procedure, such is its uncertainty, that it is questionable whether it deserves a place among the regular and accredited remedies for the cure of this disease.

A few cases of cure of the arterial tumor by *vaccination* have been reported. The remedy is, of course, applicable only to persons whose system has not been previously protected by this operation; and it is necessary, in order to be successful, that the virus should be inserted at different points, so that the effects of the resulting inflammation shall be deeply felt by the whole growth. The operation is sometimes followed by violent inflammation and high constitutional disturbance, threatening convulsions, and other serious accidents.

The *seton* is, perhaps, on the whole, more reliable than any other of these subordinate remedies; introduced underneath the tumor, and left there till suppuration is fully established. If the growth be small, a single thread may suffice, otherwise three or four may be necessary, or, perhaps, even a larger number. A small needle, inserted into a handle, is used, the cord being dragged through so as to fill the puncture made by the instrument, thereby preventing hemorrhage. I have treated three cases of small arterial tumors on the scalp successfully by this method.

Compression is sometimes employed, generally through the medium of the pad of a truss, or of a piece of ivory, coin, or sheet lead, confined by adhesive strips and a roller. To prove efficient, it must be made in a steady, uniform manner, the cases to which it is chiefly adapted being those in which the tumor is diminutive, and situated upon a hard, bony surface. The procedure is exceedingly unsatisfactory.

g. When the tumor is irremediable by the various measures now described, and is so situated as to admit of it, *amputation* may become necessary. Much as such a step is to be regretted, no one, I conceive, should hesitate to take it when the disease occupies a finger, hand, arm, foot, leg, or thigh.

SECT. II.—VENOUS TUMORS.

Under this head may be described a morbid growth, composed chiefly of dilated and varicose veins, held together by connective tissue; situated, for the most part, upon the scalp, cheek, lip, and chin, but also liable to occur in other regions, as the trunk and extremities. The submucous cellular substance of the mouth, tongue, and vulva may, likewise, be mentioned as occasional seats of the disease, and there is one form of hemorrhoidal tumor which evidently closely assimilates itself to it in structure. Varying in size and prominence, it may, originally, not be larger than a small pimple, which, gradually spreading in different directions, may ultimately acquire an extraordinary bulk, forming a considerable projection, and occupying a diameter many inches in extent. Its color is usually purple, or claret, either continuously, or intermixed with various shades of red; occasionally it is dark-mottled, especially when the enlarged veins lie nearer the surface at one point than at another, thus rendering their contents distinctly visible through the attenuated integument. In its consistence it is soft and spongy, diminishing sensibly under pressure, but speedily regaining its former bulk when the pressure is removed. It is free from pulsation, bruit, and expansion, and is comparatively little influenced by mental emotion. Sometimes the growth is tardy, at other times rapid; it is usually congenital, but may occur at any period of life; sometimes, and most generally, without any assignable cause, and at other times as a consequence of external injury. At first there is commonly no cutaneous involvement, the tumor being strictly limited to the

cellular tissue; by and by, however, the skin becomes uniformly attenuated, or thickened at one spot, and atrophied at another, and thoroughly incorporated with the morbid structure. As the disease advances, but generally not until the tumor has attained considerable bulk, ulceration may take place, followed by occasional hemorrhage, chiefly of a venous character, and easily checked by pressure.

The venous tumor consists of a network of dilated capillaries, not of new development, but simply an exaggeration of those which are peculiar to the part where the morbid growth is situated. They are connected together by loose cellular tissue, are more or less tortuous in their disposition, and have exceedingly thin, delicate walls, so that, when a body of this kind is excised, they immediately collapse, the structure, which previously formed a large mass, shrinking away into a little, spongy remnant. In the specimens which I have had an opportunity of examining, no abnormal vascular cells or fibrous bands were distinguishable; and, as the operations performed for their removal were almost bloodless, it is evident that the arteries which entered into their composition must have been exceedingly small and few in number. In very old and large growths of this kind, some of the individual veins are occasionally of enormous size, as well as remarkably tortuous, and contain fibrinous and earthy concretions, lodged in separate compartments. Such occurrences are most frequently met with in venous tumors on the trunk and buttocks.

The venous tumor is most easily dealt with by excision, and, unless the growth be of inordinate volume, such a procedure will be almost bloodless. Should any considerable artery be embraced in the general mass, it must, of course, be secured, either during the dissection, or immediately after it has been completed. The same rule of cutting round the tumor, and not into it, should be observed here as in the removal of arterial growths.

When the knife is objectionable, a venous tumor, if small, may readily be destroyed by the subcutaneous injection of a few drops of a strong solution of persulphate of iron. The procedure is perfectly safe, and productive of but little suffering. I have performed the operation in several cases with very gratifying results. The diseased tissues usually slough off in from five to eight days. Such growths may also be readily destroyed by strangulation, either with the ligature alone, or with the ligature and needle, in the form of the twisted suture; if very large, however, they must not be meddled with in this way, otherwise, violent inflammation arising, the operation may prove fatal.

CHAPTER VIII.

DISEASES AND INJURIES OF THE BONES AND THEIR APPENDAGES.

THE bones, being organized upon the same principles as the soft structures, are liable to similar diseases, both of a benign and a malignant nature. The presence of earthy matter, however, to which the bones are indebted for their solidity and strength, so as to render them fit organs for locomotion, exerts, as is well known, a modifying influence upon their diseases, not only as it respects their frequency, but also their progress, the character of their products, and the mode of their termination. This influence is particularly noticeable, on the one hand, in the difficulty with which inflamed osseous tissue suppurates, and, on the other, in the facility with which it becomes softened and deprived of its vitality, even, apparently, under very slight action. Inflamed soft texture generally suppurates with remarkable readiness, and often becomes the seat of large abscesses; in pure osteitis, on the contrary, pus is rarely seen in any form, much less in that of abscesses, such an occurrence being usually impossible, first, on account, it may be supposed, of the peculiar habits of the secernent vessels, and, secondly, because of the absence of free cellular substance, which, in the soft tissues, always serves as a bed for the reception and accommodation of the purulent fluid. Bones inflame with difficulty, but when the morbid process is once fairly lighted up, it is sure to produce serious structural disorder, often followed by the worst consequences, as softening, protracted ulceration, hypertrophy, fragility, and even necrosis, or the death of the affected parts. In tertiary syphilis, gout, rheumatism, and scurvy, the bones frequently suffer immensely, receiving and harboring disease with great facility. They are a common seat of various kinds of tumors, especially the benign, some of which, as the exostoses, are very similar to, if not identical with, their own structure, while others are essentially different in most particulars. The heterologous formations have all been observed in the skeleton, but their great rarity has been a subject of remark by every systematic writer. The most common of these formations is the tubercular, which plays so important a part in caries of the carpal and tarsal bones, in Pott's disease of the spine, and in strumous affections of the larger joints of the extremities.

SECT. I.—PERIOSTITIS.

The occurrence of periostitis is by no means infrequent, its causes being those of osteitis, with which, especially in its acute form, it is usually associated. Among the most common of these causes are various kinds of external injury, such as fractures and dislocations, blows, contusions, gunshot wounds, and the application of escharotic substances; and the effects of gout, rheumatism, and syphilis, operating upon a disordered and broken-down state of the system. There is one form of whitlow which consists essentially of periostitis, attacking usually one of the fingers, and liable, if neglected or improperly treated, to terminate in extensive suppuration and necrosis of the distal

phalanx. Inflammation of the periosteum, of a very severe and destructive nature, is occasionally produced by deep-seated abscesses, extending to, and irritating that membrane, as happens, for example, sometimes in phlegmonous erysipelas, where the matter burrows extensively among the surrounding tissues. Two forms of the disease are met with, the acute and chronic, the latter being the more common.

ACUTE PERIOSTITIS.

In the acute form of inflammation, the fibrous membrane is somewhat discolored, being commonly of a reddish, pink, or lilac hue; its vessels are loaded with blood, and its substance is sensibly softened, as well as slightly thickened from interstitial deposits. Its attachment to the bones is also considerably diminished, so that it may be pretty readily peeled off, and the cellular substance immediately over its outer surface is generally infiltrated with sero-albuminous matter. These changes, which are present, in greater or less degree, in all cases of periostitis, are often very conspicuous upon the fragments of a broken bone, and in incised wounds of the muscles, involving the membrane in question.

The disease not unfrequently passes into suppuration, the occurrence being particularly liable to happen in the periosteum of the bones of the inferior extremity, as the femur and tibia, and in the phalanges of the thumb and fingers; in the former as a consequence of cold acting upon a strumous constitution, or of the effects of mercury, or of mercury and syphilis, and in the latter as a result of whitlow. Much diversity exists in regard to the progress of the suppurative action; most generally it is rather tardy, but there are cases in which it proceeds with extraordinary rapidity, committing excessive ravages in a few days. However this may be, the pus is rarely of a healthy, laudable nature, but almost always very thin, bloody, and offensive, with flakes of curdy matter and the *débris* of broken-down, softened tissue.

Mortification is another termination of this disease, the occurrence being characterized by the dirty, ash-colored appearance of the affected membrane, which is, moreover, very much softened in its texture, and saturated with a foul offensive fluid, emitting an unmistakably gangrenous odor. Such an event is necessarily associated with necrosis of the corresponding bone, and frequently, also, with mortification of the endosteum, all perishing together in consequence of the destruction of their vascular connections. The best examples of this mode of termination occur in the periosteum of the alveolar processes of the jaws, from the abuse of mercury, and in that of the tibia from the effects of syphilis. The sloughs, which are always tough and shreddy, are usually thrown off with considerable difficulty, owing to the tardy and imperfect action of the circumjacent structures.

Symptoms.—The symptoms of periostitis are such as usually attend inflammation of the deep-seated structures generally, the pain being of a violent and pulsatile character, and the swelling of the soft parts diffuse and œdematous, with excessive heat of surface, and more or less constitutional disturbance. The occurrence of suppuration is announced by a marked increase of suffering; and as the pus accumulates the superincumbent integuments assume a shining, glossy, erysipelatous aspect, pitting under pressure, and imparting a distinct sense of fluctuation. Both in suppuration and mortification the pain is exquisite, and the patient generally labors under high fever and often also under delirium.

In periostitis consequent upon a syphilitic taint of the system, the suffering is always worst at night, the pain being of a severe, aching, or gnawing character, and invariably aggravated when the patient becomes warm in bed. Small, circumscribed swellings, or nodes, frequently exist, and are exquisitely

tender on pressure and motion, the skin over them being red, inflamed, and œdematous. The contents of these swellings are generally of a thick gummy character, possessing none of the properties of genuine pus.

In gouty and rheumatic periostitis the pain is deep-seated, wandering, or migratory, and generally very severe; the soft parts over the seat of the disease are discolored, glossy, and puffy; slight effusions of sero-plastic matter often exist beneath the affected membrane, forming small, rough, and irregular swellings, which are easily detected by the finger; the system is disordered by fever; the perspiration is acid and copious; and the urine is scanty and high colored, depositing a large quantity of lateritious substance upon the bottom of the receiver. The most reliable symptoms, in a diagnostic point of view, are, the shifting character of the disease, the involvement of the joints, and the history of the case.

Treatment.—In the treatment of periostitis, a primary object is to seek for the cause of the disease, and, if possible, to remove it. The traumatic form is to be managed upon ordinary antiphlogistic principles, and need not, therefore, detain us here. Idiopathic periostitis is often a self-limited affection, tending to terminate in suppuration, despite the best directed efforts of the surgeon. Examples of this constantly occur in whitlow and in some varieties of necrosis, in which periostitis commonly plays an important part, the morbid action being apparently dependent rather upon some inscrutable constitutional trouble than any special local cause. General treatment can seldom be altogether dispensed with in any case, while in many it constitutes our most valuable resource, no progress of a favorable character being made without it. In the more severe forms, bloodletting, active purgatives, and the saline and antimonial mixture, will probably be required, along with anodynes, to allay the excessive pain which is so often present. The most important topical remedies are leeches, iodine, blisters, and saturnine lotions with laudanum. If great tension exist with a tendency to suppuration, deep-seated incisions are made, without waiting for fluctuation, which is often extremely difficult of detection, unless the affected structure happens to be very superficial, as in periostitis of the tibia. The necessity of this operation cannot be too strenuously insisted upon, as it is the only way in which we can afford prompt relief to the suffering, and obviate extensive and irremediable mischief, as must inevitably be the case when the matter is permitted to burrow. When mortification takes place, the same treatment must be adopted as under ordinary circumstances.

In syphilitic periostitis the best remedy is iodide of potassium, in doses of from five to ten grains three times a day, either alone or in union with bichloride of mercury. If nodes form, they will generally disappear under the influence of the application of iodine, blisters, or mercurial inunctions, and will seldom demand interference with the knife.

Rheumatic and gouty periostitis will require the use of colchicum, with systematic purgation, and occasionally, perhaps, slight ptyalism, with leeches, fomentations, and alkaline and anodyne liniments.

CHRONIC PERIOSTITIS.

The periosteum is often the seat of chronic inflammation, its substance becoming thickened and indurated from the effusion of plastic matter. The hypertrophy—for so it may be termed—often involves a considerable extent of surface, forming a diffuse, incompressible swelling, fibrous, cartilaginous, or even osseous in its character. Sometimes, on the other hand, the enlargement is very small and circumscribed, not exceeding, perhaps, the end of the little finger or half a dime. It may be caused by some specific constitutional poison, especially the syphilitic, or by external violence, as a blow, fall, or

kick, as is often the case when it exists on the skull. However induced, its development is attended with a constant, deep-seated, gnawing pain, which is usually most severe at night when the body becomes warm in bed, and which occasionally assumes a true neuralgic character. After continuing for an indefinite period, it often remains stationary, or it gradually disappears by absorption, or it excites suppuration in the superimposed tissues.

These chronic affections of the periosteum are generally peculiarly obstinate and intractable, requiring specific remedies, frequently varied and long continued, for their cure. Iodide of potassium and mercury, Donovan's solution, and the different preparations of arsenic, with blisters, iodine, leeches, the vapor bath, and mercurial fumigations, are the means most likely to prove beneficial. In obstinate cases, resisting the ordinary remedies, free incisions, extending through the substance of the thickened and indurated membrane down to the very bone, will afford more relief than anything else, especially if the wound be made to suppurate abundantly.

Bony tumors, growths or deposits of this membrane are to be treated upon the same principles as exostoses, properly so termed. When small, not painful, or not inconveniently situated, they will probably require no attention. Occasionally they disappear spontaneously, or under the influence of very simple remedies. Such formations are nearly always caused by the effects of the gouty, rheumatic, or syphilitic poison, and are, therefore, generally greatly benefited by iodide of potassium and a mild course of mercury.

Finally, the periosteum is sometimes the seat of the heterologous formations, as the melanotic and tubercular. In carcinoma of the bones, the membrane is now and then implicated secondarily, but is rarely, if ever, the primary seat of this malady. In a number of dissections which I have made of encephaloid disease of the bones and soft parts, I have found it entirely intact, not even thickened or indurated.

SECT. II.—ENDOSTEITIS OR OSTEOMYELITIS.

Under this name, one of recent introduction into surgical nomenclature, may be described a disease of the medullary membrane, now known as the endosteum, possessing all the characters of true inflammation. Faint traces of such an occurrence are to be found in several authors of the last century, but it is only within the last few years that special attention has been called to it, or that the subject has been studied in a scientific manner.

The *causes* of this affection, which may be either acute or chronic, and which can hardly, in any case, exist uncombined with more or less osteitis, are generally of a traumatic nature, consisting of fractures, gunshot wounds, the lodgment of foreign bodies in the substance of the bones, violent blows, contusions, concussion of the spongy tissue, and laceration of the endosteum by the saw in amputation of the limbs, of which the lesion is by no means an uncommon consequence, as is shown by the suppuration and necrosis which so often follow this operation. There can be little doubt that the inflammation is frequently produced by the mere concussion of the limbs, transmitting its injurious effects along the canals of the long bones, thereby, perhaps, partially detaching portions of the lining membrane, and so inducing serious disruption of the circulation. Cold is another cause of endosteitis, and there is reason to believe that many of the cases of necrosis of the shaft of the femur, tibia, and other long pieces of the skeleton, originate in this manner. Occasionally the malady depends upon some constitutional taint, as the syphilitic, strumous, or scorbutic, awaking inflammation consentaneously in the endosteum, osseous tissue, and periosteum.

The *morbid anatomy* of the disease is best studied in one of the long

bones, as the femur or tibia, after amputation. If several days have elapsed since the operation, the membrane will be found to be of a pale pink hue, more or less injected, and apparently a little thickened, the marrow is abnormally soft, and the cells of the spongy structure of the canal are pervaded by a sero-sanguineous fluid. At a later period, when the inflammation is more fully established, the discoloration of the endosteum is of a more decided character, being of a deeper red with a shade of brown or purple, the fatty matter is broken up into a semi-liquid substance, and, in addition to the bloody sanies just alluded to, evident traces of pus are seen, forming numerous little points, of a yellowish aspect, which, gradually coalescing, at length assume the character of small abscesses. When the disease is uncommonly violent or protracted, portions of the endosteum are found to be converted into real eschars, of a brownish color, and of a characteristically fetid smell; the periosteum opposite the seat of the morbid action becomes detached, and the intervening portion of the bone, thus deprived of its vessels, speedily perishes.

In the chronic form of the disease, which sometimes lasts for years, the osseous structure is rendered abnormally hard, dense, and heavy, the medullary canal is in great measure, if not entirely, obliterated, and the endosteum at the seat of the morbid action is completely destroyed. Small cavities filled with a soft oily material, or fatty gelatinous substance, and surrounded by softened, vascular, reticulated tissue, are not unfrequently found; and cases are occasionally met with, although rarely, in which there are small abscesses and dead pieces of bone. When the disease is of long standing, the affected bone is generally more or less changed in its form, rough on the surface, and remarkably compact and heavy.

The *symptoms* of endosteitis are vague and unreliable, it being difficult, if not impossible, to distinguish them from those which attend inflammation of the bones and their fibrous envelop. Indeed, it is only when the disease occurs as the result of injury, as after amputation, that anything even like a plausible conjecture can be formed as to its real nature. Under such circumstances, upon taking off the first dressings, the wound opposite the end of the bone will probably be found to be gaping and filled with pus, the bone itself being either entirely denuded, or only slightly covered with lymph below, while the medullary membrane is of a reddish or brownish color, and more or less vascular. If six or eight days have elapsed since the operation, the exposed medullary surface will be likely to be studded with pale, flabby, unhealthy granulations, somewhat sensitive to the touch, or perhaps even quite painful, and discharging an abundance of thin, sero-sanguinolent fluid. Around this red and inflamed circle, the compact layer exhibits an unusually white, glistening appearance, without any trace of reparative action; in fact, the bone seems to be more dead than alive, or, if not actually dead, it will soon be. Superadded to these phenomena, there is occasionally a discharge of marrow, with or without fragments of the medullary membrane; a sure sign of the inflamed and disorganized state of the parts.

Endosteitis is always attended with considerable swelling and puffiness of the soft structures immediately over the affected parts, but there is not necessarily any discoloration of the surface, or any unusual pain. Considerable irritative fever is commonly present; the skin has a peculiar sallow hue; and there are apt to be rigors, alternating with flushes of heat, and followed by copious sweats, generally of a disagreeable acid nature. When the disease is idiopathic, there may be tumefaction and pain, deep-seated and throbbing, at the site of inflammation, but neither of them of so distinctive a character as to be of any service in a diagnostic point of view.

Endosteitis cannot be considered otherwise than as a dangerous malady; for, when severe or extensive, it is not only apt to cause extensive necrosis,

but may destroy the patient by the induction of phlebitis in the principal veins of the corresponding limb, and abscesses in the different viscera, especially the lungs and liver. Occasionally, it would seem to be capable of assuming a sort of endemic tendency. Thus, in 1814, nearly all the patients at the Hôtel Dieu, in Paris, who died after amputation, and the number was quite considerable, were observed to have suppuration in the medullary membrane of the long bones.

The *treatment* of endosteitis must be conducted upon general antiphlogistic principles, local and constitutional, in the hope of limiting morbid action and preventing the occurrence of suppuration and gangrene. If the medullary canal be exposed, some mildly stimulating injection, such as a very weak solution of nitrate of silver, tannin, or acetate of zinc, may be useful, the part being protected from the atmosphere by lint wet with a similar fluid, or an emollient cataplasm. If the membrane be affected in its continuity, and there is much swelling of the soft structures, free incisions may be necessary in order to relieve tension and promote the escape of effused fluids; and if there be reason to apprehend the existence of medullary abscess, as there will be if there be deep-seated, aching, gnawing, or boring pain, with œdema of the subcutaneous cellular tissue, the surgeon must not hesitate to cut down upon the matter with the crown of a small trephine as the only chance of averting still more serious consequences.

In the strictly chronic form of the disease, the chief reliance of the surgeon is upon iodide of iron and potassium, with minute doses of bichloride of mercury, tonics, cod-liver oil, change of air, and counter-irritation. In the more hopeless cases, it may be necessary to trephine the affected bone, or even to resort to amputation.

SECT. III.—OSTEITIS.

Osteitis, or inflammation of bone, at one time regarded as uncommon, is, on the contrary, of frequent occurrence, especially in early life, owing, doubtless, to the great vascularity of the osseous tissue at that period rendering it more susceptible of disease than in old age, when many of the vessels shrink and disappear. The lesion may be primitive or consecutive, acute or chronic; and in either case it may be limited to a particular portion of a bone, or pervade its entire length and breadth, although this is unusual. The spongy tissue suffers more frequently than the compact, a circumstance which is apparently due to the greater vascularity of the former than of the latter; and what is particularly remarkable is that in the first the disease often passes into ulceration, while in the latter it more frequently causes necrosis, or mortification, the two structures being evidently endowed with different powers of resisting the effects of inflammation. The pieces most liable to be affected are those which are naturally the least covered by soft substance, as the tibia, fibula, ulna, clavicle, and frontal bone. The disease is generally slow in its progress, and hence a considerable period may elapse before there is any very appreciable alteration of tissue. Cases, however, occur, where it proceeds with immense and overwhelming rapidity, suppuration, ulceration, and even mortification appearing in less than forty-eight hours from the commencement of the attack.

If a bone laboring under inflammation be carefully examined, it will be found to exhibit several important structural changes of great interest. At first it is simply enlarged, although less so than is usually imagined, because much of what appears to be enlargement is due rather to swelling of the periosteum, which is nearly always present under such circumstances, than to any actual expansion of the osseous tissue itself. Gradually the affected

bone loses its density, becoming softened, and infiltrated with a sanguinolent fluid, of a sero-plastic nature, and assuming a bright reddish hue, the capillaries being very numerous, turgid, and distinct. As the disease advances, the osseous fibres separate from each other, and the widened intervals are immediately filled with inflammatory deposits, often intermingled with little clots of pure blood. These alterations are always attended by an absorption of earthy matter, which has the effect of rendering the bone both soft and spongy, at the same time that it causes an actual diminution of its weight. The lamellæ of the compact substance are resolved, as it were, into their primitive distinctness, the Haversian canals are greatly enlarged, and the cells of the areolar texture are remarkably rarefied. When the disease has reached its maximum, the bony tissue is frequently so soft as to admit of being bent and cut with considerable facility. When the inflammation is superficial, affecting the outer layers of a bone, it always promptly extends to the periosteum, which, in consequence, becomes hot, red, and swollen, its substance being infiltrated with serous and plastic effusion. If, on the other hand, the inner structure is involved, the endosteum is sure to suffer, assuming a discolored, bloodshot appearance, while the adipose matter is either rapidly absorbed, or converted into a soft diffuent mass, of a light reddish hue, and of a peculiarly fetid character. When the inflammation of the bone is at all extensive, both periosteum and endosteum participate in the morbid action, and it is in these cases, more especially, that, the circulation being cut off by fibrinous exudations, necrosis is so liable to arise.

Osteitis may terminate in resolution, the morbid phenomena gradually disappearing, and the affected structures regaining their primitive texture; or the disease may cease, and the bone become indurated and enlarged in consequence of interstitial osseous deposits; or, lastly, the inflammation may pass into suppuration, ulceration, softening, or mortification, the results resembling those of inflammation of the soft parts. It is seldom that a bone, after having been inflamed for any length of time, will not, upon recovery, remain somewhat hypertrophied, or larger and harder than it was before the attack, as seen in fig. 280. It is, in fact, nature's mode of cure, the process which she employs for repairing the mischief committed by the disease.

Fig. 280.

Hypertrophy of the tibia from inflammation.

Causes.—The causes of osteitis are either traumatic or constitutional, the former consisting of injuries inflicted in surgical operations, fractures, contusions, and wounds, especially gunshot and punctured, and the latter of a syphilitic, strumous, scorbutic, rheumatic, or gouty taint of the system, together with the operation of cold. The disease may begin directly in the osseous tissue, or this may be involved secondarily, in consequence of the extension of the disease from the surrounding parts. Thus, in dislocations, particularly compound, and also in simple dislocations of the larger hinge-joints, as the elbow and knee, the inflammation consequent upon the accident is nearly always communicated to the contiguous extremities of the bones, rendering them soft and brittle, and liable to give way under slight influences. In like manner the periosteum often becomes the propagator of the morbid action; for, although, in general, this membrane serves to ward off

disease, forming a kind of wall between the soft structures and the bones, yet this barrier is not unfrequently overleaped, and inflammation kindled up in the very centre of these pieces. A great similarity is thus found to exist between the bones, periosteum, and endosteum, on the one hand, and the lungs, pleura, and bronchial mucous membrane on the other, experience having proved that disease cannot be present in any considerable degree, or for any length of time, in any one of these component elements without being propagated to the rest, which subsequently have often to bear the chief brunt of the incited action.

Symptoms.—The symptoms of osteitis bear a great resemblance to those of periostitis and endosteitis, and hence the most adroit diagnostician often finds it difficult to discriminate correctly between them. Practically, an error of this kind is of no special moment, as the treatment is essentially similar in the three affections, but as a matter of science it would certainly be desirable in every instance to ascertain, if possible, in what structure the disease is located, or, if all are implicated, in what degree. There is really, however, no one symptom, or group of phenomena, upon which the least reliance can be placed as a means of discrimination. It may be said that the pain in osteitis is more intense, agonizing, and deep-seated, than in inflammation of the periosteum and endosteum, and yet this is true only as a general rule; in the great majority of cases the difference is too slight to be appreciable. The same is true in regard to the swelling of the soft parts, and the constitutional disorder, which are often considerable in all these affections, but as they do not possess any distinctive features, are of no value in a diagnostic point of view.

Acute inflammation of bone is generally attended by the same symptoms as acute inflammation of the soft structures. The pain is excruciating, the part feeling as if it were torn, or bored, or as if insects were feeding upon it; it is deep-seated, more or less circumscribed, and increased by motion, pressure, and damp states of the atmosphere; it is also usually more violent at night when the patient becomes warm in bed, especially when it recognizes a constitutional origin. The swelling is extensive, firm, and almost inelastic, pitting, perhaps, after a time, under the application of the finger; the skin has a glossy, shining appearance; and there is intense heat of the surface, conjoined, in most cases, with an erysipelatous blush. The constitution sympathizing powerfully with the local disorder, there is high fever, with excessive thirst, a full, bounding pulse, and great dryness of skin, with all the minor phenomena of general incited action. If the disease be not promptly restrained by appropriate antiphlogistic measures, the soft parts suppurate, the event being announced by rigors and delirium, followed by copious sweats.

Acute osteitis is seldom dangerous to life, but may prove fatal if it be extensive, or complicated with other maladies, by the induction of erysipelas, pyemia, or constitutional irritation. Such an event will be most likely to happen in young scrofulous subjects, or in persons worn out by the effects of syphilis. The malady often terminates in serious and irremediable structural disease of the affected part, as softening, caries, and necrosis, requiring important operations, which are themselves frequently a source of much risk. Recovery, in any event, is generally extremely tedious.

The symptoms of *chronic osteitis* are such, in general terms, as characterize chronic inflammation of the soft structures. The bone is the seat of more or less pain, circumscribed, increased by motion and pressure, and usually aggravated at night, often depriving the patient of sleep and appetite. Enlargement of the affected part, with swelling and induration of the overlying tissues, is commonly a prominent phenomenon. Sooner or later suppuration occurs, followed by the formation of sinuses, difficult to

heal, and the seat of a constant discharge of thin, ichorous, sanious, or unhealthy matter, occasionally mixed with osseous particles. The constitution frequently sympathizes with the local disorder, as indicated by the pallor of the countenance, the gradual emaciation, and other evidences of failing power.

Treatment.—The treatment of osteitis must be conducted upon general antiphlogistic principles, of which bleeding, if the patient be at all robust, tartar emetic, purgatives, calomel, and opium, with perfect rest both of the part and body, constitute most essential elements. The prompt abstraction of blood by the lancet, or by leeches from the affected structures, will generally prove of marked benefit in cutting short the disease, or, rather, in limiting the sphere of its action. Calomel should be given as soon as the patient has been well bled and purged, and should be steadily continued until gentle ptyalism has been provoked. There is no remedy which, after proper depletion has been premised, exerts so powerful and controlling an influence over inflammation of bone as this; and, although it should not be used causelessly, or without due precaution, there are few cases to which it is not applicable. To prevent it from running off by the bowels, and, at the same time, to mitigate the excessive general and local distress, it should be administered in combination with large doses of opium, repeated as frequently as the exigencies of the case may seem to require.

The best local remedies, besides leeches, are hot anodyne fomentations, light medicated cataplasms, dilute tincture of iodine, and blisters, the latter being applied in such a manner as to cover in the whole of the affected surface, and allowed to remain on until thorough vesication has been produced. If matter form, or even if there be merely great tension, the knife must be used, the incisions being long and deep, extending down to the very substance of the bone. Without such an expedient relief is impossible. If the pus be allowed to accumulate, it will be sure to burrow, insinuating itself freely among the muscles, and perhaps even between the periosteum and bone, thereby detaching these parts from each other, and thus inducing extensive necrosis. What is done for the soft tissues, under such circumstances, should be done also for the affected bone, although practitioners are generally agreed to let it take care of itself. Is this good practice? The surgeon makes it a rule in inflammation of the soft structures to relieve pain and swelling by early and free incisions, and he finds that the procedure is usually followed by the most happy results, texture being saved and much suffering avoided. Why should he not adopt a similar treatment in osteitis attended with swelling and excruciating torture in consequence of effused fluids? Several openings might be very easily made into the affected bone with the crown of a very small trephine, the soft tissues being carefully divided as a preliminary measure. The operation never fails to be beneficial, and there is reason to believe, from what I have seen of it in my own practice, that if it were more frequently resorted to than it is there would be much fewer cases of necrosis and caries than are now seen to follow this disease.

In chronic osteitis our chief dependence is upon alterants, purgatives, and counter-irritation, of which the best form is an issue made with the hot iron as near as possible to the seat of the disease. A free discharge should be established and steadily maintained until the morbid action is effectually broken up. The most reliable alterant is iodide of potassium in union with bichloride of mercury, carried, in obstinate cases, to gentle and somewhat persistent ptyalism. Such a course is particularly indicated in syphilitic osteitis, but is hardly less beneficial in the rheumatic, gouty, and strumous forms of the malady.

SECT. IV.—SUPPURATION AND ABSCESS.

Suppuration of the external surface of bone is a very common occurrence, and may arise from various causes, as fracture and other external injury, or a syphilitic taint of the system. As the morbid action, however, which precedes and accompanies the suppuration, is usually associated with inflammation of the periosteum, it is difficult, in most cases, to determine which structure is really the source of the purulent matter. When the osteitis is of long standing, or characterized by inordinate severity, the pus is occasionally diffused through the proper substance of the bone, but such an occurrence can only happen in the event of the osseous tissue having undergone previous softening, the removal of the earthy matter being followed by the formation of cells or cavities for the lodgment of the fluid. If a vertical section be made of a long bone, as the tibia, in an advanced state of inflammation, it will be found that the pus, presenting itself in small globules, will be scattered both through the Haversian canals and the cells of the areolar substance, no disposition being manifested in the little depôts to arrange themselves into abscesses. The intermediate structure is of a reddish color, filled with fibrinous exudation, and so soft as to be easily divided with the knife. This punctiform variety of suppuration is seldom so conspicuous as in inflammation of bone complicated with endosteitis.

Abscess of bone, distinct, circumscribed and well-defined, such as we see in phlegmonous suppuration of the soft parts, and as is represented in fig. 281,

Fig. 281.

Abscess in bone.

Fig. 282.

Large chronic abscess of the tibia, the bone being much thickened as well as expanded round the cavity.

is an occurrence of extreme rarity. The formation takes place slowly, an unusual degree of chronicity being one of the natural concomitants of the disease. The most common seat of abscess is the head of the tibia, or the head and lower extremity of that bone, the expanded and rarefied tissue of which is peculiarly well adapted to such an occurrence. The abscess ranges in size from that of a pea to that of a pigeon's egg; is generally solitary; is lined by a thin though distinct membrane; and is occupied by a dark-colored, ill-elaborated pus, more or less fetid, and intermingled with aplastic matter or curdy flakes similar to those observed in strumous pus. The surrounding tissues are softened, congested, and infiltrated with sero-sanguinolent fluid. The manner in

which the abscess terminates is variable; when seated near the extremity of a bone, it sometimes manifests a disposition to discharge its contents into the contiguous joint; at other times, and more generally, it maintains its position, becoming as it were encysted by the deposition of new bone around

it, as delineated in fig. 282. Finally, in a third class of cases, the matter continues to accumulate, apparently for a long time, and pressing upon the osseous tissue in every direction, gradually expands the bone into a large shell, capable of holding several ounces, and so thin and soft as to be bent and cut like cartilage.

The *symptoms* denotive of the formation of pus are usually such as characterize this event in the other tissues, only that the local suffering is generally more intense, especially if the matter has no free vent. The existence of abscess in the interior of a bone is indicated by a dull, gnawing, heavy pain, circumscribed, deep-seated, remittent, and more like a violent toothache than anything else to which it can be compared. In many cases it is of a throbbing, boring, tearing, or lancinating nature. It is always worse at night than in the day, and is usually so intense and exhausting as to make serious inroads upon the general health, the patient soon becoming wan and sallow, and affected with hectic irritation. Occasionally the pain completely intermits, the parts being wholly free from suffering for many hours, and even days together; more generally, however, it is continued with partial remissions. The soft structures, at the seat of the abscess, are always exquisitely tender, especially at one particular spot directly over the matter, more or less tumefied, glazed, and œdematous, often pitting on pressure. The formation of matter is generally announced by rigors, alternating with flushes of heat, and similar attacks are very common during the progress of the disease, particularly in the early part of the night, the body being usually drenched under such circumstances, towards morning, with acid, offensive perspiration.

Although the symptoms of abscess are in general well marked, yet, as they are liable to be simulated by other affections, they cannot be said, in the true sense of the term, to be characteristic. The principal affections with which they are liable to be confounded are necrosis and deposits of new bony matter, compressing and irritating the parts so as to keep up intense pain and tenderness, similar to what is produced by collections of pus in the soft structures. Fortunately, accuracy of diagnosis is of little consequence in these cases, as the treatment is essentially the same, whether the symptoms arise from abscess, the lodgment of dead bone, or interstitial osseous deposits. The discrimination between abscess and neuralgia, which often closely imitate each other, is of more importance, on account of the difference of treatment, but so far as I know there are no diagnostic signs by which the distinction can be effected.

Abscess of the osseous tissue admits of relief only in one way, and that is by efficient evacuation with the trephine, for in no other manner can the pent-up fluid be reached. The operation is not always as easy as might at first be imagined, owing to the excessive firmness of the affected bone, in consequence of interstitial deposits, which often give it the closeness and density of ivory. The best instrument is a common cranium-trephine, with a caliber from three to four lines in diameter, with sharp, well set teeth, and fluted at the surface, so as to make a wide track. If any difficulty is apprehended on account of the extraordinary hardness of the bone, it will be proper to have two saws, of precisely the same size, in order that there may be no delay in the operation in the event of an accident. The surgeon, taking the site of pain and swelling, or the "tender spot," as his guide to the seat of the abscess, exposes the bone by a free incision, either single, T like, or crucial, as may be deemed necessary, and then turning aside a small portion of periosteum, applies the trephine, fig. 283, the centre-pin being protruded until the instrument has made for itself an adequate groove. The arrival of the saw in the abscess is generally denoted by a sudden cessation of resistance, and by the escape perhaps of a few drops of pus mingled with blood. If no matter be found after sinking the instrument to a considerable

depth, it is applied at some other point, in the vicinity of the former, in the hope of a more successful result, for it is often quite impossible, in these cases,

Fig. 283.

Trephine.

to hit the precise spot where the matter is located in a first or even a second attempt; on the other hand, however, care must be taken not to make too many perforations, lest the bone be thereby unduly weakened or suffer other injury. Moreover, it is not to be inferred by any means, that, although no pus has been detected, the operation will, therefore, be a failure; perhaps the instrument may have come in contact with a small sequester, lying loose in the cellular tissue of the articular extremity of the bone, and by removing this, rapid recovery may take place; or, instead of this, the pain and other symptoms may have been occasioned by the pressure of interstitial deposits, and the excision of a disk of bone may afford relief on the principle of taking off tension, as a free incision does in deep-seated purulent collections in the soft structures.

The abscess having been opened, its cavity is washed out with the syringe, as much to get rid of the sawdust as to clear away pus and stimulate the pyogenic sac; a narrow tent is then inserted into the bottom of the opening, and the wound gently supported with adhesive strips, the after-treatment being conducted upon strictly antiphlogistic principles. The relief from the operation is often immediate, and there is no class of cases in which the efforts of the surgeon are generally rewarded with more unalloyed satisfaction. The patient, tortured for months with pain and sleepless nights, is suddenly translated from torment into Elysium.

SECT. V.—CARIES OR ULCERATION.

Caries is a disease of the osseous tissue, strictly analogous to ulceration of the soft parts. It is essentially of an inflammatory type, and is characterized by an increase of vascularity, softening, and disintegration, the earthy matter being separated from the animal, and eliminated along with the discharges, which are often quite profuse, especially when the malady has made considerable progress. Caries differs from ordinary osteitis chiefly in this, that it is attended with actual loss of substance, the affected tissue being gradually broken down, excavated, or destroyed, whereas, in the latter, it retains its different elements, although in an altered condition, the principal changes consisting in congestion, softening, and sero-plastic infiltration. There are other points of difference, as the seat of the two diseases, the age at which they respectively occur, and the nature of the concomitant secretions, which will be rendered evident by a careful study of the subject.

Caries is most liable to occur in those pieces of the skeleton which are distinguished by the abundance of their areolar tissue. Hence it is most common in the vertebræ, the sternum, the innominate bones, the bones of the carpus and tarsus, and the articular ends of the long bones, especially of the femur, tibia, and humerus. The compact tissue is more frequently the seat of necrosis than of caries; indeed, the affection cannot occur here unless this tissue has previously undergone a certain degree of softening, so as to prepare it, as it were, for the disintegrating process which characterizes it.

Young persons are most subject to caries, particularly children under ten years of age; it is seldom that it is met with even so late as middle life, and

then chiefly as a result of some specific taint of the system, more especially the syphilitic. I am not aware that sex exerts any material influence upon its production, for I think it has occurred in my own practice with nearly equal frequency in males and females. Temperament and occupation may predispose to it, but if this be so we have no positive proof of the fact. Strumous children are particularly obnoxious to caries, and this circumstance, of which daily observation furnishes abundant evidence, long since created a doubt in my mind whether the disease is not really, in a great majority of cases, of a tubercular nature. The further I examine the subject, the more I am satisfied of the truth of this opinion. Most of the children that are brought to me with this disease, as it occurs in the spine, the hand, foot, and ends of the long bones, present all the characteristic features of the scrofulous diathesis; and I am quite sure that this experience, instead of being peculiar to myself, must be common to all practitioners. I do not, therefore, throw out this view as a mere conjecture, but as a conviction, and shall speak of it hereafter as the basis of important therapeutic indications.

Causes.—The causes of caries are of two kinds, local and constitutional, of which the latter are by far the more common and influential. As appertaining to the first, are various injuries, as blows, kicks, falls, fractures, contusions, and concussions, disturbing the circulation and innervation of the osseous tissue, or depriving it of its fibrous covering, and thus modifying its nutritive action. In the bones of the foot, especially those of the tarsus, the disease is sometimes induced by the penetration of a foreign body, as a nail, or splinter of wood. The sawing of the bones in amputation and resection, and their accidental division by sharp instruments, is occasionally followed by caries, both extensive and protracted. Cases occur where the disease is produced by the pressure of an aneurismal tumor, and by the application of escharotic substances.

Among the internal causes of caries may be cited whatever has a tendency to induce general debility, or to impoverish the fluids and solids, and, consequently, to exhaust the innervation. Hence we may place at the head of the list severe and protracted courses of mercury, the operation of the syphilitic poison, a gouty or rheumatic state of the system, scurvy, scrofula, profuse loss of blood, and severe attacks of dysentery, diarrhœa, typhoid fever, and eruptive diseases, as scarlatina, measles, and smallpox. All these circumstances are, as is well known, capable of producing ulceration both in the skeleton and the soft parts, as is proved by the numerous sores which so often arise in different regions of the body, as the sequelæ of these affections, and which we usually find so difficult of cure.

Of all the internal causes, however, of caries, there is none which, in my opinion, exercises so powerful an influence in the production of this disease as scrofula. In making this remark, I do not mean to say that there is always, under such circumstances, a deposit of tubercular matter; on the contrary, I am satisfied that there is, in most cases, merely a tubercular diathesis, predisposing the part to the disease, and thus rendering it less capable of resisting its effects when once it is established. As in strumous ophthalmia there is often serious disease, and yet no evidence whatever of tubercular deposit, so in strumous caries a bone may be completely softened and disintegrated, without any secretion of strumous matter, properly so termed. In both cases the diathesis exists, but not the tubercular matter. As this is the most frequent cause of caries, so is this form of the affection also one of the most difficult to remove.

Morbid Anatomy.—If a carious bone be subjected to careful examination, it will be found to exhibit marked differences in its appearances, according to the duration of the disease and the nature of the affected piece. In the earlier stages, the osseous tissue is merely inflamed, as is evinced by its vas-

cular and softened condition; its spongy texture is rarefied, and occupied by a serous, oily fluid, intermixed with a good deal of the coloring matter of the blood, thus giving it a reddish aspect. It can be cut with the knife, or even indented with the finger, especially if the bone be a carpal or tarsal one, and, upon macerating it, the water soon becomes covered with a layer of fatty matter. Exposed to the air, it dries with difficulty, and assumes a pale, yellowish hue, verging slightly upon greenish. When the disease has reached its more confirmed stages, the bone is found to be excavated, or riddled with cavities, of variable size and shape, sometimes lined by a kind of pyogenic membrane, and filled with thin, sanious, and offensive matter, having none of the characteristic properties of laudable pus. Occasionally small fragments of bone lie loose in these cavities, being unable to escape on account of their disproportionate dimensions to the size of the opening in the surface of the affected piece. The osseous tissue is now extremely soft and brittle, breaking down readily under the finger; it is still more porous than before, and is of a grayish, brownish, or blackish color. It is apparently destitute of vessels, and gives out a considerable quantity of oily or greasy matter on maceration, the fat floating on the surface of the fluid. In many instances, however, the quantity of fat is very small, and the bone has rather a dryish than an unctuous appearance. In a chemical point of view, the only notable difference between carious and healthy bone is the greater amount of cartilage and fat in the former than in the latter, the quantity of cartilage often forming as much as thirty-seven per cent., while the amount of fat is upwards of three. This quantity of fat, although much greater than what exists in the normal state, is not sufficient to justify the opinion expressed by some that caries essentially consists in adipose degeneration of the osseous tissue.

The osseous tissue immediately around the softened and disintegrated structure is always more or less inflamed, being preternaturally red and vascular; the periosteum is thickened, spongy, and injected; and the endosteum

Fig. 284.

Caries of the astragalus, with softening and incipient separation of the cartilage.

exhibits all the phenomena of an active participation in the disease. The compact lamella has often a worm-eaten appearance, and it is not uncommon to find it partially incrustated with bony matter. The soft parts around are infiltrated with sero-plastic matter, indurated, closely matted together, and otherwise altered. In articular caries, there is always more or less involvement of the cartilages, which are gradually softened and disintegrated, as in fig. 284, large pieces often coming away with the discharges.

The ravages of caries of the osseous tissue, consequent upon the effects of tertiary syphilis, are well displayed in fig. 285. The disease commenced in the soft palate, from which it gradually extended to the bones of the cranium and face, causing a free communication between the mouth, nose, orbits, and frontal sinuses. Fig. 286, from a specimen in my collection, affords a good illustration of caries of the head of a bone.

Symptoms.—The symptoms of caries are usually obscure, especially in its earlier stages, the line of demarcation between it and osteitis being impossible to be determined. It is only when the affection has terminated in suppuration, ulceration of the soft parts, as in fig. 287, or the formation of sinuses, that its real character can be fully made out. Prior to this the surgeon may suspect the nature of the disorder, but he cannot by any means be certain of it. All the symptoms, in the first instance, are those simply of osteitis.

There is a dull, heavy, aching pain, which appears to be deeply seated in the substance of the bone, and which gradually increases in extent and severity with the progress of the morbid action; the part feels exquisitely tender to

Syphilitic caries of the skull.

Fig. 286.

Caries of the head of the humerus.

the touch; the skin has a glazed, reddish appearance, and there is marked tumefaction, which, though somewhat diffused in its character, is generally particularly distinct at the focus of the inflammation. The local phenomena

Fig. 287.

Caries of the tibia, with an ulcer in the skin.

gradually augment in intensity, the pain assumes a throbbing disposition, the swelling becomes more pointed, and presently the loose, flabby integuments give way by ulcerative action, thus allowing the contents of the abscess—for such in fact the case now is—to drain off. The bone thus laid bare exhibits a foul and corroded aspect, at the same time that it feels soft and rough to the finger. If the examination be conducted with the probe, as it must be when the bone is deep-seated, the instrument will be found to pass very readily into its substance, which is already softened and partially disintegrated, a short time being generally sufficient to effect important changes.

The *sinuses* leading to the seat of the disease are either straight or tortuous, and vary in length from a few lines to several inches, according to the depth of the affected bone, and, above all, the place of opening of the resulting abscess. In general they are multiple, most of them opening by separate orifices, so as to give the surface a cribriform appearance. In chronic cases the sinuses are lined by a species of false membrane, and the situation of each is indicated by a mass of reddish granulations, somewhat mammillated in shape, in the centre of which the aperture of communication is generally easily detected with the point of the probe. This nipple-like body, which is often entirely insensible, and almost always smeared over with pus, projects con-

siderably above the surrounding level, and is of great diagnostic value, as it is invariably denotive of carious or necrosed bone. The sinuses here described do not commonly all form at once; perhaps there may be only one or two at the beginning, the rest being superadded during the progress of the disease, or, perhaps, as one closes another appears. Whatever may be their mode of development, the parts around are more or less indurated, inflamed, and tender on pressure.

The *discharge* furnished by the affected bone is extremely variable; in general, however, it is of a thin, ichorous, sanious, or bloody character, loaded with earthy matter, extremely fetid, and so irritating as to erode the parts with which it comes in contact. It usually tarnishes silver—a circumstance which shows that it contains sulphuretted hydrogen gas—and is often so profuse as to cause serious exhaustion. The earthy matter is easily detected by its gritty character, by rubbing the fluid in while it is suspended between the thumb and finger, and frequently amounts to two per cent. of the entire discharge. Sometimes the pus is of a laudable nature, but when this is the case it may be assumed, as a general rule, that it is furnished by the adjacent soft parts rather than by the bone itself. Whatever its character may be, it is not uncommon for it to contain flakes of lymph, *débris* of cellular and aponeurotic substance, and even considerable fragments of bone and cartilage; the latter being most apt to show themselves when the sinus penetrates a neighboring joint.

The *constitutional* disturbance is not always proportionate, so far as we can judge, to the amount of the local disorganization. The general health is often but little affected, especially in the early stages of the disease; by degrees, however, it begins to give way, and ultimately it always suffers severely, the patient losing flesh and strength, the countenance becoming wan and pallid, and the sleep and appetite being destroyed. If the disease is at all extensive, or if, even when it occupies but a small compass, it opens into a large joint, as, for example, the knee, hectic irritation soon sets in, and, making rapid inroads upon the system, speedily reduces the patient to the very verge of the grave. The pain is often excruciating, particularly at night and in damp states of the atmosphere, and is one of the principal sources of exhaustion.

Diagnosis.—The diagnosis of caries can only, in general, be determined by a careful consideration of the history of each individual case. Until ulceration of the soft parts occurs, the nature of the disease must almost necessarily remain an enigma. The only affection with which it is liable to be confounded is necrosis, from which it may generally be easily distinguished, before the skin has given way, by the comparatively small amount of pain attending it, as well as by the lesser degree of constitutional disturbance, and by the fact that caries is usually met with in the short bones, while necrosis mostly occurs in the shafts of the long ones. When sinuses have formed, the eye, finger, and probe will usually be able to determine the diagnosis, by the appearance and feel of the affected structure. In both cases the bone is roughened, but usually much more so in necrosis than in caries; in the former it always retains its original consistence, whereas in caries it is so much softened as to be readily penetrated by the probe. Nothing of a definite character can be learned from the nature of the discharge, since it is nearly identical in the two maladies. Occasionally valuable information may be obtained from a consideration of the exciting cause. Thus, osteitis from syphilis terminates more frequently in necrosis than in caries, the reverse being the case when the inflammation is dependent upon a scorbutic or strumous taint of the system. To this statement, however, numerous exceptions occur, and the diagnosis must, therefore, at least in most cases, be a matter of time and of repeated critical examinations.

Prognosis.—The prognosis of caries is generally unfavorable, a spontaneous cure, although not impossible, being an extremely uncommon occurrence. When the disease is of limited extent, a cure may often be promptly effected by operative measures directed against the affected parts, but under opposite circumstances nothing short of resection or amputation holds out the slightest prospect of relief. In many cases the affection continues for years, apparently neither advancing nor materially receding, the general health in the meantime experiencing but little change; on the other hand, however, its progress is sometimes very rapid, and the constitutional disturbance proportionately great, hectic irritation, loss of strength, and emaciation setting in early, and steadily proceeding until the patient dies completely exhausted. As a general rule, it may be stated that caries is less likely to terminate favorably when it assails the vertebræ and the articular ends of the long bones than when it appears in any other portions of the skeleton, except, perhaps, the carpal and tarsal bones, in which the malady is often so extremely obstinate as to require the removal of the limb in order to save life. The prognosis is, of course, other things being equal, more unfavorable in sickly and debilitated persons than in such as are healthy and robust at the time of the attack.

Treatment.—The treatment of caries, notwithstanding the modern lights of pathology and therapeutics, is extremely unsatisfactory, if not entirely empirical. That it should always, if possible, be conducted with strict reference to the nature of the exciting cause, whatever this may be, is a self-evident proposition. When the disease has been induced by a syphilitic, strumous, or scorbutic taint of the system, remedies calculated to meet these respective contingencies will of course promptly suggest themselves to the mind of the practitioner, as most likely to fulfil the particular indication of the case; but where no such affection is visible, and where, in fact, nothing whatever of an appreciable character exists, he must disregard all rules, and limit himself to the application of general principles. In all instances, whether the disease be owing to constitutional or local causes, great care should be taken to combat inflammation, by the observance of the most perfect rest, to give vent to effused fluids, and to remove any fragments of bone as soon as they are sufficiently detached to warrant such a procedure. Among the general means, a properly regulated diet is one of the most important; it should be perfectly plain and simple, but at the same time nutritious, so as to build up the system, and create a better state of the blood, which is generally so much at fault in caries of nearly all portions of the skeleton. Chalybeate tonics, quinine, nux vomica, and cod-liver oil are the most valuable internal remedies; aided, as occasion may seem to demand, by blue mass and alkalies, to modify and improve the secretions. Much purging must be avoided, as it would inevitably prove prejudicial by its debilitating effects. Exercise in the open air is often of great service, but to render it efficient care must be taken not to move or irritate the diseased bone while it is being employed. Salt bathing, followed by dry friction, will be of benefit in imparting tone and vigor to the cutaneous capillaries; and in many cases the general health is immensely improved by a residence at the sea-side.

In commencing the *local treatment*, the first object should be to allay the irritation of the soft parts by attention to rest and position, and by the application of leeches, fomentations, and poultices, or warm water-dressings, medicated with laudanum and acetate of lead. When there is much induration from plastic deposits, the skin should be freely painted twice a day with the dilute tincture of iodine, and if the case prove obstinate a large blister should be used, experience having shown that, in superficial caries, this is more effectual in arresting the inflammation and bringing on the suppurative crisis than any other remedy. Even in deep-seated caries it frequently

answers an excellent purpose, promptly arresting the excessive pain, and promoting the absorption of effused fluids. As soon as evident fluctuation exists, or even before, if there be inordinate tension and throbbing, a free incision should be made, extending, if possible, into the very depths of the bone, so as to admit of the most thorough drainage. To allow the matter to be pent up for days and even weeks, as often happens in the hands of timid practitioners, must always prove excessively injurious, from the tendency which the fluid, under such circumstances, has to burrow among the surrounding structures, detaching them from each other, and leading, in the end, to the formation of numerous sinuses. Besides, the early evacuation of the matter greatly abridges the suffering, constitutional as well as local, and thus prepares the system better for the future struggle. I have never seen a case where the retention of pus, whether among the soft parts, in the osseous tissue, or within a joint, has been productive of benefit; it always acts as a foreign substance, maintaining local and constitutional irritation, and hence I never hesitate to get rid of it as promptly and effectually as possible. These remarks are applicable to caries both of the superficial and deep-seated pieces of the skeleton. When the matter is pent up in the interior of a bone, as, for instance, in the articular end of the femur or tibia, evacuation should be attempted with the trephine.

The means now described are all merely of a palliative nature; they relieve pain, swelling, and constitutional disturbance, but are entirely incapable of curing the disease, however slight. To fulfil this indication other remedies are necessary, and these may be arranged under two heads, those, namely, which are used with a view of modifying the affected tissues, so as to afford them an opportunity of regaining their normal characters, and those which are resorted to for effecting riddance of the diseased bone, either in part or in whole.

Under the first of these heads are to be mentioned various *detergent* and acidulated preparations, as the solutions of the chlorides, creasote, nitrate of silver, and acetic, nitric, and hydrochloric acid, their strength varying with the age and constitution of the patient, and the state of the parts, the contact being effected by means of a large glass syringe, two operations being sufficient in the twenty-four hours. The chlorides are particularly serviceable in these cases on account of their cleansing and deodorant effects, while the acids act more directly upon the osseous tissue, stimulating the capillary and absorbent vessels, and thereby promoting a more healthy tone, at the same time that they produce disintegration of the earthy matter of the diseased bone. These remedies, and all others of a kindred nature, are certainly not without some benefit in the milder and more accessible cases of caries, but they all have the disadvantage of being difficult of application, as well as uncertain in their results, and can rarely be relied upon for a cure. I have, therefore, of late years, entirely abandoned their use with this intention, and now employ them only with a view to their detergent and deodorant effect, preferring, of course, the chlorides to any of the other articles for this purpose.

The *actual cautery*, formerly so much vaunted in the treatment of certain forms of caries, especially in that of the carpal and tarsal bones, is obnoxious to the same objections as the remedies just mentioned. In applying it, it is necessary not only to divest the affected bone pretty thoroughly of its soft parts, but to employ the greatest circumspection, otherwise a much larger amount of tissue may be destroyed than is desirable. Moreover, the eschar is always a long time in coming away, and the iron has generally to be used again and again before a cure is finally effected.

Under the second head are included the *operations* necessary for scraping or cutting away the diseased structure, excising the affected bone, either in

part or in whole, and amputating the affected limb, when the case is unmanageable by other means.

As a general rule, all operative interference, having for its object the removal of the carious matter, is carefully abstained from until the disease has become strictly chronic, or, in some degree, ceased to spread. If this injunction be disregarded, injury, and not benefit, will be certain to follow our efforts, the irritation excited by them giving new impetus to the morbid action. The precise time for interference cannot, of course, be specified, but it is evident that no attempt should be made to scrape or cut the bone so long as the superimposed parts are in a highly tender, tumid, and inflamed condition. The proper treatment, under such circumstances, consists in the use of leeches, medicated fomentations, and other antiphlogistic measures calculated to soothe the irritated structures, and prevent the spread of the disease.

When the caries is of small extent, it may generally be got rid of by means of a burr-head drill, similar to that used by the dentist for removing caries from decayed teeth previously to plugging. With such an instrument, of which the adjoining sketch, fig. 288, affords a good idea, the whole of the diseased substance may often be cut away in a few minutes, with little pain to the patient, and no detriment whatever to the neighboring parts, which should always be turned aside immediately prior to the operation, care being taken in doing so not to interfere with any important structures. Every bone-case should have from three to six drills, of varying size and shape, so as to meet every contingency that may arise in practice. Several trephines, pliers, gouges, chisels, and scrapers, should also be at hand, and, when this is the

Fig. 288.

Scraper.

case, it is difficult to conceive how any surgeon can fail in accomplishing his object. In operating upon the tarsal and carpal bones, I have generally derived material service from the use of a short, stout scalpel, with a semi-sharp convex extremity, and a large handle. Such an instrument is peculiarly advantageous in paring the surface of deep-seated cavities. When the ligaments and cartilages are involved, the operation can hardly be completed in a satisfactory manner without a pair of blunt-pointed scissors, with long, thick, narrow blades. The raspatory is useful in smoothing carious cavities after the removal of the disorganized substance. During the operation the diseased cavity is kept free from blood by means of sponge mops.

When all the diseased structure has been removed, free use should be made of the syringe in order to effect thorough clearance of the affected cavity. Unless this be done, more or less of the bony matter will be left, thus keeping up irritation and discharge, and interfering with the reparative process.

Considerable *hemorrhage* often attends these operations, the blood sometimes proceeding from small arteries, but more generally from numerous points, as if it came from the pores of a sponge. In the former case, the ligature will usually be required, more particularly as the vessels are unable to retract on account of the indurated condition of the surrounding parts, while in the latter the temporary application of the sponge, wrung out of cold water, will commonly speedily arrest the flow. Should this, however, not answer the purpose, the bleeding cavity should be stuffed with lint, soaked in a strong solution of alum, or of persulphate of iron, the plug being retained no longer than may be absolutely necessary.

Doubt is often experienced, in these operations, as to the amount of substance to be removed, the precise line of demarcation between the sound and diseased structures not being always easy of determination. A good diagnostic, under such circumstances, is to wash the fragments in water, when, if they be carious, they will exhibit a whitish, grayish, greenish, or blackish appearance; whereas, if they are healthy, they will be found to be vascular and red, and to retain their normal consistence, presenting none of the fragile and porous characters which distinguish them in the former case.

Bleeding having been arrested, the edges of the wound are loosely approximated by suture, and the limb, placed in a favorable position for drainage, is wrapped up in a bandage, extending from the distal extremity upwards beyond the seat of operation. Water-dressing is afterwards used, either cold or warm, as the case may seem to demand, and strict attention is given to antiphlogistics generally. Occasionally it is found requisite to insert a tent, to conduct off the matter, and prevent premature closure; and for some time the bony cavity should be injected twice or thrice daily with tepid water and Castile soap, or some gently detergent lotion. The great dangers after the operation are erysipelas and pyemia, which it is only necessary to mention in order to put the practitioner upon his guard respecting their occurrence.

The *healing process*, after such an operation, exhibits itself by the development of granulations, which, under the microscope, display very much the

same appearance as those of the soft parts. The vessels, as shown in fig. 291, from a drawing made for me by Dr. Packard, have a remarkably looped and varicose arrangement. It was taken from an ulcerated patella, which was covered with an immense number of the most beautiful scarlet granulations, not as large as the smallest pin's head, closely grouped together, and exceedingly tolerant of rude manipulation. The section was magnified sixty diameters.

Excision of an entire bone is sometimes necessary for the relief of this disease. Such a procedure is most frequently required on account of caries of the carpal and tarsal bones, upon

Structure of a granulation in a bone.

which it may frequently be performed with great advantage, a useful limb being generally left even after the removal of several of these pieces. In the long bones, the operation is usually limited to the articular end, or to this and a portion of the shaft. Respecting the manner of executing this operation, and the estimate to be placed upon it, in a curative point of view, special mention has been made in the chapter on excision, so that any further discussion of the subject here will be unnecessary.

When the disease is so extensive as to be uncontrollable by the means now described, and the attendant discharges are so copious as to give rise to profuse night-sweats, marasmus, and colliquative diarrhœa, *amputation* of the limb, comprising the carious bone, will afford the only chance of safety, and should be performed without delay. It is surprising how the system usually rallies after such an operation. The patient, in the course of a few days, generally looks like a new being; his sweats and diarrhœa soon leave him, and he rapidly improves in health and spirits, making often an excellent recovery.

SECT. VI.—NECROSIS OR MORTIFICATION.

The word necrosis denotes the death of a bone, and is strictly synonymous with mortification, gangrene, or sphacelus, used to designate the death of a soft structure. The immediate cause of the occurrence is inflammation, eventuating in an arrest of the circulation and innervation of the osseous tissue.

Necrosis is most common in those bones which are most superficial, or which lie immediately beneath the integuments, as the tibia, ulna, lower jaw, clavicle, the inferior portion of the femur, and the phalanges of the fingers. The long bones suffer more frequently than the short, and the short than the flat, the reverse being the case in caries, for the reason that, in the former, the compact tissue is most commonly affected, and in the latter, the spongy.

Children under fifteen years of age, particularly such as are of a strumous diathesis or habit of body, are the most common subjects of this disease. This is more especially true of the idiopathic form; for traumatic necrosis probably occurs as readily in adults and old persons as in young. Of the influence of sex, climate, and occupation, upon the production of the disease, nothing very satisfactory is known. If it be more common in boys than in girls, a circumstance, however, which has not been established, it is, probably, simply because the former are more exposed to the exciting causes of necrosis than the latter, and not because of any sexual peculiarity. It has been generally supposed, and not without reason, that the occurrence is most common in cold, damp, and variable regions; and the explanation of this seems to be that the inhabitants of these countries are particularly prone to suppression of the cutaneous perspiration, which, in individuals predisposed to disease, may, it is alleged, readily cause death of the more superficial bones. It has been ascertained that persons engaged in the manufacture of lucifer matches are liable to necrosis of the jaw, from the contact of the fumes of phosphorus with the interior of decayed teeth; and it is not improbable that there are other pursuits which may conduce to destructive inflammation of the osseous tissue, although of their precise nature and mode of action we are not informed.

Causes.—If we inquire into the idiopathic form of necrosis, we shall find, as has just been intimated, that it is most common in young strumous subjects, having well marked evidence of scrofula in other parts of the body, or, at all events, signs of a strumous predisposition, as evinced by the delicacy of the skin, the languid circulation, the tumid belly, and the deficient temperature of the extremities. I am certain that this has been the case in the great majority of the instances that have come under my own observation, and I believe that this, in the main, agrees with that of other writers. It is in persons of this description, more particularly, that we so frequently meet with the worst species of necrosis of the tibia, femur, and humerus, telling so fearfully upon the constitution, and so often requiring amputation in order to save the patient's life. The most common cause of the disease, in this class of subjects, is exposure to cold, as when a boy, overheated by play, sits

down in a current of air, and thus suddenly repels his perspiration; or when, under similar circumstances, he strips himself, and plunges into cold water. He is not made aware, perhaps, for several days that he has received any injury; but, all of a sudden, he is seized with violent pain in one of his limbs, attended with severe rigors alternating with flushes of heat, and, upon examining the affected part, he observes that it is exquisitely tender on pressure, more or less swollen, and covered with an erysipelatous blush. The local and constitutional symptoms progressing, matter soon forms deep beneath the muscles, the swelling becomes more and more circumscribed, and, ulceration taking place, the contents of the abscess thus gradually find their way to the surface, leaving the bone dead below. Such is the manner in which necrosis is generally produced in weakly, scrofulous subjects, and it is hardly necessary to add that all the attendant phenomena are indicative of a rapidly destructive osteitis.

Tertiary syphilis is another cause of necrosis, and the history of this disease has shown that the osteitis growing out of it is more apt to occasion death of the bone when the patient has been subjected to free courses of mercury for its cure, than when the malady has been treated on general antiphlogistic principles. The two poisons coming together, and mingling their baneful influence, induce a form of ossific inflammation which is extremely prone, especially in persons of a worn-out, debilitated constitution, to terminate in gangrene of the bones—those of the nose, palate, upper jaw, leg, and arm in particular.

Protracted courses of mercury, especially in young subjects of a strumous diathesis, or exhausted by diarrhœa, cholera, or eruptive diseases, often cause necrosis of a frightful character, generally of the jaw-bones, but sometimes, also, of other pieces of the skeleton. What is termed dry salivation is frequently more destructive to the gums, teeth, and jaw-bones than salivation accompanied by profuse discharge. The debility produced by the injudicious use of drastic purgatives and tartar emetic has occasionally caused necrosis of the bones of the extremities, head, and trunk. Scurvy has been known to produce similar effects, although more commonly it causes caries. In short, there is reason to believe that idiopathic necrosis may be induced by whatever has a tendency to bring about an impoverished condition of the blood and solids.

Among the local causes of necrosis may be enumerated wounds, contusions, fractures, and chemical irritants; in the tibia, the probability is that mere concussion, as happens when a person falls from a considerable height and alights upon his foot, is often sufficient to produce a destructive form of osteitis. Gunshot injuries are a common source of the occurrence, whether the bone be merely grazed by the passage of the projectile, or whether the ball lodges in its substance and acts as a foreign body. Mere denudation of a bone, however occasioned, is frequently followed by its death, especially when the loss of periosteum is very considerable, or if, even when it is comparatively trivial, it is accompanied by the laceration of the nutrient artery, or extensive destruction of the soft parts generally. Under such circumstances, the necrosis is usually limited to the outer compact structure, the part ultimately coming away in the form of an exfoliation. Such an event, however, is by no means inevitable. The periosteum may be stripped off to a considerable extent, and yet, if the bone be in other respects healthy, or enjoy a tolerably active circulation, granulations will spring up, and thus gradually repair the breach. It is only when the vascular connection between the two structures has been materially impaired, or totally destroyed, that necrosis will be likely to ensue, the bone becoming white and dry, and eventually dark and even black. These appearances are well illustrated in what so often happens in compound fractures, attended with protrusion of

the end of the bone divested of its fibrous covering, and in the phalanges of the fingers in whitlow.

It will thus be perceived, without going into further details, that death of the osseous tissue may be produced by constitutional or local causes, and that these causes differ in no respect whatever from those which induce mortification of the soft parts. Furthermore, it will be observed that they are such as usually give rise to inflammation generally in all structures without exception.

Extent.—Necrosis may be partial or complete, simple or complicated, superficial or deep; that is, it may affect merely a portion of a bone, or it may pervade its entire structure; it is said to be simple when it is limited to a single piece, and complicated when it attacks several, either simultaneously or consecutively. It is seldom that an entire bone perishes. Such an occurrence is sometimes observed in the pieces of the carpus and tarsus, in consequence of external injury, but it is extremely uncommon in the long bones; in these the shaft alone generally suffers, the articular ends retaining their vitality. Necrosis of the whole lower jaw has been repeatedly noticed as a result of the action of phosphorus, and some interesting cases in which the entire bone was successfully removed on account of this disease have been related by Dr. Carnochan and Dr. James R. Wood. Finally, necrosis may be limited to the outer surface of a bone, involving merely its superficial laminae, the dead portion being ultimately detached in the form of a thin scale or plate; or it may invade its entire thickness, and then not unfrequently begins in the very depths of the cancellated tissue, in consequence generally of injury or disease of the medullary membrane.

The occurrence of necrosis, the elimination of the dead bone, usually called the sequester, and the formation of new bone as a substitute for the old, or that which has died, involve some very curious pathological and physiological processes, and therefore deserve attentive consideration. The symptoms which immediately precede, and those which accompany the death of the bone, are such, generally, as are denotive of violent inflammation, deep-seated, attended with excruciating pain, and rapidly tending to the suppurative crisis, the mischief being often done in a few days, and sometimes even in a few hours. Action, general as well as local, is excessive, and both the part and system occasionally fall a prey to its devastating influence, especially when there is involvement of a large neighboring joint, as now and then occurs when the necrosis attacks the inferior extremity of the femur, and extends into the knee. Progress, however, is not always so swift and overwhelming; often it is quite the reverse, the part and system suffering but little, and the malady pursuing apparently a chronic course.

A very common way in which the occurrence of gangrene of a long bone is announced is as follows. The patient, usually a lad from six to ten years of age, after having been overheated or exposed to severe cold, retires at night apparently perfectly well, but towards morning he is aroused by pain in the thigh or leg, deep-seated, circumscribed, of a sharp, aching character, and so excessively severe as to deprive him of further sleep and rest. The soft parts over the seat of the disease soon become exquisitely tender to the touch, swollen, and discolored, the surface having a glazed, dusky, reddish, or purplish tint, and pitting under pressure, in consequence of the infiltration of the subcutaneous cellular tissue. These local phenomena are always attended by severe constitutional disturbance. There is high raging fever, with a tendency to delirium, and excessive restlessness; the pulse is full, hard, and frequent; the skin is hot and dry; the thirst incessant; and the urine, thick and scanty, is surcharged with urates. By and by, violent rigors set in, succeeded by flushes of heat, the pain assumes a tensive, throbbing character, the swelling becomes more diffuse, extending often to a great distance

up and down the limb, as well as widely circumferentially, the discoloration acquires an erysipelatous blush, and a careful examination soon detects, what, indeed, the existing symptoms sufficiently declare, the presence of pus, deep seated, lying partly between the affected bone and the periosteum, and partly on the outside of the membrane, in the cellular tissue of the muscles and aponeuroses, which it often extensively dissects and separates from each other, forming large pouches from which it is frequently difficult to dislodge it. Sometimes the abscess opens into a neighboring joint, and thus becomes a source of additional mischief, exciting inflammation in the synovial membrane, perhaps ultimately followed by destructive softening of the cartilage, and caries or necrosis of the end of the bone.

The quantity and quality of the matter found at this stage of the disease are very various. In the more severe cases it often amounts to several pints, whereas, under ordinary circumstances, it may not exceed that many ounces. The quantity furnished by the bone itself, or, rather, by the bone and periosteum, is always comparatively small, most of it being supplied by the soft structures over and around the seat of the disease. In most cases of spontaneous necrosis, it is found to be of a decidedly strumous character, being of a yellowish color, verging upon greenish, and of a thick cream-like consistence, interspersed with tough curdy matter, or flakes of lymph. In general it is more or less fetid—sometimes excessively so, particularly when long retained—and mixed with shreds of dead cellular tissue. Cases are met with where the matter is thin, ichorous, or sanious, but such an occurrence is unusual until after the bursting of the abscess, and the evacuation of its contents.

When the matter has been discharged, whether spontaneously or artificially, there is always a material improvement in the symptoms, both local and general, and an opportunity is now afforded for a thorough examination of the parts. The best instrument for this is the finger, or, when the opening is not sufficient or too devious, the probe. With either of these it is generally easy to determine the extent of destruction of the periosteum, or, at all events, of its separation, and the amount of injury sustained by the osseous tissue, the surface of the bone feeling rough, and having a whitish, grayish, or ashy hue, without any appearance whatever of vascularity.

Such is a succinct account of the circumstances which immediately precede, accompany, and immediately succeed the occurrence of necrosis as it is usually met with at the bedside. The first stage of the disease is over; the matter consequent upon the inflammation has been discharged; and the inflammation itself has measurably subsided, the soft parts, however, being still swollen, indurated, tender, and painful, as well as entirely disqualified for the performance of their normal functions. Nature, never idle, now begins the double work of elimination and repair, both usually very tardy, often imperfect, and sometimes altogether unsatisfactory, the powers both of the part and system being inadequate to accomplish the object. In gangrene of the soft structures, the separation of the eschar is generally an easy matter compared with that of a bone, provided the patient's strength holds out; the process, once fairly commenced, proceeds rapidly and energetically, the surgeon each day seeing decisive evidence of the fact; soon the line of demarcation between the dead and living parts is perceived; then granulations are observed to spring up in the intervening chasm; and, finally, the reparative efforts still advancing, the breach is gradually closed over with new skin, a circumstance clearly denotive of the completion of the cure. But it is altogether different in necrosis; here the detachment of the slough is a matter of time, commonly requiring many weeks, and sometimes even a number of months, for its satisfactory conclusion, and even then generally demanding the interference of art before it can finally be effected. The cause

of the difference is sufficiently obvious. In the one case there is an active circulation and an energetic system of absorbents, the former furnishing an abundance of plastic material for the repair of the lost tissues, and the latter exerting themselves to cast off the dead substance; in the other, on the contrary, everything is the reverse, and the parts labor under the additional disadvantage of being loaded with earthy matter, which is obliged to be softened and disintegrated before it can be removed by the vessels whose duty it is to get rid of it.

The necrosed substance may, as already seen, embrace merely a portion of the periphery of a bone, as, for example, its outer layer; or it may include its entire thickness, and also the greater part of its length. In the former case it constitutes, when detached, what is called an *exfoliation*, and in the latter a *sequester*, a distinction of considerable importance, not so much on account of the extent of the dead substance, as of the manner in which the breach of continuity is repaired, or a new bone formed.

An *exfoliation* is commonly merely a thin scale, plate, or lamella of the outer, peripheral portion of a long bone, of variable color and consistence. In general, it is either whitish, grayish, or of a light brownish hue, rough, more or less porous, and so brittle as to break under very slight pressure. No vessels are perceptible in it, and in most cases the animal matter seems to be almost completely abstracted. Maceration deprives it of its dark color, while immersion in dilute nitric acid for a few days completely destroys its proper texture, converting it into a soft, gristly substance.

The *sequester*, properly so called, varies much in size and shape, consisting, at one time, of a part only of the circumference or length of a bone, and, at another, of its entire shaft, with perhaps a portion of its articular ends. A rather common form is that represented in the adjoining sketch, fig. 292, from a preparation in my collection; it was a part of the body of the tibia, in which all the spongy structure was completely destroyed, while the compact was remarkably hard and firm. The dead bone is always rough, pitted, excavated, or spiculated; it is of a grayish, brownish, or blackish color, and emits, when struck with a probe or piece of metal, a peculiar hollow sound, by which it is usually readily distinguished from sound bone. In the cylindrical pieces, as in the femur and tibia, it is generally dense and dry; in the short and flat, on the contrary, it is porous, moist, brittle, and easily crumbled. The analyses of Von Bibra have shown that there is a very great reduction of organic matter in necrosis with a corresponding increase of earthy, the latter being as much as eighty per cent. of the entire mass. The same experimenter has proved that the difference is considerably less in the traumatic variety of the lesion than in the idiopathic.

Repair.—While the absorbents are engaged in detaching the dead bone, with a view to its ultimate expulsion, the capillaries take upon themselves the duty of throwing out material for the formation of the substitute, or new bone. The process by which this is accomplished is the same as that which presides over the creation of the original structure. The first step consists in a deposit of plasma, the result of the incited action of the vessels caused by the irritation of the necrosed bone, and this substance, becoming organized, is gradually converted into fibro-cartilage, which, in turn, gives way to cartilage, as this ultimately does to osseous matter, the period required for the completion of the development varying, according to the age and

Fig. 292.

Necrosis of the tibia.

vigor of the patient, and the character and amount of the local disease, from a few weeks to several months. The new bone is at first a mere shell encasing the old, and thus serving to separate it from the surrounding parts, which ill brook its presence. In time, however, it increases in thickness, being often from three to six lines in depth, and occasionally, though not generally, it is fully as large as the original piece. Its surface is usually somewhat rough, and it is not uncommon to observe upon it considerable eminences and depressions, owing evidently to the irregularity of the developmental process. The new substance, too, has comparatively little areolar tissue, and hence, if some time have elapsed since its formation, it always cuts with great difficulty, the resistance offered by it being much greater than that of the pre-existing structure. In cases of long standing, indeed, it often acquires the solidity and density of ivory, so that it requires great patience and perseverance to penetrate it with the saw and pliers. The vessels, under such circumstances, are always very small and sparse, and the Haversian tubes are traced with difficulty. In the long pieces, after the death and removal of the shaft, there is never a complete reproduction of the medullary canal and its lining membrane, or of the endosteum. In fact, the new bone, although it possesses all the essential attributes of the osseous tissue, is, nevertheless, a very imperfect type of the original, and hence much less capable of resisting the effects of disease and accident.

The appearances of the new bone, encasing the old or dead, are admirably depicted in fig. 293, taken from a specimen in the collection of Professor Pancoast. Owing to the ravages of the disease, amputation became necessary.

Necrosed tibia, the dead bone lying loose within the new.

Cloacæ in a necrosed tibia.

In viewing the new bone as it surrounds the old, its surface is found to be pierced by several apertures, to which, from their fancied resemblance to the rectal pouch of a bird, the term *cloacæ*, fig. 294, is usually applied. These openings, which play an important part in the expulsion of the dead bone, owe their existence to a deficiency of periosteum, or of secreting structure, as is proved by the fact that, when the formation of new osseous tissue goes on uniformly round every portion of the periphery, the old bone will be completely imprisoned, thus not only obscuring the diagnosis but rendering the removal of the sequester a matter of great difficulty and perplexity. The size of these cloacæ varies in different cases, from that of a three cent piece to that of a quarter of a dollar, their shape being generally rounded, or somewhat oval. Not unfrequently, however, they present themselves in the form of long, irregular fissures, or slits. Their number is indefinite; sometimes there is but one, while at other times there are as many as half a dozen, the latter number being by no

means uncommon in necrosis of the shaft of the tibia. Whatever may be the size, form, or number of these apertures, they always communicate with the surface of the limb in which the affected bone is situated, the passages

between them constituting so many channels for the discharge of matter and the ultimate elimination of the sequester, although this, owing to the inadequate dimensions of the cloacæ, is seldom effected without the intervention of art. It is an interesting fact, and one of no little practical value, that these openings are always situated in that portion of the new bone which is least covered by soft parts.

There has been much dispute among pathologists, as to the agents by which the new bone is produced, and the question can hardly be said to be even yet definitively settled. Without entering into any details, I may state, as the result of personal observation, that the perfection of the new bone will generally be found to be in proportion to the integrity and activity of the periosteum. I have always found that, when this membrane has suffered much during the inflammation which precedes and accompanies the necrosis, the reproductive process, or new osseous epigenesis, is tedious and difficult, and often extremely inadequate, the new bone being comparatively small and stunted, and, therefore, ill adapted to the purpose of a substitute bone. The part which the periosteum plays in the development of the new bone is well shown in the formation of cloacæ, which, as already stated, is clearly dependent upon the partial destruction of that membrane. If the periosteum everywhere retained its integrity, the new bone would be without a solitary opening, and the consequence would be that the sequester, or slough, would always be an encysted or imprisoned body. When this membrane has perished along with the bone, as occasionally happens in the shaft of the tibia or femur, the new bone will be formed by the surrounding structures, whatever these may be, but under such circumstances it is so imperfect, short, and thin, as hardly to deserve the name of substitute, to which, in general, it is so well entitled.

When the eschar presents itself as an exfoliation, or thin superficial scale, the breach is repaired through the medium of granulations, which, being derived from the old bone, are extremely vascular and sensitive, and soon assume the ossific process, throwing out an abundance of proper material for the accomplishment of the object. A similar process appears to be set up when the central portion of a bone perishes; for here the endosteum being also destroyed, it can have no agency in the reproductive act. When this membrane retains its vitality, it must necessarily exert an important influence as an epigenetic agent.

The idea has been broached, and warmly defended, that when the shaft of a bone is necrosed, so as to leave merely its articular ends, the new bone is formed exclusively by these ends, the osseous matter extending gradually towards the middle of the chasm, and ultimately coalescing there. Such a theory, however, is altogether untenable, being contrary to what occurs in the growth of the original bone, which always takes place by several distinct points, one of which is invariably central. However well the surviving extremities might perform their duty, yet, as there is no central nucleus, serving as a point of departure for the ossific matter, it is easy to conceive that the bone would always necessarily be so deficient at that particular spot as to disqualify it materially for the performance of any useful functions.

Symptoms.—The symptoms which attend necrosis, in its earlier stages, have already been pointed out; those which accompany the separation of the old bone and the formation of the new, are, in general, sufficiently characteristic. The most important of these are, little ulcers, surrounded by large unhealthy granulations, arranged in a papilla-like manner; sinuses leading from these ulcers down to the dead bone; and a discharge, more or less constant and copious, of thin, fetid, sanious matter, or of thick, white, inodorous pus; accompanied, in all cases, by a certain amount of hardness and swelling, pain and tenderness on pressure, wasting of the soft parts above and below the seat of the disease, and marked impairment of the functions of

the neighboring joints. The general health always suffers; the patient is wan and emaciated; and, if the irritation is at all extensive, he will usually have hectic fever. In some cases the end of the sequester sticks out at one of the cloacæ, thus at once declaring the real nature of the complaint; but more commonly the dead bone is completely imprisoned by the new, and can only be reached by the probe or finger, carried along the sinuses leading from the surface to the cloacæ. In order to ascertain whether the separation has been effected, or whether the dead bone still maintains its relations, in some degree, with the living, the surgeon may often advantageously use two probes, introducing one at each extremity of the eschar, and moving them alternately in different directions, as may frequently be easily done when the detachment is complete. In general also useful information, in this respect, may be obtained from a consideration of the history of the case, as the size of the affected bone, the age of the patient, and the commencement of the attack. Thus, other things being equal, it will usually be found that a small bone will be more readily separated than a large one, and the bone of a young subject than that of an old one, while in every instance the process may be supposed to be more advanced in proportion to the period that has elapsed since the death of the bone.

Prognosis.—The prognosis of this disorder is variable. In general, it may be considered to be favorable when it is owing to external or local causes; when it is confined to the outer portion of a bone, the necrosis occurring in the form of an exfoliation; when it is simple and of moderate extent; and when the patient is young, robust, and of a good constitution. On the other hand, the cure is difficult, and the issue doubtful, when the disease is extensive and complicated with other affections; when it attacks pieces which are of high importance on account of their functions or situation; when it occupies the interior of a bone, and involves several parts of it; when it arises from an internal or constitutional cause, as struma or syphilis; when it extends into the adjacent joints, especially when these joints are of large size; and, lastly, when the patient is enfeebled by age, long suffering, or previous disease.

The time required for the development of the substitute bone will depend, as already stated, in great measure, upon the situation and extent of the disease, the age, health, and condition of the patient, and various other circumstances which will readily suggest themselves to the reader. That the whole of a necrosed bone may be regenerated, is a fact so well established as no longer to admit of any doubt. The new bone, however, as intimated elsewhere, is always, at best, only an imperfect copy, although, as it respects its functions, it usually answers the purpose well enough.

Treatment.—The treatment of necrosis must of necessity depend very much upon the circumstances of each particular case. There are three indications, however, which deserve special attention, the first of which is to limit and moderate the inflammation which is the immediate cause of the mischief, the second, to watch nature during the separation of the old bone and the formation of the new, and the third, to promote the removal of the sequester, slough, or eschar.

The first of these objects, which should always be kept clearly in view by the practitioner, is to be attained, of course, by the proper employment of antiphlogistic remedies; by the lancet, if the patient be plethoric, purgatives, the antimonial and saline mixture, light diet, repose, and the free use of opiates to allay pain and induce sleep. The affected parts, placed in an easy, elevated position, are leeches and fomented, or, what is particularly serviceable, painted with a strong solution of iodine at least three times in the twenty-four hours, the surface being protected in the intervals with an emollient anodyne cataplasm, or medicated water-dressing. In some instances,

great benefit is derived from the application of a blister large enough to encircle nearly the whole of the affected limb, and kept on sufficiently long to produce thorough vesication. By these means, the surgeon not only limits the inflammation, but promotes the absorption of effused fluids, and hastens the suppurative crisis, which is always inevitable, to a greater or less degree, in every case of this kind. As soon as fluctuation is perceived, or even before, if there be inordinate pain and tension, or deep-seated matter, a large incision is made at one or more points, in the direction of the long axis of the bone, in the hope of saving osseous as well as soft tissue, especially the periosteum, the integrity of which is so essential to the development and formation of the substitute bone. In making the opening, due attention is, of course, had to drainage, and to the prevention of its premature closure.

The second indication is to watch the part and system during the sloughing process and the stage of reparation, in order that they may be enabled to perform with facility the arduous and important duties before them. The case requires active vigilance rather than active treatment; care, on the one hand, that the disease do not spread, and, on the other, that the debility consequent upon the drainage and irritation do not obtain the mastery, and so bring on fatal exhaustion. A certain amount of inflammation must necessarily attend both processes, and, therefore, action must not be too much repressed, lest nature be thwarted, or, at all events, embarrassed in her operations, operations which are both salutary and needful. A nutritious diet will generally be required, and the patient will often be immensely benefited by animal food and milk punch, ale, porter, or wine, and the use of quinine, iron, and aromatic sulphuric acid, especially if he have hectic fever and night-sweats. If he can move about on crutches, he should take gentle exercise daily in the open air; or, if this be impracticable, he should be pulled about in a hand-car, or be swung upon a hammock. Attention is, of course, paid to the bowels and secretions. Pain is allayed by anodynes. The principal local remedies are leeches, provided there is any disposition to over-action, the daily application of iodine, and the use of the bandage to support not merely the affected parts but also the distal portion of the limb, which, when this precaution is neglected, has usually a tendency to become œdematous. Fœtor is allayed, and discharge moderated, by the chlorides, introduced by the syringe and sprinkled upon the dressings. Much has been said about the employment of solvents, thrown through the principal sinuses upon the dead bone, in the vain hope of promoting its gradual disintegration and elimination. Special stress used to be laid upon various acid solutions, particularly the nitric, hydrochloric, and pyroligneous; but experience has proved that they are always productive of harm, from their irritating effects upon the new bone and the soft parts, whilst, unless they are intolerably strong, they can exert no destructive influence whatever upon the sequester itself. If such lotions be employed at all, they should, therefore, be employed in the mildest possible form, simply with a view to their detergent and alterant effects, which are often very salutary, expediting the sloughing and restorative processes. In general, however, all the good that can be expected to result from such remedies may be accomplished by injections of tepid water, impregnated with Castile soap, a little potassa, or common salt, followed, if there be much fœtor, by a weak solution of chlorinated soda. If new abscesses form, as occasionally happens, they must meet with prompt attention.

During this stage, a stage, I repeat, of comparative inactivity, inquiry is made into special diatheses, or states of the system. The patient may be strumous, and, therefore, be in need of anti-strumous remedies; or his system may be impregnated with the syphilitic poison, and a course of mercury, or of iodide of potassium, may be required. It must be obvious that no satis-

factory progress can be made, in any case, towards a cure so long as the system is borne down by the pressure of a vitiated state of the solids and fluids.

The third indication is to get rid of the sequester, for so long as this remains it must necessarily act as an irritant, keeping up inflammation and discharge in the parts with which it lies in contact. It was generally supposed, until recently, that the dead bone, during its sojourn among the living tissues, was acted upon by the absorbent vessels, so as to diminish, more or less, its size and weight, the idea having apparently derived support from the altered and pitted condition of the surface of the affected piece. The notion, however, has been completely dispelled by the experiments of Mr. Gulliver, who ascertained, as might, indeed, have been anticipated, that such an occurrence is altogether impossible. Pieces of necrosed bone, carefully weighed before and after exposure, were confined on suppurating surfaces, in the medullary canal, and in the subcutaneous cellular substance for months, and in one instance for upwards of a year, without undergoing the slightest alteration whatever. A paper, detailing nineteen experiments of this kind, may be found in the twenty-first volume of the Transactions of the Medico-Chirurgical Society of London.

Seeing, then, that the dead bone acts as an extraneous body, and that it is in nowise amenable to the agency of the absorbents, the indication plainly is to remove it by operation. Such a step is the more imperative because of the manner in which it is imprisoned, the substitute bone forming a firm and solid case around it, and thus effectually preventing its extrusion. The only circumstance which should make the practitioner at all hesitate, is the doubt which may arise in his mind respecting the probability of the dead bone being completely detached, and the new one sufficiently advanced to enable it, after the removal of the sequester, to maintain its position without bending under the weight of the limb, in turning in bed, walking, or sitting. If he is satisfied of this, as he usually may be after a careful examination of all the facts of the case, he should at once proceed to adopt measures for the accomplishment of his object. The instruments which will be required for this purpose are various; but, in general, it will be necessary to have several scalpels, a trephine, a Hey's saw, an elevator, pliers, chisels, and stout forceps, with a good syringe for washing away the osseous *débris* after the operation is over. The adjoining cuts represent some of the more important of these instruments.

The incisions should always be made in the direction of the long axis of the bone, out of the way of the great vessels and nerves. The best plan usually is to select one of the principal cloacæ, or, when two or three are close together, especially if they be on the same plane, to connect them, thereby affording more room to work in. When the soft structures are much diseased, they may be included in an elliptical incision, as, in this event, it may be best to get rid of them. When it is deemed advisable to connect two or more cloacæ, the object may be easily attained by a Hey's saw, or, if the new bone is not very thick and firm, by the pliers. The trephine is chiefly of use when the openings in the substitute bone are very small, or when this bone possesses unusual density and thickness, rendering its division extremely difficult by the more ordinary instruments. Access having thus been obtained, the sequester is to be seized by one of its extremities, with a pair of forceps having long, thin blades, serrated on their inner surface, and from a third of an inch to half an inch in width, the handles being well curved, so as to facilitate prehension and maintenance.

When the sequester is unusually long, it may be necessary to divide it at the middle, and extract each piece separately; an operation which is always easily performed with the pliers or chisel.

The dead bone having been extracted, the next step is to wash out the canal left by its removal with a few syringefuls of cold water to clear away any little pieces, fragments, or *débris* that may have been left. Attention to this injunction, although generally neglected, will greatly expedite recovery by facilitating the growth of healthy granulations. The hemorrhage attending the operation is often quite free, the blood oozing out at every point, in consequence of the great vascularity of the parts, both osseous and soft, and occasionally requires plugging of the cavern with lint steeped in some styptic lotion, as a saturated solution of alum, or alum and tannin. It is not often that any artery requires to be tied.

Fig. 296.

Fig. 297.

Fig. 298.

Fig. 299.

Instruments for removing dead bone.

The operation being completed, the edges of the wound are drawn lightly together with adhesive strips, and the limb, placed in an easy position, is bandaged from the distal end upwards, the parts more immediately affected being kept constantly wet with cold water, or a weak spirituous lotion. The dressings are removed in forty-eight hours, when the wound is well syringed, and covered with an emollient poultice, to favor the granulating process. The only general means usually required are light diet and a little attention to the bowels, with a full anodyne after the patient is put to bed. If the new bone is not sufficiently strong to prevent the limb from bending or breaking, it must be supported by appropriate splints, or, what is better, a case made of sole-leather, gutta-percha, or trunk-maker's board.

Soon after the sequester has been removed, whether by nature or art, the new osseous shell begins to contract, and by degrees assumes the shape of the old bone, which it is designed to replace. While this change is going on externally, osseous matter is deposited upon the inner surface of the shell, as well as upon the articular ends of the surviving portions, thereby gradually filling up the cavity, the period required for this being generally in proportion to the size of the eschar. The medullary canal, in case of there having been one, is, as already stated, seldom re-established.

It is not often, at the present day, that, with proper management, the practitioner is not able to effect a cure in necrosis; in general even with little deformity or loss of function. Cases do, however, occur, where, in consequence of neglect or injudicious treatment, the neighboring structures are so extensively and ruinously involved as to render it difficult, if not impossible, to save the patient without sacrificing the limb. Such an event will be particularly liable to happen when a large joint is implicated, as, for instance, that of the knee in necrosis of the thigh, or of the ankle in necrosis of the tibia. Under such circumstances, hardly anything short of amputation will be likely to answer; and a similar procedure may become necessary when the patient's constitution is so much shattered by previous or concomitant disease as to preclude the possibility of its holding out during the time which may be required for the separation of the dead bone from the living. In other cases, again, amputation may be demanded on account of hemorrhage from some large sinus, presenting itself either as a general oozing, or as a flow from an artery of considerable size, opened by ulcerative action, under circumstances when the loss of a few more ounces of blood might prove fatal. It is impossible, however, to exercise too much caution in attempting to decide so grave a question. In weighing the several points involved in its consideration, we must not lose sight of the fact that cases, apparently of the most forlorn character, where life literally hangs, as it were, by a thread, will sometimes promptly recover upon the removal of the dead bone. Finally, it must not be forgotten that excision of an entire bone has often been advantageously performed, especially of late years, recovery taking place with comparatively little deformity.

SECT. VII.—SOFTENING.

The essential characteristic of osteomalacia, *mollities ossium*, or softening of the bones, is a diminution of the firmness and solidity of the osseous tissue, depending upon the gradual removal of its earthy constituents, and the depo-

Fig. 300.

Madame Supiot, in a posture quite practicable in the advanced stage of the disease.

sition of a reddish sero-albuminous, oily, or greasy substance. The malady is often confounded with rachitis, but differs from it in the circumstance, first, of its being a disorder of adult life; and secondly, in being always attended with severe pain; whereas rickets is peculiar to infancy, and free from local suffering.

Extent.—Softening of the osseous tissue varies in degree and extent, occurring at one time as a very slight affection, with hardly any appreciable change of structure, and at another as a most serious lesion, in which it is difficult to distinguish any trace of the normal substance. In regard to its extent, it may be general or partial, in the one case pervading the

entire skeleton, while in the other it is limited to particular bones, or portions of bone. Of general osteomalacia, the case of Madame Supiot, which has long since become classical, and which has been so minutely described by Morand, the younger, in the Memoirs of the Academy of Sciences of Paris, for 1710, affords a characteristic, as well as a most extraordinary example, as shown in fig. 300. This female, who was thirty-seven years of age at the time of her death, had her bones so completely softened that they could be bent like wax, and put in almost any position, although she herself had lost all control over them, her head and left arm being the only parts she could move. Most generally the disorder is confined to particular bones, especially the ribs, sternum, vertebræ, and pelvic pieces.

Morbid Anatomy.—The osseous tissue in this disease gradually loses its firmness and solidity, becoming ultimately so soft and pliant that it may be easily bent, if not cut. It is of a pale reddish color, often inclining to yellow, is specifically lighter than the healthy structure, and is infiltrated with a turbid, viscid serum, removable by pressure. Occasionally the osseous fibres are widely separated from each other, so as to leave large cells, which are filled with a bloody-looking, adipose substance. When this is the case, the bone is sometimes remarkably pliant, bending like semi-concrete wax. Boiling completely dissolves it; and exposure to the air, by abstracting its moisture, sensibly diminishes its weight. Such are the principal changes observable in the osseous tissue. The periosteum over the affected part is abnormally thick, rough, and but feebly adherent; it is of a grayish hue, deeply injected, and, like the bone, infiltrated with sanguinolent matter. Upon being macerated, however, it is found to retain its fibrous structure. The marrow is converted into a reddish, greasy sanies; and the medullary membrane is wasted away to a few soft, cellular shreds. The cartilages sometimes participate in the softening, while the muscles are pale, atrophied, and infiltrated with a reddish fluid.

The softening generally involves the whole thickness of the bone; but cases occur in which the outer table remains unchanged, consisting of a thin, brittle shell. The disorder obviously consists either in an inordinate absorption of the phosphate of lime, upon which the solidity of the osseous structure naturally depends, or in a deficient deposition of this matter into its meshes. It has already been mentioned that the bones become specifically lighter in this disease; and Dr. Bostock has ascertained the additional fact that they contain nearly eighty parts of animal substance in the hundred. The experiments of this gentleman were afterwards confirmed by those of Dr. G. O. Rees, of London, who, from a careful analysis of three diseased specimens, taken from the same adult subject, obtained the following results, which he has compared with those furnished by healthy bone:—

	Diseased.		Healthy.	
	Earths.	Animal matter.	Earths.	Animal matter.
Fibula . .	32.50	67.50	60.02	39.98
Rib . . .	30.00	70.00	57.49	42.51
Vertebra .	26.13	73.87	57.42	42.58

On examining this table, it will be observed that, in the diseased as well as in the sound state, the fibula contains more earthy matter than the rib, and the rib more than the vertebra. In health, the vertebra and rib approach very nearly in their proportions of animal and saline ingredients, whereas, in softening, a considerable difference obtains.

Causes.—What are the causes of this remarkable disease, or the circumstances which influence its origin and development? Upon this subject, unfortunately, science is almost completely silent. A great variety of causes have been accused as being capable of producing it, more especially a gouty,

rheumatic, syphilitic, or scorbutic state of the system; but, in admitting such an agency, it should not be forgotten that vast numbers of persons labor under such a taint, and yet are never the subjects of osteomalacia. That it may occasionally induce softening of the osseous tissue is extremely probable; but that this occurrence is frequent all experience plainly contradicts. The whole course of the disease shows it to be essentially connected with a vitiated and depraved condition both of the solids and fluids; but whether the disorder of the one precedes that of the other, or whether they have a simultaneous origin, and afterwards keep steady and regular pace with each other, are questions which our knowledge is inadequate to solve. However provoked, it is sufficiently apparent that the structures which are its seat are in a state of inflammation, and that this inflammation plays an important part in the production of the changes which characterize it. We cannot, as rational pathologists, assume any other ground; for, how else can we account for the excessive vascularity of the affected tissue, the sanguinolent nature of the infiltrated fluids, the thickened, spongy, and congested condition of the periosteum, and, finally, the atrocious and constant pains which form so notable a feature in the history of osteomalacia? All these circumstances unerringly point to inflammation as the great agent in the production of these changes; changes which, when existing in the soft structures, are invariably referred to this cause, and to none other. The morbid action, whatever it may be, is always of a chronic character, and is attended with important lesion of nutrition, leading to the removal of the earthy matter of the bones, and the excretion of it from the system, or its deposition among parts where it does not naturally occur. Or, what is more probable, there is both absorption of the original solid structure and a want of secretion of new, thus causing a complete disintegration, or decomposition, of the osseous tissue. All these circumstances are sufficiently obvious and tangible; but if we attempt to go beyond them, we involve ourselves at once in difficulties, from which it is found impossible to extricate ourselves.

Age and Sex.—Osteomalacia is rarely seen before the age of puberty; its favorite period of attack is between the thirtieth and fiftieth year. Another singular feature in its history is that it takes place much more frequently in women than in men, in the proportion, it has been said, of ten to three, but upon this subject it is obviously impossible to give any definite information. It is most common in females who have borne several children, and in a number of instances it has seemed to commence within a short time after parturition. Several cases have been reported where it was hereditary, having been distinctly traced through three generations, but in none of the offspring did it show itself until after puberty.

Symptoms.—The invasion and progress of this disease are generally very insidious. The earliest, and, for a long time, the most prominent, symptom is pain in the limbs, spine, and pelvis, of a wandering, shifting character, which the patient usually supposes to be of a rheumatic nature, and which is often so severe as to cause immense distress, especially at night, and in damp, chilly states of the atmosphere. By and by, dyspnoea sets in, with palpitation of the heart, and a sense of constriction across the chest, and the patient is seized with an overwhelming feeling of prostration, which utterly unfits him for business, and usually compels him to keep his bed. If he attempts to walk his limbs bend under him, and if the effort be often repeated, they soon become badly curved; should his toe catch in the folds of the carpet, or should he be so unfortunate as to trip, or fall, or give his body a sudden twist, he will probably hear some of his bones crack, and yield under the superincumbent weight. Emaciation gradually takes place, the appetite is deranged, the skin is bathed with clammy perspiration, the tongue is foul, the bowels are irregular, being either costive or too loose, and the urine, surcharged

with earthy phosphates, is very thick, heavy, of a whitish aspect, and frequently also albuminous. In the latter stages of the malady the saliva, tears, and sweat often contain similar ingredients. Great distortion frequently occurs, the bones bending in every direction, and thus effectually disqualifying them for the performance of their functions. The chest projects like that of a pigeon, the spine is bent laterally, as well as backwards, the pelvis is twisted, or rotated upon its axis, and the whole stature of the individual is sensibly diminished, the head being thrust down between the shoulders, which are unnaturally arched and prominent. Amidst all this disturbance, however, the intellect is unclouded, menstruation is perfect, and even conception is still possible. The period at which death occurs varies from a few months to several years, its approaches being usually very gradual, and the consequence of sheer exhaustion.

Diagnosis.—Osteomalacia is liable, as already stated, to be mistaken for rachitis. While it cannot be denied that the two diseases have several features in common with each other, it is equally certain that they possess sufficient points of dissimilarity to justify us in considering them as separate affections. The chief differences are the following: Osteomalacia is rarely seen before the age of twenty-five or thirty, while rachitis is altogether peculiar to infancy and childhood, the disease in the former attacking the bones after the completion of ossification, whereas, in the latter, it assails them before they are fully developed. In softening, the patient is harassed with excessive pain and an overwhelming sense of exhaustion; in rickets, on the contrary, there is a total absence of pain, and the little patient generally retains a good share of strength. In osteomalacia there is more deformity than in rachitis; the disease is also of a more fatal character, few persons getting well, whereas in rachitis recovery is the rule, death the exception. Softening is much more common in women than in men, especially in such as have had several children; rachitis, on the contrary, is nearly equally frequent in both sexes. In softening the urine always contains a large quantity of earthy matter, whereas in rickets this excretion is usually lateritious. Finally, the two affections are signalized by marked differences in their anatomical character. In osteomalacia the osseous structure is completely disintegrated and decomposed; in rachitis, on the other hand, it is merely modified, and therefore susceptible of restoration.

Prognosis.—Osteomalacia is generally a fatal disease. Hence Solly and some other authors are inclined to regard it as of a truly malignant character. Such an opinion is, of course, untenable, but it serves to show how exceedingly unmanageable the disease has hitherto proved to be in the hands even of the best practitioners. The period at which death occurs is very variable, some patients dying in a few months, others not under several years.

Treatment.—The progress of osteomalacia can be arrested only by causing a change in the action of the secernent vessels, but as we know of no means that are capable of doing this, all that can be done, in the present state of the science, is to endeavor to improve the general health by a well regulated diet and the employment of tonics, as iron and quinine, the shower bath, and change of air. Mercury has occasionally been administered, and carried to the extent of ptyalism, but, instead of proving beneficial, it has generally been productive of injury by still further exhausting the powers of life. Phosphate of lime, as having a tendency to supply the deficiency of osseous matter, has also been tried, but apparently with no better effect. If we adopt the idea that the disease is of an inflammatory nature, antiphlogistics ought to be advantageous, but thus far their employment has yielded no good results, but rather the reverse. When the disease is fully established, confinement in the bed or upon a soft elastic mattress will be necessary, and every pre-

caution should be taken to avoid the occurrence of curvature and fracture of the affected bones. Pain must be relieved by the liberal use of anodynes.

SECT. VIII.—RACHITIS.

Rachitis, or rickets, is a disease of the osseous tissue, consisting in a deficiency both of its earthy and organic elements, as is shown by the diminished

Fig. 301.

Rickets.

quantity of phosphate and carbonate of lime, and the absence of chondrin and gelatin, which form such important constituents of normal bone. The consequence is that the different classes of bone—the long, short, and flat—become so excessively softened as, in time, to yield under the slightest pressure, bending and twisting in various directions, and thus occasioning serious and generally irremediable deformity, as observed in the drawing, fig. 301, taken from a patient in the Philadelphia Hospital.

Rickets is emphatically a disease of early infancy, being most frequently witnessed from the eighteenth to the twentieth month, although many cases occur before the end of the first year. Now and then an instance is observed as late as the twelfth year; but this is extremely uncommon, and altogether contrary to the usual course of the affection. Occasionally rachitis shows itself as an intra-uterine malady. Both sexes are liable to it, and, apparently, nearly in an equal degree. Cases have occurred in which it seemed to be hereditary, or in which it attacked several members of the same

family. It would appear from the accurate and masterly account of this disease by Glisson, published upwards of two centuries ago, that it first took its rise in the western parts of England about the year 1620, from which it gradually spread over the rest of Europe; where, however, especially in Great Britain, it is now comparatively rare. In this country it has always been extremely uncommon, even among the lower classes, whose children are its most frequent subjects.

Causes.—Much labor has been spent by writers in endeavoring to ascertain the exciting causes of rickets, but really to so little purpose that our knowledge regarding it can hardly be said, even at the present day, to be more accurate than it was in the time of Glisson and his immediate successors. From the circumstance of its appearing occasionally in several children of the same family, it has by many been considered as hereditary, nearly all the older, and not a few of the modern, authorities concurring in this view of its origin. It has also been supposed, and apparently with as little reason, to have an intimate connection with a syphilitic, strumous, or scorbutic state of the constitution. Others, again, have referred its origin to the influence of a vitiated atmosphere, such as results from living in damp, crowded, and ill-ventilated under-ground apartments; but it does not appear, so far as I am able to ascertain, that the children of such residents either in this or other

countries are particularly prone to the complaint; certainly not so much so as to render it a special object of observation. Finally, there are many practitioners who look upon it as being due to the use of unwholesome or imperfect alimentation, causing an impoverished state of the blood, with lesion of innervation and nutrition; and this is, perhaps, as plausible a view as can at present be taken of the subject. With regard to its connection with scrofula, it may be observed that rickets rarely coexists with tubercle, and also that the former disease does not generally occur so early in life as the latter. If syphilis has any agency in the production of rachitis, it requires to be proved, which it has not yet been, that the offspring of persons laboring under that malady are more prone to its attacks than other children. Whatever the exciting cause may be, there is no question that the immediate one is a deficiency of phosphate and carbonate of lime, upon which the solidity of the osseous tissue essentially depends. How far the want of chondrin and gelatin, which are such important elements of healthy bone, may disqualify the osseous tissue in rachitis for the reception of earthy matter is a problem which has not been determined.

Morbid Anatomy.—The alterations of the osseous tissue consequent upon this disease may be conveniently arranged under three heads, each possessing marked peculiarities. In the first, the bones seem to be saturated with a reddish, watery fluid; a considerable quantity of which is also interposed between their outer surface and the periosteum, on the one hand, and between the medullary membrane and their internal walls, on the other. At a more advanced period, this fluid is replaced by a sort of gelatiniform substance, which, being particularly conspicuous in the situations here specified, becomes gradually organized and vascular, and ultimately adheres with great firmness to the parts with which it lies in contact. The periosteum is thickened and injected, the nutrient vessels are remarkably enlarged, and the medullary membrane is sensibly altered in its character; the changes which it has undergone being similar to those of the fibrous envelop just mentioned, though less in degree. The lamellæ of the long bones, naturally so hard and compact, are a good deal softened, while the areolar structure is greatly rarefied, many of the cells being more than double the natural size. Similar alterations are observed in the short and flat bones.

In the second stage, a peculiar spongoid substance is formed between the periosteum and the outer surface of the bones, varying from two to three lines, or upwards, in thickness; and which, by the pressure it exerts upon the lamellæ of the compact tissue, sometimes forces them inwards upon the medullary canal, thus greatly reducing it in size, if not entirely obliterating it. Simultaneously with these changes the bones are rendered so soft that they may easily be bent, cut, and even indented with the finger.

In the third stage—that of resolution—the recently formed substance in the long bones, as well as in some of the flat and short, assumes a compact character, and becomes gradually identified with the pre-existing tissues, which at the same time regain their primitive solidity. Owing to the presence of this new matter, the bones are much larger than in the natural state, and their firmness, especially in the adult, resembles that of ivory. Hence the term *eburnation* is sometimes applied to this state of the skeleton.

When rachitis proves fatal, the body is usually found in a state of excessive emaciation; the muscles are thin, pale, and flabby; the adipose matter is almost entirely consumed; the cerebral substance is unnaturally soft; the liver and spleen are enlarged and flaccid; the intestines are attenuated and distended with gas, and there is not unfrequently marked tumefaction of the muciparous glands; the mesenteric ganglions are increased in volume and consistence; the heart is softened and smaller than common; the lungs, which are often congested, are more or less tuberculized in about one-sixth

of the cases; and the bronchical ganglions are hypertrophied, loaded with serosity, and of a deep purplish hue. Occasionally there is partial ossification of the arteries, muscles, and other structures, as if they had become the recipients of the earthy matter which naturally appertains to the bones.

Symptoms.—The symptoms of rickets possess nothing of a definite character in the earlier stages of the disease, the approaches of which are generally stealthy, and at times almost imperceptible. The child is observed gradually to lose its health and spirits, becoming dull and listless, and laboring under derangement of the digestive organs, especially flatulence and colicky pains. After a while, marked emaciation sets in; the muscles are soft and flabby; the abdomen is tympanitic; the skin is dry and sallow; the face looks pale and doughy; the urine is scanty, turbid, and lateritious; and the alvine evacuations are thin, watery, and fetid, there being nearly always considerable diarrhoea. Dentition advances slowly, and the teeth, having a black, fuliginous aspect, often begin to decay almost as soon as they have pierced the gums. The fontanels and sutures are more open than in the natural state; and the whole process of ossification is peculiarly slow and imperfect, or, rather, it may be said to be almost stationary, if not actually retrogressive. As the disease advances, the bones grow more and more soft, and, being unable to sustain the weight of the body or to resist the action of the muscles, are at length strangely and frightfully distorted. The head, although abnormally small, is disproportionately large to the size of the face, and is sunk down between the shoulders; the clavicles are bent and extremely salient; the spine is curved in various directions, especially laterally, and diminished in length; the pelvic bones are curved inwards, so as to lessen very materially the corresponding cavity; the ribs are flattened, and the chest, in consequence, is sensibly increased in its antero-posterior diameter, giving it a narrow, pigeon-shaped appearance. The bones of the extremities are shortened, bent, and twisted upon their axes, while their articular ends, or epiphyses, are softened, rarefied, and greatly expanded, thus appearing much larger and more prominent than naturally. If the child has begun to walk, he becomes daily more feeble on his legs; he waddles, trips, falls, and soon returns to his nurse's arms.

In rachitis, there is an actual arrest of development of the bones, and, although this want of growth pervades the entire skeleton, yet it is always most conspicuous in the lower extremities, the femur, tibia, and fibula being often fully one-third shorter than in the natural state, and also diminished in diameter, except at the epiphyses, which, as already seen, are always unusually large and prominent, especially if the child has been a good deal on his feet. Under such circumstances, the head and neck of the femur are sometimes forced by the weight of the body into a horizontal position below the level of the great trochanter; the individual is bow-legged, and the joints of the knee and ankle suffer great distortion from the weakened and relaxed condition of their ligaments. The flat bones, during the reparative process, become solidified and hypertrophied in their areolar texture, while the long ones are increased in thickness and strength along the concavity of their curvatures that they may be the better able to support the superincumbent pressure, and resist the effects of muscular action.

Diagnosis.—The only disease of the bones with which rachitis is at all liable to be confounded is osteomalacia or softening. The signs of distinction, however, are commonly very evident. In the first place, rachitis is an affection of infancy and early childhood, whereas mollescence never occurs until after middle age. Secondly, in rickets the softened and flexible state of the skeleton is only temporary; after a time, a process of repair is set up, and, gradually continuing, the affected tissues become at length more firm and compact than they are in the natural state; in osteomalacia, on the con-

trary, the disease, once begun, generally progresses until the patient is worn out by his suffering, no attempt being usually made at restoration. Thirdly, in rachitis there is no material alteration in the urine, whereas in mollescence this fluid is always loaded with a large quantity of earthy salts, the kidneys taking on a vicarious action, and so carrying off the material destined for the supply of the bones. Lastly, in rickets there is an actual arrest of development, in consequence of which the bones remain disproportionately short, thin, and dwarfish; in softening, on the contrary, the affected pieces retain their normal shape, although they are so changed in their consistence that they may readily be cut and bent in almost any direction.

Prognosis.—The prognosis of rachitis is generally unfavorable, for, although many patients escape with their lives, yet few recover without permanent deformity. In regard to the danger to life, it is commonly in proportion to the number of bones affected, the rapid progress of the complaint, and the age of the subject. Experience has determined that very young children are more liable to die of it than those who are more advanced in years, and those who are born of scrofulous parents than those who come into the world under more happy auspices. The duration of the disease is extremely variable; being very tardy at one time, and very rapid at another. In general, even under the most favorable circumstances, several years elapse before complete recovery occurs. The progress of the cure is often fatally arrested by some intercurrent malady, as measles, scarlatina, smallpox, or cholera. The longer recovery is postponed, the greater will be the danger of serious deformity. The duration of life is not necessarily shortened in persons who get well of rickets, cases having occurred of their having attained the age of sixty, seventy, or even seventy-five.

Treatment.—The treatment of rachitis is far from being satisfactory, or based upon sound philosophical principles. If, as has been asserted, every evil has its remedy, it is certain that human ingenuity has not yet succeeded in discovering any for this. The first point which it is of importance to inculcate is that, in rachitis, active measures are out of the question, our chief reliance being upon a properly regulated regimen and the use of tonics, with a view to the invigoration of the general system, and an improved condition of the blood, which, although it has never been thoroughly investigated in this disease, is beyond doubt materially altered in some of its component elements. Whatever, therefore, has a tendency to strengthen the patient, and enrich the circulating mass, must prove indirectly beneficial in removing the disease, and should claim serious consideration in every case.

The diet should be mild and nutritious, comprising an adequate amount of nourishment in the smallest possible space, so as not to oppress the stomach and create flatulence and acidity. The best article will, of course, be the mother's milk, or, when this is insufficient or unwholesome, fresh cow's milk, or, better still, the milk of the ass, which is now so much used in some of the larger cities of continental Europe, and which approaches nearer, in its composition, to human milk than that of any other animal. If the teeth are properly developed, a small amount of animal food will be useful, especially fat bacon, well boiled, and not too salt, with good stale bread, and a little mashed potato. The body should be washed at least twice a day with salt water, followed by dry friction, or rubbed with a moderately stiff salt towel; and, if the system be not too much reduced, cool or cold bathing will be found highly invigorating. Frequent exposure of the little patient to the fresh air, and exercise suited to his age and strength, are to be rigorously enforced. The secretions are to be improved by alteratives, especially blue mass and mercury with chalk, while the bowels must be kept soluble with rhubarb or oil, and acidity be allayed by the alkalies, especially lime water and bicarbonate of soda.

Tonic medicines, particularly quinine and iron, given in small doses, and long continued, with an occasional intermission for a few days, are always imperatively indicated, and there are few cases which are not promptly benefited by their exhibition, especially in the early stages of the disease, although they are nearly equally useful throughout its entire progress. The mineral acids, and the tincture of the chloride of iron, have long been favorite medicines, both with the empiric and the regular practitioner, and are particularly advisable when there is a coexistent scorbutic condition. Alterative doses of mercury occasionally exercise a salutary influence, especially when the patient labors under the strumous diathesis, the best form being the bichloride, in combination with a small quantity of iodide of potassium, dissolved in water. The pain, which is often considerable, is controlled by opiates, either alone, or conjoined with diaphoretics.

Lately, the phosphates, which were formerly so much employed in the treatment of rachitis, on the ground that they would tend to supply the deficiency of earthy matter, have again come into vogue, but it remains to be seen whether they really possess any advantage over the more ordinary tonic remedies, already referred to, or whether they are not, indeed, inferior to them. Their best form of exhibition is the syrup.

Doubtless, however, the best remedy of all in this complaint, so far as any individual article is concerned, is cod-liver oil, given several times a day, in doses suited to the age and other circumstances of the patient. Possessing highly nutritive and alterative properties, it is admirably adapted to support the system, to enrich the blood, and to improve the secernent powers, which are so much at fault in rachitis. It may be administered either alone or in union with some of the more important tonics above mentioned.

Finally, the bed on which the rickety child sleeps should be perfectly smooth and somewhat elastic, so as not to permit the affected bones to sink down into any depressions or hollows, and so become bent and distorted. No pillow should be used, the head, body, and limbs all resting on the same plane. The clothes should be loose and light, but sufficiently warm to afford the requisite protection to the surface. In the earlier stages of the complaint, mechanical contrivances may not only be regarded as altogether ineffectual, but as pernicious; by and by, however, as the bones become softened, they should be supported with appropriate apparatus, to prevent deformity. Walking must, of course, be avoided as long as the extremities are unable to bear the weight of the body.

SECT. IX.—FRAGILITY.

Fragility of the osseous tissue is one of those affections which are to be regarded rather as an effect of disease than as a disease itself. It consists, as the name implies, in a peculiar brittleness of the bones, in which, especially in its more advanced stages, their substance is so completely changed in its character as to give way under the most trivial circumstances. All the bones are liable to this morbid brittleness, and cases occur, although rarely, where it literally pervades the whole skeleton. In 1857, the body of a female, supposed to be upwards of seventy years old, was brought into the dissecting-rooms of the Jefferson Medical College, with upwards of eighty fractures, received a few days before in a fall from a third story window upon the pavement below. Nearly all the ribs, several of the vertebræ, and a number of the long bones were broken, and signs of former fractures existed in the humerus, thigh, scapula, and other pieces. Devergie examined the body of a woman who died under symptoms of fragility, in whose skeleton there were not less than eighty-three fractures. Dr. Gibson met with a young man,

whom I also saw many years ago, the bones of whose extremities were repeatedly broken by the most trivial accidents. The clavicles had suffered still more frequently, having been fractured altogether eight times. This universal fragility of the osseous tissue occasionally occurs at a very early period; sometimes, indeed, even in the foetus in the womb. Chaussier met with a remarkable example of this kind, where the long bones had experienced not less than one hundred and thirteen fractures, some being at the time perfectly consolidated, thus showing that they had taken place some time previously, while the rest were either recent or had partially united. The child survived its birth only twenty-four hours. General fragility, however, is a comparatively rare affection; usually it is limited to particular bones, or, still more commonly, to particular portions of a bone; and those which are most prone to suffer are the head and neck of the femur, the ribs, sternum, radius, ulna, clavicle, and superior extremity of the humerus.

When the affection exists in its highest state of development, the slightest accident is frequently sufficient to produce fracture, as a severe fit of coughing, kneeling upon a hard floor, or turning about in bed. Sometimes, indeed, the fragility is so great that the individual cannot be touched rudely, without the occurrence of the injury. Of this description was the memorable case of the woman, whose history has been recorded by Saviard, who could not be moved about in bed without breaking some of her bones. After a confinement of six months she died, when it was found that she had had fractures in all the long bones of the extremities, as well as of the clavicles, ribs, vertebræ, and pelvis, many of the pieces being so brittle that they could not be handled without crumbling into fragments, similar to old, dry bark.

Causes.—Fragility of the bones commonly comes on without any assignable cause, and the general health not unfrequently continues good until a long time after it has made its appearance. In most cases, if not in all, it is merely symptomatic of some other disease, particularly of rheumatism, gout, syphilis, scrofula, and scurvy, attended with an altered and impoverished state of the blood, and impairment of the assimilative powers. The bones themselves are very much in the condition in which they are in osteomalacia, that is, their substance is more or less softened, in consequence of the removal of a large proportion of their phosphatic material, and they are often so completely saturated with fat as to render them unfit for preparations. On the other hand, however, they are sometimes remarkably dry and brittle. These facts would seem to show that their intimate structure undergoes some important anatomical change, the immediate result, it would appear, of inflammation, not of an active but tardy character. What tends to support this view of the nature of the affection is the circumstance that long before the bones manifest any disposition to break, the patient is harassed with severe pains, deep-seated, fixed, and referred to particular portions of the skeleton, and that, upon dissection, the diseased parts are generally found to be extremely vascular, their areolar structure being profoundly injected and infiltrated with bloody matter, apparently impoverished lymph, while the periosteum is very thick, spongy, and highly congested.

Fragility of the bones is one of the usual attendants upon old age. As we advance in life, their vascularity sensibly diminishes, many of the vessels shrinking down, and becoming finally entirely obliterated. It is owing to this circumstance that old persons, especially females after the fifty-fifth and sixtieth years, are so much more liable to fracture than to dislocation, the part most prone to yield being the neck of the femur within the capsular ligament, whose areolar tissue is often astonishingly rarefied, while the compact is hardly as thick as ordinary letter paper.

This affection is sometimes observed in several members of the same family.

Dr. Pauli, of Landau, has related an instance where it was distinctly traceable through three generations on the father's side. All the grandchildren, five in number, had each had several fractures, one as many as five, in the bones of the extremities, and that mostly as the result of inconsiderable injury. They were all remarkably healthy, and there was no evidence in any of them of a scrofulous taint of the system.

Symptoms.—There are, unfortunately, no reliable signs in this affection. Hence it is usually overlooked until it has reached its highest point of development, when it is always incurable. In general, the person is laboring under severe pain, which is usually regarded as of a gouty, rheumatic, or syphilitic character, and which is rarely, under any circumstances, referred to its proper source, until after the occurrence of curvature, or fracture, from causes so slight as to awaken, for the first time, a suspicion of the existence of disease of the osseous tissue. As the disorder progresses, the appetite and strength become impaired, the pains increase in violence, and the urine is surcharged with earthy constituents, especially phosphate and carbonate of lime. This alteration in the urine is observable at an early period, and, in general fragility, goes on gradually augmenting down to the time of death, which happens at from six to eighteen months, the patient meanwhile being perfectly bedridden.

There are, then, only two circumstances which can be at all relied upon as diagnostic of this complaint; one is the severe and intractable character of the pain, deep-seated, and usually referred to the bones; the other, the altered condition of the urine, as declared by the presence of an inordinate quantity of earthy matter, especially phosphatic. When these co-exist, the suspicion will be strong that there is serious lesion going on in the skeleton, and this suspicion will be converted into certainty when, superadded to them, there occurs, without any considerable external violence, curvature, fracture, or displacement of some of the bones.

Fragility, like softening, may generally be looked upon as an incurable affection. The only exception, perhaps, to this rule is when it occurs as an effect of the syphilitic or rheumatic poison, and even then it seldom admits of complete relief unless it presents itself in a very circumscribed form. The fragility of old age is always incurable.

Treatment.—No rational treatment has yet been laid down for this disease, nor will it be possible to do so until we shall have more enlightened views of its etiology, pathology and diagnosis. Until, therefore, we are placed in possession of substantial information upon these points, our treatment must necessarily be altogether empirical. In all cases, strict inquiry should be instituted into the origin of the disorder, when such remedies should be administered as the result may seem to indicate. As a general rule, it may be stated that bleeding, except in very robust habits, is quite inadmissible, and even active purgation usually proves injurious. A tonic and supporting course, consisting of the different preparations of iron and quinine, and of the syrup of the phosphates, along with cod-liver oil, and vegetable acids, especially the citric, and a well-regulated, nutritious diet will afford the best chance of relief. Iodide of potassium and bichloride of mercury may be given in the syphilitic variety of the disorder; while in the gouty and rheumatic forms, colchicum would probably prove beneficial. To relieve the excessive pain which is so prominent a symptom in the latter stages of the affection, especially when it involves a large portion of the skeleton, anodynes must be given in full doses once or twice in the twenty-four hours. Curvatures and fractures must be treated upon general principles. In most cases, the bones unite nearly as readily as under ordinary circumstances; sometimes, however, the process is very tedious, and at other times they refuse altogether to unite.

SECT. X.—ATROPHY.

Atrophy of the osseous tissue is characterized by the partial absorption of its elementary constituents, as is evinced by its lightness and porosity. It may occur in any portion of the skeleton, but the long bones are oftener affected than the short or flat. Like hypertrophy, it may be partial or general; that is, it may involve an entire piece, or be limited to a particular part of it. Atrophy, moreover, may be concentric or eccentric. In the former variety the bone is diminished in its diameter; in the latter it retains its original size, but is reduced in weight, and rarefied in its tissue. The causes under the influence of which it may take place are, protracted pressure, chronic inflammation, deficient nervous influence, and insufficient supply of arterial blood.

a. The influence of *pressure* steadily exerted for a considerable length of time, in producing atrophy of the osseous tissue, is well exemplified in the cranial bones in tumors of the dura mater; in the sternum and dorsal vertebræ in aneurism of the aorta; and in the ribs in cancer of the mammary gland. In all these instances the compact substance is reduced to a thin, translucent plate, while the spongy texture is either wholly destroyed, or worn down to a few slender threads. The immediate cause of the wasting process here is absorption, acting simultaneously and equally upon the animal and earthy constituents.

b. Atrophy from *chronic inflammation* is probably infrequent. One of the best specimens of it that I have ever seen occurred in a colored woman, who died of pulmonary phthisis at the age of forty. The body was much emaciated, and all the long bones were remarkably reduced in weight, though they had experienced no change in their external configuration. The compact substance was wasted to a mere shell, scarcely thicker than common wrapping paper, while the cells of the spongy texture were increased many times beyond the natural size. The medullary canal was much enlarged, and filled with a greasy, reddish substance, not unlike fresh adipocire. These appearances are well shown in fig. 302, and afford a beautiful illustration of the eccentric form of atrophy.

Atrophy is sometimes the result of local injury, as a blow, wound, or contusion. The wasting in this case may be limited to the site of the original mischief, or it may extend to the entire bone, which, however, is rare. In what manner such an injury operates, whether through the agency of inflammatory irritation, or otherwise, in giving rise to atrophy, is unknown.

c. Deficient *nervous influence* is a frequent cause of atrophy both of the osseous tissue and of the soft parts. In paralysis of the lower extremities, there is generally notable wasting, not only of the muscles, but also of the long bones, which are greatly reduced in weight, rarefied in their texture and diminished in size.

d. The effect of a *diminished supply of blood* in inducing atrophy of bone is sometimes very conspicuous in old fractures. In such injuries there is often considerable wasting of the osseous tissue, in consequence merely of the obliteration of the nutrient artery by the pressure of the callus. The atrophy is always eccentric, and is usually limited to one-third, one-half, or two-thirds of the affected bone, according to the seat of the original injury, or, more

Fig. 302.

Atrophy of bone.

properly speaking, the quantity of the new matter, and the extent of the vascular obliteration.

e. Finally, there is what is termed *senile atrophy*. In old age, the bones are rendered light, porous, and brittle; the compact substance is reduced to a mere parchment-like shell, while the areolar texture is remarkably rarefied or expanded; the muscular prominences are diminished in size; the animal matter is partially absorbed; and many of the vessels are obliterated. These changes are nowhere more conspicuous than in the neck of the femur, which, in consequence, often breaks from the most trifling causes, and which, after this occurrence, is seldom, if ever, repaired by osseous matter. Fig. 303 is

Fig. 303.

Atrophy of cellular structure of the thigh-bone.

Fig. 304.

Advanced stage of senile atrophy of the thigh-bone.

a section of a well-marked specimen of this kind; the internal structure is very much rarefied; and the head of the bone, flattened and expanded, is approximated to the shaft, from the partial absorption of its neck. Fig. 304 exhibits the affection in a still more advanced stage.

Atrophy of the osseous tissue does not admit of cure. All that the surgeon can do is to amend the general health, when that is at fault, and to remove any local causes of disease when they are found to exist.

SECT. XI.—HYPERTROPHY.

Hypertrophy of the osseous tissue may be partial or general; that is, the abnormal growth may affect either a portion or the whole of a bone. The latter, however, is a very rare occurrence, though perhaps not so much so as has been imagined. Cases, indeed, not unfrequently occur in which the broad bones of the head present an extraordinary degree of development, being more than an inch in thickness, and so hard that it is almost impossible to saw them. Under these circumstances, the two tables are extremely compact, the intermediate spongy structure being totally obliterated, or, rather, re-

placed by dense earthy matter. Similar appearances are sometimes witnessed in the cylindrical bones of the extremities. In an old femur in my private collection, the medullary canal is scarcely large enough to admit a common-sized quill; the whole shaft consists almost entirely of compact substance, in

Fig. 305.

General hypertrophy—internal structure.

Fig. 306.

General hypertrophy—external characters.

many places more than six lines in thickness. The bones of the male are always larger and more distinctly developed than those of the female, and the bones of persons who take much exercise than those who are indolent, or inactive. By labor, their weight and dimensions increase; their spongy structure diminishes, whilst the compact becomes harder and more dense, and acquires an almost rock-like solidity; the muscular prominences are rendered more conspicuous; in short, everything indicates that they are in a state of general hypertrophy. The osseous tissue usually contains a due proportion of animal matter, and hence it does not readily yield under external injury.

The adjoining cuts are excellent representations of general hypertrophy of the femur of a man affected with tertiary syphilis. Fig. 305 is a section of the bone exhibiting its interior structure, which is very much condensed throughout, except at the superior extremity, where there are still some remains of the areolar tissue; the medullary canal is entirely obliterated, and the weight of the bone is nearly twice as great as in health. Fig. 306 shows the external appearance of the bone. The drawings are from a specimen in my cabinet.

The adjoining sketch, fig. 307, is a specimen of hypertrophy of the bones of the leg and foot, both in thickness and length. It

Fig. 307.

Hypertrophy involving both the thickness and length of the bone.

is from a drawing of a preparation in the collection of Professor Buchanan, of Nashville. All the bones are much enlarged, increased in weight, and ankylosed, at the ankle, tarsal, and metatarsal joints. The interosseous ligament was completely ossified. The foot and leg had been the seat of extensive ulceration, followed by exfoliation from the hypertrophied bones.

General hypertrophy of the bones is usually incurable. It is only, or chiefly, when it depends upon a syphilitic taint of the system that it admits of relief; but as this subject has already been fully discussed elsewhere, it is not necessary to revert to it here.

SECT. XII.—TUMORS.

The bones, like the soft structures, are liable to two classes of tumors, the innocent and the malignant. The former includes exostosis, fibro-cartilaginous growths, aneurism, hematoid formations, serous cysts, hydatids, and myeloid tumors; the latter, encephaloid, colloid, scirrhus, and melanosis.

INNOCENT FORMATIONS.

1. EXOSTOSES OR BONY TUMORS.

An exostosis, of which fig. 308 affords a good idea, is an osseous outgrowth, the word, which is a Greek compound, signifying a bone growing from a bone. It is in fact a local hypertrophy, a circumscribed tumor, possessing essentially the same structure as the bone from which it springs, and with whose substance it is usually intimately identified. There is perhaps no term in surgical nomenclature which has been more abused than this, or which has been applied to so many different and almost diametrically opposite diseases. Among those who have especially contributed to bring about this confusion may be cited the name of Sir Astley Cooper, who, under the appellation of exostosis, has described almost every variety of tumor, whether benign or malignant, whether fleshy, fibrous, cartilaginous, or osseous, connected with or growing from a bone. This classification, which was for a

Fig. 308.

Exostosis of the thigh-bone.

long time blindly followed by most writers, has recently given way to a more correct appreciation of the subject, and I know no pathologist whose opinion is worth much who does not consider an exostosis as essentially a local hypertrophy, free from malignancy, formed in the same manner as the primitive osseous tissue, and composed essentially of the same anatomical elements; in short, as a bone growing from a bone, and not upon a bone.

Exostosis is observed chiefly in young and middle-aged subjects, being very infrequent before puberty, and after the fiftieth year. It is more common in males than in females, and is generally confined to particular bones, as those of the cranium and of the extremities, particularly the femur, and the phalanx of the great toe.

The superior maxillary sinus is occasionally the seat of this disease. In a

specimen in my collection, the inner surface of the left antrum is literally studded with these growths, none of which exceed a small grain of wheat, which they also much resemble in shape. The tumor sometimes acquires an enormous bulk, and cases occur in which both cavities are affected simultaneously, though not in the same degree.

In the flat bones, as those of the head and pelvis, the outgrowth may occur upon either surface; in general, however, it evinces a preference for the external one, probably because it has a more perfect periosteum. When the tumor is attached to the inner surface, its tendency is to encroach more or less seriously upon the contents of the cavity which the bone assists in forming. These internal exostoses, as they may be termed, are most common in the cranial bones of syphilitic subjects.

A tendency to exostoses is sometimes observed in several members of the same family. A few years ago, I had a lady under my charge on account of a tumor of this kind on the shaft of the left radius, whose sister and brother had each a similar enlargement, the former on the occipital bone, and the latter on the clavicle. Boyer gives the particulars of a case where the disease was hereditary, the patient's father, brothers, sisters, nephews, and children, having all suffered in a similar manner.

The number of these outgrowths varies from one to a considerable number. In general, they are solitary; but cases occur where there are a great many, as if there existed a sort of exostotic diathesis, as in fact there does under such circumstances. In the Mütter collection is the skeleton of a female in which a large number of bones are thus affected.

Exostoses sometimes observe a symmetrical arrangement, tumors of the same size and shape occurring at the same points of the corresponding bones of the two sides. Such a disposition is occasionally witnessed on the frontal bone and lower jaw, but is most common on the humerus and femur, especially the inferior extremities of these pieces.

The *volume* of these growths is subject to no little diversity, some being very small, while others are extremely large, cases being occasionally noticed where they are of the size of an adult head.

The most voluminous are usually found upon the bones of the extremities, particularly the lower part of the femur, though they are also sometimes seen upon the cranial, facial, and pelvic bones, where their presence is a source of the most hideous deformity.

Their *shape* is also very variable; sometimes they have a distinct, well-defined outline, being of a globular, ovoidal, or hemispherical figure; occasionally they jut out like long, slender spines or stalactites; in another series of cases, they have a knobby, nodulated, tubercular, or mammillated appearance; and, lastly, instances occur, although they are rare, in which they present themselves in the form of plates or lamellæ. These varieties of shape are doubtless entirely due to accidental circumstances; but they, nevertheless, deserve attention, on account of their practical relations. In regard to their surface, this may be either perfectly smooth, scabrous, or spiculated; most generally the latter.

The adjoining sketch, fig. 309, represents a remarkable form of exostosis,

Fig. 309.

Exostosis of the femur.

from a drawing of a specimen kindly presented to me by Dr. Lewis, of Alexandria. It grew upon the right femur of a lady, fifty-one years old, having commenced when she was only nine years of age. The tumor, before removal, was about the volume of a cocoa-nut, oval, smooth, and very hard. The integuments over its summit had latterly become inflamed and ulcerated, followed by a discharge of sanious matter, and the protrusion of a portion of bone. The general health becoming somewhat impaired, amputation was performed at the lower third of the thigh, the woman making an excellent recovery. This case is additionally interesting from the circumstance that several of the relatives of the patient had been affected with similar tumors.

Causes.—The origin of exostoses is involved in doubt. There is no question that, in the great majority of instances, they arise without any assignable cause whatever. On the other hand, they can often be traced directly to the effects of external violence, such as a blow or kick. In the distal phalanx of the great toe, which is not an uncommon seat of the disease, it would seem probable that the pressure of a tight boot is able to produce it. Exostosis in the stump after amputation of the thigh and leg is probably caused by the jarring which the femur and tibia experience during the operation of sawing, aided, perhaps, by a partial laceration of the periosteum. A syphilitic taint of the system has generally been considered as an excitant of the complaint, and that it is capable of exerting such an influence hardly admits of doubt. Nevertheless, it is extremely probable that its agency has been greatly overrated; for I can recall but few cases that have come under my observation where it was possible to trace the relationship in a satisfactory manner. Rheumatism and gout are also often accused of causing exostosis, and although it is impossible, in the existing state of the science, to determine the character and degree of their agency in this respect, yet sufficient is known to justify the belief that it is very considerable. However this may be, it is extremely probable that these diseases play a most important part in the production of general exostoses, the history of most of the cases of the kind clearly proving such a connection.

Whatever may be the exciting cause of exostosis, there can be no doubt that the immediate cause is inflammation leading to a deposit, in the first instance, of plastic matter, and afterwards, of osseous, the process of development being precisely similar to that which presides over the formation of the original bone. The concomitant inflammation is not always seated exclu-

sively in the bone, but partly in the bone and partly in the periosteum; and cases occur where there is reason to believe that the latter is mainly involved in the production of the tumor.

Structure.—In regard to its structure, an exostosis differs in no wise from healthy bone. It is essentially composed of two parts, a compact and an areolar, the former inclosing the latter like a dense, firm layer, varying in thickness from the sixth of a line to a quarter of an inch, according to the volume of the tumor. The compact substance sometimes constitutes the greater bulk of the morbid mass, and there are cases, especially when it involves the cranium, where it is of the consistence of ivory, being so close and hard as to render it extremely difficult to saw it. Such a structure is represented in fig. 310, from a specimen in my collection. The areolar texture is sometimes directly continuous with that of the bone from which the exostosis grows; at other times, however, it

Fig. 310.

An ivory-like exostosis, showing its internal structure.

is independent of it, being either in immediate contact with the compact structure, or separated from it by a stratum of fibro-cartilage, cartilage, or fibrous tissue. Its cells are of variable size and form, and are generally loaded with fatty matter, just as in a short bone of the skeleton, or in the articular extremity of the long.

The identity of the structure of exostosis with that of natural bone is proved, moreover, by *chemical* analysis. Even when the new substance is of unusual firmness, as in the eburnized variety of exostosis, the difference is much less than might, at first sight, be imagined. The following comparative analyses of healthy bone and of an ivory exostosis, by Berzelius, places the subject in a strong light. The principal difference, it will be observed, consists in the presence, in the latter, of an unusual quantity of phosphate of lime, and in a marked diminution of carbonate of lime and salts.

	Healthy Bone.	Eburnized Exostosis.
Animal matter	33.30	28.57
Phosphate of lime and magnesia	54.20	68.88
Carbonate of lime and salts	12.50	2.00
Loss	00.00	00.55
	<hr/> 100.00	<hr/> 100.00

When an exostosis is seated in a part of the body which is habitually the subject of considerable motion, as, for example, the inferior portion of the femur, it is usually surrounded by a distinct capsule, a sort of synovial burse, the object of which evidently is to ward off friction and facilitate gliding. The inner surface of the capsule, which is of a fibro-cellular nature, and of variable thickness, is perfectly smooth, unadherent, and lubricated by a sero-oleaginous fluid, so as to qualify it the better for the performance of its functions. Where no motion is required, the growth lies in immediate contact with the natural structures, the union between them being commonly so intimate as to demand a careful use of the knife to effect their separation. Occasionally, indeed, the soft parts are partially imprisoned in the osseous tumor, thereby rendering the dissection peculiarly tedious and difficult.

Progress.—The progress of this disease is generally tardy; it is only now and then that a case occurs which pursues a different course, or where the symptoms partake of an acute character. A syphilitic exostosis occasionally attains a considerable bulk in a short time, and the same thing has been observed, though less frequently, in the rheumatic form of the complaint. Under such circumstances, the formation of the tumor is generally attended with severe pain, liable to nocturnal exacerbations, tenderness and swelling of the part, and more or less constitutional disturbance. Ordinarily, however, there is nothing of the kind; the disease comes on slowly and almost imperceptibly, the first thing that arrests attention being a small tumor, which is altogether insensible, and exceedingly tardy in its progress, years elapsing before it acquires the size, perhaps, of a pullet's egg. If it be superficial, so as to admit of examination, it will be found to be hard and immovable from the first, and so it generally continues ever afterwards, whatever may be its bulk. Meanwhile, although it may itself be entirely indolent, yet it may be productive of pain in the surrounding structures, by the compression which it exerts upon the nerves, and in this way the suffering is sometimes rendered exceedingly severe, being often of a neuralgic character, darting about in different directions, and extending far beyond the seat of the bony growth. When the tumor is situated in parts which are much exposed to motion, these parts are liable to become inflamed and tender, thus greatly aggravating the local distress. As the morbid mass enlarges it must necessarily act obstructingly, interfering with the functions of the affected structures, and ultimately, perhaps, entirely abolishing them. Thus an exostosis of the orbit may continue to increase until it pushes the eye completely out of its socket, not only filling

the whole cavity, but encroaching more or less extensively upon the cheek and cranium. In a similar manner a bony tumor may project into the pelvis, and materially impede the delivery of the child. An exostosis of a rib may compress the lungs; of a vertebra, the spinal cord; of the cranium, the brain. Another effect which such a tumor produces is to stretch, flatten, and displace the muscles, tendons, nerves, and vessels, thereby partially disqualifying them for the exercise of their functions.

Sometimes the coverings of the tumor are invaded by ulceration and even gangrene, thereby more or less freely exposing its surface, which occasionally, in its turn, takes on the same kind of action. At other times the morbid mass perishes, apparently from the want of nourishment, and is detached very much in the same manner as a slough of the soft parts. Exostoses of immense volume occasionally experience such a fate. The occurrence will be most likely to happen when the tumor has a narrow, cartilaginous base.

Diagnosis.—The diagnosis of exostosis cannot always be easily determined unless the tumor is situated superficially, when its great firmness and immobility will generally serve to point out its true character without any difficulty. When the tumor occupies some internal cavity, its nature may be suspected, but no surgeon, however skilled in the art of discrimination, can positively say to what class of growths it really belongs. Besides, an exostosis may sometimes seriously interfere with the diagnosis of other affections. Thus, a tumor of this kind, occupying the pelvic cavity, may impinge against the bladder, or even project into it, in such a manner as that the sound, coming in contact with its surface, shall impart a noise and sensation similar to those communicated by the presence of a calculus.

Prognosis.—The prognosis of this complaint varies. So long as the tumor remains small and indolent, it may commonly be considered as of little consequence; but when it increases rapidly, or is so situated as to interfere with the functions of a joint, or to encroach upon an important organ, it becomes a matter of serious import; the more so, because it is then not always possible to get rid of it by an operation, and there is generally nothing else that can reach it. When an exostosis projects into a joint, an operation becomes a hazardous undertaking, liable to be followed by the worst results; and when it occupies an internal cavity it is generally utterly inaccessible. An exostosis of the inner surface of the cranium usually proves dangerous by determining epilepsy, paralysis, and other bad symptoms; in the pelvis it may, as already stated, interfere with parturition, and in almost any part of the body it may induce neuralgia.

Treatment.—The treatment of exostosis must be guided, in great degree, at least in the earlier stages of the disease, before the tumor has acquired any considerable bulk, by the nature of the exciting cause, and hence special inquiry should always be made with reference to this particular point. When there is reason to believe that the affection has been occasioned by a deranged state of the system, or induced by the action of the rheumatic, gouty, or syphilitic poison, colchicum, aconite, and iodide of potassium, either alone, or in conjunction with bichloride of mercury, will be indicated, and can hardly fail, if judiciously administered, to prove highly beneficial. Under the influence of these remedies the growth of the tumor is often promptly arrested, and ultimately even entirely dispersed. The use of mercury is particularly serviceable in these cases, but to produce its full effects it is generally necessary to carry it to the extent of gentle ptyalism, maintained for some time, especially in obstinate cases. When the complaint gives rise to much pain, opium, conjoined with diaphoretics, will be required.

Topical applications are particularly useful when the tumor is of rapid growth, exquisitely sensitive, and the result of external injury, or of a syphilitic taint of the system. In the earlier stages of the disease, the remedies

most to be relied upon are leeches, blisters, saturnine lotions, and the tincture of iodine, employed in the ordinary way. If blisters be used, and my experience is that they are generally the most valuable of all topical means, the skin over the tumor should be raised very thoroughly, and a free discharge should afterwards be maintained by some stimulating unguent, the object being to excite a permanent pyogenic effect. In the syphilitic form of exostosis, mercurial fumigation sometimes answers a good purpose, succeeding when all other remedies fail.

When the tumor has attained considerable bulk, and, above all, when it is of long standing, and of great firmness, or productive of excessive suffering, the only chance of relief is ablation, or, if this be impracticable on account of the nature and extent of the exostosis, amputation of the affected limb. The incisions through the integuments are made as in cases of ordinary growths, the most eligible shape being the crucial, elliptical, or T-like. Free exposure is effected, and in doing this care is taken not to interfere with any important structures, the division of which might afterwards impair the usefulness of the parts. If the skin is diseased, or much attenuated, the affected portion is, of course, removed. The exostosis is then attacked with the knife and a common metacarpal saw, the former alone, if stout, being commonly sufficient to effect ablation when the tumor has a cartilaginous base, or an unusually soft structure. In general, however, the saw will be necessary, and there are many cases where the gouge, chisel, and trephine may advantageously be employed. If the tumor has a very large base, and is insensibly confounded with the substance of the bone from which it grows, it should be divided into several sections, by perforating it at different points, and then detaching them separately, or piecemeal. Various kinds of saws have been invented for removing exostoses, but they are all more or less complicated and unwieldy, and may well be replaced by the more simple instruments in common use. In whatever manner the ablation be effected, there is one circumstance which should claim special attention, and that is to make the bony wound as smooth as possible by means of the raspatory, otherwise the rough surface will serve as a serious obstacle to cicatrization. As it is, there will, in any event, be more or less suppuration, retarding the progress of the case, and the patient may congratulate himself if he escape erysipelas and other serious consequences. The hemorrhage attending the operation is usually very slight. The edges of the wound should be lightly approximated, and the parts kept constantly wet with water-dressing, either cold, cool, or tepid, according to the exigencies of each particular case.

2. FIBRO-CARTILAGINOUS TUMORS.

The fibro-cartilaginous tumor, the *enchondroma* of recent writers, depicted in fig. 311, may be developed in the cancellated structure, or upon the outer surface of the bones, beneath the periosteum. Its figure is globular; its surface rough, or nodulated; its consistence firm, dense, and elastic; its color white, or grayish. When boiled, it yields a peculiar form of gelatin, termed *chondrin*. The tumor is essentially composed of a fibrous and of a cartilaginous substance. The former constitutes the nidus in which the latter is deposited, and consists of a vast number of oblong or rounded cells, from the size of a clover-seed to that of a pea. These cavities cannot generally be distinguished until the cartilaginous element has been scraped away, or removed by maceration. The morbid mass is strikingly conglomerate, and often attains a large

Fig. 311.

Fibro-cartilaginous tumors of the hand.

bulk. When it originates, as it commonly does, in the central part of the bone, it gradually encroaches upon the compact tissue, which it expands into a thin, porous shell, either entirely osseous, or partly osseous and partly cartilaginous. Finally, the attenuated lamella gives way at one or more points, and thus allows the morbid growth to protrude beneath the periosteum, which is itself often very much altered in its character.

This tumor ordinarily affects only one bone, is not malignant, and is productive of little inconvenience, except from its size. It is peculiar to early life, is often directly chargeable to external violence, manifests no tendency to degeneration, not even when of long standing, is generally slow in its progress, and occasionally appears simultaneously in several parts of the skeleton. Every portion of the osseous system is liable to it; but the pieces most frequently affected are the metacarpal bones, the phalanges of the fingers, the humerus, and the lower jaw. To the tumor now described, especially when it is hard, fibrous, and interspersed with the *débris* of osseous matter, or red and dense, like half-boiled beef, or fresh pork, the unmeaning title of *osteosarcoma* is usually applied by surgical writers. When the disease is of long standing, the growth sometimes undergoes partial ossification, as in the specimen represented in fig. 312. Fig. 313 exhibits a fibro-cartilaginous tumor of the ribs, from a drawing of a preparation in my collection.

Fig. 312.

Enchondromatous tumor undergoing ossification.

Fig. 313.

Enchondromatous tumor of the ribs. *a.* External appearance. *b.* Internal structure.

The only remedy for this affection is free excision. All local and general means, even in its earlier stages, are unavailing.

3. ANEURISMAL TUMORS.

Aneurism of the osseous tissue consists in an extraordinary development of the minute vessels, and presents precisely the same anatomical features as aneurism by anastomosis of the soft parts. Confined usually to one bone, it may occur in several, or even in a considerable number. In one case it was discovered in the cranium, sternum, ribs, vertebræ, and innominate bone of the same subject. Its favorite seat is the upper extremity of the tibia,

just below the knee. It may arise at various periods of life, but is most common in young adults. The tumor varies in volume from a pullet's egg to a cocoa-nut.

The disease always begins in the cancellated structure, which is converted into chambers of various sizes, filled with coagulated blood, disposed in concentric layers, as in old aneurismal tumors. Some of the cells occasionally contain fluid blood, or blood partly fluid and partly clotted; but this is rare. The outer table of the bone is expanded, attenuated, and perforated, or so soft, flexible, and elastic that it may be bent like cartilage. In some instances, on the other hand, it is remarkably brittle, and may be crushed like the shell of an egg. The periosteum is thickened and indurated; but the joints in the immediate vicinity of the disease are commonly healthy, even when they are separated from it merely by a thin layer of cartilage. The vessels which ramify through the substance of the bone are tortuous, brittle, increased in size, and open by numerous little orifices into the aneurismal sac at various points of its extent.

There is a form of this affection in which the vessels, as was first clearly shown by Mr. Stanley, consist principally of enlarged capillaries, exhibiting the same general characters as an anastomotic aneurism or an erectile tumor

Fig. 314.

Anastomotic aneurism of bone.

of the soft parts. The disease, represented in fig. 314, has hitherto been chiefly noticed in the broad bones, especially those of the cranium, of young children.

The causes of this lesion are involved in obscurity. In some instances it has been traced to the effects of a blow; in others, to a fall, or jump from a considerable height. Either of these occurrences, by disturbing the vascular action of the bone, might produce the disease.

The enlargement, even in its early stage, is tense and painful; being attended with distension of the superficial veins, swelling of the surrounding structures, and slight discoloration of the skin. In a short time a deep-seated pulsation, or throbbing, synchronous with that of the left ventricle, and similar to what is witnessed in some erectile tumors, may be perceived in the affected part. In the advanced stage of the malady the beating is accompanied by a sort of undulating movement, and is easily interrupted by compressing the main artery of the limb between the tumor and the heart. The enlargement varies in size. In a case mentioned by Mr. Bell, it was more than nineteen inches in circumference, by upwards of six in length. In some instances, pressure applied to the tumor with the finger imparts a

peculiar crackling sensation, not unlike that of dry parchment or an egg-shell. The soft parts around the disease are generally œdematous, the whole limb is apt to be swollen, and the motion of the contiguous joints is constrained and painful. Towards the last the general health always seriously suffers.

The only effectual remedy for this disease, provided its location be favorable, is amputation. In the early stage relief may possibly be afforded by securing the main artery of the limb. Lallemand relates a case in which ligature of the femoral artery completely arrested an aneurismal affection of the head of the tibia; but this must be regarded as an exception to the general rule.

The anastomotic form of this disease admits of removal only when it is of limited extent. When it is situated in the cranial bones, it gradually destroys the osseous tissue, and ultimately involves the brain and its envelops, rendering interference out of the question. Several cases have been reported in which the carotid arteries were tied for this disease, but in none with any permanent benefit.

4. HEMATOID TUMORS.

There is a variety of tumors, closely allied to that just described, which, for the sake of uniformity in medical nomenclature, I shall term hematoid. It is produced by a deposition of blood in the cancellated structure, forming a firm, oval, and elastic tumor, filled with dark, solid coagula. The best specimen of this disease that I have met with, occurred to me, about ten years ago, in a man aged thirty-five, a portion of whose lower jaw I amputated, on account of what was supposed to be a bony tumor. The growth, which was about the size of a common orange, extended from the canine tooth on the right side to the middle grinder of the left, and consisted of a mere osseous shell, without any vestige of the cancellated structure; it was occupied by three red, solid coagula, the largest of which did not exceed the volume of a pigeon's egg. The cavity was only partially filled by the clotted blood, which adhered to the inner surface of the bony wall, and was evidently organized. The tumor had appeared three years before without any assignable cause. Whence was this blood derived? Did it proceed from a rupture of some of the vessels of the bone? If so, the fact could not be ascertained by the most careful examination.

5. SERO-CYSTIC TUMORS.

Serous cysts, similar to those which occur in the soft parts, especially the ovary, kidney, and liver, are occasionally met with in various pieces of the skeleton, particularly in the lower jaw, the tibia, and femur. They are always developed in the areolar tissue, and show themselves in two distinct forms, the unilocular and multilocular, of which the first is by far the more frequent, the other being, in fact, extremely uncommon. Pathologists failed, until recently, to seize the distinctive features of this disease, and to assign to it a proper place in their nosological tables. Mention, it is true, was made of it by some of the authors of the last century, especially by Bordenave, but it was only in an incidental manner, and it remained for Dupuytren to furnish the first clear account of it. It is more than probable that what the older surgeons were in the habit of calling osteosarcoma and spina ventosa were frequently, if not generally, growths of this description, with cavities filled with liquid or solid matter. I have certainly commonly found them so, and it may, therefore, be concluded, that the same thing has happened to others.

Morbid Anatomy.—The unilocular cyst varies in size from that of a hempseed to that of a pullet's egg, its shape being generally irregularly rounded,

or somewhat globular. It consists essentially of a thin, delicate, polished membrane, having, apparently, all the characteristics of the serous tissue. This membrane is closely adherent to the bony wall of the cyst, and undergoes important changes in consequence of age, and repeated attacks of inflammation, becoming dense, thick, opaque, and tough. The contents of the cyst are variable: sometimes clear and limpid, like well water; sometimes cloudy, ropy, or glutinous; sometimes sero-purulent; and finally, again, though this is uncommon, thin and discolored, from the admixture of hematin. Some of the older cavities occasionally contain solid matter, of an albuminous, curdy, or fibrous nature; and I have seen specimens in which they were occupied by a peculiar, micaceous-looking substance, not unlike cholesterine.

The multilocular cyst, represented in fig. 315, is less frequent than the unilocular. As the name imports, it is composed of a greater or less number of cells, divided by bony septa, and lined by a serous membrane, similar to that in the unilocular cyst, of which the multilocular appears to be merely an exaggerated variety. Its contents are generally of a sero-sanguinolent character, although sometimes they are clear and purely serous, like those of hydrocele. In one case, I found it thick and red, like the dregs of claret wine. In a group of multilocular cysts, a few will occasionally be seen to be filled with solid matter, or matter partly solid and partly fluid. When this is the case, it may generally be assumed that the cysts are old, and that their vessels have undergone important changes in their secretory action, in consequence of which they pour out concrete instead of liquid substance. I have witnessed instances, however, in which the material was of such a nature as to induce the belief that it was originally deposited in a solid form. However this may be, the substance is generally of a fibrous or fibro-cartilaginous character, and so firmly adherent to the walls of the cysts which contain it as to be with difficulty enucleated. Interspersed through this substance are occasionally little nodules, fragments or spicules of bone, and earthy concretions, or a combination of calcareous with osseous matter.

Age and Sex.—Serous cysts of the bones are most common in young adults and middle-aged subjects; being seldom met with before puberty, or after fifty. Both sexes are liable to them, but in what proportion, has not been determined. Their causes are involved in obscurity. In general the disease arises spontaneously. In the lower jaw, which, as has already been stated, is its most frequent seat, its origin is often ascribed to the irritation of a decayed fang, or to violence done in the extraction of a tooth; but before we can admit the influence of either as a cause of serous cysts, it must be remembered that thousands of persons constantly suffer in this way, without any such occurrence, and hence the development of these bodies may, after all, under such circumstances, be a mere coincidence. So, also, with respect to blows, fractures, contusions, and other mechanical injury, so often invoked as sources of this and other organic maladies of the bones. If they are really capable of producing such an effect in one case, why should they not in another? We must, therefore, look beyond these causes, and conclude that some other agent is concerned in their origin, although of the nature of that agent we are entirely ignorant.

Fig. 315.

Cystic disease of the femur.

Progress.—The progress of this disease is always slow. In the jaw we often meet with cases of serous cysts of six, twelve, and even fifteen years' standing, without any serious disturbance of the general health, or any particular local disorder, save what results from the pressure of the tumor upon the surrounding structures. Neither the cysts, their fibrous contents, nor the parts adjacent manifest any tendency to malignancy, and I am inclined to believe that whenever such an occurrence is observed it is to be received as a strong evidence that the growth was originally of a bad character, and not that it became so in consequence of any new epigenesis. When the tumor is large, whether it be multilocular or not, fluid or solid, it generally exhibits a marked tendency to destroy the bone in which it is located, pressing aside the compact lamella, and gradually involving its entire circumference. In the lower jaw the parts most commonly affected are the body and ramus, extending often beyond the middle line in front, and backwards as far as the condyloid process.

Symptoms.—The symptoms of cystic disease of the osseous tissue are obscure. The first thing that usually attracts attention is a dull aching pain, in some particular bone, as, for example, the jaw, which is often mistaken for toothache, or rheumatism; this gradually increases in severity and frequency, and is at length found to be dependent upon the presence of a hard tumor, or the expansion of a portion of the bone, more or less tender on pressure and motion, but unattended by any discoloration or intumescence of the overlying textures. The progress of the disease is always tardy, and it often happens that, after having attained considerable development, it remains, to all outward appearance, for some time perfectly stationary. Then, taking a new start, it again increases, and thus it continues, now advancing and now halting, until it has perhaps acquired the volume of a large orange, or even of a fist. Still, the general health continues good, there is no emaciation, and the countenance is perfectly free from that distressed, anxious, and sallow state which characterizes it in malignant disease. Even the pain is generally comparatively trivial, and if it were not for the mechanical obstruction occasioned by the encroachment of the tumor upon the adjacent parts, the patient would hardly be conscious of being unwell. If the parts be now carefully examined, they will be found to be of unequal consistence, the firmer parts being incompressible, while the softer ones readily yield under the finger, emitting a peculiar crackling noise not unlike that of dry parchment. In the absence of signs of malignancy, pulsation, lividity, and varicose enlargement of the overlying vessels, these circumstances afford the best evidence of the true nature of the disease, but if there be any doubt respecting it, this may generally be promptly dispelled by a resort to the exploring needle, the escape of serous, or sero-sanguinolent fluid determining the diagnosis. The tardy growth of the tumor and the absence of constitutional disorder are, indeed, commonly of themselves sufficient to mark the character of the malady. Between cystic and hydatid diseases of the bones no signs of distinction exist, nor is this a matter of importance, as the treatment is essentially similar.

Treatment.—The only available treatment in cystic disease is removal of the morbid mass, and some of the most brilliant exploits in modern surgery have been performed upon tumors of this kind. When it involves the jaw, the greater portion of that bone sometimes requires excision, the affected part being cut away along with a portion of the sound tissue, the same principle guiding the surgeon as in the extirpation of morbid growths of the soft structures. When the cysts are small and not numerous, they may sometimes be effectually scooped out, the cavity being afterwards stuffed with lint, and made to heal by the granulating process. On the other hand, cases occur, as when the disease involves the entire circumference of one of the bones of

the extremities, where, neither of these procedures being available, nothing short of amputation will answer.

I am aware that various plans of treatment have been suggested for arresting this disease in its earlier stages, or curing it without the knife when it has attained a considerable magnitude. So far, however, as I am informed, there are none which are entitled to any confidence. The most plausible of these are iodine injections and the introduction of the seton; the former of which experience has proved to be ineffectual, while the latter is so unscientific as not to be thought of, much less practised, in any case.

6. HYDATIC TUMORS.

One of the most remarkable diseases of the bones is the development of hydatids in their spongy structure, an occurrence which, although uncommon, has now been so repeatedly observed as to entitle it to distinct notice in a systematic treatise on surgery. The first account of these bodies was given by two Dutch pathologists, Van Vy and Vander Haar. Since then attention has been directed to them by other observers, who, minutely detailing the facts which have come under their notice, have thus laid the foundation of our knowledge of this interesting subject.

Although it is extremely probable that all the different classes of bones are liable to these formations, yet they have hitherto been observed almost exclusively in the long and flat bones, particularly in the tibia, for which, judging from the frequency of their occurrence here, they appear to have a sort of preference. They have been found three times in the frontal bone, twice in the iliac bone, twice in the humerus, once in the femur, and once in a vertebra. What was formerly known under the vague name of spina ventosa was an osseous tumor which probably occasionally contained bodies of this kind.

Situation.—Hydatids of the bones are always developed in the spongy texture of the skeleton, as this alone affords them an opportunity of growing and expanding, the compact tissue being too dense and firm to admit of their increase. The only exception to this occurs when they form in the frontal sinus, but even here there is, it will be observed, no new law in operation, since the cavity in question is, in fact, only a large cell, exceedingly well adapted as a residence for such creatures. In the tibia, the disease is always situated in the spongy structure which exists in such abundance in the head of this bone, just below the knee.

How these bodies are developed is still a mystery. That the germs are conveyed to the spongy tissue of the bones in the blood which is sent to them for their nutrition and growth is evident enough, but why they should be deposited here in preference to other parts of the body is a question which the most refined pathology is unable to answer. Nor is anything certainly known in regard to the nature of the exciting causes of these bodies; for if, as has occasionally happened, they have shown themselves in a particular portion of the skeleton after the occurrence of a blow, contusion, or other injury, it does not prove that their development was the consequence of such injury.

Sex does not appear to exercise any particular influence upon the development of hydatids of the bones, as they have been observed with nearly equal frequency in men and women. Most of the patients in which they have hitherto been found were adults, but in one instance they occurred in a child three years of age. Borchard has narrated a case where they existed in several situations in the same individual.

Morbid Anatomy.—Examination has proved that these bodies are really acephalocysts, similar to those which are occasionally met with in the liver, ovaries, lungs, and other internal viscera. Of a spherical or rounded shape,

they are sometimes irregularly flattened, or compressed, and vary in size from that of a pea to that of a marble, their dimensions being evidently influenced by their age, and the extent of the cavity in which they are developed. Their number, which is seldom large, is usually in an inverse ratio to their volume. They are inclosed in a sort of parent-cyst, soft in structure, thin, and of a whitish appearance, and they float about in the midst of a serous fluid, of a saline taste, and partially coagulable by heat, alcohol, and acids, circumstances clearly betraying its albuminous character.

The cavity in which these bodies are situated is deserving of special attention. It is evidently, in the first instance, simply one of the cells of the areolar tissue, in which the germ of the animal is deposited, and where it is destined afterwards to attain its full development. As its growth proceeds, it presses upon the osseous matter, pushing its fibres farther and farther apart, at the same time causing a partial removal of it by the action of the absorbents, until what remains is at length converted into a mere bony sheet, hardly as thick as a piece of parchment, elastic, and crackling under the finger. The shell is lined, as already stated, by a thin, closely adherent membrane, which evidently plays an important part in the development and protection of the new being. Cases occur in which it consists of several compartments, cells, or lodges, although in general it is unilocular. The bone immediately adjacent to the disease is usually thickened and roughened by irregular deposits.

Symptoms.—The symptoms attending the formation of these bodies are extremely obscure, and cannot, for a long time, be separated from those which accompany other diseases in and about the skeleton. Their growth is always very tardy, and a long time elapses before there is any pain and discoloration of the integuments. The patient is merely aware that there is some tumor, gradually augmenting in bulk, and slowly encroaching upon the surrounding parts; hard and firm at first, afterwards more soft, and ultimately becoming quite elastic, and emitting a peculiar crackling sound on pressure very similar to that of dry parchment. If it be deep-seated, it will cause a gradual wasting of the superimposed tissues, the muscles and tendons being spread out like thin ribbons, while portions of the fibrous membranes are actually absorbed. Meanwhile, the tumor mechanically impedes the functions of the surrounding parts, pain and tenderness set in, and the integuments show signs of irritation and discomfort. At this stage of the complaint the affected bone sometimes gives way under the most trivial accident, refusing afterwards to unite, or undergoing consolidation only after a long while and after much trouble. Occasionally, the most prominent portion of the tumor ulcerates, and discharges a part of its contents; such an event, however, is extremely rare. The general health remains good for years, but in the end it is always much impaired in consequence of the local distress.

Diagnosis.—The most important diagnostic signs are, the tardy progress of the tumor, the want of pain and swelling, the change from a hard, incompressible substance to one of comparative softness and even elasticity, and the complete absence of all appearance, both local and constitutional, of malignancy. After all, however, these symptoms are merely of a negative character; for at last the only reliable source of information is the exploring needle, though this also, unfortunately, is not available until the morbid growth has acquired a great bulk, and is almost on the verge of bursting. Even the elastic feel and crackling noise which, in the latter stages of the complaint, form such prominent features, are of no diagnostic avail, as they are common to several other varieties of bony tumors.

Prognosis.—Hydatic disease of the osseous tissue is always a grave occurrence, not so much on account of the damage it does to the general health as on account of the injury it inflicts upon the affected bone, weakening its

structure, and thus impairing its usefulness, generally to an irremediable extent. In several of the recorded cases the acephalocysts burst into the knee-joint, causing violent suppuration, and destruction of the functions of the articulation. In a few others, the animals perished, and shrunk up into dirty, reddish-looking masses, which afterwards became a source of irritation, followed by high constitutional disturbance, excessive pain, and hectic fever.

Treatment.—The only remedy that can at all reach this disease is extirpation, and the earlier this is performed the better, for then there is no serious structural lesion of the bone, involving the necessity of resection or amputation. As soon, therefore, as the diagnosis is fully established, the tumor should be freely exposed by an incision, either crucial or elliptical, and attacked with the saw, pliers, trephine, or chisel and mallet, as may seem advisable. Its contents being turned out, the lining membrane of the osseous shell is carefully peeled off, or, when this is impracticable, painted with a strong solution of iodine, to destroy its secreting surface, lest there should be a speedy reproduction, if not of hydatids, at all events of serous fluid. The cavity is then filled with lint, smeared with cerate, and the flaps being approximated are lightly held in place with a few strips of adhesive plaster. The cavity will gradually shrink, and a cure be effected by the granulating process.

When the case is one of an aggravated nature, involving the entire circumference of the affected bone, or when the hydatids open into a joint, the only question will be whether the treatment shall be by resection or amputation. The former procedure can only be suitable when the disease is of limited extent; and in that event, it may probably always be replaced by excision, so that, in reality, it would be difficult to imagine how or when it could be of service. Amputation will be necessary when the case is desperate, as when the bone is irremediably destroyed, or broken and unwilling to unite, or when the tumor has discharged its contents into a neighboring articulation, and has induced so much disturbance, local and constitutional, as to threaten life.

7. MYELOID TUMORS.

The osseous tissue is more liable to the myeloid tumor than any other class of textures, and it is here that the new structure generally acquires its most perfect development. Doubtless it may occur in all, or nearly all, the pieces of the skeleton, but its favorite sites would seem to be the tibia, femur, and inferior maxilla, especially the latter. Commencing generally, if not always, in the cancellated structure, its point of departure is probably the endosteum, extending from thence to the compact layers, which it gradually disparts, and converts into thin, cartilaginous plates, bending and crackling under the finger like dry parchment. Continuing its growth, it may, in time, attain the size of a fist, or even of a foetal head, encroaching seriously upon the surrounding parts, and interfering, more or less, with the exercise of their functions. The arteries leading to it are generally somewhat enlarged, and the tumor itself is commonly quite vascular. A section of it exhibits a smooth, compact appearance, of a reddish, pink, or lilac tint, inlaid, as it were, with soft bony fibres, and pervaded by little cysts, either simple or compound, and occupied by different kinds of fluids, as serum, sanguinolent matter, or altered blood, or all these substances commingled.

There are no *signs* by which this growth can be distinguished from other tumors of the bones; its rapid development, its elastic feel, and its lobulated form assimilate it very much, in its external characters, to encephaloid, and the resemblance is still further shown by the fact that the disease is liable to recur after extirpation, and also that, in its advanced stages, the patient presents all the evidences of the cancerous cachexia. The only remedy is

excision or amputation; excision, when the tumor involves the jaws, amputation, when it is seated in the bones of the extremities.

MALIGNANT FORMATIONS.

The various malignant affections of the bones may, as far as practical purposes are concerned, be all conveniently grouped under one head. Of these affections, encephaloid is much the most common; next in point of frequency is colloid, then comes scirrhus, and finally, as the most rare of all, melanosis. The origin, progress, and termination of these formations are the same here as in other organs and tissues.

1. *Encephaloid*, hematoid fungus, cerebriform cancer, or osteocephaloma, generally, if not invariably, originates in the spongy structure of the bones, from which it gradually extends to the compact lamella, and finally to the periosteum. It most commonly attacks the upper and lower jaw, and the long bones of the extremities, particularly the femur, humerus, and digital phalanges. No portion of the skeleton, however, is exempt from it. The most terrific feature of the encephaloid is its tendency to recur in some other part of the body, after it has been dislodged from its original situation. It may show itself at any period of life, but young persons are most prone to it.

Although encephaloid may occur as an infiltration, it most commonly presents itself in the form of a tumor, arranged in rounded, lobulated masses, of the color and consistence of the medullary structure of the brain. Not unfrequently it contains small cavities, filled with clotted blood, dirty looking serum, or soft, gelatinous, oily, sebaceous, or melliceroid matter. Occasionally one part of the tumor exhibits the brain-like character, while another is strictly hematoid, or composed of a mixture of blood and encephaloid. In the great majority of cases, however, the two substances are pretty intimately blended together. Vessels, sometimes of considerable volume, may be seen ramifying over the surface of the morbid growth, and dipping into its interior. The outer table of the bone is transformed into a thin, parchment-like lamella, perforated in various places, or entirely destroyed by absorption. A section of the tumor usually exhibits, in addition to the appearance just described, osseous fragments, or pieces of fibro-cartilage. The superincumbent integuments, traversed by large bluish veins, are at first soft and glossy; but at length, from the constant and increasing pressure exerted upon them, they ulcerate, and allow the fungous mass to protrude.

Fig. 316.

Encephaloid disease of the tibia.

Some of the more extraordinary alterations which the osseous structure is capable of undergoing in this disease are well seen in fig. 316, from a speci-

men in the cabinet of Professor Buchanan. The patient was a mulatto girl, about twelve years of age, who had labored for some time under a large, lobulated tumor, partly elastic and partly inelastic, situated in the lower part of the leg, and attended with great dilatation and distension of the subcutaneous veins. Amputation being performed, the stump healed kindly, and for several weeks the girl did well: but in a few months she began to complain of pain in her hip and side, and she died in less than a year, apparently from internal malignant disease. A section of the tumor displayed an immense number of osseous spicules, of extraordinary length and delicacy, whose intervals were occupied partly by cartilaginous and partly by gelatinous substance, with here and there a cyst containing bloody-looking matter. The external characters of encephaloid are well displayed in the adjoining cut, fig. 317, from a specimen in my collection.

Fig. 317.

Encephaloid disease of the thigh-bone.

2. Of *colloid* of the osseous tissue very little is known. It is most frequently met with in the diseased conditions of the bones denominated osteosarcoma and spina ventosa, which are often almost

Fig. 318.

Colloid tumor.

wholly composed of cells and cavities, filled with jelly-like matter. The question, however, respecting the identity of these affections can be determined only by future observation. A case in which a colloid tumor grew from the body of the sphenoid bone, outside the dura mater, came under my notice in 1844, in the medical ward at the Louisville Hospital. The patient died at the age of thirty-nine years from epilepsy, produced by a fall twelve months previously. On examination, Dr. Colescott and myself found, in the situation referred to, a lobulated tumor, of irregular form, and about the size of a pullet's egg, which had flattened the Varolian bridge, and evidently induced the disease in question. A section of the morbid mass, fig. 318, showed that it was composed of several compartments communicating with each other, and occupied by a white, semi-concrete substance, in all respects similar to that of colloid.

3. *Scirrhus* of the osseous tissue is extremely uncommon. It occurs exclusively in old subjects, and is usually concomitant of the same disease in the breast or some other organ. Generally limited to a single bone, it may affect several pieces simultaneously, and always begins in the cancellated structure. Its favorite seat is the femur, but it may appear in any part of the skeleton, in the short and flat bones, as well as in the long.

The heteroclite matter is deposited under two varieties of form, the infiltrated, and the tuberoid. In the former it is diffused through the areolar tissue, and exhibits the color and consistence of fibro-cartilage, or the rind of fresh pork. In the tuberoid variety the morbid mass is either solitary, or it consists of several agglomerated nodules, from the volume of a hazel-nut to that of an almond. Occasionally three or four distinct tumors are developed simultaneously in the same bone. They are of an irregularly rounded or oval shape, dense and firm in their consistence, and of a greenish, whitish, or yellowish color. The bone is seldom much altered in its size or external configuration, but is liable to be absorbed, and fractured at the seat of the disease.

4. The occurrence of *melanosis* in bone is very infrequent. It may appear in small, disseminated masses, nodules, or clusters, or in the form of an infiltration. It has been observed in various parts of the skeleton, but is most common in the pieces of the extremities, particularly the femur and tibia. Co-existing generally with melanosis in other organs, it is situated either upon the surface of the bone, beneath the periosteum, in the medullary canal, or in the spongy structure, the latter of which it sometimes dyes of a deep black color. In its progress and mode of termination it closely resembles medullary sarcoma.

General Diagnosis, Prognosis, and Treatment.—Much has been said, especially of late years, respecting the diagnosis of cancerous diseases of the osseous tissue, and from reading the accounts of these formations in the books one would suppose that their recognition was a matter of the greatest facility. Nothing, however, is more untrue. With the exception of encephaloid, it is extremely difficult to detect the real nature of any of them during any portion of their progress, and even encephaloid cannot always be satisfactorily discriminated until it has acquired an unusual bulk. In the latter case, the most reliable guides are, the early period of life at which the tumor shows itself, the rapidity of its growth, the great bulk it attains, the depth of its situation at the commencement of its development, the lobulated condition of its surface, and the extraordinary enlargement of the subcutaneous veins. In general, too, it will be found that the disease is developed in one of the long bones, as the humerus, femur, or tibia, and in preference, as it were, in their articular extremities. The moment ulceration occurs the case speaks for itself, the diagnosis being no longer equivocal.

The progress of encephaloid is generally very rapid, especially when it occurs upon the periphery of the bones, a few months usually sufficing for the formation of an immense tumor, and the complete destruction of the osseous tissue, or its conversion into a soft, sarcomatous, or fibro-cartilaginous mass, with hardly any trace of the primitive structure. The growth is commonly of a lobulated character, and of varying degrees of consistence, being soft at one part, tolerably firm at another, and perhaps almost bony at a third, according to the nature of the portion examined. As it increases in size, it displaces the surrounding textures, flattening the muscles and nerves, and thus impairing their functions; the integuments are stretched, and, in places, attenuated; and the subcutaneous veins are enlarged, varicose, and of a bluish color. The colloid tumor is also capable of attaining a great bulk, but its progress is usually much more tardy than that of encephaloid, and there is seldom any considerable augmentation of the subcutaneous veins. Scirrhus of bone usually co-exists with scirrhus of the mammary gland, uterus, or liver, and the only symptom leading even to a suspicion of its existence is the peculiarity of the attendant pain, which is usually either sharp and lancinating, or else dull, heavy, or aching, and fixed in its position, the affected part being, at the same time, exquisitely tender on pressure and motion. The patient often becomes bedridden during the progress of

the case, and the diseased bone not unfrequently gives way under the most trivial accident, as a mere twist of the limb in stepping out of the bed upon the floor. Melanosis of the osseous tissue is seldom discovered during life, unless it happen to be seated in a superficial bone, as the sternum, or one of the ribs; in nearly every instance that has yet been observed, it was present at the same time in other parts of the body.

Cancer of bone follows the same course as cancer of the soft parts. If left to itself, the malady inevitably proves fatal, and hardly any one makes a permanent recovery after an operation, however early and thoroughly executed. In all the cases of encephaloid of the extremities that I have either operated upon myself, or seen operated upon by others, there has been a speedy recurrence of disease, often indeed in less than three months, either at the cicatrice, the neighboring lymphatic ganglions, or in some internal organ, carrying off the patient a short time afterwards. I am aware that exceptional cases are sometimes reported, but they are only exceptional, and nothing more, to say nothing of the fact that there may occasionally be in these cases an error in the diagnosis, the tumor, although possessing some of the outward properties of osteocephaloma, being in fact merely a benign one, appertaining to the osteosarcomatous class of the older writers. Judging from personal observation, I am inclined to believe that malignant growths of the maxillary bones are less liable to relapse after operation than those of any of the other pieces of the skeleton, and in this view of the subject, if I mistake not, the opinion of practitioners generally coincides. Nevertheless, even here the ultimate issue of the case is nearly always unfavorable. The circumstances justifying interference in this class of maladies, have already been so fully pointed out in the chapter on carcinomatous diseases generally, as to render any further discussion of them unnecessary in this place. In regard to the choice of the operation, as to whether this should be amputation or excision, the decision must always be given in favor of the former whenever the morbid growth occupies an extremity, the removal being effected as high up, or as near to the trunk, as possible, as conferring greater safety. Thus, when the hand is involved, the forearm should be cut off near the elbow, and in encephaloma of the radius and ulna, the limb should be amputated pretty close to the shoulder. If the tumor be seated in the upper jaw, the whole of that bone should be excised, together, perhaps, with portions of the palate, spongy, and malar bones. Thorough work must be made, or interference will be productive of infinite harm. After recovery from the operation, the patient must be put upon a properly regulated diet, with an alterative and tonic course of treatment, and exercise in the open air.

SECT. XIII.—TUBERCULAR DISEASE.

Tubercles of the bones are much more common than is generally imagined. The bones usually affected are the vertebræ, the short bones of the hand and foot, and the articulating extremities of the long bones. The particular seat of tubercles is the spongy texture, though occasionally they are formed upon the outer surface of the bones, between it and the periosteum.

There are two varieties of form in which this matter is deposited. In one, perhaps the more common, the tubercles are *encysted*, the inclosing membrane, which varies in thickness from the fifth of a line to half a line, being composed of coagulating lymph, very soft at first, but gradually becoming harder and harder, until finally, in some cases, it acquires the character of fibro-cartilage. It is of a dull grayish color, is made up of delicate, inelastic fibres crossing each other in every conceivable direction, and is frequently furnished with small vessels, passing into it from the surrounding structures. The number

of tubercles is seldom very great; their size ranges from that of a pea to that of a nutmeg; and in most cases they present a yellowish, opaque appearance. When these bodies become softened, the matter will either work its way out, or pass, by a sort of fistulous route, into a neighboring joint, establishing thereby an analogy with pulmonary tubercles opening into the bronchial tubes. Sometimes a spontaneous cure takes place, the heterologous substance being absorbed, and the cyst contracting so as to obliterate its cavity.

In the second variety, the tubercular matter is deposited directly into the cells of the osseous tissue, forming grayish, semi-transparent, opaline patches,

Fig. 319.

Section of bone infiltrated with tubercular matter.

from the one-sixth of an inch to an inch in diameter. This *infiltration*, exhibited in fig. 319, is noticed chiefly in the bodies of the vertebræ and in the bones of the tarsus, where it is frequently pervaded by numerous vessels, too delicate to be discerned with the naked eye. The bony tissue immediately around is sometimes deeply injected, but seldom otherwise diseased. In this, as in the preceding variety, the tubercular deposit, after having existed for some time, gradually softens, its vascularity disappears, and the cells in which it was contained are filled with earthy matter. This, however, is not always the case; for now and then the ulcerative process continues until the bone is totally destroyed.

The *progress* of tubercular disease of the bones is always chronic, though not equally so in both forms, the infiltrated proceeding more tardily than the encysted, and causing generally also a greater amount of havoc in the osseous

tissue. No definite information, however, can be furnished in regard either to the commencement of the softening process, or to the ultimate elimination of the matter produced by that action, from the affected structures. Much will doubtless depend, in every case, upon the condition of the system, the age of the patient, and the presence or absence of local complications. As a general rule, from six to twelve months will elapse from the moment of the deposition of the tubercular substance to the completion of the softening process. The matter resulting from the disintegration of the heteromorphous deposit is similar to that which occurs in the lungs in the advanced stage of phthisis, being of a pale yellowish color, bordering slightly upon greenish, and of a thin fluid consistence, with small whitish flakes not unlike soft-boiled grains of rice. After an opening has been effected into the abscess, the discharge generally becomes very watery and bloody, as well as irritating, and comes away in large quantities, a number of sinuses often existing in the diseased parts, as if they were necessary to carry off the superabundant secretions. In many cases, broken-down osseous tissue is intermingled with the pus, passing off either as little granules or as minute fragments, which not unfrequently choke up the abnormal track, and thus excite new irritation.

The adjoining cut, fig. 320, from a specimen in my cabinet, exhibits the effects which a tubercular abscess may exert upon the osseous tissue, in causing a well-marked excavation, similar to what we see in the lungs.

The abscess that arises from the disintegration of the tubercular matter is the form which is usually met with in bone, the phlegmonous, as stated else-

where, being of extremely rare occurrence. The symptoms attending it are generally obscure, but its existence may be suspected when, along with the ordinary signs of osteitis, the affected part is the seat of circumscribed, deep-

Fig. 320.

Tubercular excavation of the cuneiform bone.

seated, gnawing pain, with excessive tenderness at one particular spot, and a glossy, shining, œdematous condition of the integuments. The breaking of the abscess is always preceded by considerable swelling of the soft structures, and by more or less disturbance of the system, the constitution frequently sympathizing severely with the local trouble. In addition to these circumstances, the history of the case, as the age of the patient, the site of the morbid action, and the absence or co-existence of strumous disease in other structures, will generally furnish useful light, and thus materially aid in the establishment of a correct diagnosis.

The *treatment* of tuberculosis of bone differs in no material respect from that of tuberculosis in the other organs and tissues. Bearing in mind the fact that the local deposit is, in general, merely a reflection of the state of the system, the judicious practitioner will not neglect the employment of such remedies as are necessary to modify this condition of the constitution and to provide for the supply of a better and richer blood. The principal means included under this head are, a well-regulated and adequately nutritious diet, cod-liver oil, and the various chalybeate preparations, either alone, or in union with quinine, mild purgatives, and gentle exercise in the open air, especially if the seat of the disease do not act interferingly.

The local remedies are, of course, of the ordinary antiphlogistic character, consisting of leeches, blisters, and the dilute tincture of iodine, with early and free incisions of the soft structures to relieve pain and tension. If the existence of an abscess is suspected, prompt recourse is had to the trephine, the operation and after-treatment being conducted upon the same principles as in acute or phlegmonous abscess of bone, already described.

SECT. XIV.—NEURALGIA.

Neuralgia of the osseous tissue is infrequent. I have seen a large number—perhaps it would be more correct to say an immense number—of cases of neuralgia of the soft structure in almost every part of the body, but only a few of neuralgia of the bones. In nearly every instance that has fallen under my observation the disease was associated with some organic lesion of the affected texture, such as abscess, caries, exostosis, or interstitial deposits into the Haversian canals and cancellated tissue, thereby compressing the vessels and the nerves distributed through their tunics. A lady, aged fifty, a personal friend of mine, had long been afflicted with neuralgia of the cranium, caused by the falling of a window-sash upon the upper and posterior angle of the left parietal bone. The pain, without observing any regularity in its accession,

gradually increased in severity, and became at length so intense as to require from one to two drachms of morphia a week, besides enormous quantities of sulphuric ether, for even its temporary subjugation. The seat of pain was a small spot, not larger than the end of the finger, and exquisitely tender to the touch. A disk of bone, embracing the affected portion, being removed with the trephine, an exostosis, not more than the eighth of an inch in thickness, was discovered upon its inner surface, which thus at once explained the nature of the case, complete recovery following the operation.

A married woman, aged twenty-eight, had suffered, at times, most acute and distressing pain from a small bony tumor at the anterior and outer part of the lower extremity of the left radius. The tumor had come on about twelve years previously, and had all along been exquisitely sensitive on pressure and even on the slightest touch. It projected but little beyond the natural level, and was unaccompanied by any visible change in the soft parts. The pain had been liable to periodical exacerbations, and was often so severe as to deprive the woman of appetite and sleep. The general health was always good, the complexion denoting rather a robust state of the system, and the menstrual function being performed with great regularity. Upon removing the tumor, I found that its substance was almost of the consistence of ivory, offering great resistance to the instruments. The pain at once disappeared, and has never returned.

I have met with a number of cases similar to the last, which may be regarded as, in some degree, typical of this affection as it usually appears in the skeleton. Most of them occurred in young females, between the ages of twenty and thirty, without, seemingly, any direct connection with the catamenial function, which was usually well executed, and without any marked hysterical predisposition. In all the cases that I have met with, the pain was liable to periodical exacerbations, not, however, by any means always coincident with menstruation, and the parts were exquisitely sensitive under motion and pressure. The pieces which I have found most frequently affected were the radius, ulna, tibia, fibula, clavicle, and cranial bones, especially the frontal and occipital. In several instances I have known the coccyx to be the seat of neuralgia, the pain being so severe as to cause the greatest possible suffering. So far as my observation goes, the disease never attacks this bone except in married women who have borne children, and I presume that it depends here, as elsewhere, upon the presence of interstitial deposits, either as a simple hypertrophy, or a small exostosis, compressing the vessels and nerves of the osseous tissue.

Neuralgia of bone generally results from direct injury, as a blow, wound, or contusion, causing inflammation in the affected part, followed by a deposit of new osseous substance. It may also be produced by a syphilitic taint of the system, as we see in the tertiary form of this disease, in which the pains are not unfrequently of a darting, shooting, lancinating nature, or else dull, heavy, and aching, as in neuralgia of the soft structures. In abscess of bone the suffering is frequently of the same character, and hence the difficulty which the practitioner so often experiences in discriminating between the two affections. The disease is frequently associated with neuralgia in other parts of the body.

The *treatment* of neuralgia of bone is too often conducted upon empirical principles; a circumstance which is doubtless due to the fact that it is generally difficult, if not impossible, to ascertain the true nature of the disease. In recent cases, especially in such as are directly chargeable to the effects of external injury, a free incision down to the seat of the disease, dividing the periosteum and even the superficial layer of the bones, will occasionally effect a prompt cure, especially if the wound be kept open for some time with stimulating dressings to promote discharge. Now and then a small issue,

made with the actual cautery, will answer an excellent purpose. When the cause is of a syphilitic nature, iodide of potassium and mercury afford the best means of relief. Quinine, arsenic, and strychnine are indicated when the disease is of miasmatic origin. In obstinate cases, the only reliable plan is removal of the affected bone with the trephine or other suitable instruments; the object being to get rid of the compressing agent, whether this be merely simple hypertrophy of the part or an exostosis, properly so-termed. Dr. Nott, of Mobile, has on two occasions excised the greater portion of the coccyx for the cure of this disease, but the results have not, I believe, been as satisfactory as had been anticipated.

SECT. XV.—FRACTURES.

1. GENERAL CONSIDERATIONS.

There is no class of injuries which a practitioner approaches with more doubt and misgiving than fractures, or one which demands a greater amount of ready knowledge, self-reliance, and consummate skill. Constant in their occurrence, and often extremely difficult of diagnosis and management, they frequently involve consequences hardly less serious and disastrous to the surgeon than to the patient himself. If I were called upon to testify under oath what branch of surgery I regarded as the most trying and difficult to practise successfully and creditably, I should unhesitatingly assert that it was that which relates to the present subject, and I am quite sure that every enlightened practitioner would concur with me in the justice of this opinion. I certainly know none which requires a more thorough knowledge of topographical anatomy, a nicer sense of discrimination, a calmer judgment, a more enlarged experience, or a greater share of vigilance and attention; in a word, none which requires a higher combination of surgical tact and power. As for myself, I never treat a case of fracture, however simple, without a feeling of the deepest anxiety in regard to its ultimate issue; I cannot retire at night or rise in the morning without a sense of discomfort, so long as I am conscious that, despite my most assiduous attention and my best directed efforts, my patient is likely to become deformed and lame for life. If this feeling were more general, it is easy to perceive that there would be comparatively few cripples from this cause, and comparatively few suits for malpractice, unfortunately so common, of late years, in this country, and so disreputable to the profession. A crooked limb, rendered so by injudicious treatment, is an unpleasant sight to a sensitive surgeon, reminding him constantly of his bad luck, his want of skill, or his inattention; not unfrequently it is a standing, living, speaking monument of his disgrace, planned by his own mind, and erected by his own hands. I would certainly not wish it to be understood by these remarks that it is always in the power of the surgeon to cure these accidents without deformity or impairment of function. To utter such a sentiment would be contrary to all experience and common sense. There are cases, and, indeed, they are not infrequent, where it is impossible to avoid such occurrences; cases where injury to bone, joint, and soft parts is so severe and complicated as to render any other result totally impracticable, however attentively and scientifically they may be treated. The physician cannot cure all diseases; such is their character that many must, of necessity, prove fatal, and of such as do not terminate in this manner, there are many which, notwithstanding the most skilful management, sadly cripple the patient for life. The only difference between the surgeon and the physician, under such circumstances, is that the former is often blamed, if not severely censured, for the result of his treatment, perhaps long, arduously, and anxiously

continued, while the latter often receives nothing but commendation and praise, when he may be no more entitled to it than the other. Every one thinks he can judge correctly of a surgeon's skill, but very few persons attempt to fathom that of a medical practitioner.

A fracture may be defined to be a solution of continuity of the osseous tissue, or, in other words, a yielding and separation of the bony fibres, occasioned either by external violence or muscular contraction. The lesion presents itself in various forms, of which the principal are the simple compound, comminuted, impacted, and complicated. To these may be added the incomplete fracture, in which a bone, instead of being entirely broken across, is divided only in a portion of its diameter.

A fracture is said to be simple when it is unaccompanied by any wound of the soft parts directly over the end of its fragments, thus exposing them to view, or, at all events, permitting them to be felt. The case is a simple one, as far as the bone is concerned, even if there be a wound in the immediate vicinity of the fracture, provided it has no direct communication with it. A compound fracture is one where the opening in the skin and muscles extends down to the bone, the ends of which often protrude through the wound, girted, perhaps, by its edges. When a bone is broken into a number of pieces, the term comminuted is applied to it. The word impacted is employed to signify that the extremity of one fragment is forced into that of the other. Finally, a fracture is complicated when it is associated with dislocation, wound, hemorrhage, laceration, or other mischief. It will greatly facilitate the discussion of the subject if we discard all these terms, with the exception of the first and last. Hence, after some general observations, we shall treat first of simple fractures, and afterwards of fractures complicated with other lesions.

All the bones of the body are liable to be broken, though not by any means with equal *frequency*. Those which are most prone to suffer in this manner are the long bones of the extremities, particularly those of the leg and forearm. The clavicle is also frequently fractured. The scapula, the two jaw-bones, the sternum, ribs, innominatum, vertebræ, sacrum, and coccyx, together with the bones of the hand and foot, are rarely broken, owing either to their protected situation, to their mobility, or to the manner in which they are united to each other and to the surrounding parts. It may be stated also, as a general law, that the long bones are more liable to give way at or near their middle than at their extremities; a circumstance of some importance in a diagnostic and practical point of view.

The relative frequency of fractures of the bones of the superior and inferior extremities has not been satisfactorily determined. It doubtless varies in different institutions and in different localities, according to the nature of the occupations of those who are the subjects of them. The following tables, composed of the statistics of different hospitals, shows the preponderance to be very slightly in favor of the lower limbs:—

	No. of cases.	Upper extremity.	Lower extremity.
Pennsylvania Hospital	1473	572	901
Hôtel Dieu, Paris	1856	850	1006
Middlesex Hospital, London . . .	1280	764	516
Native Hospital, Calcutta	1346	665	681
	<hr/> 5955	<hr/> 2851	<hr/> 3104

Respecting their *direction*, fractures may be oblique, transverse, or longitudinal. Of these varieties, the first is by far the most common, though it is impossible, from the want of statistics, to estimate its relative frequency. My experience teaches me that transverse fractures are extremely rare. In

the extensive osseous collection of Dr. Mütter, there is not a solitary specimen of the kind; and my own is equally barren. I am speaking now, of course, only of fractures of the long bones, and especially of fractures of their shafts; for in the short and flat bones such an occurrence is not without a certain degree of frequency. There is reason to believe that many of the so-called cases of transverse fractures of the shafts of the long bones are in reality oblique fractures, approaching more or less closely to the horizontal line, yet not strictly falling within it. There are few practitioners, I imagine, who will not coincide with me in this view, and who, like myself, have not had frequent occasion, upon further and more thorough exploration, to correct their diagnosis in cases of this description. If the question were one solely of a speculative nature, it would be of little consequence; but when we consider its practical bearing, it is impossible to lay too much stress upon it. As it will, however, be again adverted to when we come to speak of the treatment of fractures, nothing further need be said respecting it here. The annexed cut, fig. 321, conveys a good idea of an oblique fracture.

Fig. 321.

Oblique fracture of the bones of the forearm.

Longitudinal fractures are extremely rare, so much so, indeed, that great doubt was at one time entertained respecting the possibility of their occurrence. That they do, however, occasionally take place, is sufficiently established by the cases that have been published from time to time in our medical journals, and by the specimens that are to be seen in different museums and private collections. They are nearly always produced by gunshot violence, and have hitherto been met with chiefly in the humerus, femur, and tibia. In a very few cases the fracture has passed nearly through the entire shaft of a bone; but, in general, it is not more than a few inches in extent. Occasionally a fissure of this kind, after having passed a certain distance, runs off in an angular direction towards the surface of the bone, where it terminates, as in fig. 322. A longitudinal fracture is sometimes seen at the inferior extremity of the humerus, and also, but more rarely, at the lower end of the femur, separating one of the condyles of these bones, or even both of these protuberances, as happens when there is at the same time a horizontal or oblique fracture a short distance above the corresponding joint. A longitudinal fracture is occasionally met with in the patella.

Fig. 322.

Longitudinal and oblique fracture.

The extremities of the fragments of a broken bone exhibit much diversity in regard to their form and size; in general, one is much larger than the other, as well as more sharp, rough, and irregular, as in fig. 323. In the majority of cases, they have a ragged, serrated, or denticulated appearance, the projecting pieces of one end corresponding with the depressions in that of the other. This arrangement, which is produced by the irregular division of the osseous fibres, bears no little analogy to that which occurs in the edges of a lacerated wound. The truth is, to carry out the analogy still further, an oblique fracture is nothing

but a lacerated wound of the osseous tissue, which presents the same difficulty in regard to its perfect coaptation and speedy reunion as a similar lesion in the skin and muscles. The irregularities upon the extremities of the frag-

Fig. 323.

Appearances of the ends of the fragments.

ments are often sadly in our way, offering a great obstacle to the successful reduction and subsequent maintenance of the parts. Sometimes, indeed, the projecting pieces are so long and sharp as to pierce the integuments, or to require to be sawed off before the bone can be properly set. Such an occurrence is not uncommon in fractures of the tibia, and it is also witnessed, though less frequently, in the femur, the radius, and clavicle.

Sometimes the fracture is *impacted*, that is, the end of one fragment is forcibly driven into the other, so as to be, as it were, interlocked. Such an occurrence, of which fig. 324 affords an excellent illustration, can only arise, as a general rule, in those bones which contain an extraordinary amount of areolar substance.

Fig. 324.

Impacted fracture of the neck of femur.

As a bone may give way at any part of its extent, at its middle, or at either end, it follows that the two fragments are rarely of the same length; instead of this, there is often a most marked disparity, as is exemplified in fractures of the extremities of the long bones, as the femur, in which, especially in fractures of its neck within the capsular ligament, the superior fragment is sometimes hardly an inch and a half in length, while the other is perhaps upwards of a foot and a quarter. Fracture of the olecranon affords a similar illustration. Such an occurrence is not without its influence in regard to the treatment and final issue of the lesion; for the

nearer, as a general rule, the length of the fragments corresponds, the easier, all other things being equal, will it be to maintain their apposition, and secure prompt and perfect union.

A fracture may be single or multiple; that is, a bone may break at one or more places, sometimes as many as three, four, or even five; in other words, it may be literally crushed and comminuted. Such lesions are generally the result of inordinate violence, and are always liable to be followed by serious consequences; often, indeed, by loss of limb and life.

In fractures of the leg and forearm, affecting both bones, it is extremely rare to find the injury situated on the same level; on the contrary, there is generally a considerable distance between the two fractures, amounting, according to my observation of numerous cases, ordinarily to from one to two, three, and even four inches. The interval is usually considerably greater in the leg than in the forearm, probably because of the greater inequality in the size of its two bones. What the cause of this occurrence is it is not easy to determine; but it may be supposed that it is due mainly, if not entirely, to the manner in which these pieces are respectively articulated to the wrist and ankle-joints, in consequence of which the violence occasioning the lesion is

transmitted more forcibly along one bone than along the other, thereby compelling the former to yield before the latter. Thus, as the tibia is more intimately connected with the foot than the fibula, it follows, if this explanation be correct, that it ought to break lower down than the fibula, and this, I believe, is what usually happens, although there are many exceptions.

Fractures occur at all *periods of life*. During delivery, the bones of the arm and leg are occasionally broken in rude attempts at extraction. In 1856, an infant, four weeks old, was brought to me on account of a fracture of the shaft of the right femur, caused two days previously by a child rolling over it in bed. The thigh was much swollen, and at least an inch and a half shorter than the sound one; all the extension and counter-extension that I could make with my hands failed to restore it to its normal length. Fractures occasionally occur in the foetus in the womb. Chaussier met with a remarkable example of this description, in which each of the long bones had suffered more or less from these lesions, some of which were recent, others beginning to unite, while others were consolidated. The child survived its birth only twenty-four hours. Cases of a somewhat similar character have been reported by other observers. In childhood, the bones being remarkably flexible, on account of the large amount of animal substance which they contain, are particularly prone to give way at their epiphyses; in old age, on the contrary, they are very dense and brittle, from the presence of an inordinate quantity of earthy matter, and are therefore extremely liable to break from the slightest causes. Thus, a fracture of the neck of the femur within the capsular ligament is often produced by a mere twist of the thigh in bed, by catching the big toe in a fold of the carpet, or by stepping off the curb-stone.

Causes.—The causes of fractures are generally divided into predisposing and exciting; the first having reference to the part and system, or to local and constitutional circumstances, the second to external violence and muscular action.

The conformation, situation, and office of certain bones are so many *predisposing causes* of fracture. Thus, as was before stated, the long bones, which are the great levers of locomotion, and which, in consequence, are constantly under the influence of large and numerous muscles, are much more subject to this accident than the short or flat bones, which are more passive in their character, as well as more closely articulated together, so that any force that may be communicated to them is more easily broken. The body of the scapula is seldom broken, because it is not only thickly covered by muscles, but, having no fixed point below, it is incapable of being injured by any shock transmitted by the hand, elbow, or shoulder. The acromion process, however, owing to its exposed situation, is not unfrequently fractured; while the coracoid process, protected by the deltoid, clavicle, and head of the humerus, rarely suffers from this cause. The radius, being articulated with the hand, is more liable to break than the ulna; the fibula, owing to its slender form and brittle texture, is oftener broken than the thick and heavy tibia; and every surgeon knows how very prone the collar-bone is to fracture, its exposed situation, the peculiarity of its conformation, and its connection with the sternum and scapula rendering it particularly obnoxious to this occurrence.

Of the influence of *age*, in promoting the occurrence of fracture, mention was made in a previous paragraph, and it need not, therefore, detain us here. It may be stated, however, that, as we advance in life, there is superadded to the preternatural brittleness of the osseous tissue, another cause of fracture, namely, abnormal rigidity of the muscles, thus rendering us more liable to falls, and, consequently, more prone to the accident in question.

Various *diseases* or states of the general system have usually been regarded

as predisposing causes of fracture. Of these, the most common are syphilis, cancer, scurvy, and rickets.

That a *syphilitic* state of the system, involving the skeleton, may so affect some of the bones as to render them abnormally fragile is sufficiently established by modern observation. In 1847, I attended a man, aged thirty-one years, for a fracture of the body of the right humerus, caused, a short time previously, by throwing a small chip at a person. He was perfectly well at the time, with the exception of some nocturnal pain in the arm and forearm. He had had primary syphilis seven years previously, and had been treated with mercury. The bone united in five weeks.

It is well known that *cancer* may so alter the osseous tissue, fig. 325, as to render it preternaturally brittle, and thus predispose it to fracture. Such an

Fig. 325.

Encephaloid of the thigh, followed by fracture.

occurrence, indeed, is probably not so uncommon as is generally supposed. I have myself, however, seen only one instance of it. The patient was a female, seventy-three years old, from whom I had removed, with the assistance of my former colleague, Professor Miller, nine months previously, the left mammary gland, on account of scirrhus, under which she had labored for nearly three years. The wound healed kindly, but, some time after, the disease reappeared at the cicatrice, and gradually carried her off, not, however, before she had become extremely emaciated and bedridden. During the last month of her life, she complained of almost constant pain in the right thigh, deep-seated, and particularly severe at night; and three days before she expired, in an attempt to turn in bed, the femur broke just above its middle. The limb was free from swelling and discoloration. No cancerous matter could be detected in the affected bone, which was quite soft, humid, and brittle, for some distance above and below the seat of fracture.

Of the influence which *scurvy* exerts upon the osseous tissue, in predisposing it to fracture, the modern practitioner has little opportunity of judging, as the disease at the present day seldom appears in that violent form which characterized it in former times. As described by the older writers, it was often attended with the most horrible ravages, in which the skeleton not unfrequently

participated, the synovial membranes, cartilages, and ligaments being ulcerated, and the epiphyses separated from the bones. In 1855-6, the scurvy prevailed extensively in certain regions of the United States, especially in the Southwest, but I am not aware that it predisposed any of its subjects to the occurrence of fracture, or that it retarded the process of reunion in those who suffered from it at the time.

There are certain states of the skeleton, including *rickets*, in which the bones become so remarkably brittle as to break under the most trivial injury. Cases are recorded where, from these and other causes, nearly every one of the long bones was broken not only once, but a number of times. What is remarkable in these cases is that they usually recover quite as soon as ordinary fractures. I have in my collection a part of the skeleton of an old woman, who, in falling from a second-story window down upon the pavement

below, received not less than fifty-three fractures, involving the vertebræ, the scapula, the bones of the pelvis, and most of the bones of the extremities.

Gout and rheumatism are sometimes enumerated as predisposing causes of fracture. The following case, which I saw with Dr. Metcalf, would seem to countenance the possibility of such an occurrence.

Henry Welker, a common laborer, aged thirty-two, had always enjoyed good health until two years and a half ago, when he was attacked with articular rheumatism, affecting the principal joints, first of the superior, and then of the inferior extremities, where it had continued for the last twelve months. The only cause which he could assign for his suffering was exposure to cold and fatigue in a pork-house, where he had worked for fourteen successive winters. In December, 1855, he broke his thigh-bone, at the junction of the lower with the middle third, while pulling off his boot with his hands, the foot being at the time bent at a right angle with the leg. No pain or swelling followed the accident. The most remarkable feature in the case, when Dr. Metcalf first saw it, was the imperfect aeration of the blood, as indicated by the livid state of the face; the bowels were torpid, the tongue was coated, and there was considerable emaciation, but no disease of the heart and lungs. No chalky deposit existed in the joints. At the end of a month and a half, the parts being united, the dressings were removed, and the man was permitted to walk about on crutches. A week after this, he struck the affected thigh slightly against the rail of the bed, fracturing the bone at its upper third. Union took place in about the same time as before, the quantity of callus in each case being uncommonly large.

The *exciting causes* of fracture are two, external violence and muscular contraction. The former, which is by far the more common, may act upon a bone either directly, or indirectly through some other bone. In the first case, the force is applied to the bone itself, as in fracture of the jaw from the kick of a horse, or in fracture of the leg from the passage of the wheel of a carriage. Most fractures are of this description, and hence they are generally complicated with more or less injury of the soft structures. In the other case, the force, instead of being applied immediately to the bone, is transmitted to it through another bone, or perhaps a chain of bones. It is in this way that the radius is so frequently broken just above the wrist by falls upon the hand, the force being concentrated upon its inferior extremity, in consequence of the manner in which it is articulated with the carpus, while the ulna, which is but slightly connected with it, generally escapes. Fracture of the clavicle affords an instance of a bone being broken by indirect mechanical violence operating at two opposite points. Thus, in falls upon the shoulder, the sternal end being impelled by the weight of the body, and the acromial end by the object which it strikes against, the bone, acted upon by the two forces, gives way at its weakest part, which is usually about its middle. When a bone is very brittle, the slightest external violence may be sufficient to break it. In old people the neck of the femur is frequently fractured by the merest twist of the limb in bed, or by stepping carelessly out of the bed upon the floor.

It is not often that a bone is broken by muscular action, and yet such an accident is not, perhaps, as uncommon as is generally imagined. I have myself met with several instances of it. In three, the subjects were remarkable for their health and muscular developments, and the fracture in each was produced while they were engaged in feats of strength, in which the elbows were planted firmly upon a counter, and the hands interlocked with each other. While the muscles of the arm and forearm were in a state of the utmost tension, the humerus snapped off suddenly, with a loud noise; in two cases at its middle, and in the other at its inferior extremity. In another case, the fracture, also seated in the humerus, was caused by throwing a

small chip. In this instance, alluded to in a previous paragraph, the bone had suffered for a considerable time under nocturnal pains, and had evidently been rendered brittle by the effects of the syphilitic virus. The patient, aged thirty-one, was otherwise in good health, but the muscles of his arm were rather soft and flabby. The patella and olecranon are frequently fractured by the action of the extensor muscles of the thigh and arm. From the above cases, it is evident that a diseased state of the bone is not at all necessary to the production of this accident by muscular contraction, although such a change is perhaps generally present at the time of the fracture, and therefore deserves to be considered as a predisposing cause of it.

When the osseous tissue is preternaturally brittle, mere muscular spasm is capable of producing fracture, as in the interesting case related by Dr. Lente of a boy, twelve years of age, who broke both his thigh-bones during a severe epileptic convulsion.

2. SIMPLE FRACTURES.

The symptoms of fracture may be considered, first, in relation to the broken bone itself; secondly, in relation to the soft parts; and thirdly, in relation to the constitution.

So far as the affected bone is concerned, there are only three symptoms which are at all reliable as evidences of the existence of fracture. These are crepitation, deformity, and preternatural mobility.

Crepitation is the peculiar noise which is produced by rubbing the two ends of the broken bone against each other, and is always, when well marked, characteristic of the nature of the injury. In general, it can be both heard and felt. In order to produce it, it is necessary that the ends of the fragments should be at least partially in contact, and hence, to effect this object, the surgeon is often obliged, as a preliminary step, to extend and counter-extend the affected limb. For this reason it is always absent in impacted fractures, while in fractures of the leg and forearm, involving only one of the bones, it is usually very faint and indistinct from the difficulty of moving the broken pieces upon each other. Much swelling or great depth of muscle will also obscure the crepitation.

Deformity, although not invariably present, is, in general, one of the most prominent symptoms of fracture. It exhibits itself in different forms, as in shortening, or in angular displacement, and usually occurs at the time of the accident, the cause which produces the fracture being itself the cause of the distortion. Occasionally, however, it does not come on until several hours, or perhaps even days after; as, for example, in a partially impacted fracture of the neck of the thigh-bone, in which the patient may be able to walk some distance, and yet the limb retain its normal shape. The degree and character of the deformity are greatly influenced by the nature and situation of the fracture. Thus, the more oblique a fracture is, the greater, as a general rule, will be the displacement of the ends of the fragments, and, consequently, also, the distortion of the limb. Sometimes, as in fracture of the patella, the olecranon and calcaneum, the deformity manifests itself by a vacuity or hollow at the natural situation of the bone, and by an unusual protuberance upon the lower part of the thigh, arm, and leg, caused by the separation of the upper fragment by the action of the extensor muscles. Finally, the deformity may be much increased by the extravasation of blood consequent upon the injury, or by the effusion of serum and lymph consequent upon the resulting inflammation.

Preternatural *mobility* is, next to crepitation, the most important and reliable symptom of fracture. There are few instances in which it is wholly absent, while in the great majority it exists in a well-marked, if not in a high,

degree. It usually appears immediately after the occurrence of the accident, and continues to a greater or less extent until the completion of the consolidation of the fracture. In the impacted fracture it may be entirely wanting, or remain absent until the ends of the fragments are unlocked. In fracture of the leg and forearm, involving only one bone, the degree of mobility is sometimes very slight, the sound bone impeding or altogether preventing the motion of the affected one.

In every fracture produced by external violence, whether applied directly or indirectly to the part, there must, of necessity, be a certain degree of *contusion* of the soft structures at the seat of the injury. It may be limited to the skin and subjacent cellular tissue, or it may extend deeper, and involve the muscles, aponeuroses, vessels, nerves, periosteum, and even the bone itself. In consequence of this occurrence, there is not unfrequently a considerable effusion of blood beneath the skin, and in the connective tissue of the muscles, causing distension and sometimes discoloration. For the same reason, there is generally a good deal of pain, often of a sharp, spasmodic character, which is aggravated by the slightest motion of the parts, and by every attempt at exploration. It has its seat rather in the soft structures than in the affected bone, although the latter generally participates in it, and by the sharpness of its extremities frequently increases its severity. A short time after the accident, swelling usually sets in, and often proceeds to a considerable height, its degree being greatly influenced by the amount of injury sustained by the soft parts, by the motion to which the fractured bone is subjected, and by the state of the system at the time of the accident. As a general rule, it may be affirmed that the pain and swelling are less in fractures produced by muscular contraction than in such as are caused by mechanical violence, whether directly or indirectly applied.

Inability of motion in the affected bone, and in the portion of the limb articulated with it, is generally a prominent symptom. Cases, however, occur in which it is either very slight or where it is entirely absent. In an impacted fracture of the thigh, for instance, a patient has sometimes been known to be able to walk for a considerable distance without the slightest assistance even from a cane, and in fracture of the clavicle, I have repeatedly seen him carry his hand to his head, and even circumduct the arm.

Another symptom, consequent upon fracture, is *spasm* of the muscles at the seat of the injury; it is most common in nervous, irritable persons, and generally comes on within a short time after the accident. When severe, as it frequently is, it constitutes a source of real suffering. It is aggravated by motion and inflammation, and may continue, with more or less interruption, from several hours to several days.

Finally, the patient often experiences a sense of *numbness* in the affected part, reaching frequently to the distal extremity of the limb. This may be caused either by the injury sustained by a nervous trunk at the time of the accident, or by the compression of the soft parts by extravasated blood, or the ends of the broken bone. Sometimes it does not arise until inflammation has supervened, and then it is generally owing to the presence of an unusual quantity of serum and lymph.

The amount of *constitutional disturbance* in fracture varies, in different cases, from the slightest exaltation of the normal action to the most intense excitement, depending mainly upon the nature of the fracture, the degree of violence sustained by the soft parts, and the state of the system at the time of the accident. In very many cases, there is an entire absence of traumatic fever, while in others it is present in a very high degree, the pulse being strong and frequent, the countenance flushed, the skin hot and dry, the thirst intense, and the appetite and sleep much impaired, if not totally suspended. In the more severe forms of fracture, the patient often experiences a severe

shock, from which he may not fully recover for many days, or which may even terminate in death. Whenever there is much constitutional disturbance, the affected limb will be apt to be in a high state of inflammation, the parts being hot, swollen, and painful, and, at times, even covered with small vesicles, such as a heedless observer might easily mistake for the phlyctenulæ which so often announce the occurrence of gangrene.

Displacement of the Ends of the Fragments.—The displacement of the fragments shows itself, as already stated, in two principal directions, the longitudinal and horizontal. Of these, the former is by far the more common, as it is present, to a greater or less extent, in nearly all cases of oblique fracture, in whatever portion of a bone occurring. It is produced by the overlapping of the extremities of the broken bone, the lower being drawn above the upper, or the one riding over the other, as it is sometimes expressed. The extent of this form of displacement varies from the slightest possible change in the length of the affected bone to two, three, and even four inches, which may be regarded as its maximum. It is generally most conspicuous in fracture of the femur and humerus, while in fracture of the forearm and leg, affecting only one bone, it is either very slight or totally wanting. Finally, the displacement may be lateral, anterior, or posterior, according to the nature of the exciting cause.

In the horizontal displacement, the lower fragment may form an angle, more or less acute, with the superior, thereby giving the bone an arched appearance; or, the two pieces remaining in contact with each other, the inferior one may perform a rotatory movement, while the other continues perfectly stationary. In some cases, as in fracture of the lower end of the radius, there is often considerable lateral displacement, and similar phenomena are apt to occur in fracture of the tibia and fibula at or near the ankle-joint.

The causes of displacement are, muscular action, mechanical violence, and the weight of the limb connected with the broken bone. Of these the first is the most common, and it need hardly be added that a knowledge of the fact is of the greatest practical importance in regard to the proper management of the injury. In some instances the displacement is entirely produced by the vulnerating body. Thus in fracture of the nose, the blow which inflicts the injury also displaces the fragments. The wheel of a carriage passing over the leg may not only break its two bones, but likewise cause great deformity by forcing asunder their extremities. Finally, the displacement may be occasioned by the weight of the limb connected with the injured bone, as in fracture of the clavicle, in which the outer fragment is drawn downwards and inwards by the weight of the shoulder and arm.

Diagnosis.—The most valuable symptoms of fracture, diagnostically considered, are, crepitation, deformity, and preternatural mobility. The co-existence of these symptoms is unmistakably denotive of the nature of the accident, but, unfortunately, they are not always associated; one or even two may be absent, and hence a case that ought to be treated in the most prompt and decisive manner, may, for the want of a correct appreciation of its character, be either entirely neglected, or, at all events, grossly mismanaged. Besides, the symptoms here enumerated may be simulated by other accidents, especially dislocation, and certain affections of the joints.

The crepitation of fracture is sometimes imitated by the grating produced by an effusion of plastic matter into a joint, the sheath of a tendon, or a synovial bursæ; and the difficulty may be still further increased, if, under such circumstances, the suspected fracture is situated near a large articulation. In general, however, it will be sufficiently easy to distinguish between them by a consideration of their respective characters. In fracture, the crepitation can be both felt and heard; it is dry, coarse, or rough, resembling

the sensation and noise produced by rubbing two unequal surfaces against each other. The crepitation from plastic matter, on the contrary, is of a finer quality, or more faintly marked, and may be likened to the feel and noise caused by gently rubbing over each other two pieces of sole leather; in a word, it lacks the roughness and distinctness of the other. Moreover, it must be remembered that it is never present until after the occurrence of inflammation, whereas the other always exists from the very beginning of the accident. Crepitation, it is true, might be produced in consequence of previous disease, and the possibility of such an occurrence should not be lost sight of in our examinations. Finally, when the case is obscure, the crepitation may sometimes be detected by the aid of the stethoscope, especially when the bone is thickly covered by muscles, as in fracture of the neck of the femur within the capsular ligament, or in fracture of the ribs in corpulent subjects. This mode of examination was originally suggested by Lisfranc, but, as the expectations held out by him have not been realized, few practitioners of the present day resort to it.

The deformity in fracture manifests itself either in shortening, in lateral displacement, or, as not unfrequently happens, in the two united. Elongation is never present, in which respect fracture differs from certain forms of dislocation, in which lengthening is a prominent symptom. The degree of shortening varies from a few lines to several inches, and is, therefore, an occurrence of much value in a diagnostic point of view. It may exist from the commencement of the accident, or it may not show itself until some time after its occurrence, being materially influenced by the action of the muscles, and the nature of the treatment. Whatever the degree of the deformity may be from these causes, it may always be effectually removed by extension and counter-extension, either alone or aided by pressure; but as soon as these forces cease to operate, it is usually immediately reproduced, which is not the case in dislocation. Here, the reduction having been effected, the parts generally retain their relations until some new cause produces a new displacement.

Too much stress cannot be placed upon preternatural mobility as a sign of fracture. Next to crepitation, it is unquestionably the most important diagnostic symptom. There may be unnatural latitude of motion in a dislocation, but this can happen only when the accident is attended with extensive laceration of the ligaments of the joint; in ordinary cases there is either an absence of motion, the displaced bone being firmly fixed in its new position, or the motion is so slight as to bear only a faint resemblance to that observable in fracture.

The general expression of the affected parts, fig. 326, often affords valuable diagnostic signs. The deformity, for example, of the hand and wrist, in fracture of the lower extremity of the radius; the eversion of the toes in intra-capsular fracture of the femur, and the shortened and retracted appearance of the arm in fracture of the humerus, are generally unmistakable evidences of the nature of the accident. The manner in which the patient inclines his head and supports the elbow and forearm in fracture of the clavicle, is too significant to be overlooked by any one that has ever witnessed it. The peculiar aspect and attitude of a broken thigh,

Fig. 326.

Fracture of the lower end of the radius.

conjoined with the utter helplessness of its muscles, or the absence of all voluntary power, are signs which seldom admit of misinterpretation.

The pain, swelling, and loss of function, present in suspected fracture, are of no practical value, as similar phenomena are produced by other injuries, as contusions, wounds, sprains, and dislocations. Their occurrence being wholly accidental, must, therefore, not influence the surgeon in his attempt to form a correct estimate of the real nature of the case, or the relative value of the symptoms of this and other analogous affections.

Mode and Time of Examination.—Although the symptoms which have now been described will generally be sufficient, along with a careful consideration of the history of the case, to enable the surgeon to determine the diagnosis of this lesion, especially if he will take the trouble of comparing them with the symptoms of other accidents, it will, nevertheless, be proper, in concluding this branch of the subject, to say a few words respecting the manner of conducting the examination of the affected parts, as the ultimate issue of the case will greatly hinge upon this circumstance.

My experience satisfies me that few practitioners know how to examine a broken limb. They take hold of it as if they were afraid of giving pain, or causing suffering, and the consequence is that the result is often most disastrous. I am far from wishing to be understood as being an advocate of rough surgery; on the contrary, no one abhors it more than I do, yet there are times and circumstances when the best interests of the patient demand that he should be most thoroughly examined, no matter what amount of pain he may be compelled to undergo. But there is no need any longer of such infliction now that we can prevent suffering by anæsthesia. The patient being rendered insensible, perquisition is performed at the surgeon's leisure, slowly and deliberately, and with an eye to the ultimate result, not forgetting self. The sooner such manipulation is instituted the better, for there will be less likely to be inflammatory swelling and other obstacles calculated to embarrass our progress and obscure the diagnosis. Fractures of the shafts of the bones will rarely afford any difficulty, inasmuch as their symptoms are generally so well marked that the most casual inspection will be sufficient for their detection. But it is different when the lesion involves their extremities. Here the most laborious and pains-taking examination sometimes hardly enables the practitioner to form an accurate judgment respecting the real nature of the injury. Under such circumstances, therefore, he must not content himself with one or two trifling explorations, but he must handle the parts again and again, until he has thoroughly established the diagnosis. If, after repeated trials, he is still in doubt, it is his duty to state this doubt to his patient, and to seek the advice of a professional brother in order to aid him in solving the question. By adopting this course, he will be more likely to do justice to his patient, and at the same time escape personal blame.

For the reason already assigned, the parts should always be examined as early as possible after the infliction of the injury, but I would make no exception where some time has elapsed, and a good deal of swelling has supervened; for it is impossible that a broken bone, or the parts by which it is covered, should do well as long as its extremities are displaced, and thus permitted to fret, irritate, and perhaps prick the muscles and other structures in contact with it. Hence, the sooner the fracture is adjusted or the parts are placed in their natural relations, the more likely will they be to do well, and escape the ill effects of inflammation. There are instances, however, where, as may be supposed, immediate interference might prove highly prejudicial, using the term immediate here with reference to the surgeon's first visit. The patient may have been neglected, or his attendant may have mistaken the nature of the case, and in this manner several days may have passed

uselessly away. The limb is now found in a very swollen and painful condition, intolerant of the slightest manipulation, nay, perhaps in an erysipelatous condition. To make an elaborate examination under such circumstances would be highly improper; for it could not fail to aggravate the morbid action, and perhaps urge it on to gangrene. The hand is withheld; the limb is placed in an easy position, and antiphlogistics, both local and constitutional, are freely plied; when action has sufficiently abated, but not until then, the proper examination is effected, and the diagnosis, if possible, established.

The mode of conducting the examination varies. In the upper extremity the surgeon will usually be able to get on without any assistance, but in fracture of the thigh and leg it will often be necessary to make extension and counter-extension while the parts are subjected to methodical manipulation. When there is marked displacement, the merest touch of the hand will generally suffice to detect the nature of the lesion; but, under opposite circumstances, the nicest digital exploration may be required before a satisfactory result can be obtained. In general, it will be necessary to make pressure and counter-pressure at the seat of the injury, and to rotate the portion of the limb below the fracture upon its axis. In this manner, especially if proper extension have been made, the ends of the fragments being brought in contact may be made to yield the friction-sound, previously described, and at the same time display the full extent of their mobility. Another procedure is to grasp the two extremities of the suspected bone, and then, while the superior one is firmly held with the thumb and fingers, to roll the inferior upon its axis. If, while this is being done, both parts move together, the probability is that there is no fracture, but if the lower should move, and the upper remain stationary, there can be no doubt of the fact.

Mode of Repair.—The mode of repair in fracture is precisely similar to that of the soft parts, the only difference being the superaddition of the carbonate and phosphate of lime, or the earthy constituents of bone. In order, however, to be thoroughly understood, it is necessary to study it with reference to the situation and disposition of the ends of the fragments of the broken bone, as the rapidity and perfection of the cure are greatly influenced by the manner in which they are arranged and held together during the treatment. The more perfect this is, the more complete, generally, all other things being equal, will be the reunion. For practical purposes, the whole subject of repair may be considered as consisting of four stages.

The first stage, which, on an average, extends from the first to the eighth day, is one altogether of preparation, in which nature clears away the rubbish, and places the ends of the fragments in a suitable condition for the process of repair, properly so called. The blood which was extravasated at the moment of the accident, at and around the seat of the fracture, is in great degree, if not entirely, absorbed; the inflammatory products, especially the intermuscular, are also disposed of; the swelling subsides, the pain disappears, and there is no longer any tendency to spasmodic action, the muscles having become calm and quiet under their new relations. Any traumatic fever that may have been present will also be found to have vanished. Thus the part and system have happily passed through the preliminary stage of the reparative process.

If the parts be examined at the commencement of the second stage, it will be seen that the ends of the broken bone, as well as the periosteum, and the other soft parts in their immediate vicinity, are abnormally red and injected, and covered by plastic matter, resembling very much in its color and consistence pale currant jelly, or a thick solution of isinglass. It is usually most abundant upon the surface of the bone, and is often sufficient to lift up the periosteum; a considerable quantity is also generally seen between the peri-

ostium and the muscles, and even among the muscles themselves, all these structures being more or less actively engaged in the process of repair. A similar substance, but usually less abundant, is poured out within the medullary canal, the lining membrane of which is also in a state of inflammation, as is evinced by its discolored and injected condition. In the latter part of this stage, which lasts from the eighth to the twentieth day, the newly-effused matter, which differs in none of its properties from that which serves to unite a recent wound, becomes gradually more and more solid, until at length it assumes the consistence of a concrete substance.

The third stage is characterized by still further changes in the consistence of the effused matter, and by its gradual conversion, first into fibro-cartilage, then into cartilage, and finally into bone; or, more correctly speaking, cells are developed in the new substance, into which the osseous granules are deposited, the whole process bearing the closest possible resemblance to that which takes place in the formation of the original bone. The period at which the bony matter begins to be developed in the adult varies from the eighteenth to the twenty-fifth day, its appearance and progress being influenced by numerous local and constitutional causes, to be described under another head.

The ossific process proceeding in the way now described, two layers of bony matter are formed, one lying upon the outer surface of the fragments, the other within the medullary canal, each extending some distance beyond the seat of fracture, as is seen in fig. 327. To these two strata is confided

Fig. 327.

Fractured tibia, bisected, to show the formation of new bone beneath the periosteum, and within the medullary canal.

the office of temporarily supporting the fragments, or of holding them together until their ends are permanently united by osseous substance; a circumstance which does not take place, as a general rule, until several months later. To this new matter the older pathologists applied the term *callus*, in consideration of its hardness, which, when the process of repair is completed, is fully equal to that of the original bone, which it also closely resembles in its structure. From its office, the outer and inner callus, or that which invests the broken bone and lies in its medullary canal, is now universally known as the temporary or provisional callus, while that which is placed between the two ends of the bone, and thus serves to cement them together, is designated as the definitive or permanent callus. The temporary callus is, figuratively speaking, nature's splint, or the means which she employs to support the fractured bone until the continuity of the fragments is re-established by the deposit and organization of osseous matter between their extremities.

As the first stage in the reparative process is one of preparation, so the last is one of completion; reunion having been effected, nature now busies herself in removing whatever is redundant or superfluous, thereby fitting both bone and muscle for the resumption of their respective functions. The provisional callus, having ceased to perform its office as a splint, is gradually brought under the influence of the absorbents, its more superficial portions being taken away first, and afterwards the more deep, until the broken bone regains not only its original form and volume but also its pristine smoothness, all evidence of fracture disappearing, excepting, perhaps, a little seam or ridge corresponding with the line of junction of the two fragments. While

these changes are going forward upon the exterior of the bone, nature is busy at work in its interior, disposing of the provisional callus in that situation, and thus restoring the medullary cavity to its normal condition. This can occur, however, only when there has been perfect apposition of the ends of the fragments; for when the reverse is the case, the new bone remains permanently in the canal, as is shown in fig. 328, from a specimen in my collection.

Fig. 328.

United fracture, showing the condition of the medullary canal.

Any cartilaginous or osseous matter that may have been formed between the periosteum and muscles, or among the muscles themselves, is likewise removed as a substance foreign to the part, and therefore useless, if not positively prejudicial.

It will thus be seen that the fate of the provisional callus is precisely similar to that of the plasma which is effused between the edges of a wound, both gradually disappearing as soon as their service can be dispensed with, or as soon as the parts have acquired sufficient firmness to enable them to maintain their connection. The period required for effecting these changes in a broken bone varies from a few weeks to several months, according to the circumstances of the case.

Such is a brief but accurate account of the several changes which attend the repair of bone in the more simple forms of fracture, when the ends of the fragments are thoroughly maintained in their natural relations. Under such circumstances there is but little need of provisional callus; the ends of the fragments soon inflame, and unite almost by the first intention. But it is seldom that a patient is so fortunate; on the contrary, the fracture being generally oblique, is subject to more or less displacement, thus compelling nature to provide a temporary splint by the formation of provisional callus. I do not believe, however, as has recently been so much insisted upon, that there ever is an entire absence of this kind of callus, however intimately the ends of the bones may be in apposition with each other. To prove the truth of this remark, it is only necessary to examine the numerous specimens of fracture of the skull and other portions of the skeleton in our museums; they will conclusively demonstrate that even the most simple fracture, unaccompanied by the slightest displacement, is never repaired without the development of a certain quantity of osseous matter upon its surface. At the same time it must be admitted that the provisional callus, in such cases, is very small, and that it bears no proportion to the enormous amount of substance that is so often formed when the ends of the bone are separated from each other. Under the latter circumstances, nature labors under great disadvantage, and is, therefore, obliged to make extraordinary efforts to effect reunion, which she can do only by the development of a large provisional callus. From these facts, then, we may deduce the general law that the quantity of new bone is always, other things being equal, in proportion to the contact of the ends of the fragments, being small when this is very accurate, and more or less large when it is imperfect.

When the ends of the bone are not accurately approximated, the first thing that nature does is to round off their edges, and to close the medullary cavity by a shell of new bone, as in fig. 329; the next, is the formation of a large

provisional callus for the more secure consolidation of the fracture. The whole process is one of time and labor, not of speed and ease, as in the

Fig. 329.

Appearances of the ends of the fragments in old, ununited fracture.

former case. When the ends are completely separated but opposite, or nearly opposite to each other, they are generally united by a bridge of new bone, extending from one to the other, as in fig. 330, and ultimately affording sufficient strength for the support of the weight of the body upon the affected limb. Or, instead of this, especially in elderly subjects, the junction is effected by fibrous, fibro-ligamentous, or cartilaginous matter. Finally, osseous union is not impossible when the extremities of the fragments overlap each other to an extent even of several inches, provided they are in contact; for in this case inflammation is established in the contiguous surfaces, followed, after a long time, by a large permanent callus. We see many curious specimens illustrative of this fact, though, in general, the union is ligamentous.

There are certain pieces of the skeleton in which in fracture no provisional callus ever forms. Such are the olecranon, acromion, patella, and neck of the femur. Instead of uniting by osseous matter, as the other bones do, the cure is generally effected through the medium of fibrous, ligamentous, or cartilaginous substance, and the consequence is that the part commonly remains weak ever afterwards. Various causes conspire to produce this result, as the difficulty of maintaining the contact of the broken surfaces, and the inordinate secretion of synovial fluid, which, mingling with the effused plasma, thus impairs its vitality, and renders it unfit to become the nidus of bony deposit; but the most efficient one of all is the want of nourishment of the smaller fragment produced by the laceration of the nutrient vessels. Thus, in fracture of the neck of the femur within the capsular ligament, the upper piece, consisting of the head of the bone and of a portion of its neck, the only connection between it and the rest of the body, is by the round ligament, the arteries of which are altogether unequal to its proper support.

Treatment.—The leading indications in the treatment of fracture are to procure reunion and to prevent deformity. Before we proceed to speak of the manner of fulfilling these indications, it is proper that we should lay down certain rules for the transportation of the patient and the manner of preparing his bed.

Fractures are often received by persons at a considerable distance from their homes, either on the road, in the field, or at some secluded building. This renders it necessary to carry them to their own houses or to some hospital, in order to undergo the proper treatment. In fractures of the superior extremity, clavicle, scapula, or ribs, the requisite dressings may be applied at once; or, if this be not convenient, the patient may either walk or ride, the

Fig. 330.

Fracture of the arm-bone of a chicken. From a specimen in the author's collection.

suffering limb being supported in a sling, or, as in the case of a broken rib, the body may be swathed with a long napkin. It is only, as a general rule, in fractures of the inferior extremity, spine, or pelvis, that the patient will require to be carried, and the best way of effecting this, if the distance be not too great, is to place him upon a narrow door, a long shutter, or two pieces of board, supported by two cross-pieces, the ends of which are intrusted to four assistants, a pillow and comfort having been previously put under the patient's head and body. Or, instead of this, the transportation may be conducted by means of an easy furniture-car, provided with a good mattress, and drawn slowly along in order to avoid jolting. Whatever mode be adopted, the limb should be temporarily splinted, and placed in as comfortable a position as possible, an intelligent person sitting by his side, and rendering such aid as may be required on the way. In carrying him to his chamber, four assistants will generally be necessary, two to support the body, which they do by crossing their arms behind the trunk, and interlocking their hands, and two for the lower extremities, the surgeon himself taking charge of the broken one.

A comfortable *bed* is to a man with a broken thigh or leg an indispensable article, and the practitioner who fails to give the proper instructions respecting it, is guilty of a gross dereliction of duty. Indeed, for his own sake hardly less than for that of his patient, he should give prompt attention to this subject, inasmuch as it is impossible to effect a good cure without it. When we reflect upon the fact that in fractures of the lower limbs, the patient is often compelled to remain in the recumbent posture for weeks together, and how difficult it is, in most cases, to maintain the requisite extension and counter-extension, the force of this injunction cannot fail to be perceived in its true light. The essentials of a good fracture-bed are, first, firm and stout slats, instead of a cord or sacking bottom; secondly, a well constructed mattress of hair, moss, or cotton; and thirdly, a hole in the mattress, opposite the buttock, for the evacuation of the bowels, the opening being closed by a door of similar manufacture, and furnished with hinges and other appliances. If long confinement be necessary in one posture, or if the patient have been worn out by previous disease, an air-mattress may be required, in order to prevent bed-sores. If a sheet be used, its edges should be carefully secured to the sides of the mattress, otherwise it will soon become rumpled, and thus act as a source of annoyance.

It has been a question which has been much mooted in modern times, whether a fracture should, as a general principle, be set as soon as possible after its occurrence, or whether time should be allowed for the subsidence of the resulting inflammation. It appears singular that upon a subject so clear as this there should be any difference of opinion. It certainly requires no great knowledge of the nature of accidents to discover why such cases should receive the earliest possible attention; as long as the ends of the fragments are permitted to remain apart, their tendency inevitably must be to excite spasm and inflammation, thereby increasing the suffering of the patient and retarding his cure. Of this fact there can be no doubt, and hence my plan has always been to treat every case of the kind that has come under my observation as early as possible with the bandage and splint; applied, of course, not firmly, but gently and cautiously, simply with a view of giving support to the parts, and thus preventing further mischief from the sharp and projecting ends of the broken bone. I can hardly imagine an instance to which such treatment would not be adapted. I certainly have never seen one. We might as well expect that a man's limb would do well if it had a thorn imbedded in its muscles, as that it would be comfortable with two pieces of bone sticking in them. It is an absurdity to think it could be otherwise.

Apparatus.—Before an attempt be made to set the fracture, it is necessary

to provide the requisite apparatus for effecting its maintenance. The means which are employed for this purpose are splints, cushions, bandages, and adhesive strips.

Splints are made of various materials, as wood, trunk-board, leather, felt, gutta percha, tin, and iron, according to the nature of the fracture or the fancy, whim, or caprice of the practitioner. In fracture of the thigh and leg, especially in that form which requires permanent extension and counter-extension, the best article is *wood*, adapted to the size and shape of the limb, at the same time that it combines lightness with strength. In fracture of the superior extremity, particularly of the humerus and of both bones of the forearm, splints made of *trunk-board* generally answer best, as by a little manipulation, after immersion in hot water, they may easily be moulded to the form of the limb. A piece of pasteboard affords a capital support to a broken jaw or finger. Unoiled *leather* and *felt*, the latter being rendered stiff by gum shellac, make excellent splints, which I have often used with much satisfaction in fractures both of the upper and lower extremities. Previously to applying them, they must be softened in hot water, the sharp angles and edges having been pared off with a knife. The *tin case* I have employed a great deal, especially in fracture of the humerus at the elbow, and of the tibia at the ankle, ever since I entered the profession. *Iron* splints, in the form of the double inclined plane, are much in vogue in England; but in this country, little use is made of them. Many years ago, I was induced to make trial in a few cases of fracture of the condyles of the humerus and of both bones of the forearm, of a splint composed of light *wire*, adapted to the size and shape of the limb; but not answering my expectations, on account of its not being as manageable as I had been induced to expect, I soon abandoned it. For fracture of the bones of the hand and fingers, *carved* splints are sometimes employed. During the last twenty-five years an immense number of patented apparatus have been presented to the notice of the profession; but I am not aware that any of them have come into general use, or that they possess any particular advantage over the more common contrivances.

Splints made of *gutta percha* have recently come into vogue, not, perhaps, without reason on account of their neatness and easy adaptation. Cut into a proper shape and size, they may, after having been dipped in hot water, be readily moulded to the form of the part, which, upon cooling, they always retain. Previously to applying them, they are lined with wadding, or old linen, to prevent irritation of the skin, which this substance might otherwise induce.

Mons. Maisonneuve employs splints made by saturating a piece of cloth, linen, or muslin, with a thick solution of plaster of Paris in water, and then doubling the cloth upon itself as many times as may be requisite to obtain the proper strength, when it is immediately secured to the limb with a roller. The advantages of this apparatus are that it dries in a few minutes, and that it thus forms almost instantaneously a firm, stiff shell for the broken limb, perfectly adapted to its inequalities, exceedingly light, indisposed to absorb discharges, and admitting of easy application and removal.

Fracture-cushions are generally made in the form of small bags, stuffed with bran, fine chaff, cotton, wool, hair, moss, or any other soft material. They are designed to fill up the inequalities between the splints and the limb, and must necessarily vary in shape, length, breadth, and thickness, according to the exigencies of each particular case. Instead of cushions, simple pads or compresses are often used, especially in fractures of the superior extremities. For enveloping short splints, calico or muslin is employed; or, what I always prefer, sheet wadding. The same article answers admirably for filling up the inequalities between the short splints and the affected limb. Bags filled with sand are sometimes very convenient and useful, especially in frac-

tures of the leg. Stretched along each side of the limb, they keep up steady, equable pressure, well calculated to prevent displacement of the fragments.

The fracture *bandage* should consist of coarse linen, calico, or muslin, and should possess sufficient strength to answer the purpose for which it is intended. Nothing is worse, or more likely to cause annoyance, than a thin, flimsy bandage. If the material is new it should be washed before it is used, to rid it of its starch, and the selvage should be torn off to prevent it from exciting irritation, or producing welts in the skin. The bandage most commonly used is the ordinary single-headed roller, of a length and breadth suitable to the affected limb or part of the body to which it is to be applied. In fractures of the leg and thigh, especially such as are of a complicated character, the bandage of Scultetus may often be advantageously employed, as it can be easily undone and reapplied without the slightest disturbance of the limb. It consists of numerous strips of the ordinary roller, of equal or unequal length, according to the size and shape of the part which they are intended to surround. In applying them, they are arranged in such a manner that one overlaps another nearly one-half.

The practitioner cannot observe too much caution in the use of the bandage in the treatment of fractures. It is an agent for good or for evil; for good, if applied properly; for evil, if applied improperly. Its object is twofold: first, to afford uniform compression of the limb, thereby preventing swelling and spasm; and secondly, to retain the necessary apparatus. Its application is governed by the general principles laid down in a former part of the work, the rule being always to begin at the remote part of the limb, and to proceed thence upwards some distance beyond the seat of the fracture, care being taken to put it on with sufficient tightness to fulfil the object for which it is designed, without incurring the risk of interrupting the circulation, or of doing other mischief. If it be too slack to support the parts in a proper and uniform manner, it will be useless; if, on the other hand, it be too tense, it will give rise to severe inflammation, swelling, and even gangrene. For the want of this precaution, many limbs have been lost, and a still greater number rendered permanently useless.

American surgeons are now much in the habit of employing *adhesive strips* in the treatment of fractures, either as retentive means, or for the purpose of effecting and maintaining extension and counter-extension. In their latter capacity, I was the first, I believe, to call attention to the subject, in my *Treatise on the Diseases of the Bones and Joints*, published in 1830. I had witnessed their excellent effect in the practice of my former preceptor, Dr. Joseph K. Swift, of Easton, in a case of oblique complicated fracture of the leg, attended with so much injury of the soft parts as to interfere effectually with the employment of the gaiter and other counter-extending bands. The man had suffered a great deal of pain, until his patience was almost exhausted, when trial was made with adhesive strips, carried along the sides of the limb towards the knee, their free extremities being tied below the foot, to the transverse block connecting the two splints. Great comfort was the consequence, and the case progressed favorably from that time forward. Soon after I had occasion to use adhesive strips in a case of my own, with results equally gratifying. Since then I have employed this substance with great advantage in the treatment of fracture of the clavicle, olecranon, and patella, as well as in the treatment of fracture of the thigh and leg. Valuable papers have been published on this mode of management, within the last few years, by Dr. E. Wallace, Dr. Gilbert, and Dr. Neill, of this city, and Dr. Crosby, of New Hampshire. In a short article in the *Philadelphia Medical Examiner* for 1852, I also called attention to the subject, giving very briefly the results of my experience up to that period. Dr. John Swinburne, in a paper recently published on fractures of the long bones, states that he has

been in the habit, for several years past, of treating these injuries almost exclusively with the aid of adhesive plaster, generally dispensing with the roller and often even with splints. The importance of this agent, for the purposes referred to, will be fully pointed out under the head of special fractures.

Coaptation and Dressing.—Everything having thus been provided, and the requisite number of assistants obtained, the surgeon proceeds to restore the broken pieces to their original situation, or, to use a common expression, to set the fracture. This may be done either by simple manipulation, or pressure and counter-pressure, or by this means aided by extension and counter-extension. The former will usually suffice in fracture of the upper extremity, the jaw, and nose, while the latter will generally be required in fracture of the thigh and leg; in either case, the affected limb should be held as quietly as possible, not only during the adjustment of the fragments, but also during the application of the dressings. It need hardly be observed that these manipulations should be conducted in the most gentle manner, with an eye both to present comfort and future consequences. There is no department of surgery, where the humane practitioner may exhibit his skill and sympathy to greater advantage than in this, or where his conduct will be more closely watched and commented upon, than on such an occasion.

Extension and counter-extension are always necessary in oblique fractures of the thigh and leg, attended with displacement. By the term extension is understood the force which is required to draw the upper end of the lower fragment to a level with the lower end of the upper fragment, in order to place them in their natural relations; by counter-extension, on the contrary, is implied the resistance which is employed to prevent the limb, or even the body, from being dragged along by the extending power. The extension is generally made upon that part of the limb which is articulated with the lower piece, and the counter-extension upon that which is articulated with the upper. Thus, for example, in fracture of the shafts of the bones of the forearm, the extending power acts upon the hand, and the counter-extending power upon the arm, while in fracture of the body of the humerus the two forces are respectively exerted upon the forearm and the chest; and so in regard to fracture of the inferior extremity. When but little muscular resistance is anticipated, as in a child or feeble person, the extension and counter-extension may be applied directly to the two fragments, but at as great a distance from the seat of the injury as practicable. On the whole, however, I give the former method a decided preference, as it is much less likely to irritate and worry the muscles.

In reducing a fracture, the injured parts should be put in the most favorable position for relaxing the muscles, and the extending forces should be applied in as slow and gradual a manner as possible. If the limb be suddenly pulled, or stretched by fits and starts, the muscles which are concerned in effecting and maintaining the displacement will inevitably be thrown into violent spasmodic contraction, thus not only causing pain but, perhaps, severe injury to the soft structures, if not actually frustrating our intention. The degree of force which should be used in making extension must vary according to the amount and character of the displacement, and the number and power of the muscles concerned in producing it; in all cases it should be sufficient to remove the shortening of the limb, or, what is the same thing, to restore it to its normal length, and to surmount every obstacle that opposes the reduction. The extension is always begun in the direction of the lower fragment, and is afterwards continued in that of the injured bone, until the object of its application has been attained. The ends of the fragments being now pressed into their natural situation, the fractured part of the limb is enveloped in a suitable bandage, and immovably fixed by splints, every hollow between them and the skin being filled with cotton, to ward off

pressure. A sling, to suspend the hand and forearm, completes the dressing, if the fracture occupy the superior extremity.

In fracture of the thigh and leg, the patient lies in bed until the ends of the broken pieces have become completely consolidated, or, at all events, until he has made such progress towards recovery as to admit of the use of the starch bandage, and of exercise in the open air upon crutches. During his confinement, the limb is placed in the most favorable manner for relaxing and resting the muscles which pass over the fracture; for this purpose it should be put in the extended position, and be well secured with apparatus designed to maintain permanent extension and counter-extension. In some cases the limb is placed in the semi-flexed position, over a double inclined plane, but such a course will seldom be necessary or proper, except, perhaps, in fracture of the upper part of the body of the thigh-bone, attended with great and obstinate displacement of the superior fragment, in consequence of the joint action of the psoas and iliac muscles. In transverse fracture of the patella, the thigh and leg are sometimes placed over a single inclined plane, the foot being considerably elevated above the level of the trunk.

After-treatment.—The fracture having been reduced and dressed, the patient is carefully watched, in order that he may be safely conducted through his long and arduous confinement. His diet, for the first few days should be light and cooling, and the bowels should be opened, if necessary, by some mild aperient, as a dose of castor oil, Epsom salts, or citrate of magnesia. If fever supervene, the antimonial and saline mixture is freely used, aided, if the symptoms are urgent, and the patient is plethoric, by venesection, although such a procedure will rarely be called for. Action having subsided, the patient gradually resumes his accustomed diet, being still careful, however, to err rather upon the side of abstinence than on that of excess. Pain is relieved by anodynes; the bladder, if necessary, by the catheter.

During all this time the fractured limb is carefully watched, the patient being visited for a while at least once a day, or, if the case be at all troublesome, even twice a day, until all danger of mischief is over. If there be considerable pain and swelling, it will be well to remove the dressings at the expiration of the first twenty-four hours, otherwise they may be retained for some time longer. While I am an advocate for the careful watching of the dressings, I am opposed to frequent change, as calculated to produce injurious disturbance in the ends of the broken bone, and impediment in the process of repair. If the first dressings have been applied lightly, as they always should be, and the parts be well seen to afterwards, it is hardly possible for the patient to do badly. The great danger, in nearly all cases, as far as the safety of the limb is concerned, is during the first week; that passed, there is seldom any risk.

In nearly all fractures of the long bones there is apt to be more or less spasm, jerking or twitching of the limb, coming on within the first ten or twelve hours after the accident, much to the discomfort both of the part and system. This is owing partly to the pressure and irritation produced by the ends of the fragments, and partly to the inflammation of the muscles, and is in general easily remedied by the rectification of the displacement, aided by warm applications and a full anodyne, either alone or in union with camphor and tartar emetic. The worst forms of this complaint are met with in nervous, irritable persons, in whom it occasionally persists with great obstinacy, despite our remedies, for a number of days, much to the annoyance of all concerned.

In fractures of the thigh and leg, especially the latter, the limb must be carefully protected from the pressure of the bedclothes, by means of a contrivance, such as that exhibited in fig. 331. It

Fig. 331.

Wire rack for fracture of leg.

consists of two pieces of wood connected by several semi-circles of hoop, or wire, attached by a longitudinal piece.

In fracture of the superior extremity, the patient is often able to walk about immediately after the accident, taking out-door exercise, and, perhaps, even attending to business. But it is very different when he has a broken leg or thigh. Here, as a general rule, he is obliged to keep recumbent, often for a most unreasonable time, until, it may be, he is bedridden, and worn out with suffering. This is wrong. Such a case demands an immediate change of treatment. The starched bandage is substituted for the previous dressings, and the patient is sent out into the open air upon crutches. Prompt amendment follows; the general health rapidly improves, and the process of repair, having received a new impulse, steadily advances to completion.

As fractures are constantly liable to be followed by weakness and stiffness of the limb, the rule is to move the joint nearest the injury as soon as the union is sufficiently advanced to preclude the possibility of displacing the fragments or interrupting the consolidating process. This constitutes what is called *passive motion*, a most important element in the management of this class of lesions. It should not be commenced, as a general rule, before the end of the second week, and should be repeated once a day, or every other day, according to circumstances; it should be very gentle at first, and be gradually increased until the limb has completely regained its normal functions. During its performance the parts are properly supported by assistants, and the dressings are reapplied the moment it is over. The restoration of lost function will be greatly promoted by frequent washing with warm water and soap, followed by frictions with some sorbefacient lotion as spirits of camphor, soap liniment, or weak solutions of iodine.

As soon as the callus has acquired sufficient firmness to sustain the ends of the broken bone, the splints and bandages are either discontinued, or applied more loosely, the object now being merely to keep the parts at rest until the union is perfectly consolidated. In fractures of the inferior extremity, some days should usually elapse before the patient is allowed to rise, or bear any weight upon the affected limb; the new bone is still weak, no definitive callus has yet formed, and the patient, awkward from long disuse of his joints, is liable to fall from the slightest accident. These precautions are extremely important, and should, therefore, always receive the most scrupulous attention.

Immovable Apparatus.—The treatment of fractures of the extremities may often be advantageously conducted with the immovable apparatus, concerning which so much has been said and written of late years as a comfortable and time-saving expedient. When this method of treatment was first announced, in 1834, by Dr. Seutin, of Brussels, it was almost universally regarded with suspicion, and even now, after the numerous trials that have been made with it in different parts of the world, it is questionable whether it is receiving the attention it merits. In this country it has been but little employed at any time, either in private or hospital practice. It is difficult to determine to what this neglect is attributable, whether to fear, to indolence, or to apathy. Many practitioners are afraid that the apparatus will do mischief; others feel themselves incompetent to apply it properly; while a third, and perhaps the most numerous class of all, reject it on account of the supposed trouble attending its use. Such objections are altogether frivolous. The accumulated experience of the profession during the last twenty years is sufficient to convince any one, even the most sceptical, of the safety and utility of this mode of dressing fractured limbs. It is not, of course, applicable to all cases; but if proper judgment be exercised in their selection there are few in which, in some stage or other of their progress, it will not be beneficial. I am myself averse to the early use of the immovable appa-

ratus, convinced that the safest plan is always to wait until there is complete subsidence of the resulting inflammation and swelling. From ten days to a fortnight is a good average period for the commencement of its application; employed earlier, it may induce undue compression, and thus compel removal. I would, then, have an eye to time and circumstances; avoiding premature interference, on the one hand, and too long delay on the other.

The immovable apparatus may be prepared with various substances, all of them possessing more or less, though not equal, merit. Cowper, an English surgeon, employed compresses and bandages, saturated with a mixture of the albuminous part of eggs and wheat flour, which was replaced by Lawrence by powdered chalk. Seutin was the first to recommend starch; Velpeau uses dextrine; Smee prefers gum Arabic and whiting. Gum shellac and glue have also been highly lauded, and of late much has been said in commendation of the plaster of Paris bandage. Of these various articles the starch is perhaps the best; it certainly possesses the advantage of cheapness, and of being easily prepared, applied, and removed, as well as being always easily procurable.

The apparatus of Smee, called the *moulding tablet*, is also an excellent contrivance, nowise inferior to the starch, and but little more expensive. It consists of two layers of coarse, old sheeting, cemented together by means of a thick paste made by rubbing very finely powdered whiting with mucilage of gum Arabic. The sheeting soon dries, without shrinking, into a hard, firm substance, which, with the aid of a sponge and hot water, may afterwards be accurately moulded to the fractured limb, and worn with great comfort and efficiency.

Dextrine is a yellowish white, pulverulent substance, obtained from amylaceous vegetables and plants; it exists in union with fecula, amidine, diastase, and gum, and possesses remarkably glutinous and adhesive properties, well adapted to the object for which it is employed. Besides, it is very cheap, and generally dries in one-sixth of the time that starch does. The only objection to it is the greater difficulty of removing it. It is converted into a paste of the consistence of thin molasses, with equal parts of water and camphorated spirits, the latter being allowed to soak in well before adding the former.

Plaster of Paris, originally employed by the Moors of Spain, was first tried in Europe, as a scientific dressing in the treatment of fractures, by Professor Kluge, of Berlin, in 1829. The bandage is prepared by rubbing the dry plaster thoroughly into the meshes of a thick muslin roller, the ends of which are freely sprinkled with water previously to the application made with as few reverses as possible. The great advantages of this dressing are the rapidity with which it dries and adapts itself to the parts, and the fact that it forms an unusually firm, hard casing, which permits the limb to be handled and moved with great ease during any transportation that may be necessary to place the patient in more comfortable quarters.

The *chalk and gum bandage* forms an excellent substitute for the plaster and starch bandage. It is prepared in the same manner as the latter, over which it possesses the advantage of more rapid desiccation and of greater strength, so as to render a resort to strips of pasteboard rarely necessary. The adhesive mixture consists of equal parts of precipitated chalk and gum Arabic, made into a suitable consistence with boiling water.

The *starch bandage* which I prefer, on account of its simplicity and the facility of procuring it, is thus applied:—Supposing the leg to be the part injured, the first thing to be done is to procure a pint of starch, without any lumps, a bundle of wadding, several long rollers, two light binder's board splints, and an apparatus for maintaining extension and counter-extension until the dressing is perfectly dry. The fragments being accurately adjusted,

the limb is surrounded, in its entire length, from the toes to within an inch and a half of the knee, with two layers of wadding, in order to protect its bony prominences from the pressure of the bandage. Special pains, moreover, are taken to fill up the hollows on each side between the ankle and the tendo Achillis. A wet roller is now applied from below up in the usual manner, care being taken not to make the reverses over the edge of the tibia, lest they should occasion unpleasant, if not injurious, compression. A layer of starch is next put on, either with the bare hands or with a paint brush, the substance being well rubbed into the meshes of the cloth. Resuming the roller, it is now carried down the limb as far as its extremity, when the starch is again applied, and so on until three layers have been formed. Two splints, made of binder's board, not too thick or heavy, and accurately shaped to the foot and leg, are steeped in hot water, and, being carefully moulded to the parts, are secured with another roller, also thoroughly saturated and covered with starch. Finally, the dressing is completed by the application of a dry bandage. If the fracture is a very simple one, unattended with any disposition to displacement, as often happens when the tibia alone is broken, the limb is simply placed in an easy position upon a pillow arranged in the form of an inclined plane, or in an ordinary fracture-box; otherwise it will be necessary to use the apparatus of Desault, as modified by Physick, or some similar contrivance, in order to keep up extension and counter-extension until the bandage is completely dried; an event which seldom happens before the expiration of thirty, thirty-six, or forty hours, even in very hot weather, as the evaporation always proceeds with difficulty. The desiccation, however, may often be materially expedited by artificial means, especially by warm sand-bags stretched along the sides of the limb.

When the apparatus is perfectly dry it forms an immovable case for the limb, making equable and uniform pressure throughout, and maintaining the fragments of the broken bone accurately in apposition with each other. If the parts feel entirely comfortable, the patient may now sit up in bed or on a chair, or he may even walk about on crutches, the leg being properly supported in a sling. Generally, however, it will be found that there is for a day or two a sense of soreness, with, perhaps, some degree of throbbing, inviting recumbency rather than the erect posture. If the apparatus causes marked discomfort, by bearing unequally upon any portion of the limb, or if throbbing and swelling arise, immediate measures must be adopted for its removal. For this purpose it should be slit up along the outer side of the limb, about an inch or an inch and a half external to the crest of the tibia,

Fig. 332.

Seutin's scissors.

by means of Seutin's scissors, represented in fig. 332, one of the blades of which is probe-pointed, and therefore well adapted to the object. The limb being properly supported by an assistant, the hardened shell is gently peeled off from its surface, which is next carefully sponged with

alcohol and laudanum, or spirits of camphor, when the apparatus is immediately reapplied with the aid of a roller. Thus, by simply removing the bandage from time to time, an opportunity is afforded of inspecting the limb, and ascertaining its precise condition, not only at the seat of fracture, but everywhere else.

When the patient is able to move about on crutches, the limb should be carefully supported in a sling, arranged in the manner represented in fig. 333.

If the fracture be seated high up in the leg, the apparatus should extend a short distance above the knee, as it then becomes a matter of great moment to keep the joint in as passive a condition as possible. In compound fracture, attended with discharge, a hole should be cut in the apparatus opposite the wound, so as to admit of the necessary drainage, as represented in fig. 334.

Fig. 333.

Fracture of the thigh, done up in starch bandage.

Fig. 334.

Dressing in compound fracture of the leg.

Great care should be taken that the edges of the splints do not produce any injurious compression; to obviate this, it is usually recommended that they should be torn instead of being cut, it being alleged that, when treated in this manner, they will be much less likely to create mischief. My own experience, however, is that this is not the fact, and I, therefore, invariably bevel the inner edges with a stout knife, thus effectually preventing all risk of this sort.

It is not possible, also, to bestow too much attention upon the bandage; the care or negligence with which this is applied will make all the difference in the result, both as it respects the patient's comfort and the character of the cure.

The plaster of Paris bandage, prepared in the manner already mentioned, is applied in the same way as the starch, the limb having been previously enveloped in cotton wadding and a dry bandage. Great care is taken with the reverses and the various depressions of the limb. The bandage, moreover, must not be drawn with quite the ordinary firmness, allowance being made for shrinkage. Splints may usually be entirely dispensed with, especially if folded cloths, saturated with plaster, be applied whenever more than usual support is required, but extension must be kept up by assistants until the bandage is perfectly dry, as it always will be in a few minutes.

3. COMPLICATED FRACTURES.

The only class of fractures, besides the simple, which deserves to be considered under a distinct head is the complicated, as it is easy to comprise under this denomination every form of accident that can possibly arise either at the moment of the injury, or during the progress of the treatment. The propriety of this arrangement will become more obvious as we proceed with the discussion of the subject. In adopting this plan, I shall treat successively, and as concisely as possible, of fractures complicated with wounds, hemorrhage, dislocation, comminution of the bone, excessive laceration of the soft parts, erysipelas, pyemia, and, lastly, tetanus.

Complicated fractures may be oblique, transverse, or longitudinal, the frequency of their occurrence being in the order here enumerated. They are always caused by mechanical violence, as gunshot, falls from a great height, severe blows, or the passage of the wheel of a carriage, wagon, or railroad car. Complicated fractures from the latter cause have, of late, become very common, and are a frequent source of loss of limb and life.

The *symptoms* of this variety of fracture are, like those of simple fracture, sometimes extremely obscure, requiring great care and skill on the part of the surgeon to determine their character. In general, however, they are sufficiently well marked to enable him to distinguish them from such as attend other accidents, especially if an opportunity be afforded him of examining the parts before the supervention of much swelling. There is usually greater pain and shock than in an ordinary fracture, the resulting inflammation is more severe, and there is greater risk of violent secondary effects, as erysipelas, gangrene, copious suppuration, necrosis, caries, prostration, hectic irritation, and tetanus. In fact, complicated fractures are among the most serious occurrences that are met with in practice, being alike perplexing to the surgeon and dangerous to the patient; demanding the nicest judgment and skill for their successful management, and entailing, not unfrequently, the greatest possible suffering, horrible deformity, and loss of limb, if not also loss of life. It may be stated, as a general rule, that complicated fractures of the lower extremity are more dangerous and difficult of management than those of the superior, as well as more apt to be followed by distortion and permanent lameness.

The process of repair in complicated fracture proceeds on the same principle as in the simple form of the lesion, only that it is usually more tedious, and that it is attended with a larger quantity of callus. When there is a wound in the soft parts, the union is generally effected through the medium of granulations, which, arising from the ends of the fragments, ultimately assume the ossific disposition, and thus form the connecting link between them.

The *treatment* of this form of fracture varies according to the circumstances of the case, or the nature and severity of the complication; a fact which imposes the necessity of considering the subject somewhat in detail.

When the case is complicated with a *wound* in the soft parts, constituting what is usually called a *compound fracture*, fig. 335, and the limb is deemed capable of preservation, the first and most important consideration is the reduction of the fracture. This may generally be done by putting the limb in the most favorable position for relaxing its muscles, and by well-directed and gentle efforts at extension and counter-extension, along with proper manipulation, especially if the fracture be transverse, and the opening large; but if it be oblique, and there is a projection of one or both ends of the fragments, they occasionally fail, and compel us to resort to other measures. Under such circumstances, the soft parts which seem to gird or bind the

bone, and prevent it from yielding, should be carefully divided, when a renewed attempt at reduction will probably be successful. Should every reasonable effort of the kind, however, prove fruitless, then, instead of leaving

Fig. 335.

Fracture of the leg, complicated with wound and comminution of the bone.

the bone in its exposed situation, where it would be sure to die, the proper plan will be to cut away a portion of it, especially if it terminate in a very long and narrow point.

Whatever may be the character of the wound, its edges should be carefully approximated by suture and plaster, aided by collodion to exclude the air; or, instead of this, the wound may be covered with a light compress wet with blood, and supported by a bandage. In this way, a compound fracture may occasionally be speedily converted into a simple one, union sometimes occurring in a few days.

The *hemorrhage* in complicated fracture may be open or concealed, according as there is a wound or no wound; arterial or venous; insignificant or copious. In the first case, the bleeding will manifest itself in the usual manner, and is to be arrested by ligature or compression; in the second, it will be indicated, if it be at all considerable, by unusual swelling, attended with a sense of fluctuation or unusual softness, and by more or less discoloration of the integuments. If the principal artery of a limb has been severed, there will be an absence of pulsation in the parts below, with coldness of the surface. When no doubt remains concerning the diagnosis in such a case, the main trunk of the vessel is exposed some distance above the seat of fracture, and ligated; or, if this be deemed improper, an incision is made through the bloody tumor, and, its contents being turned out, the divided artery is sought and secured above and below the seat of injury. This, in fact, is usually the preferable procedure, especially as there must frequently be considerable uncertainty whether the effusion is arterial or venous; a circumstance which, perhaps, thus leads to the performance of a most serious operation in a case where one of a most simple character might suffice.

When the fracture is attended with a *dislocation*, the case necessarily assumes a very serious character, as it may give rise, especially if the joint involved be a large one, or the bone greatly shattered, to the question of primary amputation. In such an event the most experienced surgeon will often find it difficult to come to a prompt and correct decision. The principal circumstances which should induce him to make an attempt to save the limb are, the integrity of the patient's health at the time of the injury, together with a knowledge of his previous habits, and the simplicity of the dislocation, or the almost total absence of complication, as it respects the affected joint. If, on the other hand, the dislocation is compound, and the bone is badly broken, at the same time perhaps that it protrudes at the articulation;

if all these injuries exist, or if, along with them, serious mischief has been inflicted upon the soft parts, as a violent contusion of the skin and muscles, or the laceration of important vessels or nerves, no doubt can be entertained respecting the propriety of the operation, and the sooner it is performed after the occurrence of reaction, the better it will be for all parties concerned. I believe that a compound fracture, extending into a large joint, as the knee or ankle, and attended with extensive rupture of the ligaments, muscles, and other structures, should always, as a general rule, be treated in this way. It is true a case apparently of the most desperate character occasionally recovers, but such a consideration should not have too much weight, or induce us to neglect a measure which is sanctioned not less by reason than by experience.

When the case is not such as to demand amputation, the dislocation should always be reduced before an attempt be made to adjust the fracture. Great difficulty will sometimes attend such an operation, but this may usually be overcome by patience and perseverance, aided by the means furnished by modern improvement. It is sheer folly to postpone the reduction of the dislocation until the bone has become sufficiently consolidated to enable it to bear the requisite manipulation; one of two things would be almost sure to happen in such a case, either a reproduction of the fracture, or an utter failure to replace the luxated bone.

The most common causes of *comminuted* fracture are, gunshot violence, railroad accidents, falls from a great height, and the passage of the wheel of a carriage. If the bone be broken into several pieces, and any of them are completely detached, or so loose as to render their reunion improbable, all such pieces ought to be carefully removed; after which the edges of the wound should be gently approximated, and kept in position by sutures and adhesive strips, covered with collodion. The limb being surrounded by the bandage of Scultetus, and supported by appropriate apparatus, is placed in an easy position, care being taken to moderate inflammation by the usual antiphlogistic means. If the wound suppurates, it must be covered with an emollient poultice or the warm water-dressing, with as little disturbance as possible to the broken bone.

When the fracture is complicated with violent *contusion* of the soft structures, the retentive apparatus should be applied rather slackly, and the parts be kept constantly wet with cold water, or, what is better, a strong solution of acetate of lead and opium. If the inflammation run high, recourse may be had to bleeding, purgatives, and antimonials. The limb is carefully watched, in order that prompt advantage may be taken of any change as soon as it arises.

In consequence of injury sustained by the skin, either at the time of the accident, or from the pressure of the bandage, the cuticle is sometimes raised into little *vesicles*, filled with a thin, limpid, reddish, or yellowish fluid. Such an occurrence always awakens anxiety both in the patient and practitioner, especially if he be young and inexperienced, as it is apt to be associated with the idea of gangrene. From this, however, it may always be easily distinguished by the absence of lividity, severe pain, and other symptoms of excessive action. The proper treatment consists in puncturing the vesicles with a fine needle, and using the warm or cold water-dressing.

If the principal artery, vein, or nerve of a limb has been destroyed, at the same time that there is extensive laceration of the soft parts around, the case will probably require amputation, especially if there has been severe shock or extensive hemorrhage, with previous derangement of the general health. Such a case is, at all events, a bad one, liable to be followed by loss of limb, if not also of life. If, on the other hand, the principal artery retains its integrity in the midst of the torn and broken structures, and the patient is

young and vigorous, although he may have bled severely, we should by all means make an attempt to save the limb, having previously explained to the patient and his friends the risk which such an undertaking involves. Some of the most gratifying results that reward the care and skill of the practitioner are cases of fracture complicated with extensive laceration of the soft structures and comminution of the bone. I have several times succeeded in effecting excellent cures when, the main artery being intact, the limb hung merely by a comparatively small quantity of skin and muscle, and when I was compelled to remove a number of pieces of bone, or even saw off the ends of the fragments.

Accidents after Complicated Fractures.—The most common and important accidents after complicated fractures are erysipelas, œdema, abscess, gangrene, spasm, tetanus, pyemia, delirium, and congestion of the brain and lungs.

Erysipelas usually comes on within the first forty-eight hours after the occurrence of the injury. The disease is most apt to appear in persons of intemperate habits, and in such as are dyspeptic, or enfeebled by previous suffering, and generally adds very much to the danger of the case, perhaps already great before. Its extent and continuance will depend upon various circumstances, which will readily suggest themselves to the mind of the reader. The treatment is conducted upon general principles, our main reliance being upon the correction of the secretions, and the support of the system, by quinine, iron, milk-punch, nutritious food, and anodynes, with the topical application of tincture of iodine diluted with equal parts of alcohol.

The occurrence of *œdema* is sufficiently common in complicated fractures of old, dilapidated subjects, and is best remedied by the bandage, aided by spirituous lotions, tonics, and a nutritious diet. Punctures will seldom be necessary, and should always be used with the greatest caution.

Abscesses, diffuse, painful, and troublesome, may form either at the seat of the fracture, or in its immediate vicinity. In either case, the matter should be speedily evacuated; otherwise it may not only cause extensive havoc among the soft parts, but caries and necrosis of the ends of the broken bone, with risk of pyemia and phlebitis.

Gangrene may be produced by injudicious bandaging obstructing the circulation, excessive inflammation, or injury of the main artery, vein, or nerve of the affected limb. The occurrence is most liable to happen in unhealthy subjects, and in young persons after railroad and other severe accidents, and often makes fatal progress before its presence is suspected by the patient or his attendant. Great pain in the part of a smarting, pungent, or burning character, accompanied with discoloration and tumefaction in the distal portion of the limb, should always excite alarm and lead to a thorough examination. Tight bandaging in particular should be avoided in complicated fractures, especially in the early stages of the treatment.

Severe *spasm* frequently attends this class of injuries, but as this subject has already been discussed in connection with simple fractures, nothing further need be said respecting it here.

Pyemia, as an effect of complicated fracture, is uncommon, at least in private practice, except when the accident has been caused by railway injury, the bursting of a gun, the passage of the wheel of a wagon, or some similar violence. It is distinguished by its usual insidious character, and generally sets in from the fifth to the tenth day, its approach being announced by violent rigors, alternating with flushes of heat, great depression of the system, delirium, and excessive restlessness. The structures which are most apt to suffer are the lungs, liver, spleen, joints, and connective tissues. The treatment is supportant and alterant; by quinine, brandy, and nourishing broths, for the former; by mercury, in moderately large and properly sustained doses,

for the latter. In general, such cases fare badly, death occurring within a week from the commencement of the attack, despite our best directed efforts.

Tetanus in complicated fractures, is most liable to supervene in nervous, irritable subjects, during hot weather, although it may take place at any season of the year, as well as in every description of individuals. It is an extremely formidable symptom, which should be promptly met by the removal of the affected parts, and by large quantities of anodyne and antispasmodic remedies. If occasionally a case is cured without amputation, it forms the exception, not the rule. In such an event, there is no time for delay; whatever is done must be done quickly and effectively, at the very inception of the disease, before there is any decided evidence of stiffness in the muscles of the jaw.

Traumatic delirium is sufficiently frequent after these accidents, especially in old intemperate persons, and should be treated upon the principles laid down in a previous chapter.

Congestion of the lungs and other internal organs, as a consequence of these injuries, is most liable to occur in elderly persons, as a result of a determination of blood either from actual irritation or a sluggish condition of the vessels from protracted confinement. As such attacks are very apt to prove disastrous, everything should be done to prevent them, by getting the patient as speedily as possible out upon crutches in the open air.

Amputation.—Allusion has already been incidentally made to the circumstances which are likely to call for *primary amputation*, and it may now be added that it should always be resorted to, as a general rule, whenever, along with a shattered or comminuted condition of the fractured bone, there is extensive laceration of the soft parts, with almost total disorganization of their substance. It is true, as was before intimated, that apparently desperate cases are sometimes cured, and that limbs, so mashed and wounded as to render amputation the only probable chance of success, are now and then saved. But it is equally true that such instances are extremely rare, and if we take into account the protracted sufferings of the patient, and the likelihood of his ultimately falling a victim to his ailments, the reasons for performing immediate amputation are, to use the language of Mr. Percivall Pott, "vindicable upon every principle of humanity or chirurgic knowledge."

It is not uncommon for cases to occur in which the fracture is *multiple*, or in which the bone is broken at several points, but where the upper fracture is perfectly simple, and perhaps situated in a portion of the limb which it is desirable to preserve. Hence it becomes an important question how the surgeon is to act in such an event. To my mind, the subject is a very plain one. If it be really important to save the broken bone beyond the part that must necessarily come off, in order to make a longer and a better stump, there can certainly be no objection to such a course, provided, however, that the proximal fracture be perfectly simple in itself, and that there is no serious lesion of the soft structures, endangering limb and life by gangrene or other bad consequences. I have more than once adopted this plan, and have not, so far as I recollect, had any cause to regret it. No sensible surgeon would, of course, allow a bone to remain, under such circumstances, if it were comminuted, or if, the fracture being simple, there were serious injury of the muscles, integuments, or other important textures; to do so would only be to trifle with the safety of the case.

Secondary amputation will be necessary when, after an attempt to save a limb, and the employment of suitable antiphlogistic remedies, the parts become gangrenous; or when the consolidation of the fracture is prevented by profuse suppuration, and the patient is gradually wearing out by diarrhoea and colliquative sweats. In the first case, the operation is performed as soon as the mortification is arrested, and there is a distinct line of demarcation

between the dead and living parts; in the second, as soon as it is perceived that the suppuration cannot be arrested, and that the patient has still sufficient strength to bear the pain and shock which must necessarily attend its performance.

Statistics of Compound Fractures.—We have no very copious statistics of compound fractures of different parts of the body. The following account, for which I am indebted to Dr. Frederic D. Lente, relates to cases of compound fractures of the lower extremities, treated in the New York Hospital from January, 1848, to July, 1857, the whole number being 392, fractures of the tarsus and metatarsus not being included. Of these, 68 occurred in the thigh, and 324 in the leg. Of the former, 3 involved both thighs, and of the latter, 16 both legs. Of the entire number, 190 were cured, 182 died, and 20 were relieved. In 39, or 20.5 per cent., amputation was performed.

Of the 68 fractures of the thigh, 18, or 26.5 per cent., were cured, and 2 relieved; amputation having been performed in 7. Of the 324 fractures of the leg, 175, or 54.0 per cent., were cured, and 14 relieved. In 35, or 20.0 per cent. of these, the limb was removed. Of the whole number of cases of fracture, amputation was employed in 91, or 23.3 per cent., and of these 49, or 53.8 per cent., died.

Of 301 cases treated without amputation, 140, or 46.5 per cent., died, 3 having refused to submit to amputation.

Of the whole number of fatal cases, in which amputation was not performed, 74, or more than one-half, died within the first week; in many of these there was no reaction, and death ensued in from twenty-four to forty-eight hours.

Of 45 fractures of the thigh which occurred at or below the middle, 14 recovered, or 31.1 per cent.; while of eleven that occurred further down, 4, or 36.3 per cent., recovered.

Of 227 fractures of the leg, occurring at or below the middle, 130, or 58.1 per cent., recovered; of 30 above the middle, 17, or over one-half, got well.

Of 334 compound fractures of the thigh and leg, 164 occurred on the right side, and 170 on the left.

4. INCOMPLETE FRACTURES, OR BENDING OF THE BONES.

The bones are liable not only to break, but also to bend, as seen in figs. 336 and 337. Such an accident can only happen in young subjects, principally in infants and children, in whom the osseous tissue, containing a preponderance of animal matter, is comparatively soft, flexible, and elastic. Bending of the bones of the skull, especially the frontal and parietal, is occasionally witnessed at an early age, as an effect of external violence, as that, for instance, produced when a child falls, head foremost, down a flight of stairs, or out of a second story window upon the pavement below. Under such circumstances, the cranial bones, at the part struck, are depressed beyond their natural level, and yet there is not, so far as can be ascertained, any fracture,

Fig. 336.

Fig. 337.

Incomplete fracture of the bones of the forearm.

strictly so called; they are merely bent or indented, and if no untoward occurrence take place, they will, generally in the course of a few days, resume their proper position by their own resiliency, aided, doubtless, by the locomotive action of the brain, propelling them outwards away from its surface. In an adult, an accident, capable of producing such a result, would almost certainly lead to fracture of the skull, and that probably of a very grave character; for the reason that the cranial bones, after a certain time, are always loaded with a large quantity of earthy matter, in the form of carbonate and phosphate of lime, the presence of which renders them more or less brittle, and thus predisposes them to fractures. This tendency to fracture increases in proportion as we advance in years, and is, consequently, most distinctly marked in old age and decrepitude, in which the osseous tissue, almost destitute of animal substance, generally yields under the slightest force, the accident frequently eventuating in incurable injury.

Bending of the bones had been incidentally observed by a considerable number of practitioners, in the last century, and, indeed, even prior to that period; but the first systematic account of it was published in 1810, by Professor Jurine, of Genève, Switzerland. In 1821, a short, but valuable article, illustrated by several graphic drawings, appeared on the subject in the fourth volume of the American Medical Recorder, from the pen of Dr. John Rhea Barton, of this city. More recently, attention has also been called to the affection by Professor Hamilton, in his Report on the Deformities of Fractures, made to the American Medical Association in 1855, and also in an article in the New York Journal of Medicine for November, 1857.

I have myself met with this accident in nine cases, in children whose ages varied from three to eleven years, three being girls, and the remainder boys. Although it is most common in the ulna, radius, and clavicle, yet it also sometimes occurs in other pieces of the skeleton, as the humerus, femur, tibia, fibula, and ribs. External violence alone is capable of producing this lesion. I am not acquainted with any cases in which it was occasioned by muscular contraction. In fact, considering that bending of the bones is exclusively confined to children, it is hardly possible that the accident could arise from such a cause; certainly not, unless there existed extraordinary muscular development with remarkable flexibility of the osseous tissue, a condition of things hardly compatible with a healthy state of the system. In the bones of the forearm, which suffer more frequently than any other, the injury usually originates from force applied indirectly, as when, for example, a child, in the act of falling, instinctively throws out the arm to protect the body, and so receives the shock upon the hand, the concussion concentrating and exploding upon the radius, or the radius and ulna. In one of my cases, the bend was produced by the body of the child being suddenly propelled against his forearm at a moment when the elbow was planted upon the floor, and the wrist lying upon a stool. Flexion of the clavicle is the result either of direct violence, or of force applied to the top of the shoulder, especially if the body be at the same time propelled in the opposite direction, as in the case of a fall.

The seat of this lesion is variable; in the long bones, as those, for instance, of the forearm, it usually occurs a short distance below their middle, but it may also take place higher up, or further down. The radius and ulna may both suffer synchronously, but very frequently one alone is affected, or, if both are implicated, they do not suffer in an equal degree.

Judging from the cases of this accident that have fallen under my observation, I am inclined to believe that it generally happens without any particular predisposition, either constitutional or local. In every instance of the kind, the subjects of the injury were in good health at the time of its occurrence.

What is the precise nature of this lesion? Is it really, as the name implies,

a mere bending of the bones, or is it a flexion combined with partial fracture? These questions are easily answered. In very young subjects, as in children not more than a few years of age, and in the milder forms of the lesion, the osseous fibres are merely extended or stretched, so as to permit themselves to be drawn out of their natural course; in cases of an opposite character, on the other hand, there is no doubt that, while some of the fibres are bent, others are both bent and broken. These conclusions are beautifully borne out by the experiments of Dr. Hamilton upon the bones of young chickens, which, from the fourth to the sixth week, and consequently before the completion of the ossific process, could be readily bent without fracture to an angle varying from twenty-five to thirty-five degrees; whereas, the bones of older chickens, thus treated, always partially broke, their fibres being incapable of withstanding the force used in flexing them.

These partial fractures, sometimes called *interperiosteal*, from the fact that the fibrous envelop of the bones remains intact, bear a close resemblance, in the mode of their production, and the nature of the resulting injury, to the appearances presented by a green hickory stick, forcibly bent over the knee, but not to such an extent as to occasion any external sign of fracture, although it will be found, upon making a section of the wood, that many of its fibres have actually been broken, while others, and perhaps the greater number, have merely been bent.

The *symptoms* attendant upon this accident are pain and deformity at the seat of the injury, loss of power in the limb, and absence of crepitation. The pain varies in degree, being sometimes slight, at other times severe; swelling soon supervenes, and the part feels numb and heavy. A marked curvature, generally very gentle, but sometimes quite abrupt, always exists at the affected part, and can seldom be completely effaced without the application of very considerable force; indeed, often not without breaking the bone entirely across, especially if it was previously partially fractured. In the latter case, there is usually at the convexity of the curvature a slight depression, capable of receiving the point of the finger, its boundaries being formed by rough, sharp, bony fibres. Further than this there is no displacement, and under no circumstances is there any crepitation. The use of the limb is always greatly impaired, but not completely destroyed, as it commonly is in ordinary fracture. Finally, I may mention, as another highly important and diagnostic sign, the great difficulty which is so frequently experienced in restoring the parts to their proper position.

The *treatment* of these accidents must be conducted upon the same general principles as that of ordinary fractures. When the bones are merely bent, slight pressure and extension will usually suffice to accomplish restoration, the affected parts being compelled, as it were, to retrace their former steps. If flexion be conjoined with partial solution of continuity, the reduction will necessarily be more difficult, and may, in fact, altogether fail, owing to the manner in which the osseous fibres are interlocked with each other, and the inability which is experienced in disengaging them, so as to induce them to slip back into their proper position. However this may be, the attempts to remove the curvature by extension and pressure should neither be too violent nor too long continued, lest they prove injurious. The object should be to restore as much as we can by gentle means; what cannot be effected in this manner, may well be left to the operation of time, the absorption of the broken and resisting osseous fibres, and the action of the muscles, which seldom fail to reinstate the parts, although from six to eight weeks may elapse before the final completion of the cure. I have generally found the use of leather splints, well padded, and accurately shaped to the limb, of great service in bringing the bones into their proper relations. When the accident

is followed by undue inflammation, recourse must be had to the usual antiphlogistic remedies, especially leeching and cooling lotions.

There is a variety of partial fracture, known by the term *fissure*, which is peculiar to the bones of elderly subjects, no well-marked instance of it having ever been met with in infants and children. Such an occurrence, which is, in general, much more interesting in a pathological than in a practical point of view, is by no means uncommon in the skull, especially along its base, where it is always associated with severe, and frequently fatal, injury of the brain and its envelops. The fissures in many of these cases are most extensive, involving the sphenoid, occipital, temporal, frontal, and perhaps even the ethmoid and parietal bones. In the other pieces of the skeleton the occurrence is more rare; but examples are occasionally seen both in the long, short, and flat bones, as the result of external violence, generally directly applied, though sometimes indirectly. The accident is sometimes produced by gunshot injury. The lesion, however induced, consists essentially in a forcible separation of the osseous fibres, and exhibits itself in a great variety of forms; the crack sometimes extending through the entire thickness of a bone, at other times merely through its outer table, and at other times, again, involving both the compact and areolar tissues, but not passing completely through them. The length of the fissure varies, from a few lines to a number of inches, perhaps as many as six or eight, although this is exceedingly uncommon. The width of the crevice is generally very slight, perhaps barely sufficient to admit the blade of a penknife. In rare cases, as when it involves the extremity of a bone, it may gap somewhat, so as to give the part an appearance as if it consisted of two fragments, firmly adherent at one end. Finally, the fissure may be straight, curved, or angular.

Of the rarity of this lesion, as an uncomplicated occurrence, an idea may be formed when it is stated that there are probably not more than three or four well-marked specimens of it in all the osteological cabinets of this city. As a conjoint lesion, it is occasionally met with in compound fractures, especially when caused by railway accidents. There are no signs by which the nature of the injury can be distinguished during life; a circumstance which is the less to be regretted, because the treatment does not differ from that of ordinary wounds, fractures, and contusions, with which it is so generally associated.

5. DIASTASIS OR SEPARATION OF THE BONES AT THEIR EPIPHYSES.

The extremities of the bones of young subjects are, as is well known, united to their shafts, or bodies, by means of cartilaginous matter, which, in some of the pieces, and in some individuals, does not assume the osseous form until after the twenty-first year, and occasionally, indeed, not until even a later period. Up to this time, consequently, these junctions are liable to be severed, so as to allow the contiguous extremities to separate from each other, and it is this occurrence that constitutes what is technically called diastasis, as seen in fig. 338.

It is probable that this accident may occur in all parts of the skeleton united in this way, although there are doubtless some in which it is more common than in others. Its occasional existence has been recognized, by dissection, in the humerus, radius, femur, and tibia, and there are few systematic treatises which do not allude to it as being now and then met with in some of the other bones. The most common cause of diastasis is a wrench of the part, violent traction, or a severe fall. I am not aware that it has ever been produced by muscular contraction; and, on the other hand, it is rarely the result of direct violence, as, for instance, the kick of a horse, or the passage of the wheel of a carriage, such an accident more generally eventuating in fracture

of the bones than in a separation of their epiphyses. The lesion may happen at any period of life, prior to the completion of ossification, but is most common from the fifth to the fifteenth year. Its occurrence in middle-aged and elderly subjects is, for the reasons already mentioned, impossible. Girls are more prone to it than boys, owing, probably, to the fact that they are more frequently exposed to its exciting causes. The affection, like fracture, may be simple, compound, or complicated. Cases are noticed in which the diastasis is blended with fracture of the shaft of the bone, and it is by no means uncommon to find that small processes of bone are dragged away with the epiphyses.

The *symptoms* of this lesion do not differ essentially from those of fracture. Its existence may generally be suspected when an accident affecting a bone occurs in a young subject, in the neighborhood of a joint; when the ends of the fragments are transverse, or nearly so; when the articular piece retains its position, while the other moves about; and lastly, when the crepitation produced by rubbing the ends of the fragments against each other is of an unusually dull, rough, grating character. Moreover, it will usually be found that the parts, when once reduced, are less liable to be dragged asunder by the action of the muscles than in case of fracture.

The prognosis is generally favorable, union taking place quite as promptly as in fracture. The treatment is also the same as in the latter accident.

Fig. 338.

Diastasis of the femur: reunited.

6. UNUNITED FRACTURES.

Fractures occasionally refuse to unite, either in consequence of causes inherent in the part or system, or on account of mismanagement growing out of the surgeon's want of attention and skill, or else out of the patient's own misconduct. It is practically important that a distinction should be drawn between a fracture that unites tardily and one that does not unite at all, or only through the medium of a fibrous, ligamentous, or fibro-cartilaginous tissue. Slow consolidation is by no means uncommon; the parts may be loth to take on the requisite degree of ossific action, and the result may be that a fracture that is ordinarily repaired in four or five weeks, may, perhaps, be still imperfectly united at the end of twice that period. The process of restoration is only held in abeyance, neither advancing nor receding; by and by it begins again, and then often proceeds with its wonted rapidity. Such cases are frequently very trying to the surgeon's patience, but they generally turn out well in the end, provided sufficient care has been taken to preserve the parts in their proper relations. In the ununited

Fig. 339.

Ununited fracture of the bones of the leg.

fracture, on the other hand, the process of consolidation is either completely prevented, or, after having progressed for some time, is at length permanently arrested. Under these circumstances, the ends of the fragments are gradually rounded off by absorption, and remain either entirely loose and disconnected, or they become adherent through the medium of fibrous, ligamentous, or fibro-cartilaginous matter. Sometimes an adventitious joint is formed, as in fig. 339, provided with a more or less distinct synovial membrane, thus permitting the ends of the bone to move upon each other with great facility.

Want of reunion in a fracture may depend upon a great variety of *causes*, some of them resident in the parts themselves, others connected with the system. Thus, it may be occasioned by the interposition of a clot of blood, or of a piece of muscle, tendon, or bone. An instance is mentioned where a fracture was prevented from becoming consolidated by the presence of a musket ball. Fragility, softening, and carcinomatous affections of the bones are usually enumerated as circumstances interfering with the reparative process, but it is not improbable that their influence has been greatly exaggerated; at all events, it is certain that in many cases of this kind, the fracture unites as readily as when the bones are perfectly healthy. Too much motion, the long-continued use of cold water, especially in persons of a nervous, irritable temperament, and tight bandaging, may also bring about this result. Some years ago, I saw a case in which, from the latter cause, the consolidation of a fracture of the thigh-bone was delayed for nearly a twelvemonth. The limb had become excessively atrophied from the long-continued and injudicious use of the roller, and it was not until after it had been entirely laid aside, and the man had been permitted to exercise upon crutches in the open air, that nature seemed to consider herself in a fit condition to commence the process of reparation, from which she had been so long detained by this mode of treatment.

Old age is no barrier to reunion, provided the patient is in good health at the time of the accident, and the fracture is not complicated. I have met with several cases of fracture of the humerus, in persons after the eightieth year, in whom the consolidation took place in the usual time.

But the most common local causes of all of tardy reunion, in injuries of this kind, are a want of accurate apposition between the ends of the fragments and the existence of undue motion. Either of these circumstances will inevitably interfere with the consolidating process, and in many cases effectually prevent it, no matter in how favorable a condition the system may be for a cure. Hence, as stated elsewhere, the importance, nay, the absolute necessity, in every instance of fracture, of carefully guarding against these occurrences until the consolidating process shall be so far advanced as to enable the fragments, so to speak, to take care of themselves.

Fractures situated at or near the entrance of the nutrient arteries unite less rapidly than those situated further off, owing to the fact that they interfere more or less with the circulation and nourishment of the osseous tissue. It is easy to suppose that a laceration of these vessels, as occasionally happens both in simple and compound fractures, might be a cause of non-consolidation, especially when conjoined with other unpropitious circumstances. Statistics show that, when the supply of blood is cut off, to any considerable extent, so as to impose upon the periosteum the exclusive duty of nourishing the fragments, either one or both pieces will become atrophied, their walls being visibly thinned, and their areolar structure rarefied.

Want of union is sometimes dependent upon the *absorption* of the ends of the fragments, or even of the greater portion of the fragments themselves. A very singular case of this kind came under my observation not long ago, in a man aged 53 years. When eighteen years old, he received two simple fractures of the right humerus, at an interval of three months, one being

situated about the middle of the bone, the other an inch and a half higher up. The first was repaired in the usual time, but the second refused to unite, the ends of the fragments becoming rounded off, as in the formation of an artificial joint; the process gradually proceeding, the whole bone was finally absorbed, nothing remaining except its condyles and a little of its head. The period occupied in the absorption was about six years, the general health being all the while unimpaired. The muscles of the arm are well developed, and, when thrown into powerful action, are capable of diminishing the interval between the shoulder and elbow to the extent of several inches. Although the man is unable to perform any of the usual movements of the member, he can readily raise a weight of upwards of one hundred pounds, and can apply his hand to various purposes. The accompanying cut, fig. 340, represents the appearance of the limb during the contraction of its muscles.

Fig. 340.

Absorption of the humerus.

The principal *constitutional causes* which interfere with the reparative process are, debility, whether from loss of blood, want of nutritive action, or exhausting disease, as long-continued fever; a gouty, rheumatic, scorbutic, or syphilitic state of the system; and loss of nervous influence, however induced. Another cause, but one which, I presume, seldom exerts much influence, is pregnancy. It is barely possible to imagine that, during this state, there may be such an abstraction of blood from the affected parts for the nourishment of the fœtus as to retard, and, perhaps, even temporarily prevent, the formation of callus. In the few cases of this kind which have fallen under my observation, I have not, however, witnessed such an effect, and I am strongly inclined to believe that this influence has been greatly magnified, if, indeed, it is not almost wholly chimerical. The same remarks are applicable to suckling. Another cause, probably much more efficient, as well as much more common, than the one just alluded to, is the protracted and inordinate use of ardent spirits, weakening the nutritive energies of the system, and rendering the blood and its vessels unfit for the performance of the important duties assigned to them in the reparative process.

Whatever the cause may be, great pains should always be taken to discover it, with a view to its early and efficient rectification. Should it consist in debility, however induced, the patient must at once be put upon the use of nutritious food and drinks, as porter, ale, wine, or brandy, aided, if necessary, by tonics, of which iron and quinine are generally the most eligible. A gouty or rheumatic state of the constitution is best remedied by purgatives, acid drinks, and colchicum. Tertiary symptoms should be met by iodide of potassium, either alone or in union with mercury, the latter of which should sometimes be carried to the extent of slight ptyalism. Debility from drunkenness must be counteracted by the judicious employment of ardent spirits, such, if possible, as the patient has been in the habit of using previously to the accident.

The local treatment must be regulated by the circumstances of each particular case. The precise cause of the tardy or imperfect union must, if possible, be clearly ascertained, and immediately remedied by appropriate measures. If it depends upon too much motion, greater quietude must be insured; any defect of contact must be redressed by a more accurate adjustment of the ends of the fragments; cold applications, if injurious, must be discontinued; and any extraneous intervening substance must be removed,

either by calling into requisition the agency of the absorbent vessels, by pressure and other means, or, as in the case of a piece of dead bone, by the knife and forceps. The cause of the defective union having been thus remedied, the case will be likely, of its own accord, to proceed to a favorable termination, the ordinary principles of treatment being, of course, observed.

The principal local remedies, besides those above mentioned, are: 1. *Cutaneous friction*, either dry or moist, by means of the bare hand, or with a piece of flannel. If moist, various liniments, lotions, or unguents may be employed, and often with decided benefit, inasmuch as they tend to excite capillary action in and around the ends of the fragments, thus promoting the formation of callus.

2. *Compression* performed by splints of leather, or binder's board and the bandage; or by an apparatus expressly constructed for the purpose, and intended to concentrate the pressure at the seat of the fracture. The compression must, in all cases, be steady and persistent, as well as uniform and gentle.

3. *Blisters* and *iodine* may sometimes be beneficially employed. Their application is particularly indicated when the want of union is dependent upon undue vascular excitement, and is, of course, entirely restricted to cases of recent standing.

4. *Friction* of the ends of the fragments against each other, as recommended by Celsus, and practised by modern surgeons. It should be performed very gently, and be repeated every four, six, or eight days, according to its effects, care being taken to keep the limb at rest in the intervals by an appropriate apparatus.

5. *Acupuncture* with a long slender needle may be tried; or a small incision may be made over the seat of the injury, and a heated wire thrust between the ends of the fragments.

6. *Cauterization* of the integuments over the seat of the fracture with some caustic alkali, as recommended and successfully employed, in 1805, by Dr. Hartshorne, of this city; or exposure of the ends of the bone, and rubbing them over with nitrate of silver, as practised by several modern surgeons.

7. *Subcutaneous division* of the ligamentous bands between the two ends of the fragments has occasionally been successfully practised. The operation

is performed with an ordinary tenotome, care being taken to cut the parts as thoroughly as possible, especially over the extremities of the broken pieces.

8. The introduction of *ivory pegs*, as originally practised by Dieffenbach, from an inch and a half to two inches in length, conical in shape, and inserted into the ends of the fragments, previously pierced with a gimlet, seen in fig. 341. They must be forcibly driven into the openings, and be retained until the consolidating process is well advanced. Excellent and rapid cures often follow this plan, as I have witnessed in several instances in my own practice.

9. The *seton*, introduced into practice in 1802, by Dr. Physick, is ordinarily, in obstinate cases, the most certain method. It should be passed between the ends of the fragments by a long, thin, flat needle, sharp and lancet-shaped at the point; or when this is impracticable, as near the site of the fracture as possible, for experience has shown that this mode of

performing the operation is nearly as successful as the usual procedure. The foreign body is retained for a variable period, longer in some cases than in others, and generally until it has excited suppurative action. The patient is carefully watched; and if the pain and swelling become severe, the seton is

Fig. 341.

at once withdrawn. Immediately after the introduction, the fragments are properly adjusted, and steps taken, if necessary, to maintain extension and counter-extension. In the first case in which this treatment was employed, the seton was retained many weeks, and the patient recovered the perfect use of his limb. The practice of withdrawing the seton at the end of a few days, as advised by some, is, I think, objectionable, for the reason that it will hardly have sufficient time, in such a case, to excite the requisite degree of inflammatory action.

10. *Perforation* of the ends of the bone by means of a peculiar instrument, fig. 342, an operation proposed, in 1853, by Professor Brainard, is sometimes serviceable. It consists in piercing subcutaneously the extremity of each fragment at several points, and cutting up the intervening tissue, with a view of exciting ossific action. The instrument is introduced in such a manner as not to wound any important structure, and is not withdrawn until the bone has been deeply, and, if need be, even extensively drilled; compression being applied to prevent subcutaneous hemorrhage. The operation is repeated once a week, or every ten days, until reunion has occurred, the limb being in the meantime kept quietly at rest in splints, and the treatment being in other respects conducted upon general principles.

Fig. 342.

Brainard's perforator, reduced one-half.

Dr. Brainard's plan is always to begin the treatment with a small instrument, and to make only three perforations. The size of the former and the number of the latter are afterwards gradually increased until he succeeds in exciting more or less tenderness, pain, and heat in the parts, which are then kept up for some period. In favorable cases, a single operation may suffice; in others, it may be necessary to repeat it four, six, or even eight times. By carrying out these rules, Dr. Brainard states that he had, up to May, 1860, cured sixteen out of seventeen cases of ununited fractures or delayed union.

11. Finally, *excision* of the ends of the fragments, an operation devised, and first performed in 1760, by Mr. White, of England, is occasionally employed. Such an operation, however, should never be resorted to without due deliberation, and until after the failure of the more ordinary and simple means. To say nothing of the difficulty of its execution, it is by no means devoid of danger; indeed, it has not unfrequently proved fatal. A very free incision is made through the soft parts down to the ends of the broken bone, which are then brought out at the wound and retrenched, either with a stout knife, a saw, or a pair of pliers. Sometimes the mere removal of the cartilaginous crust is sufficient for the purpose, an object which may be easily accomplished by scraping.

To maintain the freshened ends in accurate and steady apposition, it was proposed by Horeau, in 1805, to connect them together by means of a wire, and to retain them in this position until the completion of the cure. The procedure, which has, I believe, been generally condemned by European practitioners, has been frequently employed in this country, in consequence, apparently, of the high authority of Dr. J. Kearney Rodgers, who was the first to perform it on this side of the Atlantic. It consists, first, in cutting off the rounded ends of the fragments; secondly, in drilling a hole through each; and lastly, in tying them firmly together with a silver wire, so as to keep them closely and evenly in contact during the consolidating process.

It is generally imagined that this procedure is necessarily followed by violent inflammation, jeoparding both limb and life; but this is an error. If the operation be carefully performed, and the after-treatment conducted upon proper principles, I believe that it will commonly be found to be entirely free from danger, while the utmost confidence may be placed in its efficacy. In the only instance in which I have had an opportunity of employing this method—in a case of ununited fracture of the humerus of eleven months' standing, in a young man twenty-two years of age—the patient experienced very little pain, inflammation, or fever, during any stage of the treatment, and the result was, in every respect, most satisfactory. The following is an outline of this case, as drawn up by Dr. S. W. Gross, for the Louisville Medical Review, July, 1856. It may be premised that the fracture was situated about three inches above the condyles, and that various remedies, among others Dr. Brainard's, had been faithfully but fruitlessly employed for its relief.

The patient being placed under the influence of chloroform, a longitudinal incision, about three inches in length, was made on the posterior aspect of the arm, through the triceps muscle, over the site of the fracture. The lower fragment was found to overlap the upper about an inch and a half. The ends of the bone were surrounded by a strong fibrous membrane, which was firmly adherent to the neighboring parts, and formed a sort of shut sac, in which the bone was imbedded. About an inch of the lower portion of the upper fragment, and half an inch of the upper portion of the lower fragment, were removed with a delicate saw; but on account of their firm adhesions, and especially the shortness of the inferior piece, some difficulty was experienced in bringing them entirely into view. The fragments were conical, rounded, smooth, and invested with a thick, fibrous periosteum: no synovial membrane or fluid existed. The next step of the operation consisted in drilling the extremities of the bone, which having been done with a common gimlet, a piece of wire was introduced, to maintain them in apposition. The ends of the wire were twisted together, and allowed to protrude from the wound, the edges of which were brought together by three sutures and adhesive strips. Two splints and a roller being applied, the arm was firmly supported in a sling. There was very little hemorrhage, and no vessel required ligation. As the patient suffered a great deal of pain, a grain of morphia was given immediately after the operation. Very little constitutional disturbance followed. Nearly all the wound healed by the first intention, and at no time was there much swelling, discoloration or supuration. At the end of the eighth week, the process of reunion had advanced so far that there was scarcely any perceptible motion.

In a fortnight after this, the wire being removed, the patient went home perfectly restored, the arm being about an inch and a half shorter than the sound one. It is proper to add, that, by frequent passive motion, the elbow-joint was gradually regaining its original function.

In another case, that of a man, aged thirty-two, I treated with equal success, by an operation of this kind, an ununited fracture of the humerus of twenty-seven months' standing. The ends of the fragments were connected by two silver wires, which were permanently retained. The case is reported at length in the North American Medico-Chirurgical Review for July, 1861.

The results of some of the above operations have been placed in a striking and interesting light by the statistics of Dr. Norris. Thus, in forty-six cases in which the seton was used, thirty-six were cured, three died, three were partially relieved, and five experienced no benefit. Of thirty-eight cases of resection, twenty-four were cured, six died, one was partially cured, and seven received no benefit. Of eight treated by cauterization of the ends of the fragments, six were cured. Of eleven cases in which friction was em-

ployed all were cured. It is worthy of remark that the treatment by the seton is less successful in fracture of the femur and humerus, than in that of any other bones. The danger of the more severe operations, especially the seton and resection, follows the same laws as in amputation, increasing with the size of the limb and its proximity to the trunk.

Whatever plan of treatment be adopted, it is impossible to be too attentive in the after-management of the case, especially in securing repose and accuracy of apposition to the ends of the fragments. The limb should be promptly put up in appropriate splints, which should be taken off from time to time, and carefully readjusted, just as in the treatment of a recent fracture. If the affected bone be one of the lower extremity, as the femur or tibia, it will be well to let the patient walk about in the open air upon crutches, particularly if he have experienced much constitutional change, the limb being supported by the admirable contrivance of Professor Smith, of the University of Pennsylvania. The apparatus, as seen in fig. 343, is constructed upon the same principles as the ordinary club-foot apparatus, consisting of a shoe, and of a leg and a thigh-piece, connected by hinges, and fastened round the limb by straps and buckles.

If any of the more severe operations are performed, the treatment, for the first few days, must be strictly antiphlogistic, the patient being most carefully watched, lest the inflammation, running too high, may induce fatal consequences. If abscesses form, they should be promptly opened, and the greatest attention should, throughout, be bestowed upon cleanliness. The great danger to be apprehended after such operations is from erysipelas, pyemia, and phlebitis.

When all the known remedies, after a thorough trial, fail, and the limb is utterly useless, the only resource is amputation. Few cases, however, demanding such a terrible alternative, will be likely to arise in the present state of the science.

7. VICIOUS UNION OF FRACTURES.

In consequence of inattention of the surgeon, or a want of co-operation on the part of the patient, the ends of a broken bone sometimes unite in a very unseemly and injurious manner, entirely at variance with the beauty and usefulness of the affected limb, as represented in fig. 344. The deformity thus arising may be produced by the overlapping of the extremities of the fragments, attended, of course, with corresponding shortening; or it may be owing to the imperfect contact of the two ends, thus occasioning a certain amount of angular displacement, without any abbreviation of the length of the bone. In whatever way the deformity may be induced, it is obvious that it should be rectified at the earliest possible moment; for the longer the case is permitted to remain on hand, the more difficult it will be to afford relief. There are several procedures by which this object may be attained: 1st. Compression and extension; 2d, forcible flexion, or rupture of the callus; and 3dly,

Fig. 343.

Smith's apparatus for ununited fracture.

resection of the ends of the fragments. These methods are not, of course, all equally applicable in all cases.

Fig. 344.

Viciously united fracture of the leg.

1st. The safest as well as the most simple procedure, but one which is applicable only in the more early stages of vicious union, consists in applying pressure opposite to the seat of the deformity, in the direction of its convexity. This may be efficiently done by means of appropriate splints and bandages, or with an apparatus specially constructed for the purpose, provided with pads and screws, and appliances for making extension and counter-extension, particularly if there be marked shortening. It is not necessary to give any descriptions of these contrivances, as they may be readily fabricated by any ingenious mechanic, or even by the surgeon himself. No preliminary treatment will be required. It is nonsense to suppose that we can soften the callus by cataplasms and fomentations in such cases. The compression and extension should be made, at first, in as gentle a manner as possible, and be gradually increased and steadily maintained up to the point of easy tolerance, being occasionally intermitted if productive of pain, or likely to induce excoriation.

2dly. If the preceding method fail, or is inapplicable, recourse may be had to forcible extension, or rupture of the callus, thus compelling the displaced fragments to retrace their steps. This plan also is chiefly applicable to recent cases, but occasionally it has been employed at the end of six, eight, ten, or even twelve weeks. I have myself successfully employed it at the expiration of the second month, and repeatedly within the first three weeks. It would be difficult to say when it should be refrained from; much will necessarily depend upon circumstances, for in one case the union may be firm in a month, while in another, perhaps equally simple, if not more so, twice or thrice that period may elapse before it becomes consolidated. Perhaps as good a guide as any would be the existence of slight mobility between the ends of the fragments; if the union is very strong, the attempt to break it might be attended with fracture of the bone above or below the seat of the callus, and so complicate the case. Besides, the operation, except in the more simple forms of the affection, should not be undertaken without some preparation of the system, as it is occasionally followed by violent inflammation, erysipelas, abscess, and even death.

The operation is easily performed, before the union has become consolidated, simply by bending the limb over the knee, the patient being completely narcotized by chloroform, or by placing it upon a table, and applying pressure upon the distal extremities of the fragments. When the case is of long

standing, and the union firm, the callus can only be broken by the employment of force applied by some special apparatus, designed either to act directly upon the callus, or by means of a weight appended to the distal extremity of the bone, the fractured part projecting slightly over the edge of the table, while the portion of the limb containing the upper fragment is carefully held down by assistants. It has been ascertained by experiments, performed by Jacquemin, Bosch, Cæsterlen, and others, that the callus of a thigh-bone, broken fifty days previously, will require a weight of from fifty to sixty pounds to sever the fragments at the seat of the callus.

3dly. When the union is complete, and the preceding methods have either failed or are inapplicable, trial may be made of the plan of Dr. Brainard, consisting in the partial division of the bone, the object being to weaken it in such a manner as to admit of its more ready fracture, or gradual bending by systematic compression, as the new osseous matter becomes softened from the effects of the inflammation consequent upon the operation. The perforation is effected subcutaneously by means of a drill, the point of which is about one-fourth of an inch in breadth. If it is intended to break the bone, this should be done at once, and the limb immediately placed in a suitable apparatus. If, on the other hand, the rectification is to be effected by bending, no formal measures, for this purpose, should be adopted for the first eight or ten days, or until the osseous tissues have undergone a certain amount of softening. Several cases, including one by Dr. Brainard himself, have been successfully treated by this plan since he first directed attention to it in January, 1859.

4thly. Other means failing, the only resource that remains is *excision* of a portion of bone at the seat of the fracture, along with a portion of the callus. With this procedure, the origin of which dates back to the early part of the sixteenth century, and which was revived in the early part of this, are associated the names of a number of distinguished surgeons, both in Europe and in the United States; in the latter, those of Parry, Stevens, Mütter, Barton, and Pancoast, nearly all of whom have performed the operation successfully. The operation consists in exposing the extremities of the broken bone, and removing, with the saw or pliers, a sufficient piece to admit of accurate coaptation of the raw surfaces. The case is afterwards treated as one of ordinary compound fracture.

Finally, when relief is impracticable by any of the means now described, and the limb is sadly in the way of comfort and usefulness, the individual being perhaps obliged to labor for his daily subsistence, the only alternative is either to abandon him to his fate or to resort to amputation.

In 1851, I met with an instance of compound fracture of the tibia, in a young man of nineteen, in whom about two inches of that bone, near its middle, had been shot away, two years previously, by a rifle ball. The fibula had remained intact, and with the aid of a stiff leather splint, forming a case which reached from just below the knee to within a short distance of the ankle, progression was performed with tolerable ease, though not without the use of a crutch. If the deficiency of bone had been somewhat less, I should have been tempted to cut away a portion of the fibula, and, after refreshing the end of the tibia, to approximate the bones by silver wire; fully anticipating a good cure.

8. DISEASES OF THE CALLUS.

The callus, like all new tissues, is liable to different diseases, both during its development and after its completion, more or less hostile to its welfare and perpetuity. Some of these affections have a local origin, some depend upon the state of the constitution, and others, again, seem to partake of the

nature of both of these. Deficiency of the callus, although not, properly speaking, a disease, may, nevertheless, become a source of great difficulty on account of its inability to subserve the purpose of a supporting medium. The causes which may induce this condition, and the means of remedying it, when it exists, have already been pointed out.

An exuberant callus is by no means uncommon; it occasionally arises without any obvious cause, but more generally it is dependent upon the separation of the ends of the broken bone, as if nature were determined to effect union, despite of the neglect of the surgeon. The annexed cut, fig. 345, from a

Fig. 345.

Exuberant callus after fracture of the thigh.

drawing of a specimen in the possession of the late Professor Cobb, of the University of Louisville, affords a graphic illustration of an excess of this substance, obviously produced in this way. It is one of the most remarkable preparations of the kind that I have seen. The fracture, which was oblique, and situated just above the middle of the right femur, had evidently occurred several years before death. The callus, exceedingly porous in its structure, and very brittle, is eleven inches in circumference at the widest part, by six inches in length. From its superior extremity are detached two processes, which overlap the upper fragment, and must have materially impeded the action of the muscles of the limb.

Exuberance of the callus is occasionally produced by the presence of pieces of dead bone, which it thus incloses as foreign bodies are sometimes inclosed by a cyst, or a wall of plastic matter. The sheath thus formed, however, is always imperfect, openings existing in it in different parts of its extent for the purposes, apparently, of drainage. Neglected or badly-treated comminuted fractures, caused by gunshot, railway, and other severe injury, are not unfrequently followed by an extraordinary redundancy of callus; and as the effect of this substance is to incarcerate the fragments of the broken bone, profuse discharge, generally of an unhealthy, fetid, and sanious character, may be thus kept up for almost an indefinite period. The proper remedy obviously is the extraction of the dead fragment, a procedure occasionally of a very embarrassing character, especially when the callus is situated in a bone thickly covered by muscles, or in close proximity with important vessels and nerves. In the case of Lieut. Adams, of the United States Marine Corps, I removed not less than twenty-four pieces of this kind, some of them of considerable size, having previously made a long incision over the tumor in front of the thigh. With the aid of chisels, gouges and pliers, riddance was effected with but little loss of blood, and with no pain, as the patient was thoroughly under the influence of chloroform. Although the number of dead pieces was unusually great, yet such was the size and firmness of the callus that, notwithstanding it was obliged to be divided in almost every direction, no separation of the ends of the broken bone ensued, and the patient, after having recovered from the immediate effects of the operation, was able to walk about as before. It is proper to add that the fracture had occurred nine months previously from a blow by an escapette ball.

The callus is subject to extraordinary *brittleness*, arising from an excess of earthy matter. Such an event may occur at a comparatively early period, as a result of causes whose true nature is not always easy of detection. I believe, however, that fragility of the callus is more frequently met with in persons of a gouty, rheumatic, and syphilitic state of the system, than in any other class of individuals. However induced, the slightest injury, as a mere twist of the bone, or even muscular exertion, is generally capable of fracturing it; and, consequently, of re-separating the ends of the fragments.

Finally, callus is subject to *softening*, disintegration, and absorption, if not, also, to the fatty degeneration. The causes under whose influence these changes are effected are not always, or, perhaps, even generally, distinguishable. In some cases they are plainly due to undue compression, as from tight bandaging; in others, they are induced by premature exercise. Occasionally, the absorption can be distinctly traced to the inordinate use of mercury, carried to profuse salivation; or it may be owing to a syphilitic taint of the system, especially when this affection has reached its third stage, in which the bones and periosteum are so constantly, and often so seriously involved. But the most common cause, perhaps, of all, is an impoverished and diseased state of the blood, from the use of improper food, and especially from the want of a sufficient quantity of fresh vegetables and subacid fruits. The influence of ill health arising from this cause upon the condition of the callus, was strikingly exemplified in Lord Anson's voyage to the Pacific Ocean, in which many of the crew suffered severely from scurvy. It was noticed that those who had formerly had fractures were attacked with absorption of the callus, speedily terminating in disunion of the ends of the broken bone. Cicatrices, whether the result of the healing of wounds or of ulcers, experienced a similar fate, the parts breaking out into open sores, remarkably pale, languid, flabby, and difficult of cure. Similar effects are occasionally observed to follow attacks of typhoid fever and anemic states of the system, however engendered.

The treatment of softening and breaking down of the callus must depend upon the nature of the exciting cause, due inquiry into which should, therefore, always be made as a preliminary step. Tight bandages and splints are removed; premature exercise is avoided; iodide of potassium and mercury are administered if the cause is obviously of a syphilitic nature; scurvy is relieved by a change of diet, especially the use of subacid fruits and vegetables; and anemia is met with tonics and stimulants, as iron and quinine, with milk punch and nutritious food.

SECT. XVI.—FRACTURES OF PARTICULAR BONES.

I. HEAD AND TRUNK.

FRACTURES OF THE NASAL BONES.

Falls and blows are the causes of this fracture, which may be either simple or complicated; oblique, transverse, or longitudinal; limited to one bone or extended over both. It is usually attended with severe injury of the soft parts, and sometimes with fracture of the ascending process of the superior maxillary bone. Occasionally, again, but more rarely, there is a separation of the nasal cartilages, or fracture of the ethmoid bone, the vomer, or turbinated bone. The symptoms are generally well marked, except when there is considerable swelling of the integuments, in which case the nature of the lesion may easily be overlooked, perhaps much to the detriment of the patient. If an examination be made soon after the occurrence of the accident, the nose

will be found to be out of shape, from displacement of the fragments, one of which may be depressed towards the nostril, while the other may form an unusual prominence beneath the skin. Crepitation is also commonly distinguishable, especially if the fracture be multiple, or the bone broken into several pieces. In all cases, the point of the finger should be passed over the surface of the nose, with a view of ascertaining whether there be any irregularity or mobility, as there will be almost sure to be if there is a fracture. If, after this, there be still some doubt, it will be well to introduce a large probe, metallic bougie, or grooved director into the nostril, for the purpose of making counter-pressure, while pressure is applied in the opposite direction with the end of the finger. When there is a wound, denuding the bone, the diagnosis will seldom be difficult.

More or less *bleeding* generally attends this accident; occasionally, indeed, it is quite profuse, and in one instance it is said to have proved fatal. Another symptom which is sometimes present, is emphysema at the root of the nose, extending along the eyebrows. It usually comes on within a short time after the accident, and is owing to an escape of air from the nostril across a rent of the mucous membrane into the subcutaneous cellular tissue. It is in itself of no moment, as it usually disappears spontaneously in a few days. Sometimes violent head symptoms attend these fractures, depending upon the intimate connection between the nasal and frontal bones, which permits the jarring effects of the blow or fall to be communicated to the brain and its envelops.

Fracture of the nasal bones is not always free from *danger*, although, in general, it is so, the patient recovering without any untoward symptoms. Real danger to life is to be apprehended only when there is serious cerebral involvement, as when the lesion is associated with fracture of the cribriform plate of the ethmoid bone, separation of the dura mater at the anterior part of the base of the skull, copious effusion of blood, or severe concussion of the brain. Under such circumstances, the patient may die from shock, from compression, or from inflammation. The prognosis should, therefore, be guarded, especially as the degree of danger cannot always be estimated by the amount of visible injury. If the fracture is multiple, or the bones are crushed in, more or less deformity may be expected after the cure.

The *reduction* is generally easy. The patient being seated upon a chair, with his head resting against the breast of an assistant, any depression that may exist is to be remedied by means of a female catheter or grooved director, inserted into the nostril, and made to bear against the displaced fragment until it has resumed its proper level. Sometimes a good deal of pressure and counter-pressure will be necessary, while at other times hardly any manipulation whatever will be required, the mere passage of the finger over the seat of the fracture being sufficient to adjust the fragments. When the nasal septum, or the perpendicular plate of the ethmoid, is thrown out of place, restoration may be effected by means of the finger, or some suitable instrument, introduced into the nostril.

When the fragments have been restored to their natural level, they will usually retain their position with little or no difficulty. Sometimes, however, they have a tendency to cave in, or to fall asunder, in spite of everything that can be done to counteract it. The best remedy is a stout, adhesive strip, carried across the bridge of the nose from one cheek to the other; the plaster promptly adheres to the skin, and assuming the shape of the nose, effectually prevents further displacement. The older surgeons were in the habit of counteracting this occurrence by stuffing the nostrils with dossils of lint, smeared with ointment, and frequently changed for the sake of cleanliness. Subsequently, metallic tubes were recommended, and in modern times tubes of gum elastic have been used. All such contrivances are now very properly

dispensed with; or, if they are ever employed, it is in cases where it is impossible, in consequence of the manner in which the bones have been crushed, to remedy the displacement in any other way.

The symptoms which usually follow this accident, such as inflammation of the pituitary membrane, and swelling of the nose and face, are combated by general and local bleeding, purgatives, and other antiphlogistics. The brain is carefully watched, and any untoward symptom met at the earliest possible moment. Hemorrhage is restrained by cold applications, and elevation of the head and arms; if obstinate, by plugging up the nostrils.

Nasal Cartilages.—The nasal cartilages are sometimes broken, or broken and partially detached from the nasal and maxillary bones, the most common cause of the accident being a violent blow or fall, inflicting perhaps at the same time serious injury upon the soft parts. The nature of the case can seldom be mistaken. When the cartilages are displaced inwards the nose will necessarily be more or less flattened and depressed, and the effects will assume increased importance if the lesion be conjoined with fracture of the nasal bones and the cartilaginous septum. The treatment must be conducted upon general principles. The great aim should be to preserve the contour of the nose; and hence, after having restored the parts to their proper relations, it may be necessary to plug the nostrils with lint, well oiled, a metallic tube having previously been inserted to facilitate respiration. Leeches may be required to moderate inflammation.

In the case of a man, aged forty, brought to the Jefferson College Clinic last September by Dr. McWhinney, the septum, broken into several pieces four months previously, encroached so much upon the left nostril as to cause almost complete obstruction to respiration on that side. In order to afford relief I was compelled to cut away the whole of the offending part with a probe-pointed bistoury. The nose seemed to have been very little deformed by the accident.

FRACTURES OF THE UPPER JAW.

A fracture of the upper jaw implies the application of direct mechanical injury, in a concentrated and severe form. No ordinary force could produce such a result. In a few instances it has been caused by contre-coup, the head and lower jaw being wedged in between two hard, resisting bodies. Portions of the alveolar process, of variable shape, and even of large size, are sometimes broken off in the operation of extracting teeth. There is nothing definite at all in regard to the situation of the fracture, since it may affect any portion of the bone, its body, ascending process, horizontal plate, or alveolar process. It is always accompanied by severe injury of the soft and hard parts, and is usually of easy recognition, simple inspection, or touch, commonly sufficing for the purpose. The accident is apt to be followed by violent inflammation, requiring prompt measures for its relief.

In the *reduction*, pressure and counter-pressure are chiefly relied upon, the parts being moulded gently into their natural position by the fingers, either alone, or aided, as in fracture of the horizontal plate of the bone, by the grooved director inserted in the nostril. If the alveolar process has suffered, it may become necessary to secure its proper maintenance by tying together several of the contiguous teeth by thin silver wire. Whatever may be the nature of the case, the rule is, if possible, to save all, and take away nothing.

FRACTURES OF THE MALAR BONE.

Fracture of the malar bone is so very rare as to require merely a passing notice. Like fracture of the upper jaw, it is always produced by direct vio-

lence, is invariably attended with severe contusion, if not with other injury, of the soft parts, is, in general, readily recognized, is liable to be followed by high inflammation, and is easy or difficult of management according as there is displacement or no displacement. When the broken part has sunk down beyond its natural level, an attempt may be made to raise it, especially if there be already a wound denuding the bone, and admitting of the insertion of a suitable lever; if not, an incision is made, provided it seem probable that there will be unsightly deformity after the cure is effected, if the fragment be left in its abnormal situation. Such a procedure, although condemned by some high authorities, is much better, it appears to me, than to leave the bone where it was thrown by the accident. Fracture of the zygomatic process of the temporal bone, also exceedingly rare, is treated upon similar principles to that just described.

FRACTURES OF THE LOWER JAW.

The lower jaw-bone may be broken in any portion of its extent, not excepting even the symphysis. Fracture here, however, is uncommon, and is met with chiefly in young subjects, before the complete union of the two opposite halves of the bone. The most common site of fracture is the body of the maxilla, towards its anterior extremity, as seen in fig. 346; and next in point

Fig. 346.

Fracture of the jaw.

of frequency, at least according to my observation, is its ascending ramus. The condyle, neck, and coronoid process are seldom broken. The fracture may be transverse, oblique, or longitudinal; single or multiple; simple or complicated. When the bone yields at two points, there will necessarily be three fragments; cases occur in which the number is still greater, the bone being literally crushed. Houzelot has published the particulars of one in which the bone was broken at both condyles, through both coronoid processes, and

at the symphysis, the accident having happened by a fall from a height. Sometimes the lesion is limited to the alveolar process, or this process gives way along with the body of the jaw. In either event, there will be involvement of the gums and teeth, with, perhaps, extensive separation of the latter, or even complete evulsion. Occasionally a longitudinal fracture of the body of the bone is intersected at each extremity by a transverse or oblique one. The accident, which rarely occurs before the age of manhood, is much more frequent in males than in females.

The most common *cause* of fracture of the inferior jaw is direct violence, as a fall, blow, or kick. I have seen not less than four instances where it was produced by a blow with the fist upon the chin or side of the bone, one of the cases being a healthy lad between fifteen and sixteen years of age; the others, persons between twenty-five and thirty-two. A very common cause of this fracture is the kick of a horse. Dentists often break off portions of the alveolar process in their efforts to extract teeth. Sometimes frightful injury is produced in this way. Muscular action is capable of breaking the lower jaw. An old man, aged upwards of seventy, an out-patient of the Jefferson College Clinic, presented himself to Professor Pancoast in January, 1857, on account of a fracture of the neck of this bone, caused the night before in a violent paroxysm of conghing. The symptoms were unmistakable. The explosion of powder in firing off a pistol within the mouth has also

been known to give rise to the accident. Finally, the jaw-bone is sometimes broken on one side by a blow upon the opposite, or by counter-stroke.

The *symptoms* denotive of fracture of the body of the lower jaw are generally so well defined as to render it easy to form a correct diagnosis. Crepitation can almost always be observed in moving the fragments, and upon looking into the mouth the teeth will usually be found to have lost their natural relations. There is also commonly a perceptible inequality at the inferior border of the bone, which may always be increased by motion, and which is of itself sufficient to point out the character of the injury. When the jaw has given way on each side, the central piece will be drawn downwards by the action of the muscles of the throat, the front teeth will be out of their normal position, and the mouth will be open and distorted.

When the *ramus* of the jaw is broken, there will be a grating noise at the site of fracture, and excessive pain near the ear. From the fact that the masseter muscle is attached to and covers in both fragments, it is seldom, if ever, that there is any considerable displacement.

A fracture of the *neck* of the bone is easily detected, unless the subject is very fat, by the crepitation produced on moving the jaw, by the preternatural mobility in front of the ear, and by the manner in which the body of the bone is dragged forward by the action of the external pterygoid muscle. Similar symptoms will characterize fracture of the condyle of the bone.

In addition to the symptoms now described as characterizing fracture of different portions of the inferior maxilla, there will be more or less impediment in speaking and swallowing, difficulty in closing the mouth, and inability to masticate. The patient experiences severe pain at the seat of fracture, which is aggravated by motion and manipulation. The soft parts are usually considerably contused, if not also lacerated, and there is often smart hemorrhage, either from wound of the mucous membrane or rupture of the inferior dental artery.

Simple fractures of this bone usually get well in from four to five weeks, without any deformity or functional impediment. Those of the neck require a longer time, and more care in their management, than those of the body and ramus. Complicated fractures, on the contrary, are often followed by severe suffering, caused either directly by the resulting inflammation, or by some of its more serious consequences, as abscess, caries, and necrosis. I have known, more than once, a patient to become much emaciated from his inability to take appropriate nourishment during the long confinement of his jaw.

During the *reduction* of fractures of this bone, the patient should be seated upon a chair, his head being supported upon the breast of an assistant, and firmly held. The surgeon, passing his fingers along the base of the jaw, supposing that it is the body that is broken, moulds the parts into a proper shape, and then, closing the mouth, sees that the lower teeth rest fairly against the upper. When the fragments overlap each other, they must be drawn in opposite directions, when the slightest pressure will generally suffice to effect their reduction. If any of the teeth are loosened, or partially forced from their sockets, and they are perfectly sound in other respects, they should by all means be retained, being secured, if need be, to the adjacent ones, by a strong ligature, or a thin silver wire. It was formerly the custom to treat such teeth as extraneous bodies, it being believed that they were incapable of re-adhesion; but more enlarged observation has shown the fallacy of this opinion, and the practice would, therefore, be highly reprehensible.

The fracture being reduced, as may always be known by the evenness of the dental arch and of the inferior margin of the jaw, a piece of pasteboard, or, what is preferable, of felt, is wet with hot water, and accurately adapted to the base and sides of the jaw, so as to form a firm mould for it. This

being lined with wadding, and covered with a light compress, long enough to extend from the angles of the jaw nearly to the chin, is now confined by a roller carried round the top of the head in the form of the figure 8, one portion of the bandage lying in front of the ears, and the other behind them. The lower jaw being thus pressed firmly against the upper, the bandage is next conducted across the chin and the occiput above the ears, so as to give the fragments proper support in front. This mode of dressing, which is as simple as it is excellent, I have employed for many years, and give it a decided preference over every other of which I have any knowledge. If there be any unusual tendency to anterior displacement, it may be effectually counteracted by a stout adhesive strip, extending from the chin along the lower part of the face to the side of the occiput.

The annexed cuts, figs. 347, 348, represent the bandages of Gibson and Barton, so much employed in this country. Their mode of application will readily be perceived by an examination of the drawings.

Fig. 347.

Gibson's jaw bandage.

Fig. 348.

Barton's jaw bandage.

When there is no displacement of the fracture, as sometimes, though rarely, happens, an equally simple, but less efficient, contrivance will answer the

Fig. 349.

Pasteboard compress.

Fig. 350.

Hamilton's apparatus.

purpose, as a pasteboard mould; fig. 349, and a four-tailed bandage. The centre of the bandage being applied to the chin, the posterior tails are pinned to the front, and the anterior to the back of the patient's night-cap. I had recently under my charge a case of fracture of this bone, unattended with displacement, where a rapid and perfect cure was effected without any dressing at all.

Professor Hamilton, in the treatment of fracture of this bone, employs an apparatus consisting of three straps, one of which, composed of firm leather,

extends around the jaw and head in the direction of the coronal suture, while the other two, made of strong linen webbing, pass horizontally around the head, above the ear, the anterior being buckled to the forepart, and the posterior to the backpart of the vertical one. The great advantage of this contrivance, which is represented in fig. 350, is the strong support it gives to the parts, thus effectually preventing displacement of the ends of the fragments.

It was formerly customary, in bandaging fractures of the lower jaw, to fill up any irregularities that might exist between the two rows of teeth by the interposition of pieces of cork; but the practice, if I mistake not, is no longer pursued by the scientific surgeon; and yet it is easy to conceive of a case where, in consequence of the loss of all the incisor, cuspid, and bicuspid teeth, and the retention of some of the molar, some artificial support might become necessary for the proper maintenance of the fragments. In such a case the services of a skilful dentist should be called into requisition.

In fracture of the neck or condyle of the jaw, the maintenance of the reduction is always peculiarly difficult, on account of the action of the external pterygoid muscle. The most effective means of counteracting this disposition is to confine a thick, graduated compress behind the angle of the bone, the treatment being in other respects the same as in fracture of the body of the jaw.

When the fracture is comminuted, it will sometimes be found exceedingly difficult, if not impossible, despite our best directed efforts, to keep the fragments on a level with each other, such being their constant tendency to displacement. To rectify this tendency, it may be necessary to connect the contiguous teeth of the adjoining pieces with delicate silver wire; or, what is better, because more efficient, some of the teeth may be secured to a thin silver plate, interposed between them and the cheeks.

Wounds, contusions, and hemorrhage, complicating these fractures, are managed upon general principles; inflammation is combated by the usual antiphlogistics; loosened teeth and necrosed pieces of bone are removed as soon as they are detached; and the parts are kept steadily at rest, renewal of displacement being guarded against by the most sedulous attention both of the patient and the surgeon. The food should consist of slops, as grated cracker and milk, broths, gruel, and similar articles, and should be introduced into the mouth with a small spoon. The custom which formerly prevailed of conveying nourishment into the stomach by means of a tube carried along the nose, has become obsolete, as well as the still more reprehensible practice of extracting one of the front teeth, to afford room for feeding the patient. After the case has advanced for several weeks, a semi-solid, farinaceous diet may be allowed.

FRACTURES OF THE HYOID BONE.

Fracture of the hyoid bone is extremely rare. The cause of this immunity is to be found in the great mobility of this bone, and in the protection which it receives from the lower jaw. The accident is usually occasioned by falls or blows, or by the pressure of the thumb and fingers in attempts at choking. An instance is mentioned where it was produced by muscular action, the patient having fallen violently backwards upon his head. Persons who commit suicide by hanging occasionally break this bone with the rope. The fracture is generally seated in the large horns of the bone, sometimes in both, at other times only in one. It is liable to be complicated with injury of the larynx, lower jaw, and other parts, the skin being usually bruised and discolored. The patient is unable to swallow, to articulate distinctly, and to move his tongue, except in the most limited degree, and then not without

great suffering, and, perhaps, a sense of suffocation. Crepitation is generally sufficiently evident, especially during deglutition and when the index finger is placed in the throat in contact with the smaller fragments, the corresponding finger resting upon the neck. The pain is very acute, and is aggravated by the slightest motion. Sometimes the patient is conscious of a peculiar crushing sound at the moment of the accident. Occasionally there is laceration of the mucous membrane of the fauces, followed by pretty copious hemorrhage, as in the interesting case reported by Professor Wood, of Cincinnati.

Fracture of the hyoid bone, although not in itself necessarily dangerous to life, often becomes so in consequence of its complications; but, even in the most simple cases, it is generally exceedingly troublesome on account of the great mobility of the fragments, and the tendency in the supervening inflammation to be followed by severe swelling. Occasionally abscesses form, the detached piece becomes necrosed, and the neck is pierced with fistulous orifices, which are slow in healing. The accident has hitherto been noticed chiefly in aged subjects, probably on account of the great brittleness of the bone at this period of life.

In the *treatment* of this fracture, attention must be paid to the position of the head, which should be inclined forward, and maintained in a state of the utmost quietude, by an appropriate bandage secured around the chest. If there be much displacement, readjustment should be attempted by means of the finger in the throat while counter-pressure is made externally. Perfect silence should be enjoined. If there be much pain and swelling, leeches should be applied to the neck, followed by saturnine and anodyne fomentations; the bowels should be freely evacuated by stimulating injections, and fever should be combated, if necessary, by bleeding at the arm. For the first few days, the patient should abstain as much as possible from food and drink; at all events, he should take no more than what is just sufficient to sustain life. If he cannot swallow, a stomach tube must be used, but, in general, this will not be necessary. After the swelling of the neck has measurably subsided, an attempt should be made to keep the fragments in place by a compress and adhesive strips, though little, it must be confessed, is to be expected from such a course. If any portion of the bone becomes necrosed, an early opportunity is sought to extract it. In ordinary cases, the fracture will unite in from six to eight weeks.

• FRACTURES OF THE LARYNX.

The cartilages of the larynx may be broken by external violence, as a blow, the kick of a horse, or the pressure of the thumb and fingers. The accident is most liable to happen in elderly subjects, after the partial ossification of these bodies, and the one which is most apt to suffer is the thyroid. The fracture may be simple, comminuted, or complicated. The only reliable diagnostic symptoms are crepitation, displacement of the fragments, and preternatural mobility. The common accompaniments are difficulty of articulation, breathing, and deglutition, loss of voice, cough, hemorrhage, and probably also emphysema, from an escape of air into the surrounding cellular tissue.

Most of the cases of this accident prove fatal, either soon after its occurrence from suffocation, or more or less remotely from the effects of inflammation.

Fractures of the laryngeal cartilages, unless attended with serious displacement, require little else than the ordinary antiphlogistic measures, with perfect quietude of the head and neck. When there is extensive separation of the fragments, interfering with respiration, laryngotomy may be required,

both to afford an opportunity to readjust the broken pieces, and to prevent death by suffocation.

FRACTURES OF THE CLAVICLE.

The clavicle, owing to the delicacy of its structure, its exposed situation at the top of the chest, and its connection with the shoulder and arm, is extremely liable to break. Of 2358 cases of fractures of different pieces of the skeleton, referred to by Malgaigne, 228 occurred in this bone, and of this number nearly three-fourths were observed in the male, thus showing a remarkable disparity in regard to the relative frequency of the lesion in the two sexes. The accident is not peculiar to any particular period of life; I have witnessed it in a child under six months of age; and Dr. W. Keller, of this city, showed me a case last winter in which it took place in the fœtus in the womb, in consequence of a fall of the mother upon the wheel of a carriage, at the eighteenth week of gestation. The child, at the time of my examination, was several months old, and the seat of the fracture, which had involved the right clavicle, near its middle, was indicated by a marked forward angular projection of the ends of the fragments, which, however, were firmly united, the consolidation having been completed before birth. A similar case was lately shown me by Dr. William B. Atkinson, the fracture having been produced by a blow from a door upon the abdomen when the mother was gone seven months in pregnancy.

Fractures of this bone may be simple, compound, or comminuted; unilateral or bilateral; transverse or oblique; partial or complete. A transverse fracture of the clavicle is among the rarest of accidents; as for myself, I have never met with an instance of it, either in the living subject, or in any of the specimens in our museums. The bone nearly always gives way obliquely, the ends of the fragments being generally rather long and sharp, and often distinctly serrated. When very sharp, they sometimes project through the skin, or, at all events, press against it with so much force as to cause severe uneasiness, and great difficulty in maintaining apposition. It is very uncommon for the bone to break at several points; such an accident, in fact, can only happen from the application of direct force. Simultaneous fracture of both clavicles has been observed only in a few instances. I have two clavicles in my possession, from the same subject, which were both broken at the same point, but whether at the same time, I am unable to say.

The *seat* of fracture is usually at or near the middle of the bone, where it is thinnest and weakest. Of twelve preparations now before me, it is in eight about this point; in three it is towards the acromial extremity, and in one towards the sternal. Fracture of either end is, I suppose, very uncommon, as I have never met with an instance, either during life or after death.

Great *displacement* generally attends fractures of the clavicle, as shown in fig. 351; now and then, however, we see cases where the broken ends main-

Fig. 351.

Fracture of the clavicle.

tain their natural relations, as I have myself noticed in two instances. Such an event can only occur when the fracture is incomplete, as sometimes hap-

pens in children, or when the periosteum is only partially divided, and the patient has taken care not to permit any dragging of the shoulder. As a general rule, the outer fragment will be found to be drawn downwards, forwards, and inwards, by the weight of the limb and by the action of the deltoid,

Fig. 352.

Complete oblique fracture, near the middle of the clavicle.

small pectoral, and subclavian muscles; the inner, on the contrary, is usually somewhat raised by the sterno-cleido-mastoid, but not nearly as much so as its extraordinary prominence would seem to indicate, its tendency to displacement in that direction being pretty effectually counteracted by the great pectoral muscle and the costo-clavicular ligament. These appearances are well seen in fig. 352. In fracture of the extremities of the clavicle, the loss of apposition is usually very slight, its occurrence being prevented by the manner in which the bone is attached to the scapula and the sternum. In comminuted fracture, the displacement is sometimes so great as to render reposition impracticable, the mid-

dle fragment being occasionally tilted perpendicularly up.

The accident is generally *caused* by indirect violence, as a fall upon the shoulder, in which the sternal extremity of the bone is impelled by the weight of the body, at the same time that the acromial end is thrust forcibly in the opposite direction by the object struck against. Not unfrequently, however, it occurs from direct injury, as a blow or fall. In one instance I knew it to be produced by the kick of a gun, in shooting at a flock of pigeons. Children often break their collar bones by tumbling out of bed, or rolling down a flight of stairs. When both clavicles are broken, one generally gives way by indirect, and the other, immediately after, by direct force.

The *symptoms* of fracture of the clavicle are generally well marked. The shoulder has a singularly sunken appearance, being drawn downwards, forwards, and inwards by the weight of the limb and the action of the muscles, especially the deltoid and small pectoral; the head and trunk are inclined towards the injured side; there is impossibility of rotating the arm, or of carrying the hand to the face; and the patient commonly supports the elbow in order to take off the weight of the limb from the broken bone. Upon examination, the seat of the fracture is generally readily discovered by the eye, the deformity being nearly always extremely conspicuous; and the finger, as it traces the outline of the bone, cannot fail to detect any existing irregularity. Crepitation is elicited by taking hold of the elbow and pushing the arm upwards, outwards, and backwards, in a direction opposite to that of the displacement. The same procedure will serve to efface the deformity, which, however, will be instantly reproduced upon the removal of the restraint. When the fracture is imperfect, or unattended with displacement, the diagnosis can only be established, as a general rule, by a careful digital examination, aided by the alternate elevation and depression of the shoulder.

Although, in general, the patient is unable, in fracture of the clavicle, to carry his hand to the head, yet I have met with some very striking exceptions to this rule, both in children and adults. In a man, aged forty, whom I saw a few years ago with Dr. Dennis O'Reilly, the patient could execute this movement with quite as much facility as with the other limb. He could even swing it about without any pain or inconvenience. The fracture, caused by a fall on the edge of a doorstep, was situated towards the acromial extremity

of the bone, and was attended with marked displacement. Children, according to my observation, are more subject to this anomaly than grown persons.

My experience is that fractures of the clavicle are seldom cured without more or less deformity, whatever pains may be taken to accomplish the object. In some of my cases I have found it impossible, despite all the efforts I could command, to effect accurate restoration of the ends of the fragments. This difficulty will, I think, be most likely to occur when the fracture is seated at or towards the acromial extremity of the bone, in which event the outer fragment is frequently, if not generally, thrown backwards in such a manner as to render it almost impossible to bring it to its natural position. From the cases that I have seen of this fracture, as treated by other surgeons, and from the numerous specimens of it to be found in our museums, I am satisfied that a cure without deformity is a very uncommon result. It is gratifying, however, to know that deformity, even when considerable, does not, as a general rule, at all impair the usefulness of the limb. Union will, of course, be materially retarded, but in time nature will succeed in rounding off the ends of the fragments, and in connecting them firmly together, either by an osseous clasp or a kind of bridge. When union fails to occur, the power of the arm is always weakened. In ordinary cases, consolidation takes place, in the adult, in about five weeks, and in children, in eighteen or twenty days.

In the *reduction* of fracture of the clavicle, all that is generally necessary is, to take hold of the elbow and to carry the arm upwards, outwards, and backwards, a procedure which rarely fails to effect approximation of the ends of the fragments. If anything more is required, the fingers may be passed along the broken bone, so as to assist in moulding the parts into proper shape. During the treatment the indication is to maintain the shoulder in the position here adverted to; and for this purpose it will be necessary to support the limb in such a manner as to bring the elbow against the antero-lateral aspect of the chest, while the forearm rests against the front, the fingers lying across the opposite clavicle. To confine them in this position, the best dressing is a number of adhesive strips, of appropriate length, to reach around the limb and shoulders, so as to form, in the first place, a kind of immovable sling, and, secondly, to secure the arm to the side of the trunk. When this dressing, which is more easily applied than described, is carefully put on, it answers the object much better than any of the numerous contrivances that have ever been invented for the cure of this fracture. The strips, which should be from an inch and a half to two inches in width, may be so arranged as to make a certain degree of pressure, through the medium of a compress, directly upon the seat of the fracture, or, if this be deemed unnecessary, the seat of fracture may be kept under constant surveillance by letting it remain uncovered. The dressing, if properly applied, need not be renewed oftener than once or twice during the treatment, if, indeed, at all. If the patient be an adult, and the skin be covered with hair, the surface should be previously shaved. When there is a tendency on the part of the shoulder to sink forwards and inwards, it should be counteracted by a wedge-shaped pad in the axilla, the large extremity being directed upwards, and confined by suitable tapes to the opposite shoulder. In general, however, I have not found it necessary to resort to such an expedient.

Next to the adhesive strip dressing, which I have used and recommended for some years past, in the treatment of fractured clavicle, I prefer a very simple contrivance, somewhat after that of Velpeau. It consists of a wedge-shaped pad, and an ordinary roller, carried round the limb, shoulder, and trunk, so as to confine the parts in the position already indicated. The different turns of the bandage should be secured to each other by a large number of pins, which thus serve to keep them effectually in place. I seldom use less than from thirty to forty, and I find that, when this is done, the bandage

may be worn with great advantage for several successive weeks, without the slightest derangement. In warm weather, however, it should be removed at least as often as every ten days for the sake of cleanliness, especially if the patient perspire much.

An ingenious apparatus for the treatment of fracture of the clavicle has been devised by Dr. R. J. Levis, of this city, which, combining most of the principles of that of Dr. Fox, so long and so extensively used in this country, commends itself by its simplicity, lightness, efficiency, and cheapness. It consists of a short, firm, axillary pad, supported by two straps which are buckled to a broad supporting band. From the front of this band, which crosses the upper part of the back, and descends on the anterior portion of the chest, giving a firm surface of support, is suspended a sling in which the elbow is sustained. On the back of the sling, behind the elbow, is fastened a strap which crosses the back obliquely, and coming in front on the sound side, is buckled to the front end of the supporting band.

In adjusting the apparatus, the pad is first placed in the axilla by passing the arm through the opening between the straps above the pad. The wide band is then thrown across the shoulders, the elbow placed in the sling, and the long strap attached to the back of the sling carried across the back and finally buckled at its front attachment to the wide supporting band.

In removing the apparatus from the patient, it is only requisite to loosen the front attachment of the latter strap, which will allow the sling to drop from the elbow.

The extra buckle, which is noticed at the front end of the wide supporting band, comes into use when the apparatus is reversed for the opposite shoulder.

The apparatus of Dr. Levis may be made of any strong material, as drilling, webbing, or soft leather, and its different pieces may be attached together with buckles, or, if more convenient, with buttons, or tapes. Fig. 353 exhibits the various parts of the apparatus, and fig. 354 a front view of its application.

Fig. 353.

Levis's apparatus.

Fig. 354.

The French surgeons were formerly much in the habit of using the stellate or figure-of-8 bandage, represented in fig. 355. It consists of a wedge-shaped

pad and a long roller, carried alternately round each shoulder, after which the arm and forearm are secured to the side and front of the chest in the usual manner. The bandage of Desault, once so much employed in this country, has fallen into deserved neglect. Boyer's apparatus for fracture of the clavicle is represented in fig. 356.

Fig. 355.

Figure-of-8 bandage.

Fig. 356.

Boyer's apparatus.

Dr. Dugas, of Georgia, is in the habit of treating fractures of this bone without a pad, simply with a triangular piece of thick, unbleached muslin, to each angle of which is attached a bandage from three to four yards in length by three inches in width. The apparatus, which is described at length in the Southern Medical and Surgical Journal for 1852, is applied in such a manner as to form a sling for the elbow and forearm, at the same time that the arm is firmly secured to the side.

When both clavicles are simultaneously fractured, the treatment should be conducted upon the same general principles as when one of these bones alone is broken. Some of our practitioners have derived important aid, under such circumstances, from the use of a yoke, invented by Dr. Hutton, the end of the splint being furnished with holes, and allowed to project several inches beyond the shoulders, thus affording excellent points of support for the tapes of Fox's apparatus. The annexed drawing, fig. 357, represents this apparatus as modified by Day.

Fig. 357.

Hutton's "yoke splint," modified by Day.

FRACTURES OF THE SCAPULA.

Fractures of the scapula are extremely uncommon. Of 1,902 cases of fractures of different pieces of the skeleton, treated at the Middlesex Hospital, London, only 18, according to Lonsdale, occurred in the shoulder-blade. At the Hôtel-Dieu, at Paris, the scapula, in 2,358 cases, was broken only in 4. On the contrary, a remarkable disproportion of such cases sometimes occurs in the hands of particular surgeons. Thus, Dr. Dugas has met with four cases of this accident, and Dr. Bulloch, of Savannah, with not less than six, although neither has seen an unusual number of other fractures. The injury may show itself in various forms and directions, and may occupy either of the two processes of the scapula, its neck, its body, or its inferior angle.

a. The *acromion process*, fig. 358, being the most exposed portion of the scapula, is more frequently broken than any other part of this bone, the accident being usually caused by a blow upon the top

Fig. 358.

Fracture of the acromion process.

of the shoulder, or by violence applied directly to the process itself. It may also be produced by force transmitted along the humerus by a fall upon the elbow or palm of the hand. There is reason to believe that what is sometimes regarded as a fracture of this process is nothing but a separation of its epiphysis, which frequently fails to coalesce with the rest of the bone until late in life. I have seen quite a number of examples of this kind, and there is not a cabinet, however small, that does not furnish similar proofs. The osseous consolidation is occasionally postponed until after the age of forty. The fracture is generally somewhat oblique, and its signs are so peculiar as to be characteristic. The natural rotundity of the shoulder is destroyed; the outer fragment is drawn down by the weight of the arm, which hangs motionless by the side of

the body; the head of the humerus can be felt in the axilla; there is a depression at the situation of the fracture; the distance between the shoulder and the top of the sternum is diminished; and a distinct crepitus may be detected on pushing up the arm in contact with the displaced fragment. In addition to these symptoms there is acute pain at the seat of the injury; the limb cannot be raised by its own efforts; and the patient inclines his head towards the affected side, and supports the forearm as in fracture of the clavicle.

Fracture of the acromion process is distinguished from dislocation of the humerus into the axilla by the circumstance that, in the former, the limb is movable, but fixed in the latter; that the signs of the accident are easily effaced by elevating the arm, but immediately recur when the surgeon lets go his hold, whereas, in dislocation, the reduction always requires a certain degree of force, and does not relapse when it has been effected; in the former, moreover, there is usually crepitus, but not in the latter. In tracing the spine of the scapula, the finger, as it approaches the acromion process, will sink down if there be fracture, whereas the spine will be unusually prominent if there be dislocation.

The *union* is usually ligamentous instead of osseous, owing to the difficulty which is experienced in preserving the contact of the fragments. This occurrence will be more likely to happen when the tip of the acromion is broken off than when the fracture is seated near its root.

The leading indications in the *treatment* of this lesion are, first, to secure

the arm and forearm firmly to the antero-lateral part of the chest; and, secondly, to raise the humerus against the top of the shoulder-joint, so that its head shall serve as a splint for the broken process. For this purpose, the same bandage is used as for fracture of the clavicle, but the axillary pad is dispensed with, lest the broken piece should be pushed too far outwards.

b. In fracture of the *neck* of the scapula, fig. 359, the coracoid process and glenoid cavity are detached from the rest of the bone in an oblique direction. The accident is one of great rarity, so much so that many surgeons have doubted the possibility of its occurrence. It can be produced only by great direct violence, though one case is known where it was caused by muscular contraction in a young lady, in the act of throwing her necklace over her shoulder, the bone having doubtless been exceedingly brittle from some organic defect. The symptoms are always well marked. The acromion is unusually prominent, the head of the humerus is felt in the axilla, the shoulder has a flattened appearance, the limb is lengthened, the coracoid process is thrown down below the clavicle, between the deltoid and pectoral muscles; severe pain and numbness are experienced in the axilla, and a distinct crepitus is perceived on rotating the arm upon the scapula. The accident bears, at first sight, considerable resemblance to dislocation of the humerus into the axilla; but from this it is always readily distinguished by the facility with which the parts may be restored to their natural situation, by the immediate return of the symptoms when the limb is left to itself, and by the existence of crepitus. From fracture of the neck of the humerus it may be known by the circumstance that, in the latter, the shoulder retains its rotundity, and that the limb, instead of being lengthened, is shortened; the acromion also is much less prominent. In two cases of this accident, observed by Dr. Dugas, the fracture, produced by a blow upon the shoulder from a falling tree, was instantly followed by paralysis of the limb and cessation of pulsation in all its arterial trunks; a consequence, evidently, of injury done to the axillary vessels and nerves. Treatment having been neglected, no union took place, and the arms have never regained their functions.

This fracture is retained with difficulty, and is liable to be followed by stiffness of the shoulder-joint, atrophy and paralysis of the muscles of the arm, and other disagreeable symptoms. It is managed in the same manner as fracture of the clavicle, a pad being placed in the axilla, the elbow being kept well raised, and the scapula thoroughly steadied until reunion has occurred. If the parts are much contused, leeches, fomentations, and other antiphlogistics may be required. Passive motion should be instituted at the end of three weeks, and renewed every few days afterwards. Consolidation may be expected in two months.

It is not improbable that the edges of the glenoid cavity may occasionally be broken off, either by direct force, or in consequence of the sudden and violent propulsion of the head of the humerus. It is remarkable, however, that the existence of such a lesion has never been demonstrated by dissection. Is it not likely that some of the bad forms of luxation of the shoulder-joint, in which the reduction is maintained with great difficulty, and which are so

Fig. 359.

Fracture of the neck of the scapula; according to Sir A. Cooper.

liable to terminate in permanent ankylosis and ruin of the articulation, are cases of this description? The subject is worthy of greater attention than it has hitherto received. In the annexed cut, fig. 360, copied from Mr. Fergusson, the fracture extends through the glenoid cavity.

Fig. 360.

Fracture of the glenoid cavity.

c. The *coracoid process* is sometimes broken in consequence of a severe fall or blow, generally a short distance from its tip, the fracture being usually ac-

Fig. 361.

Fracture of the coracoid process.

companied with evident contusion of the soft parts, and similar lesion of the acromion, clavicle, or humerus. The accident, which is of very rare occurrence, is characterized by inability to raise and adduct the arm, by preternatural mobility, by depression of the detached fragment by the conjoined action of the small pectoral, two-headed flexor, and coraco-brachial muscles, and by the detection of crepitus on moving the arm upon the shoulder, the finger being placed between the deltoid and great pectoral muscles. The adjoining sketch, fig. 361, taken from a preparation in Professor Neill's collection, affords an illustration of a well-marked specimen of fracture of the coracoid process.

The treatment consists in confining the arm and forearm to the anterior part of the chest by means of a bandage and sling, care being taken to keep the elbow well raised, so as to fix the top of the scapula, and support the broken part. By this procedure, the pectoral and flexor muscles of the arm are relaxed, and prevented from acting injuriously upon the tip of the coracoid process.

Violent inflammation, occasionally terminating in profuse suppuration, and even in death, is apt to follow this accident, owing to injury inflicted upon the pectoral muscles and the axillary vessels, nerves, and glands. The matter being deep-seated, has great difficulty in reaching the surface, and is, therefore, disposed to burrow extensively among the surrounding structures. The proper remedy is an early and free incision at the most dependent portion of the abscess.

d. The *body* of this bone, fig. 362, rarely suffers from fracture, and then only from great direct violence, causing at the same time serious injury in the soft parts. In one case, recorded by a foreign writer, the accident is said to have been produced by muscular action. The fracture exhibits no regularity in regard to shape, is often multiple, and is rarely attended with displacement.

Fracture of the body of this bone occasionally extends through its spine, so as to divide it into two nearly equal vertical parts, as in a case which I saw, in 1860, with Dr. Rohrer. The patient was a strong laboring man, aged thirty-seven, who, in a fall from a scaffold, struck his right shoulder

violently against the corner of a plank, fracturing the scapula through its spine and body near its centre. Five days had elapsed when I made my visit. The parts were then much swollen and ecchymosed, the top of the shoulder was depressed and forced forward, and there was a marked irregularity between the ends of the fragments, the outer being drawn downward and forward, so as to form with the posterior a kind of triangle, thus , with distinct crepitation upon the slightest motion. The man was unable to put his hand to his head, but could easily touch the opposite shoulder. He experienced great pain at the time of the accident.

To steady the shoulder-blade, which is the leading indication in the treatment of this accident, two large, narrow, and moderately thick compresses should be placed along its axillary and vertebral borders, and confined by a broad roller carried round the upper part of the trunk; or, instead of this, they may be secured by means of large adhesive strips. The arm and forearm are then fastened to the anterior part of the chest, as in fracture of the clavicle.

In the case above described, apposition was easily maintained by a modification of Desault's apparatus.

e. Fracture of the *inferior angle* of this bone is occasionally met with; it is marked by preternatural mobility, by displacement of the smaller fragment by the action of the great serrated muscle, and by acute pain at the seat of the injury. The diagnosis may readily be established by fixing the top of the scapula and moving the lower angle; if they follow each other, it will be an evidence that there is no fracture, and conversely. The treatment is the same as in fracture of the body of the bone.

Fig. 362.

The ordinary situation of fracture of the body of the scapula.

FRACTURES OF THE RIBS.

The central ribs, from their exposed and fixed position, are much more liable to be broken than the upper and lower; the former being safely protected by the collar-bone, the scapula, and numerous thick and strong muscles, while the latter, from their great shortness and mobility, can readily glide out of the way of any injury that might otherwise affect their integrity. However this may be, they usually yield at their more prominent points, in an oblique direction, a transverse fracture being here, as elsewhere, an unusual occurrence. The accident is most frequent in elderly subjects, children and young persons seldom suffering. The causes are twofold, external violence and inordinate muscular action. The first produce their effect either in a direct or an indirect manner; most commonly in the former, as when the ribs are struck by a fall or blow, or when the body is traversed by the wheel of a carriage. In the second case, the ribs, being impelled by forces operating upon their extremities, break at or near their middle, as when, for example, the back of the chest is pressed against a wall by a railroad car. When these pieces are acted upon directly, their curvature is diminished; but increased when the violence is applied indirectly. I recently attended an old lady who had the eleventh rib of the left side fractured by her granddaughter, a stout girl of fourteen, by throwing her arms round the body, in a friendly embrace, on going to bed. In 1837, a number of persons met with

severe injuries of this kind, by being severely squeezed in a crowd in the Champs de Mars, in Paris. A rib has occasionally been broken by mere muscular contraction in the act of coughing, but such an occurrence is unusual, and implies an abnormal condition of the osseous tissue.

The number of ribs broken at any one time is variable. The largest number I have ever met with was eight; sometimes, however, it is still greater. In a specimen in my collection, from the body of a woman, aged upwards of seventy, who threw herself out of a second story window, there are not less than fifty-nine fractures, twenty-seven on the right side and thirty-two on the left.

The fracture may occur simultaneously upon both sides, as in the case just mentioned; and it may be either simple, or complicated with other injury, as rupture of the intercostal artery, wound of the soft parts, and laceration of the pleura and lung.

A fracture of the more superficial ribs is often easily detected simply by placing the hand upon the part where the violence is supposed to have been inflicted, and requesting the patient to cough. The bones being thus obliged to undergo a sudden motion, the lesion, if it exist, will be almost sure to show itself by the occurrence of crepitation and preternatural mobility. If, however, the fracture be placed under cover of a large quantity of muscular and fatty matter, as it will be in certain situations in robust and corpulent subjects, the surgeon may find it very difficult, if not impossible, to detect it. Should this happen to be the case, the examination should be repeated again and again, until the diagnosis is satisfactorily determined. The difficulty will be increased if only one rib be broken, or if the broken bone retain its normal position; on the other hand, the diagnosis may be established at a glance if the injury be extensive, and attended with marked displacement, as when it has been inflicted by a fall, or by the kick of a horse. Finally, the patient, as he takes a deep inspiration, is occasionally sensible of a peculiar cracking noise at the site of the fracture.

The pain which attends the fracture of a rib is generally very acute, and, without being strictly limited to the seat of the injury, is always more severe there than anywhere else; it is exasperated by the respiratory movements, and is commonly so violent as to compel the patient to breathe entirely with the aid of the diaphragm. Every attempt at a full inspiration, coughing, or sneezing, is followed by exquisite suffering. In very aggravated cases, the pain resembles that of pleurisy, and is accompanied with intense thoracic oppression. If the lung has been wounded by a spicule of bone, or the projecting end of the broken rib, there will probably be spitting of blood, if not hemoptysis, and, perhaps, also emphysema. In the latter case, the air may fill the cavity of the chest, causing a hollow sound on percussion, and total extinction of the respiratory murmur, attended with great increase of dyspnoea. Should the air escape into the subcutaneous cellular tissue, as when there is injury of the costal and pulmonary pleuræ, it will form a diffused tumor, soft and crackling, and at once indicative of the nature of the case. More or less copious hemorrhage will be present when there has been laceration of an intercostal artery, the blood sometimes passing into the chest, but more generally escaping externally.

The ribs being firmly connected to the costal cartilages in front, and to the vertebræ behind, it is impossible for them to undergo any shortening when they are fractured, or for the ends of the fragments to overlap each other, as in fracture of the long bones. Derangement, however, may take place in almost any other direction, although the angular displacement is by far the most common, and this may be either outwards or inwards, figs. 363 and 364, according to the manner in which the injury was inflicted, the latter being usually produced by direct violence, the former by indirect. It is

seldom, however, that more than one end of the bone is displaced in this direction at the same time. The Mütter cabinet contains several specimens in which one of the fragments projects above the level of the others.

Fig. 363.

Angular displacement outwards.

Fig. 364.

Angular displacement inwards.

Fractures of the ribs are not always devoid of danger, even when they are perfectly simple, or apparently free from all complication. Their number may be so great as to cause severe shock, or such an amount of local and constitutional disturbance as to produce alarming illness and even death. The danger is generally greater, all other things being equal, in fracture of the upper ribs than in fracture of the middle and lower, because a greater degree of violence is generally required to produce it. A fracture complicated with injury of the lung and pleura must be looked upon as a serious occurrence, as it is sure to be followed by more or less inflammation, if not by hemorrhage and pneumothorax. An escape of air beneath the skin is a matter of no consequence, except as indicating serious lesion within the chest. Hemorrhage from a wound in an intercostal artery is usually rather troublesome than dangerous.

The following case, which fell under my observation in August, 1854, strikingly illustrates the danger of fracture involving a number of ribs, without any very serious complication.

Mrs. Hall, of Monmouth, Illinois, a tall, slender woman, aged fifty-four, fell, while the railroad cars were in the act of running off the track, against the top of one of the seats, breaking eight of the ribs on the left side. The second, third, fourth and fifth bones were fractured in front, about two inches

and a half from their cartilages, while the eighth, ninth, tenth and eleventh, had given way behind, within a short distance of the spine. There was no displacement of any of the fragments, excepting the posterior one of the tenth rib, which projected slightly inwards towards the chest, and pierced the pleura. Excessive pain, dyspnœa, crepitation, and preternatural mobility, marked the accident. The cough was violent, and the patient was unable to lie in bed. The ordinary treatment was pursued, but without any material benefit, and the woman died at the end of the fourth day, exhausted by her suffering. The left side of the chest contained about three ounces of coagulated blood, evidently furnished by the wounded pleura, but there was no sign of inflammation, except at the seat of the upper fracture, where the serous membrane was a little roughened by lymph and slightly ecchymosed. The lung was free from disease. The other organs were sound.

Fracture of the ribs, without complication or displacement, is best managed by encircling the chest with a broad bandage, drawn sufficiently tight to compel the patient to perform respiration chiefly by the diaphragm; the intercostal muscles, and consequently, also, the ribs, being rendered perfectly passive. The bandage should be from eight to ten inches in width, and long enough to extend at least twice around the body. The ends being fastened by two pieces of tape, a scapulary is attached to prevent the cloth from slipping. Or, instead of this, the chest may be surrounded with broad strips of adhesive plaster, arranged so as to overlap each other partially, and drawn with sufficient firmness to keep it perfectly motionless. Female patients may wear, with great advantage, their usual corsets, a triangular piece being cut out in front and below to allow due play to the diaphragm. In addition to the bandage, I usually employ a thin, flat compress, as a small folded napkin, to give greater support to the broken bone.

Similar dressings will answer when there is outward displacement of the fragments, only that it may be necessary to employ a somewhat thicker compress; but how are we to proceed when the end of the broken bone is driven inwards towards the chest, perhaps into the pleuritic sac and the lung? Should it be let alone, or ought we to follow the practice of the older surgeons, and make an attempt to elevate it with the finger, the gimlet-screw, or the trephine? It is evident that counter-pressure by means of thick compresses applied to the extremities of the rib can be of no use. If there be a wound, it might be easy enough to insinuate a small lever, and raise the bone, if not to its proper level, at least out of harm's way. As for myself, I should certainly not meddle with the case, even if the depression were very considerable, unless the symptoms were most urgent, and not then until I had given a fair trial to other means, as the bandage and ordinary antiphlogistics, especially the lancet and full doses of anodynes. If relief did not soon follow, or if the suffering, instead of diminishing, rapidly increased, and it was perfectly obvious from the violence of the pain, cough, and expectoration, that a piece of rib had been forced into the substance of the lung, I should then, I think, not hesitate to make an attempt to raise the offending fragment, or, failing in this, to remove it altogether. Cases requiring such heroic measures must be exceedingly rare, and hardly deserve formal mention in a work of this kind.

Wounds, contusions, and hemorrhage, consequent upon these accidents, must be treated upon general principles. If air collect within the chest in sufficient quantity to cause excessive respiratory embarrassment, it should be let out with a delicate trocar, introduced through a valve-like opening in the skin. Pain and cough are relieved in the usual manner. If the local distress be urgent, leeches may be used, followed by the application of a large opiate plaster. The patient observes the semi-erect posture in bed, and remains

within doors until he feels that he can exercise with impunity. If his bandage become insupportable, he must not lay it aside, but simply slacken it.

The annexed drawing, fig. 365, affords an illustration of the manner in which the ribs are sometimes tied together by bony matter after fracture. It was taken from a specimen in my collection.

Cases occasionally occur where the rational symptoms of fracture of the ribs exist, but in which the characteristic signs are absent. Under such circumstances, the rule is to treat the patient precisely as if the bones were really broken.

Fig. 365.

Fractured ribs united by osseous matter.

FRACTURES OF THE COSTAL CARTILAGES.

Fracture of the costal cartilages is so uncommon that a long time elapsed before surgeons were willing to believe it a possible occurrence. That it does take place, however, is a fact fully established by modern observation; and, what is remarkable, experience has shown that it is not always necessary for these bodies to be ossified before they can be broken, although this is usually the case. The accident is invariably produced by external violence, either directly or indirectly applied, and is observed chiefly in elderly subjects. The fracture is usually single, and the pieces which are most liable to suffer are the fifth, sixth, and seventh, owing probably to their great length and to their exposed situation. The direction of the fracture is commonly somewhat oblique; the ends of the fragments often overlap each other, the posterior passing in front or behind the anterior, which, from its connection with the sternum, serves as the fixed point.

The same symptoms which serve to denote a fracture of the ribs will serve to point out one of the costal cartilages. The accident may be simple or complicated, but, in general, it is comparatively free from danger. The broken ends are united through the intervention of a clasp or ferule of bone, in which the cartilaginous tissue remains unchanged. The reduction and maintenance of this fracture are often very difficult, but by a careful observance of the rules laid down in speaking of fracture of the ribs, the surgeon will usually succeed in effecting a cure in six or eight weeks. Malgaigne advises the use of a broad truss for keeping the fragments together, the pad making direct, but gentle pressure upon their extremities. In obstinate cases, the ends of the fragments might be united by the silver wire.

FRACTURES OF THE STERNUM.

This bone may give way in almost any portion of its extent, but more commonly near its middle, the direction of the fracture being generally somewhat oblique. A few instances of longitudinal fracture of the sternum have been observed. Blows, kicks, and falls are the ordinary causes of the accident. Chaussier relates a case where it was occasioned by violent muscular contraction during labor, and several examples of a similar nature have been recorded by more recent observers. In 1858, Dr. Rohrer, of Chestnut Street, had the kindness to show me a case, in a large, heavy, muscular man, aged forty-seven, who met with a transverse fracture of the upper part of

this bone, from inordinate contraction of the sterno-cleido-mastoid muscles, in jumping, while intoxicated, from a shed eleven feet high upon the earth below. The heels striking the surface obliquely, threw the body violently backwards, the head and neck coming in contact with the edge of a board, which projected several inches above the pavement. The fracture no doubt occurred in consequence of the effort which the man made to regain his equilibrium.

The ends of the fragments either preserve their natural relations, or, if there be any displacement, it is in the direction of the thoracic cavity; in which case the broken bone may lacerate some of the contained viscera, cause effusion of blood into the anterior mediastinum, and perhaps induce emphysema by wounding the lungs.

When the fracture is attended with displacement, it may usually be detected at a glance, or by merely passing the finger over the line of injury. Grating, sometimes audible at a considerable distance, and increased at every respiratory effort, is generally present. The pain is excruciating; recumbency is, for a time at least, impracticable; and there is great dyspnoea, along with cough, spitting of blood, and other symptoms of internal injury.

In Dr. Rohrer's case, above mentioned, there was, even several days after the accident, a marked depression at the site of fracture, with considerable irregularity of the ends of the fragments, which was much increased when the patient sat up in bed. During recumbency, when he coughed hard, the hand, placed over the seat of the injury, could distinctly feel the fragments ride over each other, the upper evidently moving more freely than the lower. It seemed as if their edges were beveled off obliquely, that of the lower piece from above downwards, and from before backwards, and that of the upper in the opposite direction. Two or three times, as the man coughed, a distinct grating noise was heard. Percussion upon the spine, immediately opposite the fracture, had also the effect of displacing the ends of the fragments, and a similar result followed when firm pressure was made upon the anterior surface of the fragments. When Dr. Rohrer first saw the case, the upper fragment was thrust backwards towards the thoracic cavity, fully one inch behind the level of the other; but it was easily restored to its natural situation by bending the chest backwards over a thick pillow. The pain at the seat of fracture was comparatively slight; but the suffering in the back of the neck and head was very distressing. There was neither cough nor emphysema, and the fever that followed was slight.

The *prognosis* of fracture of this bone varies according to the mildness or severity of the accompanying lesion. When the thoracic organs have sustained much violence, the patient may die from shock, hemorrhage, or emphysema; or, if he be so fortunate as to survive the immediate effects, he may perish from the secondary consequences of inflammation of the lungs, abscess of the mediastinum, or disease of the bone itself. In the Mütter Museum at the Jefferson College is a skeleton in which a fracture of the sternum, near its middle, had undergone perfect reparation, although not without considerable deformity from the want of accurate apposition. Evidence of fracture exists in a number of other bones, and there must also have been a remarkable predisposition in the individual to the development of exostoses.

The *treatment* of fracture of the sternum is in great measure restricted to the application of a compress and bandage, to afford support to the chest, and assist in securing the quietude of the intercostal muscles. If there be any serious internal complications, local and general bleeding, active purgatives, antimonials, and anodynes, may be required, aided, perhaps, by medicated fomentations. If the fracture be simple, no attempt should be made to rectify depression of the offending fragment, unless it is perfectly certain

that it acts as a cause of compression of the heart or lung. In such a case, and also when there are loose pieces of bone projecting into the chest, restoration should be effected at all hazard, and that with the least possible delay. To accomplish this, the patient may lie across a table, upon a kind of double inclined plane, in order to extend the spine, and afford the muscles that are attached to the extremities of the sternum an opportunity of drawing the ends of the broken bone asunder. While this is being done, pressure should be made upon the parts in a direction opposite to that of the displacement, at the same time that the lungs are, if possible, thoroughly distended with air. Or, this failing, the bone, the body being still in this position, may, perhaps, be raised by a small, delicate elevator, used subcutaneously, if a wound was not previously made. If this also prove unsuccessful, I should not hesitate, in view of the urgency of the case, to apply the trephine, or to remove a sufficiency of bone with a Hey's saw. A similar proceeding may become necessary when matter forms in the anterior mediastinum, or when a portion of the sternum is assailed with caries or necrosis.

FRACTURES OF THE VERTEBRÆ.

The vertebræ are so compactly constructed, so strongly articulated, and so thickly covered by muscles as to render their fracture a matter of great difficulty. The most common causes are violent blows or falls, giving rise at the same time to severe injury of the soft parts. Occasionally, but very rarely, the lesion is produced by contre-coup, as when a person falls from a great height and alights upon his feet, the force being transmitted along the extremities and the pelvis to the spinal column, where, concentrating itself upon a particular bone, it breaks its substance or severs its ligamentous connections. Any part of such a bone may give way, its body, plates, and processes being all liable to yield under the influence of the causes here mentioned. The symptoms and effects of this lesion must be considered with reference to the different divisions of the vertebral column, as the cervical, dorsal, and lumbar, each possessing certain peculiarities growing out of its relations with the spinal cord and the nerves which are detached from it.

In fracture of the *cervical vertebræ*, the symptoms vary according to the situation of the affected bone. Thus, if the lesion be above the fourth piece, or the principal origin of the phrenic nerve, and the spinal cord is at all compressed, the diaphragm will be paralyzed, the respiration will be more or less embarrassed, and death will follow, either immediately or within a short time after the accident. If, on the other hand, the fracture is seated below this point, there will be paralysis, to a greater or less extent, of the superior extremities, difficulty of breathing, relaxation of the anal sphincters, incontinence of urine, and tympanitic distension of the abdomen. If the injury done to the soft parts is not very severe, recovery may follow, but in most cases death takes place in from three to five days.

In fracture of the *dorsal vertebræ*, the upper extremities will be free from paralysis, unless the injury is seated very high up, when they may participate in this affection with the sub-diaphragmatic portions of the body. The bowels, in either case, will be torpid and distended with gas, and the bladder will be unable to expel its contents. The patient seldom lives longer than a fortnight, although in some rare cases life is prolonged for several months. In this event, the bowels and bladder may partially regain their original tone, but the urine soon becomes loaded with phosphatic matter, and the lining membrane of the organ suffers from chronic inflammation, adding thus greatly to the patient's distress.

When the *lumbar vertebræ* are broken, the lower extremities are generally deprived both of volition and sensibility, the feces pass off involuntarily, and

the bladder is unable to contract upon its contents. Life usually lasts longer than in fracture of the dorsal vertebræ, the paralysis not extending so high up, and consequently not involving so many important organs. In the majority of cases, the patient dies in five or six weeks; but sometimes, though rarely, he survives a much longer time, his bladder, meanwhile, suffering as in fracture of the other divisions of the spine.

The symptoms here enumerated may follow fracture of any portion of a vertebra, except, perhaps, that of the spinous process, where the suffering is generally comparatively slight, unless the lesion is complicated with serious mischief of the spinal cord.

Fracture of the *spinous* processes of the vertebræ occasionally occurs independently of the bodies of those bones, as seen in fig. 366, the usual exciting cause being a blow, fall, or kick. Preternatural mobility and lateral displacement, with more or less contusion and discoloration of the soft parts, are the most reliable phenomena.

Fig. 366.

Fracture of the spinous process.

Fig. 367.

Fracture of the vertebral arches.

Fracture of the *arches* of these bones, of which the accompanying cut, fig. 367, affords a good illustration, is often comminuted and attended with depression of the fragments, some of which may be driven into the substance of the spinal cord, crushing and pulpifying it. It is generally produced by violence directly applied, and is not unfrequently quite as dangerous as a fracture of the bodies of the vertebræ.

The *transverse* processes of the vertebræ can only be broken, as a general rule, by excessive force, as the passage of a ball, or a fall from a considerable height. Hence the result of such accidents is commonly very unfavorable.

The *diagnosis* of fractured spine is usually rather a matter of inference than of positive conviction. Its most important elements are the mode of production of the injury, and the paralysis of the extremities, but it should be recollected that this symptom may depend entirely upon lesion of the spinal cord, unconnected with fracture of the vertebræ. Owing to the small size of these bones and the manner in which they are covered in by the muscles of the back, it will generally be impossible to detect either crepitation, deformity, or preternatural mobility. All these phenomena may, however, be present in fracture of the spinous processes.

Dissection, after an injury of this kind, will usually reveal more or less displacement of the broken bone, which is sometimes quite comminuted, laceration of the connecting ligaments, and injury of the spinal cord, with more or less extravasation of blood in the spinal canal and the surrounding parts. The cord is compressed, bruised, pulpified, perhaps nearly completely

severed, pieces of bone sometimes being imbedded in its substance, as shown in fig. 368.

The *prognosis* of these accidents may be inferred from what has been said respecting their symptoms and effects. If the patient escape immediate destruction, he will almost certainly succumb under his suffering at no very remote period; or, if his life should be spared, he will be doomed to carry on a miserable, bedridden existence, palsied and otherwise crippled in the exercise of some of his more important functions.

In the *treatment* of this accident, very little is to be done in the way of restoring displaced fragments, all such attempts being not only uncertain, but, even if successful, likely to aggravate the danger by the additional mischief that is inflicted upon the spinal cord. The same remark is applicable to the operation of cutting down upon the injured part, and removing the offending portion of bone with the trephine or saw, as proposed by the late Mr. Henry Cline, of London, and practised by him and other surgeons. In all the cases, amounting probably to ten or a dozen, in which this procedure has been employed, including those of Dr. John Rhea Barton and Dr. Goldsmith, no particular benefit has followed; a circumstance that might have been expected when it is recollected how seriously the spinal cord is generally injured by the depressed fragment. The operation, although not without difficulty, on account of the great depth at which the offending bone is situated, may be executed by any competent surgeon, with but little loss of blood; and, I must confess that, notwithstanding the want of success which has hitherto attended it, I should feel very much tempted to resort to it, if the symptoms were such as to render it certain that the lesion was accompanied by depression.

Whether an operation be performed or not, it is the duty of the surgeon to adopt prompt measures for the prevention of inflammation; with this view blood is taken freely from the arm, and also by leeches from the seat of the injury; the bowels are relieved by purgatives, or stimulating enemas, and pain is abated by full doses of anodynes, combined, if there be much fever, with antimonials. The bladder is carefully watched, and the urine, if retained, is drawn off regularly twice or thrice a day, instead of allowing the catheter to remain permanently in the bladder. The patient should be kept on his back, upon an air-bed, his head resting upon a low pillow, and his position being as seldom changed as possible. Great care is taken that he is not turned upon his face for any purpose whatever, as he might be almost instantly asphyxiated while in this situation, from the imperfect descent of the diaphragm, caused by the pressure of the abdominal viscera, on account of the paralyzed condition of the abdominal muscles, and their consequent inability to offer any resistance to the weight of the body. After the lapse of five or six weeks, the back and limbs should be frequently rubbed with stimulating liniments, and a large issue should be established in the vicinity of the injury with the Vienna paste or the actual cautery. Along with these means, trial may be made of small doses of strychnine, in union with iron and quinine.

When the lesion is confined to the spinous processes, the fragments must be moulded into shape, and retained by two long, thick compresses, stretched along the side of the spine, and secured with a circular bandage, fastened by

Fig. 368.

Fracture of the vertebræ.

a scapulary. If the broken pieces, however, be much shattered, so as to preclude the possibility of their reunion, the best plan will be to remove them.

Fracture of the *odontoid process*, although a very uncommon occurrence, is sometimes met with, and, as might be supposed, generally proves promptly fatal from injury done to the spinal cord. Now and then, however, a remarkable exception is found. Thus, in a case related by Professor Willard Parker, the patient survived the accident five months, at the end of which time he suddenly expired from displacement of the process, during some inadvertent movement of the head, a result favored by the destruction of the occipito-axoid ligament. The dissection showed that the odontoid process had been completely broken off, and that its lower extremity had been turned

backwards towards the spinal cord, as in fig. 369.

The patient was a man, forty years of age, who had been thrown violently from his carriage, alighting upon his head and face, about fifteen feet off. After recovering from the immediate effects of the accident, he was able to resume his business as a milkman, which he followed, diligently and uninterruptedly, every day for four months. He complained, however, constantly, from the time of the accident, of pain in the occipito-cervical region, and was always obliged to support his head, which he was incapacitated from rotating. The only visible deformity was a protuberance of the neck, just below the base of the occiput, to the left of the median line, with a corresponding indentation.

Fig. 369.

Fracture of the odontoid process of the axis. A. Broken surface. B. Odontoid process.

FRACTURES OF THE PELVIC BONES.

a. The *innominate bone* may give way in various parts of its extent, but the one which is most apt to suffer is the upper crest, owing probably to its exposed situation. The acetabulum is sometimes broken by a severe blow upon the hip, or by a counter-stroke, as when a person falls upon his knee or foot, thereby driving the head of the femur into the pelvis. In the adjoining cut, fig. 370, from a preparation in the possession of Professor Neill, the fracture runs in a semicircular direction through the acetabulum.

Fig. 370.

Fracture of the acetabulum.

In young subjects, the innominate bone is occasionally separated at the acetabulum into its three primitive pieces. Whatever may be the site, form, or extent of the fracture, it can happen

only through the agency of direct mechanical violence, which, at the same time, generally seriously compromises the soft structures, both outside and inside the pelvis. The most frightful accidents of this kind that have fallen under my observation have been the result of railroad injury, caused by the body being jammed in between a car and a wall, literally crushing the bone, and fatally implicating the bladder and other organs.

The *symptoms* of this accident will necessarily vary according to the seat and extent of the fracture. When the bone has given way at the cotyloid cavity, the nature of the case may usually be recognized by the circumstance that the head of the femur is drawn upwards, and the great trochanter somewhat forwards, so that the limb is diminished in length, and the foot inverted. When the head of the thigh bone is impacted in its new position, the limb may be firmly fixed, as in dislocation, but, in general, it will be found to be more or less movable, and to afford a distinct crepitus when an attempt is made to rotate it.

b. In fracture of the *pubic* and *ischiatric* bones, the corresponding limb is either somewhat shortened, or it retains its natural length; the fragments are pushed either directly downwards, forwards towards the femur, or backwards towards the acetabulum; the patient is unable to sit, stand, or walk; and on placing one hand upon the ilium, and the other upon the pubes, crepitation may usually be perceived. A well characterized fracture of the pubic and ischiatic bones is delineated in fig. 371, from a preparation in the collection of Professor Neill.

Fig. 371.

Fracture of the pubic and ischiatic bones.

c. Fracture of the crest of the *ilium* is characterized by more or less displacement, preternatural mobility, and crepitation; the pain is severe, and progression impracticable. The nature of the accident is sometimes rendered apparent by the existing deformity and by slight manipulation.

Besides the above symptoms, denotive of fracture of different parts of the innominate bone, there is always more or less contusion of the external soft parts, and not unfrequently, also, serious injury of the pelvic viscera, followed by loss of motion of the inferior extremities, retention of urine, and other distressing affections. The prognosis should, therefore, be very guarded, as such accidents are generally fraught with danger, death often occurring in a few days from inflammation or extravasation of urine, or at a later period from abscess, phlebitis, and other mischief.

Owing to their peculiar character, it is usually found very difficult to reduce these fractures, or to prevent relapse after this has been done. To effect restoration, our main reliance must be upon pressure, while the maintenance is best accomplished by well arranged compresses, secured by a body bandage. When no displacement exists, all such dressings may very properly be dispensed with. In either case, the utmost quietude is enjoined; the patient must lie upon his back, his shoulders being elevated, and the thighs flexed, to relax the muscles about the pelvis; inflammatory action is promptly dealt with, and the bowels are relieved by stimulating purgatives and enemas. The bladder is carefully watched, retention of urine being relieved by the catheter.

d. The *sacrum* may be broken by falls, blows, gunshot violence, and similar injury. The fracture is generally discoverable, especially when there is displacement, by mere manual examination, as the patient lies upon his abdomen. It is attended with severe pain at the affected part, and great difficulty in walking, accompanied, when there is lesion of the sacral nerves, with paralysis of the lower extremities, retention of urine, and involuntary discharge of the feces. The danger attending this accident is always considerable, on account of the mischief done to the soft parts; hence, even if the patient survive the immediate shock of the injury, he may perish afterwards from the effects of inflammation of the pelvic viscera.

When there is displacement of the fragments inwards, reposition may be attempted by the insertion into the rectum of a stout bougie, a lithotomy scoop, or a vesical sound, care being taken not to do any injury to the mucous membrane; or, if the displacement be very slight, the bone may be left in its new situation, as no harm can be caused by so doing. Backward displacement may be easily remedied by pressure with the finger, relapse being prevented by a compress and a T bandage. Recovery is promoted by rigid recumbency and antiphlogistics.

e. The *coccyx* is sometimes broken by a fall, by a kick upon the buttock, and by the passage of the child's head in labor. The accident is most common in elderly subjects, in whom the joints of this bone have been destroyed by a deposit of osseous matter. The characteristic signs are preternatural mobility, acute pain, and crepitation on introducing the finger into the rectum. During labor, the occurrence of the accident is sometimes rendered evident by a sense of yielding and a peculiar noise perceived by the attendant as he is engaged in supporting the perineum. If displacement exist, it is remedied by pressure upon the surface and counter-pressure with the finger in the rectum. It is very important, especially in the female, that the *coccyx* should be preserved in a continuous line with the sacrum, otherwise serious deformity of the pelvis may ensue, interfering with defecation and parturition. After the reduction has been effected, the parts should be supported with a compress, confined by adhesive strips; perfect quietude and lateral recumbency should be observed; and the bowels, without being acted upon at all frequently, should be maintained in a strictly soluble condition.

2. SUPERIOR EXTREMITY.

FRACTURES OF THE BONES OF THE HAND AND FINGERS.

The symptoms of fracture of the bones of the thumb and fingers are so obvious that anything like a formal account of them is quite unnecessary. The treatment is best conducted by a leather, felt, or gutta-percha splint, accurately moulded to the shape of the member and the palm of the hand, to which it must be well secured by appropriate rollers.

The *metacarpal* bones are sometimes broken by machinery, and I have met with two instances in which the fourth and fifth of these pieces had given way under a blow of the fist, the part struck being, in one of the cases, the face, and in the other the forehead. There was marked displacement upon the back of the hand, from the projection of the anterior fragment, with distinct crepitus and swelling of the soft parts, but hardly any pain. The treatment consisted in the use of a well-padded tin case for the palm of the hand, extending from just above the wrist, and of a short, narrow splint for its dorsal surface, firm pressure being made with it over the seat of fracture. Union occurred in a month, with no apparent deformity.

The *carpal* bones are never broken, except by direct violence, which always seriously implicates the soft parts, not unfrequently necessitating removal of the hand. The nature of the accident is usually apparent from the attendant deformity, the excessive pain, loss of function, and crepitus on manipulation. Reposition of the fragments having been effected by pressure and counter-pressure, retention is secured by means of two splints, either of binder's board or wood, long enough to extend from the middle of the forearm to the ends of the fingers, the hollow of the palm being well padded, and the limb supported in a sling.

FRACTURES OF THE SHAFTS OF THE RADIUS AND ULNA.

The radius and ulna may be broken conjointly by direct violence, or, as more frequently happens, by a counter-stroke, as when a person falls upon the hand, and the force is concentrated by transmission upon the forearm. The fracture, although it may occur at any point, is most common in the inferior half of these bones, and rarely takes place at the same level, whatever may be its cause. In general, too, it is oblique, and not transverse, as is usually supposed. The nature of the accident is commonly sufficiently apparent from the angularity of the fragments, seen in fig. 372, and their preternatural mobility, to say nothing of the facility of eliciting crepitus on rotating the hand. The patient experiences an inability to supinate and pronate the limb, the forearm is in a state of semi-flexion, and acute pain is felt at the seat of the injury.

The chief danger in this fracture, as it ordinarily exhibits itself, is from the tendency of the ends of the fragments to sink inwards into the interosseous space, and to become united by a common callus, thereby materially impeding the usefulness of the limb, by destroying the functions of supination and pronation. With ordinary care, however, such an accident is not likely to happen, and, in most cases, the consolidation is completed in from thirty to thirty-five days, without any deformity, or ultimate inconvenience. The vicious union here mentioned is well shown in fig. 373, from a preparation in my collection.

The fracture having been adjusted in the ordinary manner, the forearm is bent at a right angle with the elbow, and enveloped by a roller, extending from the fingers upwards. Two thick binder's board splints are next applied along the anterior and posterior surfaces of the broken bones, and secured with the remainder of the bandage. They should be a little wider than the limb, and long enough to reach from just below the elbow to the extremities of the fingers, both being well covered with wadding, and accurately moulded to the parts. The hand and forearm are then suspended in a broad sling, and confined to the chest in such a manner as that the thumb shall look directly upwards.

In my own practice I have, of late years, entirely dispensed with the compresses upon which so much stress has been laid by practitioners for counteracting the tendency which the ends of the fragments have to approach each other at the interosseous space. I am satisfied that they are not needed for this object, and that all the compression that can be required, at least in ordinary cases, can be effected by the two splints, which are always employed in the treatment of fracture in this situation. The bandage, too, has received a great deal of unjust blame in these cases, it being alleged that, if applied directly to the surface, it will force the bones together, and thus bring on the result adverted to in the foregoing paragraph. It would unquestionably be

Fig. 372.

of the ends of the frag-
ments in fracture of
the ulna and radius.

Fig. 373.

Fracture of the
shaft of the ra-
dius, with vicious
union.

easy enough to produce such an effect, but it need hardly be added that this would be an abuse, and not a proper use of the bandage, its appropriate office being to afford equable support to the muscles of the broken limb for the purpose of preventing swelling and spasmodic action. Whenever it causes such an amount of compression as to force the fragments towards each other, it cannot fail to excite pain and inflammation, if not still worse consequences. It is the manner, then, in which the application is made, and not the application itself, that is objectionable in the treatment of this fracture. As to the splints, they should be carefully moulded to the shape of the limb, a narrow interval being left between them at its radial and ulnar borders. When the binder's board splints cannot be obtained, light pieces of wood may be used.

When the fracture is multiple, consisting, for example, of three fragments, the intermediate one having lost its support may have a tendency to sink in towards the interosseous space. To counteract this disposition, a thick, narrow pad may be placed along the mesial border of the loose piece, in an opening in the anterior splint, so as to enable the surgeon to make the pressure more firm and direct. But even here such an expedient will rarely be necessary, if the parts have been moulded into position prior to the application of the apparatus.

FRACTURES OF THE ULNA.

Fractures of the ulna may with great propriety be divided into those which take place at its body, its inferior extremity and its two principal processes, the olecranon and coronoid.

1. *Shaft.*—The body of the bone is most commonly broken in the lower half of its extent, in an oblique direction, as exhibited in fig. 374, from causes acting directly upon the forearm. The accident, may, however, be produced by a counter-stroke; and one instance is known where it was occasioned by muscular action in wringing clothes, the patient being a stout, healthy girl of eighteen. The fracture is evinced by a marked depression at the inner border of the forearm, by the mobility of the fragments, and by the crepitus on rotating the hand. The lower fragment alone is generally displaced, being drawn over towards the interosseous space by the inferior pronator muscle, while the other, in consequence of its firm connection with the humerus, remains stationary. An exception to this is seen in the adjoining figure.

Fig. 374.

Fracture of the shaft of the ulna.

Great care is necessary in the treatment of this fracture, lest the upper end of the lower fragment retains the vicious position into which it is forced at the time of the accident, and is induced ultimately to become soldered to the inner margin of the radius. To prevent this occurrence, the hand should be permanently inclined towards the thumb, the means for doing this being two splints, the extremities of which are rendered somewhat sloping from behind forwards, in a direction opposite to that of the splints employed in the management of fracture of the corresponding end of the radius. Such an expedient will be much more efficient than the use of the long, thick, and narrow compress, generally recommended for that purpose.

The head of the ulna is sometimes broken off, either separately, or along with the head of the radius. The circumstance is easily detected by the mobility of the part, by the disabled condition of the wrist-joint, by the severity

of the pain, and by the concomitant distortion. The treatment is conducted with two splints, aided, if necessary, by two compresses applied directly over the seat of the fracture.

2. *Olecranon Process*.—Fracture of the olecranon, seen in fig. 375, is caused either by direct violence, or by the inordinate action of the three-headed ex-

Fig. 375.

Fracture of the olecranon process.

tensor muscle, attached to its upper extremity. Situated at various points of its extent, the fracture may be transverse or oblique, single or multiple, simple or complicated.

The *symptoms* are, semiflexion of the limb, impossibility of extending the forearm, a hollow at the back of the elbow, fig. 376, and a movable prominence at the postero-inferior surface of the arm, along with more or less pain and swelling. The interval between the two fragments varies from one and a half to two inches, and may be augmented or diminished at will by moving the forearm. The radius may be rotated upon the ulna, and crepitus may be elicited by the approximation of the extremities of the broken bone. Sometimes the very tip of the olecranon is severed, and then there is no separation of the fragments. The same thing may happen when the fracture is oblique, or transverse, provided it is not below the ligamentous expansion of the extensor muscle.

Fig. 376.

Fracture of the olecranon process.

The *union* of this fracture is generally fibro-ligamentous, as seen in fig. 377, from a specimen in my collection. The cause of this kind of union is

Fig. 377.

Fracture of the olecranon process united by fibrous matter.

threefold; first, the want of proper nourishment of the upper fragment; secondly, the difficulty of maintaining accuracy of apposition; and, lastly, the accumulation of an inordinate deposit of synovial fluid, all, but especially the first, interfering with the healing process. I have, in a few instances, seen osseous union; but such an occurrence is extremely rare, and is not at all likely to happen if there be any considerable separation of the fragments, or when the fracture extends through the lower part of the process. The period required for the repair of the injury varies from six to eight weeks, and many months generally elapse before the patient regains a good use of his limb. When the lesion is of a complicated nature, violent inflammation of the elbow-joint may arise, sometimes ending in permanent ankylosis.

The *treatment* consists in maintaining the limb in the extended position, by means of a wooden splint, long enough to reach from the fore part of the middle of the arm to the same point of the forearm, as represented in fig.

Fig. 378.

Apparatus for fracture of the olecranon process.

378. A roller having been applied from the fingers upward, the small fragment is drawn into its proper place, where it is confined by a few long adhesive strips and a compress, the whole being firmly secured by carrying the roller round the joint somewhat in the form of the figure 8; or, instead of this, the arm is bandaged from the shoulder downwards, so as to obtain a more perfect control over the extensor muscle, the great agent in effecting displacement. Passive motion is instituted at the end of three weeks, and frequently renewed, to prevent ankylosis. If the fracture is associated with severe injury of the soft parts, leeches, fomentations, and other antiphlogistic measures must be employed.

3. *Coronoid Process*.—A considerable number of cases of fracture of the coronoid process of the ulna, exhibited in fig. 379, have been reported, both

Fig. 379.

Fracture of the coronoid process.

in systematic treatises and in medical periodicals, but it is very questionable whether even a minority of them should be considered as true examples of that lesion. I have myself never met with the accident in the living subject, and I am not aware that a solitary specimen of it exists in any of the osteological collections, private or public, in the United States. Professor Hamilton, who has investigated this subject with his usual care and ability, is very decidedly of the opinion that most of the published cases of this accident are unworthy of acceptance, either because they were badly observed or imperfectly reported, and because the existence of scarcely any of them has been verified by dissection. Some years ago, an instance of reputed fracture of the coronoid process occurred in a young man, a patient in the Louisville Hospital; but, although the symptoms were such as are usually described as characteristic of that lesion, I am by no means satisfied that it really was of that nature. In the case of a boy, about nine years of age, treated by Dr. A. A. Scott, of Missouri, by whom the particulars have been kindly communicated to me, the coronoid process is stated to have formed a distinct prominence upon the anterior and inferior surface of the humerus, a short distance above the joint, movable from side to side, the olecranon being at the same time displaced slightly backwards, and the forearm somewhat flexed. The accident was caused by a fall upon the hand while the arm was forcibly extended.

If we may credit the reported cases of this fracture, it is evident that it takes place mostly in young subjects. It has generally been supposed that it may be caused by inordinate contraction of the anterior brachial muscle;

but if any one will take the trouble to examine this muscle at its lower extremity, he will find that it is impossible for it to produce this effect, since the only connection which it has with this portion of the ulna is at the very base of the coronoid process, all the rest of the prominence being entirely free, and therefore beyond the reach of the influence of the anterior brachial. Such an accident might possibly occur in this way if the coronoid process were, like the olecranon, an epiphysis, but this is not the case. Hence the most reasonable conclusion is that fracture of this prominence is always produced either by direct injury, as by the passage of the wheel of a carriage, or, as probably more commonly happens, by force applied to the hand, impelling the ulna and radius violently upwards against the lower extremity of the humerus:

In whatever manner the fracture is produced, the *symptoms* are not generally so clearly marked as one might at first suppose. That this is the fact is sufficiently evident from a study of the reputed cases of the accident, in which the diagnosis has generally been attended with unusual difficulty. The ulna, having lost its purchase in front, will necessarily be drawn backwards and upwards by the action of the three-headed extensor muscle, so that the accident will present all the appearances of a dislocation of the bone in this direction, the prominence of the olecranon being characteristic. The patient is unable to flex the limb, and the detached portion of bone can be felt just above the elbow, where it may be readily grasped and moved about, especially soon after the accident, before any swelling has come on. By bending the forearm at a right angle with the arm, and drawing down the fragment of bone, crepitation might possibly be elicited, but this must, in any event, be very faint and indistinct. The accidents with which this fracture is most liable to be confounded are fracture of the humerus and dislocation of the ulna and radius backwards.

The *union* of this fracture is universally considered as taking place by fibro-ligamentous tissue, and there is no doubt that this is the fact, as appears sufficiently evident when we reflect upon the small size of the detached piece of bone, the difficulty of keeping it in place, its imperfect nourishment, and its close connection with the joint; circumstances which are so many impediments to the formation of osseous matter. In young subjects, and under proper management, a cure may generally be looked for in four or five weeks.

The *treatment* is quite simple, being conducted with a view to the thorough relaxation of the flexor muscles of the arm. For this purpose, the forearm, after having been carefully bandaged from the fingers up as far as the elbow, and the arm from the shoulder downwards, in the opposite direction, is placed at a right angle, as seen in fig. 380, in a tin-case or suitable splints, and supported in a sling, care being taken to prevent the radius and ulna from slipping backwards, away from the condyles of the humerus. The fulfilment of this indication will generally be materially aided by the use of adhesive strips, carried around the joint in the same manner as in fracture of the olecranon. Passive motion should be instituted at the end of three weeks, and perseveringly renewed from time to time, lest ankylosis ensue.

Fig. 380.

Apparatus for fracture of the coronoid process.

FRACTURES OF THE RADIUS.

1. *Shaft*.—Fracture of the body of the radius may take place independently of that of the ulna, as shown in fig. 381, and is the more frequent accident of the two; its most common seat is the inferior half of the bone,

Fig. 381.

Fracture of the shaft of the radius.

and its ordinary cause a fall upon the palm of the hand. Dr. Packard, of this city, has reported a case of fracture of the upper portion of the radius, caused by violent muscular exertion in driving a pair of horses.

The *symptoms* are usually well marked, there being more or less deformity, preternatural mobility, inability to perform the motions of pronation and supination, and the detection of crepitus upon rotating the hand. The ends of the fragments have a singular tendency to approach the interosseous space, and hence, if the case be not judiciously managed, there is apt to be permanent distortion, with partial loss of function of the limb. One of the evil consequences of this tendency is the want of osseous union, or the formation of a false joint within two and a half or three inches of the wrist. I have seen a number of well-marked examples of this kind, and I know of no fracture where an unskilful surgeon may show his ignorance to greater disadvantage.

The limb, being bandaged in the usual manner, is steadied by two splints, extending as far forwards as the extremities of the fingers, the hand being inclined inwards towards the ulna, and maintained in a state midway between pronation and supination. For this purpose, the ends of the splints should be shaped somewhat like the handle of a pistol, as this arrangement will afford an opportunity of bearing upon the radius in such a manner as to force the lower fragment outwards in contact with the superior, thereby counteracting the tendency above alluded to. If this point be strictly attended to, the cure can hardly fail to be perfect. Ordinarily consolidation may be looked for in four weeks.

2. *Superior Extremity*.—This bone is occasionally broken at its superior extremity, the fracture detaching its rounded head, or extending through its neck. It is very rarely that the bone gives way at the bicipital tubercle. The injury could hardly be produced in any other way than by direct violence. Owing to the manner in which the parts are enveloped by the muscles, the symptoms are usually indistinct, and the diagnosis is, consequently, rather difficult.

The usual *symptoms* are deformity just below the elbow-joint, caused by the flattening of the muscular prominence in that situation; the projection of the upper end of the lower fragment in front of the limb being drawn thither by the two-headed flexor muscle, impossibility of executing the functions of rotation, and the rapid supervention of severe swelling. To render the diagnosis certain, the best plan is to grasp the head of the radius with the thumb and index finger of one hand, and to rotate the forearm with the other. If there be fracture, its existence will be rendered evident by the head of the bone refusing to obey the motions of the inferior fragment. By adopting this manœuvre, it will hardly be possible to mistake the nature of

the case, unless there be so much swelling as to prevent the bone from being felt, in which event the examination must be repeated when the tumefaction has measurably subsided.

In the *treatment* of fracture in this situation, the limb is placed at a right angle with the arm, in a state midway between pronation and supination, and the same splints are employed as in fracture of both bones of the forearm, care being taken to extend them as high up as possible, in order that they shall afford adequate support to the upper fragment. When there is great disposition in the pronator muscle to draw the lower fragment over towards the interosseous space, a compress may be used, but not otherwise.

The annexed drawing, fig. 382, from a preparation in my collection, exhibits a rare form of fracture, in which a portion of the head of the radius has been chipped off, and permanently united to the contiguous border of the coronoid process of the ulna. The specimen was obtained in the dissecting-room, and nothing is, therefore, known of its history.

Fig. 382.

Fracture of the head of the radius.

Inferior Extremity.—The frequency of fracture of the lower extremity of the radius, its liability to be confounded with dislocation of the wrist-joint and the imperfect recovery of the functions of the hand which so often follows it, sufficiently attest the importance of the subject, and afford a satisfactory reason for the extraordinary attention that has been accorded to it by modern surgeons. Among those who have particularly interested themselves in elucidating the question, I am happy to mention Dr. John Rhea Barton, who, in a short, but graphic paper, published in the Philadelphia Medical Examiner for 1838, was the first to describe, with any degree of accuracy, the nature and treatment of fracture of this bone at the radio-carpal articulation. In 1814, Dr. Colles, of Dublin, gave an account of a fracture which he had repeatedly found at the distance of about an inch and a half above the joint, and more recently the whole question has been examined anew by some of the French and British surgeons, particularly Mr. R. W. Smith, of Dublin.

Two circumstances powerfully contribute to the production of this fracture, namely, the large amount of spongy substance entering into the composition of the inferior extremity of this bone, and the peculiarity of its connection with the wrist-joint. The relative quantity of this matter in its lower and middle portions, and also the difference in their compact structure, are very striking. These appearances, which are sufficiently conspicuous even in young subjects, are remarkably prominent in elderly persons, in whom the spongy substance of this part of the bone is generally exceedingly rarefied and infiltrated with oily matter, while the compact is often merely a thin crust, hardly as thick as an egg-shell, and scarcely less brittle. The peculiar mechanism of the wrist-joint cannot fail to strike the surgeon. From the intimate manner in which the radius is articulated with the scaphoid and semilunar bones, any shock received upon the palm of the hand is readily communicated to it, causing it, if the force be at all severe, to give way under its influence; whereas the ulna, which has no such close relation, generally escapes without injury.

Fracture of the lower extremity of the radius may happen at any period of life, but is most common in middle aged and elderly subjects. As the result of indirect violence, I have not seen an instance before the eleventh year.

Respecting the *site*, direction, and extent of fracture of this part of the

radius, the greatest possible diversity exists. Generally the injury is situated low down, within a short distance of the joint, or within the joint; but the line of fracture is often considerably higher up, as an inch, an inch and a quarter, and even an inch and a half, at the junction, or even beyond the junction, of the lower extremity of the bone with its shaft. Sometimes the seat and direction of the fracture correspond to the line of union of the epiphysis.

Fig. 383.

Multiple fracture of the lower extremity of the radius.

In regard to its *direction*, the fracture is generally oblique, extending from above downwards, and from the dorsal to the palmar surface. Of forty-seven cases analyzed by Mons. Goyrand, of Aix, forty-three were of this description, the degree of obliquity varying much in different instances, the fissure being sometimes almost horizontal.

The fracture of the lower end of the radius is frequently *multiple*, or comminuted; indeed, I am inclined to believe that this form of injury is more common than the simple. In the annexed drawing, fig. 383, from a preparation in the pathological collection of the New York Hospital, there are four fragments, and in several cases I have seen as many as five and six. Occasionally there are two fissures, one transverse, or nearly so, and the other vertical, detaching the head of the bone from its shaft.

In Barton's fracture, the lesion always extends through the articular surface of the bone, affecting more particularly its posterior margin, and is frequently attended with separation of the styloid process.

Fracture in this situation may be *complicated*, first with fracture of the styloid process of the ulna, or of the head and shaft of that bone; secondly, with dislocation of the wrist-joint; and, thirdly, with serious injury of the soft parts. Some years ago I attended, along with Dr. Chenoweth, a young man in whom this bone was split in two by a transverse and oblique fissure, the larger fragment being completely detached, and thrown forwards and inwards over the ulna, whence, as it was impossible to replace it, I removed it by incision. A good recovery took place with hardly any impairment of the functions of the wrist-joint. In my private collection is a specimen of transverse fracture of the lower extremity of the radius, extending into the joint, and detaching the head of the bone by several small, vertical fissures. In this case I had an opportunity of dissecting the parts in consequence of the removal of the forearm, above its middle, by another surgeon, several weeks after the occurrence of the accident. The hand and wrist were much swollen, and infiltrated with pus, which was also freely diffused through the sheaths of the flexor tendons, while the cellular tissue along the inner part of the palm contained a good deal of blood. The joint was filled with matter, and the scaphoid and semilunar bones, as well as the ulna, which was dislocated backwards, were almost completely divested of cartilage.

The ends of the broken pieces are sometimes *impacted* in this fracture, the superior being driven into the cancellated structure of the inferior; but such an occurrence, although said to be common, is, if I may judge from the cases that I have had an opportunity of examining, quite infrequent. When the force causing the impaction is very great, the inferior fragment may literally be crushed by the superior.

The accident nearly always results from a fall upon the hand, in which the patient, stretching out the limb, receives the shock upon the palm, whence it

is transmitted to the inferior extremity of the radius. Occasionally, though much more rarely, the fracture takes place by a fall upon the back of the hand. The lesion is also produced by direct violence.

The most conspicuous *symptom* of this fracture is the singular deformity of the hand, giving the limb the appearance of a dislocation of the wrist-joint, as exhibited in fig. 384. This is owing to the fact that the lower fragment

Fig. 384.

Fracture of the lower extremity of the radius.

along with the carpus is drawn upwards and backwards, from an inch to an inch and a half above the joint, by the action of the extensor muscles of the thumb, while the upper fragment forms a slight projection on the palmar aspect of the forearm. Immediately above the posterior prominence is a well-marked depression, which gradually slopes off towards the ulna, and is generally sufficiently large to receive the little finger. These appearances are always very striking when the limb is held in a situation midway between pronation and supination, and are easily effaced by extension and counter-extension, although they are promptly reproduced when these forces cease to act. The lower extremity of the forearm has a rounded form, from the increase of its antero-posterior diameter; the fingers are usually flexed, and the patient is unable to supinate the hand, which is, moreover, completely powerless; the pain is excessive, and considerable swelling soon arises, especially along the palmar aspect of the limb. Crepitus may usually be detected by pressure just above the wrist-joint. With these phenomena before him, a surgeon must be exceedingly stupid if he does not speedily detect the nature of the injury.

Instead of being thrown backwards, the inferior fragment is sometimes forced in the opposite direction, forming a projection in front of the forearm, beneath the flexor tendons. Another tumor, more conspicuous, and consisting of the lower extremity of the inferior fragment of the radius, occupies the dorsal surface; it extends across the entire breadth of the limb, and is bounded above by a well-marked furrow, more distinct internally than externally. The accident, which is exceedingly rare, closely simulates dislocation of the carpus forwards, but may readily be distinguished from it by the presence of crepitus, and the facility with which the symptoms can be made temporarily to disappear under slight manipulation.

The adjoining sketch, fig. 385, represents a fracture of the inferior extremity of the radius, complicated with luxation of the ulna. The signs of both injuries are characteristic. The drawing was taken from a private patient.

The *prognosis* of this fracture is greatly influenced by the nature of the case and the manner in which it is managed. If, as occasionally happens, there is no dis-

Fig. 385.

Fracture of the lower end of the radius.

placement, or serious complication, consolidation may be looked for in from twenty-five to thirty days, without deformity or permanent impairment of function. Under opposite circumstances, nothing but the utmost care and circumspection will be likely to insure a successful cure. In any event, the patient must not expect to regain the complete use of his wrist and fingers for several months, as there is a great tendency, in almost every case of the kind, in the resulting inflammation to extend to the synovial membrane of the digital articulations and of the sheaths of the tendons. This fact should always be explained to the patient at an early stage of the treatment, otherwise the surgeon may be unjustly censured for what he cannot possibly avoid.

Among the various contrivances for maintaining the contact of the fragments, I may mention, as an excellent one, that devised by the late Dr. Henry Bond, of this city, which I can recommend, from my own experience, as well calculated to fulfil every indication that can be presented by such an injury. It consists, as shown in figs. 386 and 387, of two splints, one of medium-

Fig. 386.

Bond's splint, being the part for the back of the forearm.

sized binder's board, and the other of thin, light wood, furnished with a block and edges of thin sole-leather, about an inch in height, the whole pre-

Fig. 387.

The same, for the front of the forearm and hand.

sending somewhat the appearance of a shallow trough. They are long enough to reach from a short distance below the elbow to within an inch of the knuckles of the metacarpal bones, the block of the latter resting in the hollow of the palm, and both being well padded with wadding. Having encircled the thumb and each finger with a narrow bandage, the better to control the resulting swelling, and the fracture having been adjusted by pressure and extension, a roller is next passed around the limb as high up as the superior part of the forearm, special care being taken that it shall not produce the slightest constriction anywhere. The splints are then placed in their proper position, and fastened in the usual manner. If there be any tendency to displacement, which, however, rarely happens after the first few days, a narrow, square compress, not more than a third of an inch in thickness, is laid over the projecting fragment, to give greater concentration and effect to the pressure of the apparatus opposite to the seat of fracture. Sometimes it is found necessary to use a compress on each side of the wrist; but such is the accuracy with which the palmar splint fits the parts that this portion of the dressing may generally be altogether dispensed with. There is no use, in any

case, of an interosseous compress, as there never is any tendency in the fragments to inward displacement. The advantage of the apparatus of Dr. Bond is that, while it maintains the thumb perfectly at rest, and consequently prevents its extensor muscles from disturbing the fragments, it permits the patient to move his fingers about freely in front of the block; a circumstance of no trifling importance in an accident so liable to be followed by inflammation of the sheaths of the tendons. The hand and forearm are, of course, supported in a sling.

In the absence of Dr. Bond's apparatus, a good dressing may be made of two thin pieces of wood, or stout binder's board, a little wider than the forearm, well padded, and of the same length as the preceding, care being taken, in applying them, to fill up the hollow of the hand and the intervals between the splints and limb with cotton. It will also be well, in this case, to give the anterior extremities of the splints a sloping inclination from above downwards, so as to put the extensors of the thumb slightly upon the stretch, as seen in fig. 388.

Fig. 388.

Dressing for fracture of the lower end of the radius.

A very simple but efficient method of treating fractures of the inferior extremity of the radius was recently suggested by Dr. John Swinburne, of Albany, New York. It consists in confining the forearm upon a single splint, stretched along its posterior aspect from the elbow to the metacarpophalangeal joints, and composed of a thin piece of wood, the width of the limb, and provided with two compresses, one of which fills up the concavity of the carpus, while the other supplies the deficiency in the straight line of the arm above. The splint is secured with adhesive strips, the application being commenced at the elbow, and then continued, at intervals of several inches, down the limb to the hand, which, the displaced parts having been previously adjusted, is firmly fastened in such a manner as to allow perfect freedom to the thumb and fingers. The annexed cuts, figs. 389, 390, and

Fig. 389.

Fig. 390.

Fig. 391.

Dr. Swinburne's apparatus for fracture of the radius.

391, afford a good idea of the apparatus and of the appearance of the limb after its application.

The above dressings will answer equally well, whatever may be the charac-

ter of the displacement, whether backwards or forwards. Passive motion is instituted at the end of a fortnight, proper support being given to the fracture while this is being made. The proceeding is afterwards repeated every other day, until the end of the fourth week, when the apparatus may generally be discontinued, the bandage alone being used. If the joints of the fingers are stiffened, they should receive special attention at each dressing.

FRACTURES OF THE HUMERUS.

Fractures of the humerus are of frequent occurrence, and are of great practical importance, from the difficulty which so often attends their diagnosis and treatment. They may take place in the shaft of the bone, at its surgical neck, at its head within the capsular ligament, and at its condyles.

1. *Shaft.*—The simplest fractures of the humerus are those which occur in its shaft, as they are most easily detected and treated, and least liable to be followed by deformity and loss of function. Caused occasionally by direct violence, they more frequently result from falls upon the palm of the hand, in attempts to save the body from more serious injury. In several instances that have come under my observation, and which are alluded to in another part of this section, the accident was produced by muscular contraction; in one case, while the patient was in the act of throwing a chip. The fracture is usually oblique, a transverse one, properly so termed, being exceedingly uncommon. A complicated fracture of the shaft of the humerus is occasionally met with, as a consequence of the explosion of firearms, the contact of machinery, or the passage of the wheel of a carriage.

The *symptoms* of fracture of the humerus in this situation are usually characteristic, the deformity, preternatural mobility, and crepitus being well marked. In general there is some shortening, but the amount of this varies very much, according to the obliquity of the fracture and the development of the limb; in ordinary cases, it is very slight, the weight of the arm being sufficient to counteract the action of the muscles, at least to a considerable extent. The direction of the displacement is regulated by the line of fracture; if this is below the insertion of the deltoid, the inferior fragment will be drawn inwards, but outwards if it be above that point. However this may be, any deformity that is present is easily effaced by extension and counter-extension. The limb is completely powerless, and is always supported by the patient at the wrist.

The *treatment* of this fracture is very simple, the only apparatus necessary being two splints, and a roller applied from the fingers up. The splints may consist of two stout pieces of unoled sole-leather, or binder's board; one extending from the axilla to within an inch of the internal condyle, and the other from the shoulder-joint to the corresponding point of the outer condyle, the two, when applied, nearly meeting each other. By soaking them in hot water, they may be accurately moulded to the shape of the limb, and, when this is done, it is impossible to conceive of anything better adapted for the treatment of such a case. The forearm and hand are, of course, supported in a sling, and, for the sake of greater security, the arm may be fastened by a few turns of a bandage to the side of the trunk, though this is not at all essential. Special care is taken not to raise the elbow, as a certain degree of weight is necessary to prevent overlapping of the fragments. This mode of dressing fractures of the shaft of the humerus I have practised for many years, and it requires no argument to show its superiority over the old four-splint apparatus, still used by many surgeons. If the lesion be simple, reunion will generally occur in a month.

2. *Inferior Extremity.*—Fracture of the condyles may be caused by a fall upon the point of the elbow, by a blow, or by the passage of the wheel of a

carriage. I have repeatedly known it to be produced by a fall upon the palm of the hand, the limb being at the time in an extended position. The accident may be simple, or, as not unfrequently happens, complicated with serious mischief to the joint and soft parts. Both condyles may be broken, or one only may be affected. In the former case, a longitudinal fracture usually extends some distance along the centre of the bone, and then terminates, probably at a distance of an inch and a half to two inches above the joint, in an oblique or transverse fissure in the lower portion of the shaft of the humerus, thus producing three fragments. Not unfrequently, however, there is a separation merely of one of these prominences, the fracture being then usually directed obliquely downwards into the joint. In a third series of cases, the small projection over the inner condyle is broken off, either obliquely or perpendicularly, without any involvement whatever of the articulation.

The *symptoms* of fracture of this portion of the humerus vary according to circumstances, as might be expected from a consideration of the structures of the elbow-joint. When both condyles are severed just above the articulation, the radius and ulna project backwards, a hollow exists at the bend of the arm, the forearm is slightly flexed, and the distance between the elbow and wrist is sensibly diminished. When the fracture involves both the condyles and the inferior extremity of the shaft of the bone, there will be, in addition to these phenomena, an increase in the width of the bend of the arm, and an appearance of greater flattening. The accident, whether accompanied by this occurrence or not, is liable to be mistaken for dislocation of the radius and ulna backwards; but the diagnosis may generally be readily determined by the fact that the symptoms which mark the former lesion promptly disappear on extending the limb, and that crepitus may be produced when the forearm is rolled upon the humerus.

When the inner condyle alone is detached, as exhibited in fig. 392, the

Fig. 392.

Fracture of the internal condyle.

ulna projects backwards, but resumes its natural position on extending the limb; the condyle forms a tumor at the back part of the elbow; crepitus is perceived on bending the forearm; and, if the forearm be extended, the humerus will advance in front of the ulna as the latter recedes.

A fracture of the external condyle, shown in fig. 393, is characterized by

Fig. 393.

Fracture of the external condyle.

the existence of a tumor at the outer and back part of the elbow, by crepitation on rotating the radius, by the supine position of the hand, by inability to move the joint, and by the constant semiflexion of the forearm.

When the tubercle over the internal condyle is broken off, the diagnosis is easily established by the great mobility of the fragment, the ready production

of crepitus, and the other ordinary signs of fracture. The accident is usually caused by a fall upon the elbow, and is unaccompanied by any displacement of the bones of the forearm.

Whatever may be the nature or extent of these fractures in the vicinity of the elbow-joint, there are always severe pain and complete inability to move the limb. Considerable swelling soon follows, and effusion rapidly takes place within the articulation, obscuring the characteristic features of the injury, and rendering the diagnosis proportionately difficult. When such a state of things exists, leeches, fomentations, and other antiphlogistic measures may be necessary before the parts will be sufficiently tolerant of the requisite manipulation.

The inferior extremity of the humerus occasionally gives way just above the condyles, generally in a more or less oblique direction, as seen in fig. 394. Such an occurrence may, unless great care be taken, be readily confounded

Fig. 394.

Fracture of the lower end of the humerus.

with dislocation of the ulna and radius backwards, which its symptoms, at first sight, closely resemble. The signs of distinction are, the mobility of the limb, and the facility with which the parts can be restored to their natural position, followed by the immediate return of deformity upon discontinuing the extension. The accident, which should be treated on the same principles as fracture of the shaft of the humerus, is extremely liable to be followed by stiffness of the joint.

In children, prior to the completion of the ossific process, there is sometimes a separation of the epiphysis of the inferior extremity of the humerus, induced by falls upon the hand or elbow. The symptoms resemble those of fracture in this situation in the adult, there being an unnatural projection at the back of the joint, caused by the retraction of the lower fragment along with the bones of the forearm, and the ready production of crepitus on extending the limb. The accident is treated as if it were a fracture.

I know of no fractures which I approach with more doubt and misgiving than those of the inferior extremity of the humerus, involving the elbow-joint. I know of none which are more liable to be followed by severe inflammation of the synovial membrane, extensive effusion, ankylosis, and deformity. Even in the more simple forms of these injuries, and where the treatment has been most skillfully conducted, there is generally great risk of an unfavorable result; at all events, a long time will be sure to elapse before there will be anything like a good use of the articulation. The prudent surgeon will, therefore, inform his patient, at the commencement of the attendance, of the nature and probable consequences of the case. From five to six weeks is the average period necessary for the reunion.

The nature of the deformity, in badly-treated fracture of the condyles of the humerus, may exhibit itself in quite a variety of ways, depending upon

the peculiar mode of treatment. Sometimes a posterior projection remains, caused by the displacement of the lower end of the bone backwards; not unfrequently the limb has a strangely twisted appearance, either in the direction of pronation or supination; occasionally it is permanently flexed or extended; and sometimes, again, the limb is greatly increased in breadth.

Most practitioners, I believe, are agreed upon the propriety of treating these fractures with the limb in the flexed position. I know of but few that pursue the opposite plan, and the arguments which they have adduced in its favor have by no means convinced me that it is at all equal to the other method. It is but just to say, however, that I know nothing of its comparative merits from experience, inasmuch as I have never, in a solitary instance, adopted it, having always been satisfied with the rectangular position. To maintain the limb in this situation, I have long been in the habit of employing a light and well-shaped tin-case, extending from the axilla to the metacarpo-phalangeal articulations. This, being properly lined with wadding, affords an admirable support to the limb, and effectually prevents displacement of the fragments, whatever may be their size or number. Great care should be taken to protect the inner condyle from pressure, otherwise it may become seriously inflamed, if not ulcerated. To obviate this occurrence, a small gap may occasionally be made with advantage in the case, opposite this ledge of bone. A case made of gutta percha, felt, thin wire, or sole-leather, answers quite as well as one of tin, and is even superior to it, inasmuch as it admits of more accurate adaptation to the irregularities of the limb. The forearm is supported in a sling, in a state midway between supination and pronation.

There are no fractures which require more constant vigilance after their adjustment than those about the elbow-joint. The dressings should, therefore, be examined for some time, from day to day, in order that they may be changed whenever they become either too tight or too slack, and especial pains must be taken that the bandage, in the first instance, is applied very loosely, due allowance being always made for the resulting swelling. If some time have elapsed since the occurrence of the injury, and the pain and tumefaction are very severe, measures should be used to reduce the inflammation before the limb is put up. Passive motion is commenced at the end of two weeks, and repeated every forty-eight hours until all danger of ankylosis is passed. As soon as the fracture is sufficiently repaired to bear the change, the rectangular apparatus is taken off, and a more obtuse one substituted in its place.

Fig. 395.

Complicated fracture of the elbow.

Fractures of the elbow are often of a *complicated* character, fig. 395, especially when caused by railway injury, or falls from a great height, penetrating

the joint, extensively lacerating the soft parts, and, perhaps, comminuting the bones. Such accidents are always fraught with danger, both to limb and life, and usually promptly require amputation. Even supposing that the limb could occasionally be saved under such circumstances, the patient's recovery will be extremely tardy, and when, at length, he does get well, it will be found, as a general rule, that the joint will be worse than useless, only serving as a hindrance.

3. *Superior Extremity.*—The superior extremity of the humerus includes the hemispherical head of this bone and its two necks, the anatomical and surgical; the former being the narrow, constricted portion between the head and its tuberosities, and the latter all that portion which intervenes between these prominences and the insertion of the broad dorsal muscle, its length varying from an inch and a half to two inches, according to the stature of the individual.

a. *Fracture of the Head.*—Fracture of the head of the humerus is an extremely uncommon occurrence, so much so, indeed, that its possibility was for a long time a matter of controversy among surgeons. The cases, however, that have been reported by Bichat, Astley Cooper, Dorsey, Gibson, R. W. Smith, Malgaigne, and others, have effectually dispelled all doubt upon the subject. I saw, myself, many years ago, in a patient of Dr. George McClellan, an instance of the kind, which had been mistaken by the attendants for a fracture of the acromion process, and the true nature of which was not detected until several years after the occurrence of the accident, when the man, who was upwards of forty years of age, died of another disease, and an opportunity was thus afforded of examining the parts. The fracture had extended obliquely from above downwards through the head of the bone; and, although it had become perfectly consolidated, there were several rough prominences which, while they unmistakably indicated the seat of the injury, greatly impeded the movements of the shoulder-joint. The accident had been caused by a fall from a carriage.

In a specimen in my private collection, obtained from the body of an insane woman, upwards of seventy years of age, whose skeleton presented the appearance of having been broken in numerous places, the head of the humerus is completely detached from the anatomical neck, the articulating surface, which retained its smooth and polished aspect, being tilted over the great tuberosity against the posterior surface of the bone, to which it is firmly and inseparably united by osseous matter, the fracture having evidently happened a long time before death. Directly opposite to the prominence thus formed, on the inner surface of the humerus, is another large projection; fully an inch in length, having the character of a stalactitic exostosis. The bicipital groove is completely effaced. The whole bone is extremely light, its weight being hardly two ounces and a half. The annexed cut, fig. 396, conveys a good idea of the distinguishing features of this remarkable, if not unique specimen.

Fig. 396.

Fracture with detachment of the head of the humerus.

When the head of the humerus is completely detached from the tubercles along the anatomical neck, it must necessarily act as a foreign body, speedily perishing from the want of nourishment. In some cases, however, it is en-

abled to preserve its vitality, although imperfectly, by remaining in connection with the rest of the bone through the intervention of a few bands of fibrous tissue.

b. Fracture of the Anatomical Neck.—In children, prior to the completion of ossification, the head of the humerus is occasionally separated from the shaft of the bone, very near the point of attachment of the capsular ligament, or at the anatomical neck. The accident is generally caused by a fall on the elbow, or by violence applied to the shoulder, and is very liable to be mistaken for other injuries. In old persons, the head of the bone, fig. 397, is sometimes not only broken off, but thrown down into the axilla, where it forms a distinct tumor that can easily be felt by the hand, but which does not obey the movements of the arm. Such an accident always seriously complicates the case.

Intra-capsular fracture of the humerus is occasionally impacted, the upper fragment being propelled into the inferior. The occurrence, which is extremely uncommon, is met with exclusively in old subjects, laboring under atrophy and great fragility of the osseous tissue. The head of the bone can be felt in the glenoid cavity, there is a slight hollow below the acromion, the axis of the arm is directed inwards towards the coracoid process, and the elbow is somewhat separated from the trunk. Crepitation is either very faint or entirely wanting. The length of the humerus is diminished, but generally in so slight a degree as to render it unavailing in a diagnostic point of view.

c. Fracture of the Surgical Neck.—Fracture of this portion of the humerus is uncommon, but may take place from the same causes as fracture of the shaft of the bone; sometimes from a fall upon the hand or elbow, sometimes from direct violence, and sometimes, although rarely, from muscular action. The injury is always attended with marked displacement, forming an important feature in its history. The superior fragment, yielding to the influence of the spinatus muscles of the scapula, is generally drawn outwards and slightly

Fig. 397.

Fracture of anatomical neck of humerus.

Fig. 398.

Fracture of the surgical neck of the humerus.

forwards, while the inferior one is directed inwards towards the side of the trunk by the pectoral, broad dorsal, and large teres muscles, attached to the inner border of the bicipital groove. At the same time that this portion of the humerus is dragged inwards, it is usually somewhat raised by the joint agency of the muscles that pass from the scapula to the forearm; the extent of the displacement, however, is commonly trivial, inasmuch as the weight of the limb is almost sufficient to counteract its occurrence.

The *diagnosis* of these different fractures is not always so easy as might, at first, be supposed. Their character is often greatly obscured by the swelling, and the consequent difficulty of making a thorough examination. In general, there is marked deformity at the shoulder-joint, the deltoid muscle is flattened, the arm is twisted upon its axis, and, if the injury is situated on

the outside of the capsular ligament, there is usually slight shortening of the humerus, with distinct projection of the upper end of the lower fragment. If extension and counter-extension be made, so as to draw the parts in place, crepitation will be elicited, followed by a recurrence of all the previous symptoms the moment the surgeon relinquishes his hold. In all cases of doubt, it will be a good plan to grasp the head of the humerus firmly with the thumb and fingers of one hand, while with the other we seize the elbow and move the arm on its axis. If fracture be present, it will almost be sure to be detected by the crepitation produced by the manœuvre, whereas, if there be a dislocation, no noise will be perceived, and there will also be little or no mobility. When the head of the bone is fractured, and thrown off the glenoid cavity, the symptoms will be of a compound character, the crepitation and abnormal mobility co-existing with flattening of the deltoid muscle, extraordinary saliency of the acromion process, and a remarkable fulness in the axilla, caused by the presence of the displaced bone, at the same time that the upper extremity of the inferior fragment projects prominently upwards and inwards.

Treatment.—Fractures of the superior extremity of the humerus must all be treated upon the same general principles as fractures of the shaft of the

Fig. 399.

Welch's shoulder splint.

bone. The limb being bandaged from the fingers up, two splints, broad and hollow, made of unoled sole-leather, binder's board, gutta-percha, or gum sheeting, are applied, one on the outside, and the other on the inside of the limb, the former being long enough to extend from the external condyle to the top of the shoulder, which it should cover well in, since it is of paramount importance to give firm support to the broken parts, as in fig. 399. The inner splint should be carefully padded at its superior extremity, in order that it may not chafe the skin or exert any disagreeable pressure upon the axillary vessels and nerves. No cushion will be required for the axilla. The arm is carefully secured to the side of the chest, and the forearm is supported in a sling, but the elbow is left free, in the hope that its weight will tend to prevent overlapping of the fragments. Passive motion is instituted at the end of the third week, and firm union may reasonably be expected in a fortnight more. A long time, however, will elapse before the joint will completely regain its functions, if, indeed, it ever does. Permanent lameness will almost be

inevitable, if the fracture be intra-capsular and comminuted, owing to the difficulty of readjusting the fragments.

When fracture of the superior extremity of the humerus is complicated with *dislocation*, the proper plan, of course, is to restore the displaced bone to its natural position before an attempt is made to readjust the ends of the fragments. The operation, however, will necessarily be one of extreme difficulty, on account of the shortness of the superior piece, which thus deprives the surgeon of the advantage of a suitable lever. His whole reliance must, therefore, be upon well-directed pressure and counter-pressure, while the patient is fully under the influence of an anæsthetic, complete muscular relaxation being of paramount importance to success. When the operation fails, it has been recommended to let the dislocated head of the bone remain in its unnatural situation, and to bring the upper extremity of the lower fragment in contact with the glenoid cavity, in the hope that, in time, as the bone becomes rounded off, it will contribute to the restoration of the motion of the limb. Such an idea, however, it seems to me, must be perfectly delusive; for

it is impossible to see how, under such circumstances, nature could make anything like a good or useful joint. Instead, therefore, of pursuing such a practice, I should not hesitate; if a case of the kind were to present itself to me, to cut down upon the dislocated bone, and push it back into its natural position. The broken pieces being placed in contact, and the wound carefully closed, I should not apprehend any bad results from inflammation and its consequences. Excision of the head of the humerus is seldom followed by serious effects; and, although the two cases are not exactly parallel, yet I should neither expect to lose my patient, nor make him a stiff joint.

Fractures of the surgical neck of the humerus are occasionally *impacted*, the upper extremity of the inferior fragment being forcibly driven into the cancellated structure of the lower end of the superior fragment. Such an occurrence is most common in old subjects, after the age of fifty-five, in consequence of interstitial absorption of the osseous tissue, and may be produced either by a blow upon the shoulder, or, what is more common, by a fall upon the elbow. The extent of the impaction varies from a few lines to half an inch or more. As the bone retains its continuity, the symptoms of the accident are usually very obscure, there being neither mobility nor crepitation, unless the fragments are unlocked by being forcibly pulled asunder. Nevertheless, there is generally some deformity, perceptible upon firmly grasping the humerus, and an alteration in the axis of the limb, which often looks as if it were twisted, together with severe pain, and usually also more or less contusion of the soft parts. If the impaction be extensive, there will, in addition, be some degree of shortening of the arm, or a slight diminution in the distance between the shoulder and elbow. These circumstances, conjoined with the fact that the patient has received a severe injury, that there is loss of motion in the joint, and that all the symptoms of dislocation are absent, afford sufficient evidence of the probable nature of the case.

The impacted fracture requires no special treatment on its own account. Experience and common sense alike dictate the propriety of letting it alone.

Nothing, certainly, can be gained by pulling the fragments forcibly asunder, except mischief and trouble. Instead, then, of such interference, the surgeon contents himself with supporting the limb, and combating inflammation by leeching, fomentations, and other means; taking care, in due time, to institute passive motion, lest ankylosis should arise.

d. Great Tuberosity.—Fracture of this portion of the humerus, although uncommon, is probably not quite as infrequent as is generally supposed, the obscurity of its symptoms rendering it extremely apt to be mistaken for other lesions in and around the scapulo-humeral articulation. The accident is liable to occur at almost any period of life, except, perhaps, in early childhood, and is always caused by a fall or blow upon the forepart of the shoulder, the force being concentrated upon the upper extremity of the humerus so as to separate the large tubercle from the hemispherical head and shaft of the bone. The existence of the fracture is denoted by considerable flattening of the deltoid muscle, by a remarkable increase in the width of the upper portion of the arm, which is nearly double what it is in the natural state, and by the presence of two osseous prominences, one of which, consisting of the detached tuberosity, is situated at the superior and outer part of the joint, and the other, formed by the head of the humerus, at the upper and inner part. The acromion is abnormally salient, and the arm is separated from the side, but can be approximated to it without difficulty, and in fact readily pronated in every direction by the surgeon.

The most important *diagnostic* signs are the great increase in the breadth of the articulation, the refusal of the thumb to sink into the glenoid cavity, as it always does in dislocation of the shoulder, the preservation of the length of the limb, and the production of crepitation upon rotating the humerus by seizing

it just above the elbow while the surgeon encircles the head of the humerus with both hands. Another important evidence is the fact that the deformity is readily effaced by manipulation, but instantly reappears when it ceases.

Reparation, generally of an osseous character, is effected in from four to six weeks, according to the age of the patient, and the amount of the resulting inflammation, which is always very considerable, in consequence of the concomitant contusion of the soft parts. Owing to this circumstance, the motions of the joint usually remain imperfect for many months; and in not a few cases, even when the greatest vigilance is exercised, they are never completely regained, owing to a redundancy of callus and the formation of osseous excrescences around the articular surfaces.

In the *treatment* of this fracture, one of the leading indications is to neutralize the action of the muscles which are attached to the tubercles of the humerus, the larger one receiving the insertion of the two spinate and the small teres, and the lesser the subscapular, which necessarily tend to draw the fragments away from each other, the subscapular being materially aided in this by the action of the broad dorsal, the great pectoral, and the short head of the flexor of the arm. To accomplish this object, the limb is put up in two leather splints, the inner one of which is nicely padded above to prevent undue pressure upon the axillary vessels and nerves, while the outer one should be bent well over the top of the shoulder. No cushion will be necessary, especially if the precaution be used of securing the arm and forearm properly to the chest. The elbow is carefully supported in a sling, but not so firmly as to push the head of the bone too high up towards the acromion process. For the first five or six days after the accident, leeches and fomentations may be required, and passive motion should be instituted in three weeks.

3. INFERIOR EXTREMITY.

FRACTURES OF THE FOOT.

Fractures of the bones of the foot do not require any special notice, as their management is conducted upon the same principles as that of fractures of the hand. From the fact that they are generally complicated, the treatment must be largely antiphlogistic, and the surgeon will have cause to congratulate himself if he is not occasionally obliged to amputate the foot, or exsect some of its bones. It need hardly be added that any loose and displaced fragments should always be promptly removed, even when there is no external wound, and when it might be perfectly easy to effect replacement; for such pieces would not only be likely to act as foreign bodies, but they might, in the event of vicious reunion, seriously interfere with the wearing of a boot.

The *calcaneum*, or heel-bone, notwithstanding its exposed situation, the importance of its functions, and the manner in which it lies beneath the tibia and fibula, is seldom the subject of fracture. Direct violence is the most common cause of the accident, which is often attended with severe lesion of the neighboring structures, both soft and hard. Falling from a great height, in which the person alights upon his heel or foot, is the manner in which it commonly happens. The bone being thus forcibly acted upon, on the one hand, by the weight of the body, and, on the other, by the resistance offered by the surface struck, yields at its weakest point, breaking, perhaps, into several pieces. More rarely the accident is produced by the inordinate contraction of the muscles of the calf, as in dancing and leaping; but in this case it is only the posterior extremity of the bone that suffers, its tip being the part generally torn off. The amount of displacement varies according to circumstances, being necessarily very slight when the fracture extends across the body of

the bone, whereas it is always very considerable when it involves its back part, on account of the action of the gastrocnemial muscles, which, exerting their influence through the tendo Achillis, sometimes draw up the posterior fragment from an inch and a half to two, three, four, and even five inches. Authors speak of an impacted fracture of the calcaneum, but such an occurrence must be extremely uncommon.

The *signs* of this fracture are always sufficiently characteristic when the posterior portion of the bone is broken off, the hollow at the heel, the protuberance at the lower and back part of the leg, and the impossibility of extending the foot, being unmistakable evidences of the nature of the accident. Upon bringing down the upper fragment in contact with the inferior, crepitus may be obtained, though it will be very faint if the tip only of the bone has been detached. The diagnosis will be more difficult when the fracture extends across the body of the calcaneum; for then there will be no displacement, the latter and interosseous ligaments keeping the posterior fragment in position. In general, however, it may be determined by the history of the case, and by making pressure upon the calcaneum in different directions, thus eliciting crepitation if fracture actually exist.

A fracture of the calcaneum from the laceration of its fibres is usually slow in uniting on account of the difficulty of keeping the fragments in contact, the muscles of the calf constantly tending to separate the upper from the lower. For this reason, the union will frequently, if not generally, be ligamentous instead of osseous, and a long time will, therefore, be required for the complete restoration of the functions of the foot. When the fracture is caused by direct violence, the repair is effected in the ordinary manner.

When there is much contusion of the soft parts, it may be necessary to use antiphlogistics for moderating the inflammation, before applying permanent dressings. The nature of these dressings must depend upon the presence or absence of displacement. In the former case, the chief obstacle to the cure is the contraction of the gastrocnemial muscles, which must, therefore, be effectually controlled until the consolidation has advanced sufficiently to enable the upper fragment to maintain its position independently of extrinsic aid. The least objectionable contrivance for fulfilling this indication is a short splint, of stout tin, well padded, and adapted to the shape of the limb, the anterior part of which it should cover from the middle of the leg as far nearly as the toes. When tin cannot be obtained, wood, sole-leather, or binder's board, may be used. The object of this splint is to maintain the leg and foot in a permanently extended position, for in proportion as this is effected will be the relaxation of the muscles of the calf. To maintain the upper fragment in place, the leg and foot may be bandaged in opposite directions, adhesive strips and a compress having previously been applied around the heel and sole. This position should be continued for at least six weeks, or until there is reason to believe that the connecting medium is firmly established. The apparatus of Petit, formerly so popular in the treatment of this form of fracture, should not be used, as it is anything but a suitable contrivance, the tendency of the cord and slipper being to displace the upper fragment, and to irritate the soft parts about the heel.

In the other variety of fracture, as there is no displacement, all that is necessary is to subdue inflammatory action, and to keep the foot and leg in a quiet and relaxed position with a tin case, or two light side splints, the limb lying upon its outer surface over a pillow.

FRACTURES OF THE TIBIA.

The tibia, like other long bones, is liable to give way at various points of its extent, but more frequently below its middle than anywhere else. A

fracture of its condyles is unusual, and its occurrence is always denotive of great direct violence. Occasionally the bone is broken near its upper extremity, from an inch to an inch and a half below the knee. The internal malleolus is sometimes detached by a twist of the foot, by a fall upon the sole of the foot, or by direct injury.

Most fractures of the shaft of the tibia are oblique, very few, if any, transverse; nevertheless, as the fibula retains its integrity, there is seldom any considerable displacement, the sound bone acting as a splint to the broken one.

Fig. 400.

Oblique fracture of the tibia.

It is not often, however, that the fragments completely retain their apposition; in general, there is some degree of separation, which may always be easily detected, even when there is considerable tumefaction, by passing the finger along the tibia, and tracing its outline. If there be a fracture, it will manifest itself by an abnormal depression at some particular point, or by an unnatural projection, sufficiently obvious to establish at once the nature of the case. The amount of this projection is often very great, especially when the upper fragment is very long, sharp, and oblique, in which event it is generally extremely prominent, and with difficulty prevented from piercing the skin. The annexed drawing, fig. 400, from a preparation in my collection, conveys a good idea of this form of injury. For the reason just mentioned, there will usually be an absence of crepitation, or if there be any evidence of this kind, it will be very faint and unsatisfactory. The fracture, if perfectly free from complication, will commonly unite in from four and a half to five weeks.

Fracture of the internal malleolus is met with in various forms. In some cases, the process is broken off at, or close to, its connection with the lower end of the tibia; in others, near its free extremity; but the most common site of the lesion is about the centre of the process. Its direction is nearly always oblique; rarely, if ever, strictly transverse or perpendicular. Occasionally the process is broken at several points, thus constituting a comminuted fracture. Finally, cases occur, although rarely, in which

the fracture coexists with fracture of the lower extremity of the fibula. The diagnosis is easily established by the position of the foot, which is always

turned upwards and inwards, as if it were partially dislocated, and by the facility with which the detached piece of bone can be moved about with the thumb and finger; a procedure which also readily elicits crepitation.

Fig. 401.

Tin case.

The most simple contrivance for the *treatment* of fracture of the tibia, is a tin case, fig. 401, accurately shaped to the limb, provided with a foot-piece, and reaching a few inches above the knee. A bandage is applied in the usual manner, and any tendency to displacement is easily counteracted by means of a compress, arranged so as to bear gently and equably upon the ends of the fragments. I have never found it necessary to employ any other apparatus than this, no matter where the tibia was broken. When the fracture involves the malleolus the foot-piece will effectually prevent displacement. In fracture of the

superior extremity of the tibia, extending into the condyles, the plan usually adopted is to place the leg and thigh in the straight position, so as to compel the condyles of the femur to support the broken bone, extension and counter-extension being made with two long splints. Such a contrivance, however, will be altogether unnecessary, if we employ the tin case, especially if it be made sufficiently long to embrace the inferior third of the thigh, thereby completely counteracting any tendency on the part of the muscles of the limb to draw

Fig. 402.

Dr. Welch's splints.

the upper fragment backwards into the popliteal space. An efficient apparatus for these fractures will also be found in Dr. Welch's splints, fig. 402;

Fig. 403.

Dr. Bauer's splints.

and in the wire splints of Dr. Bauer, fig. 403, the latter being particularly valuable on account of their light, airy, and pliable character.

FRACTURES OF THE FIBULA.

Fracture of the fibula is, relatively considered, a sufficiently common occurrence, its frequency being due apparently to the slender form of this bone, to its superficial situation, and, above all, to the important part which it plays in the formation of the ankle-joint. The accident may take place at any portion of the bone, but is most common, by far, in the inferior fifth of its extent, owing to its intimate connection with the astragalus, which, constituting the pivot of the foot, readily receives and transmits the various shocks to which the latter is so continually exposed. Of fractures of the shaft and head of the fibula, no particular description is necessary, since they are always easy of detection, and since the treatment does not differ materially from that of

similar injuries of the tibia. But it is different with fractures of the inferior fifth of the bone, where, as just stated, the lesion is most common, and where, from being usually associated with other mischief, it is extremely liable to be followed by deformity and permanent lameness. For these reasons, fractures in this situation require to be studied with more than ordinary care.

Fractures of the fibula are much more common on the right side than on the left. In 207 cases collected by Dupuytren, more than two-thirds involved the right leg. The statistics of Malgaigne show that it is most frequently met with between the ages of twenty-five and fifty, and that men are more than four times as liable to it as women. Of 104 cases examined by this author, not a single one occurred before the fifteenth year.

The *causes* of fractures of this portion of the fibula can be properly appreciated only by a careful examination of their mechanism. The tibio-tarsal articulation, being a hinge-joint, admits chiefly of flexion and extension, its lateral movements being restrained by the two malleoli, and the ligaments by which the bones of the leg are connected with those of the foot. Hence, the latter cannot be turned outwards or inwards to any considerable extent without producing a fracture of the former, the site of injury being determined by the particular inclination of the limb. Thus, when the foot is forcibly abducted, its inner edge resting on the ground, the upper surface of the calcaneum will be pressed violently against the external malleolus, in a direction parallel to the fibula, which will, consequently, yield at its weakest point, which is about an inch and a half above the joint, at the part sometimes called the neck of the bone. In most cases there is a rupture of the deltoid ligament, if not also a fracture of the internal malleolus. When the foot is forcibly adducted, the astragalus becomes the immediate cause of fracture, for this bone, turning upon its antero-posterior axis, escapes from the arched cavity formed by the tibia and fibula, and, pressing against the outer malleolus, breaks the fibula nearly at the same level as in the preceding case, the direction of the fissure being usually somewhat oblique. The external lateral ligament is either torn or violently stretched.

The most ordinary cause of this fracture is a fall upon the foot, in which this portion of the limb is forcibly inclined laterally, at the moment the weight of the body impels the bones of the leg forcibly against those of the foot, rendered stationary by the resistance offered by the ground. The fibula may also be broken across by violence applied directly to the part, as a blow, or the passage of the wheel of a carriage. Of 207 cases of this accident recorded by Dupuytren, 120 were the result of forcible adduction, and 60 of forcible abduction, the rest being caused by direct violence.

However the fracture may be induced, the superior extremity of the inferior fragment is always thrust inwards against the tibia, while the inferior extremity of the superior fragment either remains fixed, or inclines in the same direction. The latter usually happens when the injury is direct, the former when it is indirect.

Fracture of the
fibula.

The inferior extremity of the fibula is sometimes broken almost vertically; such an occurrence, however, must be extremely uncommon, and I have seen but two instances of it, both of them being specimens in the Mütter collection. In one, represented in fig. 404, the bone looks as if it had been split, the fissure extending upwards, almost in a straight line, fully an inch and a half; the posterior, longer, and larger fragment being pushed considerably backwards, so as to form with the other an intermediate triangular space. In the other bone the fracture is also vertical, but the separation is much less.

The *symptoms* of fracture of the lower extremity of the

fibula vary according to the circumstances of the case. When this bone alone is severed, the chief signs will be slight eversion of the foot, a depression at the site of injury, and some change, usually not very conspicuous, in the contour of the ankle-joint. When the internal malleolus is broken off, or when the tibia has given way a short distance above the articulation, these characters will exist in a more marked degree, and point out unerringly the nature of the lesion. The foot will be so much abducted as to present the appearance of being dislocated outwardly; the width between the two malleoli will be much increased; the hollow at the line of fracture will be quite deep; and the external margin of the foot will be considerably elevated, while the internal will be proportionately depressed. Upon taking hold of the foot, it will be found that it is unusually movable, and that it can easily be restored to its natural relations, but that the moment we cease our grasp it will return to its former position. In performing these manipulations crepitus is very easily felt; and, upon tracing the outline of the lower portion of the bone, the finger will usually sink in at the seat of fracture, owing to the fact, previously mentioned, that the upper end of the lower fragment always falls over towards the tibia. A good deal of ecchymosis is often present, and a considerable amount of swelling quickly follows, obscuring the characteristic features of the injury, and embarrassing the diagnosis. The only accident with which fracture of the inferior extremity of the fibula is liable to be confounded is a sprain of the ankle-joint, from which, however, it may always readily be distinguished by the great distortion which attends it, and by the presence of crepitus.

A simple fracture of the fibula in the inferior fifth of its extent will, if properly treated, usually unite in a month, without any deformity of the limb, although even then a considerable time will elapse before the ankle-joint will perfectly regain its functions. When the injury is complicated with rupture of the ligaments, fracture of the corresponding portion of the tibia, or other serious lesion, the repair will be much slower, and there will be danger, unless the case is managed with the most consummate skill, of permanent deformity and lameness, the former manifesting itself in an everted condition of the foot and in increased width of the ankle-joint.

The material point in the *treatment* of fracture of the fibula in this situation is to maintain the foot in a position the reverse of that which it assumes in consequence of the injury. To accomplish this object, which is designed to draw away the upper extremity of the lower fragment from the tibia, and to restore it to its proper relations, the limb, after having been enveloped in the ordinary bandage, with the precaution of not compressing it opposite the site of fracture, is placed in a tin case, the foot being directed permanently inwards. The requisite inclination may easily be imparted by means of a piece of roller, or a few adhesive strips, carried around the instep and heel, and attached to the inside of the leg. Or, instead of this, the fracture may be treated with Dupuytren's apparatus, fig. 405, consisting of a light wooden

Fig. 405.

Dupuytren's apparatus.

splint and a wedge-shaped cushion; the former reaching from the upper third of the leg to about three inches below the sole of the foot, and the latter from

the same point to a level with the ankle. The limb being bandaged in the same cautious manner as in the former case, the apparatus is stretched along its inner surface with the tapering end of the pad upwards, and secured, first above, and then below, the roller being passed around the foot and ankle in such a manner as to turn the internal margin of the foot upwards and inwards. The limb may afterwards be kept in the extended position, or, what is preferable, be placed, half bent, upon its outer surface over a large pillow. The parts are diligently watched, the dressing being changed as occasion may seem to require, and passive motion instituted at the end of the third week.

FRACTURES OF BOTH THE TIBIA AND FIBULA.

Fractures of both bones of the leg are sufficiently common, particularly in young and middle-aged subjects, and are deserving of special attention, on account of the difficulty of their management, and their liability to be followed by deformity and lameness.

Much diversity obtains in regard to the *seat* of these fractures, as well as concerning their direction, and the nature and extent of their displacement. In twenty-two specimens, contained in Dr. Mütter's collection and my own, I find that in ten the tibia and fibula were broken at their inferior extremity, the line of separation in none of them extending beyond three inches above the joint. In four the tibia gave way at its lower third, and the fibula at from two to three inches and a half from its head, or junction with the upper end of the tibia. In six of the cases the tibia was broken from two to three inches above its inferior articulating surface; in two of these the fibula had yielded at its middle, and in the remaining four at different points of its extent. In only two cases had both bones been broken at the same level; in one of these the fracture occurred at the middle of these pieces, and in the other a little below that place.

In the twenty-two cases the tibia had been broken only twice above its middle; whereas, the fibula had given way above this situation in six cases. In sixteen of the cases the seat of fracture of the tibia was either at the ankle-joint, or below the middle of the bone, generally in its inferior fourth or third. In ten cases of fracture of the fibula the seat of the injury was either at the joint, or within the first three inches from its articulating extremity.

From the above examinations it follows: first, that the tibia and fibula rarely break on the same level; secondly, that both bones are most liable to yield either at the ankle-joint, or, at all events, within the first three inches above that joint; and thirdly, that the fibula is more frequently fractured at its superior extremity than the tibia.

An examination of these specimens has supplied me with some other interesting facts. Thus, I have found that the fracture in nearly all was more or less oblique, the line of separation in fifteen specimens of broken tibia extending from above downwards, and from without inwards. As a natural consequence of this occurrence, the superior extremity of the inferior fragment projected outwards towards the fibula, which it touched in several of the preparations, on account of a want of proper adjustment during the treatment; the lower extremity of the upper fragment, on the contrary, projected inwards, and had apparently generally been much the sharper of the two. The fibula, in most of the specimens, afforded evidence of having been broken across more abruptly than the tibia, but still with a considerable degree of obliquity in almost every instance that I inspected.

In recent fracture of the tibia, complicated with fracture of the fibula, the inferior extremity of the upper fragment is generally remarkably sharp, and, in consequence, often protrudes through the integuments at the time of the injury, the same cause that produces the lesion forcing it across the soft

parts. Or, if it is not pushed out at the moment of the accident, it often escapes afterwards, through ulceration, induced by the pressure which it exerts upon the soft parts. The obliquity of fractures of the tibia is often very extraordinary, and there are few cases in which it does not become a source of great suffering to the patient, and of annoyance to the surgeon, on account of the trouble that is experienced in keeping the fragments in their proper relations.

A rare form of fracture of these two bones is represented in fig. 406, from a specimen in my collection. The tibia, it will be perceived, is broken off

Fig. 406.

Fracture of the tibia and fibula at the ankle-joint.

just above its articulating surface without affecting the internal malleolus, while the fibula has given way about an inch and a quarter above the joint.

Fig. 407.

Fracture of the bones of the leg at the ankle-joint.

The foot is characteristically everted. In fig. 407, also from a specimen in my possession, the fracture embraces both the extremity and the malleolus of the tibia; the fibula being broken off a few lines above the joint. Fig.

Fig. 408.

Broken articulating surface of the tibia.

408 exhibits the appearance of the broken articulating surface of the tibia.

The *causes* of fractures of both bones of the leg are either direct or indirect, just as when these pieces suffer separately. A very common mode in which the accident happens is a fall upon the pavement, as when an individual slips in consequence of the presence of ice, or when, as he is rapidly walking, the foot is suddenly caught in a hollow, or between two hard resisting objects, so as to throw the whole weight of the body upon the leg. Another way in which the lesion is produced is a fall from a considerable height, as when a person is precipitated from a scaffolding. Jumping out of a carriage under full speed often produces fracture of the tibia and fibula. In many cases, the injury is occasioned by direct violence, as by the passage of the wheel of a carriage, the kick of a horse, the caving in of a sand bank, or the fall of a heavy stone.

The *symptoms* of the injury, however induced, are generally well marked, if not positively unmistakable. In nearly every case the limb is shortened

from one and a half to three inches, and there is also, generally, great deformity in its diameter, both depending upon the overlapping of the fragments, which, as already stated, is frequently very extraordinary. Besides, upon making extension and counter-extension, it is generally easy to elicit crepitation. When the fracture is very oblique, the lower end of the superior fragment may usually be felt immediately beneath the integuments, forming a sharp, prominent projection in front of the limb, or at its inner aspect. Sometimes the soft structures are much bruised and ecchymosed. Another remarkable symptom, one which, indeed, is seldom absent, is a spasmodic twitching of the limb, coming on soon after the accident, and frequently lasting for several weeks, much to the annoyance and distress of the patient.

When the fracture is situated just above the ankle, the foot will usually be a good deal everted, causing an appearance of dislocation outwards, as exhibited in fig. 409.

The *prognosis* of fracture of both bones of the leg may be gathered, in part, from what precedes. In the more simple forms of the injury, attended with but little obliquity, a good cure can generally be effected in from four to five weeks. If, however, the obliquity is uncommonly great, it will be found extremely difficult, if not impossible, to effect consolidation in a manner altogether unexceptionable, however skilfully and zealously the treatment may be conducted. More or less deformity will almost be inevitable, either in the length or in the diameter of the limb; owing to the remarkable tendency which the ends of the fragments have to overlap each other, and which it is often impossible to counteract successfully, whatever means may be adopted for the purpose.

Fig. 409.

Fracture of the lower end of the tibia and fibula.

as can be determined, impair their usefulness, as must always necessarily be the case with the latter. I have several times met with this occurrence when the lesion was confined to one of these bones, and I am not able to say whether one is more liable to give rise to it than the other. Moreover, it does not seem to be necessary to its production that there should be any approximation of the ends of the opposite fragments, as it may take place when they are perfectly straight, although the former condition no doubt acts as a predisposing cause.

Fractures of both bones of the leg, if attended with shortening of the limb, require to be treated by extension and counter-extension, steadily and persistently maintained throughout, otherwise, as just stated, deformity will almost be inevitable. If, on the other hand, the fracture be transverse, or nearly so, such a procedure may of course be dispensed with, the object being attained by confining the leg in a tin case, or fracture box, care being taken to keep the great toe constantly on a line with the inner border of the patella, the surest evidence that there is no rotation of the ends of the fragments upon each other. Any tendency to forward, backward, or lateral displacement is generally easily counteracted by means of compresses and short splints. The limb may then be placed in an easy position upon a slightly inclined plane, made of a bolster or pillow, or it may be suspended by a cord

and pulley to the tester of the bed, as may be found most agreeable or convenient.

Counter-extension may be made when the fracture is oblique, by means of a box provided with a foot-board, and two lateral splints, one extending to the perineum, and the other to the axilla, as I have generally myself preferred; or with the contrivance of Dr. Neill, consisting of a box, reaching as high as the middle of the thigh, the counter-extension being made with adhesive

Fig. 410.

Dr. Neill's apparatus for fracture of the leg.

strips, passed through holes at the upper part of the apparatus, and tied on the outside, as exhibited in fig. 410.

The use of the gaiter, fig. 411, in the treatment of fractures of the leg and thigh, attended with shortening and deformity, cannot be too pointedly condemned, as it is almost impossible, in any case, however carefully watched,

Fig. 411.

Application of the gaiter.

Fig. 412.

Application of the handkerchief.

to prevent chafing, and other inconvenience. A similar remark is applicable, only more forcibly, to the handkerchief, fig. 412, at one time so much employed for this purpose. Both appliances are most villainous, and should therefore be proscribed, especially as an admirable substitute may always be found in the adhesive strips, secured to the sides of the limb, fig. 413, and tied at the bottom of the foot-board.

Fig. 413.

Application of adhesive strips for making extension.

The annexed cut, fig. 414, represents the method of treating oblique fractures of the leg, recommended by Dr. Swinburne. A narrow, delicate splint and foot piece are fastened by means of adhesive plaster, while counter-extension is made from the knee by strips of the same material looped about the limb below the joint. A strong cord is then passed through this loop,

and thence on through a hole in the side splint, opposite the lower part of the thigh, in order to afford the requisite degree of tension. If, after the apparatus has been applied, the limb is not sufficiently steady, adhesive strips must be used, as represented in the engraving.

Fig. 414.

Dr. Swinburne's mode of treating fracture of the leg.

Suspension of the leg may sometimes be advantageously practised, both as it respects the comfort of the patient and the welfare of the fracture. It may be done according to the method recommended, many years ago, by Professor N. R. Smith, of Baltimore, or the very simple contrivance of Mr. Salter, of England, depicted in fig. 415, representing the limb surrounded by the appa-

Fig. 415.

Salter's apparatus for suspending the leg.

ratus and slung to the tester of the bed. The case in which the leg rests is made of light metal; and the whole contrivance is so arranged as to admit of lateral motion, and also of sliding up and down, simply by the rolling of the pulley-wheels upon the horizontal bar.

The apparatus of Dr. Smith may be used for fractures of any of the long bones of the lower extremity, whether simple, compound, or complicated. It consists, as is seen in fig. 416, of two pieces, united by a hinge, after the fashion of a double inclined plane, one corresponding with the thigh, and the other with the leg, the latter supporting a shoe, which is attached by a thumb-screw, and is so arranged as to be rotated outwards or inwards, thereby elevating or depressing the toe, as may be deemed most desirable. The two pieces are supplied with side boards, joined by bows of iron beneath; and they are so constructed, both at the knee and at the foot, that they may be elongated or shortened at pleasure. Moreover, a short crutch, movable and well padded, is secured to the inner and upper extremity of the thigh portion, in order to prevent injurious pressure upon the perineum. Another piece,

well padded, movable, and composed of iron, is appended to the superior and outer part of the apparatus, and is fastened round the trunk by a strong band. The thigh and leg rest on slings attached to the side-pieces, the latter being confined in the apparatus by its own weight, aided by a bandage,

Fig. 416.

Dr. N. R. Smith's suspending apparatus or double inclined plane.

while the former is supported in front by a well padded, flexible splint. The whole contrivance is suspended to the ceiling, or the tester of the bed, by a single cord, attached below the knee, near the centre of gravity of the limb and apparatus. The cord ascends with a slight obliquity from the trunk, so as to effect the requisite extension, by making gentle traction on the limb, which is completely grasped by the apparatus, and consequently firmly held by it. In this manner, the member is compelled to obey all the accidental and necessary movements of the body, thus obviating all strain and tension at the seat of fracture.

COMPLICATED FRACTURES OF THE LEG.

Fractures of the leg are not unfrequently complicated, whether involving both bones or only one, as in fig. 417. In the latter case, the tibia, much more frequently than the fibula, is the piece that is most liable to suffer.

Fig. 417.

Complicated fracture of the leg.

Such accidents are produced in various ways; sometimes by violence applied to the foot, as when a man jumps out of a second story window, or falls from a scaffolding; but more generally by direct force, as the passage of the wheel of a carriage, a blow from a stone, or the kick of a horse. When produced

by these and other similar causes, the lesion is usually situated in the inferior portion of the leg, towards the ankle-joint, which is not unfrequently penetrated. Fractures of the leg, occasioned by railway violence, are always of a comminuted character, the bones being extensively crushed, and the soft parts severely lacerated and contused, if not actually pulped. Hemorrhage, both venous and arterial, often sadly complicates such injuries, and, along with the shock, sometimes proves speedily fatal, the system, perhaps, never fairly reacting after the accident. Complicated fractures of the leg, of a very bad character, are also frequently produced by machinery in rapid motion, and by gunshot violence. Sometimes, again, especially when there is unusual brittleness of the osseous tissue, the bones are frightfully broken by causes so trivial as to surprise us how they could have induced such a result.

In whatever manner complicated fractures of the leg may happen, the ends of the fragments, particularly those of the tibia, are extremely liable to protrude at the wound; the latter often in such a manner as to render it very difficult to effect replacement, owing to its being tightly girt by the edges of the opening in the integuments, and also to the great length which so frequently distinguishes it. The symptoms of such accidents are always sufficiently characteristic, since there is usually not only great deformity, but likewise, as just stated, exposure of the ends of the broken pieces. Nevertheless, although no difficulty can attend the diagnosis, under such circumstances, so far as the existence of fracture is concerned, yet the surgeon should always institute a most careful and searching examination, with a view of ascertaining the real condition of the soft structures, the welfare of which is often much more deeply interested than that of the bones themselves. The first object, in every case of the kind, should be to determine what should be done; whether an attempt should be made to save the limb or to cut it off. As a general rule, it may be stated that when—if I may use an antithetical and apparently contradictory expression—the complicated fracture is simple, that is, without any serious lesion of the soft parts, an effort should always be made to preserve the limb, especially if the patient be young and robust, and the bone not comminuted, although perhaps broken at several different points. It is true, such cases sometimes terminate unfavorably, both as it respects limb and life; and it should also be borne in mind that the injury sustained both by the soft and the osseous tissues may be much greater and more serious than the eye and hand can possibly detect. The dangers, too, from tetanus, pyemia, erysipelas, secondary hemorrhage, and profuse and exhausting suppuration, are not to be overlooked by the surgeon in his laudable endeavors to save a patient from mutilation; nor is he to forget that such lesions, especially when seated near the ankle-joint, are extremely liable to be followed by ankylosis.

When the bones are severely comminuted, the soft parts terribly lacerated, or the ankle-joint extensively opened—in short, when the limb has been frightfully bruised, torn, and crushed—no one would hesitate to use the knife the moment sufficient reaction has taken place to enable the system to withstand the additional shock. The case even then is frequently a bad one, the patient often rapidly sinking from exhaustion, or soon after from the effects of pyemia.

When an attempt is made to preserve the limb, the first indication is to arrest hemorrhage; the second, to coaptate the ends of the broken bone; the third, to place the limb in an easy, comfortable, retentive apparatus; and the fourth, to moderate the resulting inflammation. These intentions are to be fulfilled in conformity with the general principles laid down under the head of general observations on fractures. If the ends of the fragments are unusually long and sharp, and disposed to protrude despite of the ordinary precautions, the best plan will be to retrench them; being careful, however, to

cut off as little as possible. The edges of the wound are accurately approximated by suture and collodion, every precaution being used to exclude the atmosphere. The best fracture apparatus is the wooden box, fig. 418, so much used in this city, both in private and hospital practice, consisting of four pieces, one corresponding with the back of the leg, and two with its sides, the fourth being intended for the foot. The latter, projecting nearly perpendicularly, is provided with two mortise holes, for the reception of the extending bands. The two lateral pieces are secured each by two hinges to the back board, so as to admit of being opened or shut at pleasure during the application and removal of the dressings. The limb, enveloped in the bandage of Scultetus, is carefully laid into the box, previously closed, and partially filled with coarse bran, which is afterwards piled on until the whole leg and the spaces on each side of it are completely covered in. The advantage of the bran, thus used, is that it affords not only easy, equable, and comfortable support to the broken bones, but also that it readily absorbs the discharges, and prevents the deposit of the ova of the fly, so common during the hot months of this and other countries. Substitution is effected whenever the substance becomes soiled and caked. For a knowledge of this mode of treating compound fractures of the leg, the profession is indebted to Dr. John Rhea Barton, and there is no question that it is one of the most valuable improvements that have been introduced into the management of this class of injuries at the present day, whether it be viewed merely with reference to the comfort of the patient, the safety of the limb, or the convenience of the surgeon.

Fig. 418.

Fracture-box.

Fig. 419.

Compound fracture of the leg, dressed.

The necessary extension and counter-extension are easily effected by adhesive strips. For the first week or ten days, leeches and cold water-dressing will generally be required. Should suppuration arise, the most soothing application will be a linseed poultice.

A very common mode of dressing compound fractures of the tibia alone is by M'Intyre's screw splint, represented in fig. 419, well padded, and extended; an opening being left in the bandage opposite the wound.

FRACTURES OF THE PATELLA.

Fracture of the patella, figs. 420 and 421, although comparatively an uncommon event, is of great practical importance, from its proximity to the knee-joint, and the imperfect manner in which it is usually repaired. It may extend through the bone in any direction, transversely, obliquely, or verti-

cally, the frequency of the occurrence being in the order here stated. When the fracture is comminuted, the fissures often exhibit the most irregular arrangement.

Fig. 420.

Transverse fracture of the patella.

Fig. 421.

Oblique fracture of the patella.

The *causes* of the accident are two, external violence, and muscular action. The transverse fracture is nearly always produced by the latter, or by the joint agency of the two, while the oblique and vertical are invariably the result of direct injury, as a fall, blow, or kick. In the latter case, consequently, there is frequently severe contusion of the soft parts, and sometimes the knee-joint is even laid open. The transverse fracture is produced by falls in which the leg is strongly flexed upon the thigh, while the body is thrown suddenly and forcibly backwards, thereby putting the extensor muscles powerfully upon the stretch, the line of fracture usually taking place just above the middle of the bone. Jumping out of a carriage, and falling backwards upon the ground, is one of the most common ways in which the accident is occasioned. Circus-riders and ballet-dancers sometimes break this bone in the act of leaping in the exercise of their profession.

The *symptoms* of fracture of the patella are generally well marked. In the transverse form of the lesion, the nature of the accident is at once detectable by the change in the contour of the knee, by the inability to extend the limb,

Fig. 422.

Fracture of the patella.

and by the displacement of the upper fragment, as seen in fig. 422. In many cases, the person is conscious, at the moment of the injury, of something having given way, and perhaps he may have even heard the peculiar characteristic snap. If he attempts to get up and walk, he will be almost sure to fall, from his inability to extend the leg and support the weight of the body upon it. The displacement is usually considerable, the superior fragment being drawn upwards upon the fore part of the thigh by the extensor muscles. The height to which it may be carried varies according to the extent of the destruction of the ligamentous connection of the tendon of these muscles. When the separation is complete, it may amount to two and a half, three, and even four inches, while under opposite circumstances it may not exceed six, eight,

or ten lines. The distance between the two fragments is always increased by bending the leg. The front of the knee has a flattened appearance, and upon passing the finger over it its point will be found to sink down abruptly as it were into the joint. The lower fragment is stationary, but the upper is easily moved, and may, by thorough extension of the limb, be brought down into its normal situation, so as to enable us to detect crepitus. If some time has elapsed since the occurrence of the accident, considerable swelling may be present, obscuring somewhat the diagnosis.

In respect to its mode of *union*, the transverse fracture of the patella holds the same relation as a similar injury of the olecranon. In both cases the nutrition of the fragments is seriously impaired by the laceration of the ves-

sels, and in both great difficulty is experienced in maintaining coaptation. Hence it is a law that the union takes place by ligament and not by bone. In all the cases of this fracture that I have been able to examine, both in the living subject and in museums, I have not met with any in which the consolidation was completely osseous. A few such cases, however, have been described by surgeons. In the inferior animals, it is not uncommon, if care be taken to keep the ends of the bone accurately in contact. When the interval between the broken pieces is very considerable, as, for example, when it amounts to two inches, the union is established by the aponeurotic tissue which naturally covers the patella, and which, in this case, extends from one fragment to the other, the plastic matter which is poured out in consequence of the injury not being capable of becoming organized and converted into ligamentous matter. Whatever may be the nature of the connecting medium, it is important that it should be as close and perfect as possible; for it is found that the joint will always be weak and unprotected precisely in proportion to its length and thinness.

The annexed cut, fig. 423, represents a sketch from a specimen of fracture of this bone in the cabinet of Professor Pancoast. It will be seen that the patella is broken into three pieces, the superior one being drawn up in front of the thigh, far away from the joint, and nearly four inches from the inferior, which consists of a mere little strip, hardly two lines in width, corresponding with the lower edge of the bone. No union followed, owing, doubtless, to bad management or neglect, and the consequence must have been a very imperfect use of the limb.

The *treatment* of transverse fracture of the patella is attended with serious difficulty on account of the trouble experienced in controlling the action of the extensor muscles, whose tendency is constantly to draw the superior fragment upwards away from the lower. To counteract this tendency, therefore, constitutes the chief indication of the treatment. This can be effected only by maintaining the leg steadily and faithfully in a complete state of extension, the thigh being at the same time flexed upon the pelvis, and the body kept in the semi-erect posture. In this manner, the extensor muscles are thoroughly and effectually relaxed. The most efficient contrivance for insuring this position of the limb is a strong, well padded tin case, long enough to reach from the middle of the thigh, to the corresponding point of the leg, a roller having previously been applied from the toes upwards, and another from the groin downwards. The superior fragment, having been brought into place, is next confined by numerous adhesive strips, carried around the bone above and below the joint, and connected afterwards by vertical and transverse pieces. The dressing is completed by the application of a long, thick, and rather narrow compress, extended around the upper border of the patella, and confined by the two rollers passed around the joint in the form of the figure 8. Managed in this way, it is hardly possible for the fracture to suffer the slightest displacement, or to conceive of anything better calculated to fulfil the end in view. The tin case maintains the limb in the extended position, the adhesive strips and compress retain the upper fragment in contact with the lower, and the two rollers, applied in opposite directions, aid powerfully in controlling muscular contraction.

When a suitable case cannot be procured, the object may be attained by

Fig. 423.

Old fracture of the patella, showing the separation of the fragments.

the use of a wooden splint, well padded, and stretched along the posterior part of the thigh and leg. The adjoining drawing, fig. 424, represents the mode of dressing transverse fractures of the patella, pursued by Professor Hamilton, and also, with slight modifications, at the Pennsylvania Hospital.

Fig. 424.

Apparatus for fracture of the patella.

The plan is an excellent one, and seldom fails to effect a good cure; often with hardly any interspace between the ends of the fragments. The letters require brief explanation: *a* is the bed; *b*, floor of the splint; *c*, foot-piece, provided with holes and side-pins; *d*, inclined plane, constructed so that it may be raised or lowered at pleasure; *e*, cushion, thicker under the knee than at either end; *f*, roller, not completely applied, to secure the limb to the inclined plane; *g*, adhesive strips, laid over a compress, and crossed under the splint, those from above passing through a notch in the board behind the knee; *h, h*, ends of the compress.

As ankylosis is one of the occurrences most to be dreaded after this fracture, passive motion should be employed as soon as there is reason to believe that the union is sufficiently advanced to admit of it. This will usually be by the end of the third week. It should afterwards be repeated, at first every other day, and then every day, until all risk of this accident is passed. The limb must not be used for the ordinary purposes of progression for three or four months, experience having shown that, if it be exercised too early, the connecting bond will become gradually more and more elongated, and thus materially interfere with the restoration of the functions of the joint. At the expiration of four weeks, the tin case may be taken off, and a leather splint substituted, the patient walking about upon crutches.

A portion of the patella may be broken off obliquely, and, suffering no material displacement, may readily unite by bony matter, as any other fracture. A similar result generally follows when the fissure is *vertical*, with little or no separation of the fragments, the tendency to which is very slight, as the broken pieces are not influenced by muscular contraction. The prognosis is, therefore, other things being equal, always favorable, although, owing to the proximity of the knee-joint, a considerable period will usually elapse before there will be perfect restoration of the functions of the limb.

The signs of these fractures are sometimes very obscure, especially if there be much swelling of the soft parts. In general, however, the nature of the case may be determined by the impaired motion of the knee-joint, by the fixed character of the pain, and by making pressure upon the patella in opposite directions.

The limb, having been enveloped in a bandage, should be kept at rest in

an elevated and extended position until there is a complete subsidence of inflammation, when the starch dressing should be applied, the patient being permitted to move about upon crutches. If the fracture be vertical, or nearly so, it will be necessary to support the fragments by means of two compresses, stretched along the lateral borders of the bone, and confined by adhesive strips and a roller. When the fissure is very oblique, the displacement may be such as to demand a course of treatment similar to that necessary in a transverse fracture.

When the patella has once been broken transversely, it is exceedingly liable to a recurrence of the accident from comparatively slight muscular contraction. The judicious practitioner should, therefore, always put the patient upon his guard in this respect. The fracture may occur at the same point, but generally it takes place a little higher up. Finally, when one patella has been broken, the other is apt to suffer in the same manner, owing to the imperfect use of the affected limb, and the consequent liability of the patient to fall.

FRACTURES OF THE FEMUR.

Fractures of the femur deserve the most attentive study; for not only are they of frequent occurrence but they present themselves under every possible variety of form, and there are no injuries of the kind which, to use the language of Pott, "so often lame the patient and disgrace the surgeon." Any portion of the bone may give way, and hence it is customary, in treating of the subject, to speak of fractures of the shaft of the femur, of its condyles, and of its superior extremity, or of its neck, and of its trochanters.

1. FRACTURES OF THE SHAFT.

The shaft of the femur may be broken in any portion of its extent, but there are three points which are particularly obnoxious to fracture. These points are the upper fourth of the bone, the middle, and the inferior fourth, the relative frequency of the accident being in the order here stated, although it is generally asserted that the bone yields more frequently at or near its middle than anywhere else. This idea, however, accords neither with the results of my observations upon the living subject, nor with my examinations of specimens of fractured bones in different collections. The relative difference, however, is, no doubt, very slight. A brief account of the lesion, as it occurs at these several points, will suffice to place the subject in a proper practical light, and serve to prevent those sad mistakes, often so disastrous both to the patient and the attendant.

Fractures of the Upper Fourth of the Shaft.—The most common site of fracture of this portion of the bone is from two and a half to three inches and a half below the small trochanter; the line of fracture is almost always oblique, extending from behind forwards, and from above downwards, being frequently from an inch and a half to two inches in length. A transverse fracture here is an exceedingly rare occurrence. It is also very uncommon to see the bone give way just below the small trochanter, and it is worthy of note that, when it does break at this point, it is generally complicated in its character, or associated with extra-capsular fracture, properly so termed.

The *symptoms* of fracture seated in this portion of the femur are generally so obvious as to indicate at once the nature of the injury, the characteristic signs consisting of great shortening and angular deformity. The shortening varies from two to four inches, and usually exists in full force immediately after the receipt of the injury. The superior portion of the limb is remarkably distorted, being convex on its external surface, with a corresponding

concavity internally, occasioned by the overlapping of the ends of the broken bone, the upper nearly always lying in front of the lower, and both being usually directed somewhat outwards. In ten specimens of fracture of the upper fourth of the shaft of the femur, now before me, I find that in all, except one, the upper fragment is in front of the lower, the reverse being the case in the other. In these ten specimens the superior piece is drawn forwards and outwards in six; in two it is tilted upwards and inwards; and in two it is raised up and in a straight line with the lower, or without any lateral deviation whatever. The distance of the fracture from the small trochanter ranges from two inches and two-thirds to three inches and a quarter.

In the six specimens in which the superior fragment is directed forwards and outwards, the lower fragment is also inclined outwards in four, the junction between them being such as to give the bone more or less of an arched appearance, the convexity being external and the concavity internal. In the two specimens in which the upper end is directed forwards and inwards, the lower end, in one, is inclined inwards also, and in the other it is straight, or in a line with the superior fragment. In seven of the eight specimens in which the displacement is lateral, the inferior fragment is more or less strongly everted, and, consequently, the knee and foot, during life, must have been in the same position.

The fractures, so far as can be determined, were all oblique, the line of disjunction, in nine, extending from behind forwards, and from above downwards, one only being in the opposite direction, and in this the lower fragment lies in front of the upper, overlapping it four inches. The distance at which the ends of the bone are separated anteriorly, varies from half an inch to an inch and three-quarters. The angle which the superior fragment forms with the inferior, does not, in any of the ten specimens, exceed 45° , while in most it falls considerably short of this.

I have been thus particular in giving the results of these examinations, on account of their practical bearing upon fractures of the superior extremity of the shaft of this bone. Sir Astley Cooper, and those who have adopted his views, have evidently formed very erroneous ideas, not only as regards the extent and direction of the displacement of the upper fragment, but also of its causes. Thus it has been asserted that the upper end often overlaps the other almost at a right angle, which is not the case in any of the specimens that I have examined; on the other hand, it has been alleged that the two pieces are usually inclined outwards, which the specimens alluded to also disprove, there being no lateral deviation whatever in two, while in two others the projection was inward, leaving thus only six cases of outward displacement. The displacement forwards of the upper end is due to the joint action of the psoas and iliac muscles, assisted perhaps by the pectineal and the short head of the adductor, while it is dragged outwards mainly by the agency of the external rotators. The lower fragment, on the contrary, is drawn up by the action of the flexor muscles of the thigh, and outwards by the tensor, vastus, and gluteal muscles. That the direction of the fracture materially influences the direction of the displacement is shown by the fact that in the only specimen out of the ten examined by me in which the line of fracture extended from before backwards, and from below upwards, the lower fragment overlapped the upper, and that to a great extent.

Although the specimens here described are, I conceive, of great pathological and practical value, yet it must not be forgotten that any inferences deducible from their examination are impaired, in some degree, by the fact that the displacement which characterizes them may have been influenced more or less by the nature of the treatment. Thus, in consequence of the use of splints, the ends of the fragments, originally inclined inwards or outwards, may have been pushed and held in the opposite direction, thereby

completely reversing the primitive order of the deformity, as caused by the direction of the fracture, the weight of the limb, and the action of the muscles.

The annexed drawings, two of which are from my own preparations, will serve to illustrate the nature of the displacement so often met with in fractures of the superior portion of the shaft of the femur.

Fig. 425.

Fig. 426.

Fig. 427.

Fracture of the shaft of the femur; upper portion.

Fractures at the Middle of the Shaft.—A fracture at the centre of the shaft of the femur is, according to my observation, an uncommon occurrence; most generally the bone gives way some distance above or below this point. The line of fracture is, for the most part, very oblique, extending from behind forwards and from above downwards, and the consequence is that the superior fragment nearly always overlaps the inferior, the upper extremity of which is drawn backwards, and usually, also, somewhat outwards, by the action of the flexor muscles, causing thus an amount of shortening of from two and a half to three and even four inches, with more or less angularity at the site of injury, and marked eversion of the limb. The lower end of the superior fragment, on the contrary, forms a prominent projection on the fore part of the thigh, easily perceived by sight and touch. The symptoms are of course characteristic.

A perfectly horizontal fracture of the shaft of the femur is an extremely uncommon occurrence; so much so that, although the phenomena might be such as to lead to the suspicion of its existence, the idea that it really is an injury of that kind should not be carried out in practice, lest, the requisite extension and counter-extension being omitted, permanent shortening should follow. When there is no marked tendency to displacement, it will generally be found that the fracture, instead of being transverse, is slightly impacted, or that its extremities, being denticulated, are interlocked with each other,

and thus held in place. Comminuted fracture of this portion of the shaft is not uncommon, especially in old subjects, laboring under fragility of the osseous tissue.

The accident may be the result of direct violence, as a kick or the passage of the wheel of a carriage, in which case it is often of a compound or complicated character; or it may be occasioned indirectly by a fall upon the foot or knee.

Fractures of the Inferior Fourth of the Shaft.—Fracture of the inferior portion of the shaft of this bone derives a special interest from the fact that, when occurring very low down, the inferior end of the upper fragment may, especially if it be very long and sharp, penetrate the joint, and thus seriously complicate a case otherwise easy of management. The fracture, moreover, is liable to be compound, the upper piece piercing the muscles and integuments just above the knee. As in fracture of the other divisions of the shaft, already described, so in this the line of the solution of continuity generally ranges from behind forwards and from above downwards, a transverse fracture, properly so termed, being extremely uncommon. The degree of obliquity is variable, but generally it is so considerable as to cause great shortening of the limb and angularity of the part; which, together with the everted state of the knee and foot, are characteristic signs of the accident. The inferior fragment is always drawn backwards and upwards, its superior extremity forming a distinct prominence in the popliteal region, which can easily be effaced by restoring the pieces to their natural position. When the fracture occupies the lower extremity of the shaft, nearly on a level with the joint, the upper fragment may descend so far down as to push the patella away from the trochlea of the femur, over upon the tibia, so as to create an appearance simulative of partial luxation of this little bone. If several hours have elapsed since the receipt of the injury, the diagnosis is sometimes obscured by the tumefaction of the joint; but, in general, whatever may be the condition of the parts, any existing doubt may be cleared up by a thorough examination of the limb.

The relative position of the fragments in this fracture are well depicted in fig. 428, from a specimen in my cabinet.

Fig. 428.

Fracture of the thigh.

The causes of fracture in this situation are commonly of a direct nature, a greater amount of force seeming to be necessary to produce it than when it is situated higher up. It may, however, be induced in an indirect manner, as when a person, falling from a considerable height, alights upon his foot or knee, the violence of the shock being concentrated upon the inferior portion of the femur.

Treatment.—The treatment of fractures of the shaft of the thigh-bone may

be conducted according to several plans, of which that by extension and counter-extension, the limb being in the straight position, is, as a general rule, the most eligible, fulfilling, as it does, more effectually than any other, the different indications presented by this class of injuries. Before any steps, however, are taken to adjust the broken pieces, it is the duty of the attendant to see that a suitable bed is procured for the comfortable accommodation of his patient, as well as for the secure management of the case. This subject having already been discussed in a previous part of the work, it will, therefore, be sufficient for my present purpose, if I merely allude to it here, with the hope of enforcing its importance upon the mind of the reader. I am so thoroughly convinced of the utter impossibility of treating fractures of the femur successfully without a good bed, that I should consider any surgeon justifiable in declining to undertake the management of any case unless his efforts were properly seconded in this respect. There must be no compromise upon the subject; for, if the cure turn out badly, no allowance will be made by the patient and his friends for any deficiencies, short-coming, or want of co-operation on their part. The whole blame falls upon the professional attendant, it being very properly assumed that he ought to know better than any one else what the emergency demands, and that he should, therefore, spare no pains to meet it. Every fracture-bed should have slats, a good, firm, but elastic mattress, and arrangements for the evacuation of the bowels, so that the patient may not be compelled to rise when he wishes to relieve himself. These essentials are all admirably combined in the ingenious contrivances of Dr. B. H. Coates, Dr. Addinell Hewson, and others, which my limits, however, will not permit me to describe.

When both thighs are broken, or even when only one is affected, Jenks's fracture-bed, represented in fig. 429, will be found extremely convenient, both

Fig. 429.

Jenks's fracture-bed.

for evacuating the bowels and for making up the bed. It is thus described by Dr. Gibson:—

"It is composed of two upright posts about six feet high, supported each by a pedestal; of two horizontal bars, at the top, somewhat longer than a

common bedstead; of a windlass of the same length placed six inches below the upper bar; of a cog-wheel and handle; of linen belts, from six to twelve inches wide; of straps secured at one end of the windlass, and at the other having hooks attached to corresponding eyes in the linen belts; of a head-piece made of netting; of a piece of sheet-iron twelve inches long, and hollowed out to fit and surround the thigh; of a bed-pan, box, and cushion to support it, and of some other minor parts."

For the purpose of securing quietude of the limb, and accuracy of apposition of the ends of the fragments, numerous contrivances have been devised, all possessing, apparently, more or less merit, and yet not one of them so perfect as to be wholly unexceptionable. A bare description and delineation of all the fracture apparatus now before the profession would form a stately volume. The surgical cabinets of some of our medical schools contain cart-loads of such material, most of it as effete as the contents of a curiosity-shop. Much of this apparatus has been patented, and extensively distributed by the inventors. The character of most of it is familiar to me, and I do not hesitate to declare that a large proportion of it is most villainous. The great and fundamental principles which every contrivance of the kind must necessarily possess is enjoyed by all, though in different degrees of perfection, and it cannot be doubted that the constant multiplication of such machinery, and the implicit confidence reposed in it by the younger members of the profession, have been a prolific source of the many disastrous results that have so frequently, especially of late years, attended the treatment of fractures of the thigh. I have long been satisfied that the more simple the apparatus is, the more easily is it managed, and the more likely to prove efficient. With a proper knowledge of what is needed, and a little ingenuity on the part of the surgeon, the requisite means for the successful management of almost any case of fracture of the femur, however bad, may generally be provided upon the spur of the occasion, or, at all events, within a reasonable time after the occurrence of the injury.

In children, I have usually found the most convenient and suitable apparatus to be a case made of stout, unoled sole-leather, long enough to extend from the groin to an inch and a half below the heel, and sufficiently wide to come well round the limb, especially the thigh. It is supplied with a foot-piece of the same material, and is well padded at its upper extremity, to prevent undue pressure upon the perineum. The outside portion of the trough is continued for some distance over the hip, to which it is secured by a spica, or common roller, carried round the thighs and pelvis. A splint, also of leather, or of binder's board, gutta-percha, or thin wood, is stretched along the forepart of the limb from the groin to the patella, wadding being suitably interposed to ward off pressure; the apparatus is held in place by means of an ordinary bandage, adhesive strips having been previously secured to the leg and attached to the foot-piece. The dressing is completed by placing the limb, with its apparatus, in an easy position upon a hair or cotton bolster, gradually tapering upwards, its thickness below not exceeding four inches. By this simple contrivance I have always found it easy to obtain the requisite extension and counter-extension, the perineum affording a *point d'appui* which effectually prevents the ascent of the apparatus, while the foot-piece serves to keep the foot in place, at the same time that it receives the extending bands.

In fractures of the thigh-bone in adults, a more substantial apparatus is usually necessary, as there is generally a greater tendency to muscular contraction and displacement of the fragments. The apparatus which is usually employed in this country is that of Desault, as modified and improved by Physick, consisting of one long splint, fig. 430, extending from below the sole of the foot to the axilla, and of a short one extending from the same point to the perineum. They are connected below by a transverse bar, for

receiving the extending bands, and along the leg and thigh by strips of bandage. The counter-extension is effected by a suitable thigh belt, the ends of which are passed through the mortise holes near the upper end

Fig. 430. of the splint. The apparatus is, however, an awkward one, constantly subject to derangement, and the results obtained by its aid are by no means so gratifying as they should be. It has always been found extremely unsatisfactory in my practice, and hence I have, for many years, never employed it in a single case, having given the preference to the fracture-box, represented in fig. 431. This box, which I used, for the first time, upwards of twenty

Fig. 431.

The author's fracture apparatus.

years ago, extends from the tuberosity of the ischium to a level with the sole of the foot, which rests against the vertical piece, provided with two slit-like holes for the passage of the extending bands. The posterior surface of the box is hollowed out for the more easy accommodation of the thigh and leg, while the side-pieces, fastened by hinges to the horizontal one, project so as to come to a level with the surface of the limb in front. To the outside of the box is secured a movable splint, about two inches in width, crutch-shaped and well padded above, and long enough to reach into the axilla, while another, similarly arranged and constructed, is attached to the inside, being intended to press against the perineum. The whole apparatus is made as light as possible, and any intervals that may exist between it and the limb, after it has been properly adjusted, may be filled with cotton, tow, or, what is preferable, especially in compound fractures, with wheat bran, the latter answering an admirable purpose, under such circumstances, not only affording an agreeable protection to the broken bone, but absorbing the discharges and preventing the development of maggots, which are so liable to form in such cases in hot weather. In changing the dressings, all that is necessary is to let down the sides of the box, the extension being kept up, if necessary, in the meantime, by an assistant having hold of the foot. A broad

Physick's long splint.

leather splint, or one of binder's board, extending from the groin to the knee, should cover the thigh in front; it should be accurately moulded to the parts, and be firmly secured in its place by means of pieces of tape encircling the box.

Instead of the fracture-box now described, use may be made of two splints, one of binder's board and the other of wood, the former, which is intended for the inside of the thigh, reaching from the groin to the knee, while the other, placed along the outside of the limb, extends as high up, on the one hand, as the crest of the ilium, and, on the other, as low down as four inches below the level of the sole of the foot. These splints being well padded, are secured with an ordinary roller, the adhesive strips being attached to the inferior extremity of the long one, in order to keep up the requisite degree of extension.

Within the last few years adhesive plaster has been much employed in this

Fig. 432.

Dr. Gilbert's fracture apparatus.

city, both for maintaining extension and counter-extension in fractures of the thigh, chiefly through the influence and writings of Dr. Gilbert and Dr. Neill. The practice, which is rapidly coming into general vogue, is unquestionably, as stated elsewhere, a great improvement upon the ordinary means heretofore in use, as it not only tends to preserve better and closer union of the ends of the fragments, but, what is a matter of great moment to the patient, prevents the pain, chafing, and ulceration, which so frequently attend the old methods. The treatment is equally serviceable in simple and compound oblique fractures of the lower extremity.

In a remarkable case of compound fracture of both thigh-bones, in a boy eleven years of age, recently under the care of Dr. Gilbert, a most excellent cure was effected by means of adhesive plaster, aided by the apparatus, represented in fig. 432; the dressings being removed on the forty-fifth day. A long splint, it will be perceived, was stretched along the outside of each limb, from a few inches below the sole of the foot to within a short distance of the axilla; the extending strips, tied under the sole of the foot, and secured to a horizontal block, were controlled by a tourniquet; while the counter-extending strips were carried along the pelvis, both in front and behind, and firmly fastened by transverse bands passed round the hip-bones, the back, and abdomen.

Fig. 433.

Dr. Hodge's method of counter-extension in fracture of the femur.

A valuable addition to the long splint, affording increased means for making counter-extension, was suggested, in 1860, by Dr. H. Lenox Hodge, of this city. It consists, as will be seen by a reference to figs. 433 and 434, of a bar of wrought iron, secured to the outer and upper part of the splint by bolts with movable nuts, and bent to the right or left, in accordance with the side to which it is applied. The splint should be sufficiently wide above to permit the rod, which terminates in a horizontal hook, about six inches in length, to pass clear of the patient's arm and shoulder. A long strip of adhesive plaster, at least two inches and a

half in breadth, is extended along the front of the body from the pelvis to the top of the shoulder, and thence down the back to the buttock, leaving, as it crosses the shoulder, a short loop, in which is placed a small block of wood, which is fastened by means of a tape to the hook of the bar. To prevent the long strip from becoming detached, the body is completely encircled, at different heights, by three horizontal bands.

Fig. 434.

Bar of wrought iron for counter-extension.

The advantages of this contrivance are, that the extension and counter-extension are made in a straight line, that the dressings maintain their place much longer than the ordinary ones, and, lastly, that, as the patient cannot sit up in bed, there is less danger of displacement of the ends of the broken bone. The only objection to it is that the circular adhesive bands might impede the respiration, but any trouble that might thus arise will generally speedily disappear of its own accord.

Professor N. R. Smith has for a long time treated fractures of the thigh with great ease and success, with what he calls the *anterior splint*. It consists, as seen in fig. 435, of a single piece, made of wire, of the size of a

Fig. 435.

Dr. N. R. Smith's anterior splint.

No. 10 bougie, and bent at each extremity, the whole representing the form of a long parallelogram, three inches wide above, and two inches and three-quarters below. It must be long enough to reach from a point a little above the anterior spinous process of the ilium to an inch beyond the toes, when the thigh, leg, and foot are extended, three feet eight inches being a good average length for adults. The side-pieces are firmly connected by cross-pieces at a distance of about eight inches. Thus constructed, the wire frame is easily bent to suit the case in hand. The angle at the tibio-tarsal joint, six inches from the extremity, is about 120° , to secure an easy posture for the foot; that at the knee and the one at the hip are each about 160° , the latter being seven inches from the upper extremity.

The splint, properly padded or tightly wrapped with a muslin bandage, and secured to the limb by a roller extended from the toes upward, is suspended, by means of a pulley, cord, and loops to the ceiling, as represented in fig. 436, a compress being placed upon the instep and another upon the groin, to ward off pressure. The proper position of the hooks is a matter of great consequence. In general, the upper one should be attached nearly over the seat of the fracture, and the lower a little above the middle of the leg, the object being the thorough equalization of the pressure of the splint. The roller, confining the apparatus, should be well stitched to prevent it from slipping, and great care taken that it do not make undue constriction. This apparatus, the efficacy of which has been thoroughly tested in numerous cases, is exceedingly light and comfortable, and is equally well adapted to fractures of the thigh and leg, in every portion of their extent.

Fig. 436.

Dr. N. R. Smith's mode of treating fractures of the thigh.

An excellent mode of treating fractures of the thigh, attended with very gratifying results, and originally suggested by Dr. Gurdon Buck, is pursued at the New York Hospital. The long splints are entirely dispensed with, the extension being made by the action of a weight and pulley, and counter-extension by the usual perineal strap lengthened out and fastened to the head of the bedstead. A piece of adhesive plaster, from two and a half to three inches in width, is stretched along the sides of the limb, to a short distance above the knee, and confined with a roller extended from the toes up, the middle of it forming a loop below the sole of the foot. A thin block of wood, the width of the plaster, and long enough to prevent pressure over the ankle, is inserted into the loop, and thus serves to receive the extending cord, which is fastened to an elastic rubber band passing round the block, and playing either over the footboard of the bedstead, or, if there is none, a temporary frame, perforated at a height of about five inches above the level of the mattress. The thigh, at the seat of fracture, is surrounded with short splints, the heel is supported upon a thin, wedge-shaped hair cushion, and a bag, filled with sand or bran, is placed along the outside of the leg and foot to

Fig. 437.

Dr. Buck's fracture apparatus.

prevent rotation. The amount of weight to be employed must be determined by the age of the patient and the other circumstances of the case. A child

under eight years of age will seldom require more than five or six pounds, while an adult may require from fifteen to twenty. The most suitable perineal band is a piece of India-rubber tubing, of one inch calibre, two feet in length, with a ring at each end, stuffed with bran or cotton lampwick, and covered with canton flannel, wrapped spirally round it, and renewed whenever it becomes soiled. The apparatus of Dr. Buck is represented in fig. 437.

The treatment of fractures of the thigh, lately introduced by Dr. Swinburne, recommends itself by its simplicity and efficiency, and deserves, in my judgment, the favorable consideration of the profession. It consists, as will be seen by a reference to the annexed sketch, fig. 438, exclusively of extension

Fig. 438.

Dr. Swinburne's method of treating fractures of the thigh.

and counter-extension, without splints, the perineal and crural bands being secured to the bedstead, as in Dr. Buck's apparatus, and composed of similar materials. Free use is made of adhesive strips at the leg and foot, and also, if necessary, at the thigh. With such an arrangement, the affected limb may be inspected or measured as often as may be desired, all danger of embarrassing the circulation is done away with, perfect cleanliness may be preserved, and any topical applications that may be required may be made and removed with the utmost facility. The advantages of this method are particularly conspicuous in complicated fractures of the thigh. Dr. Swinburne states that he has treated in this manner upwards of forty cases of fractures of the femur and tibia with very little, if any, shortening, except in the intra-capsular form of the accident.

Whatever apparatus be employed, whether those now described, or others of a similar character, there are several circumstances which should claim the special attention of the practitioner in the treatment of fractures of the shaft of the femur, and which may be stated in the form of aphorisms.

1st. Care must be taken that the ends of the broken bone are steadily maintained on a line with each other; any tendency to angularity, lateral distortion, or tilting up of the fragments must be promptly counteracted by pressure opposite the point of projection. This disposition manifests itself, more or less, in nearly all fractures of the femur, and should never for a moment be lost sight of, lest it be not discovered until it is too late to remedy it. It is particularly strong when the fracture is seated from two and a half to three inches below the small trochanter, in consequence of the action, on the one hand, of the iliac and psoas muscles, and, on the other, of the external rotators; the former, as before stated, tilting the lower end of the superior fragment forwards, and the latter outwards. For want of attention to this circumstance, wretched deformity of the limb is a frequent consequence of this lesion.

2d. Proper care must be taken that no *shortening* occurs. To prevent this, constant vigilance must be exercised in regard to the tightening of the

extending and counter-extending bands. If any doubt exist, a comparative estimate must be made from time to time of the length of the two limbs, by stretching a piece of tape from the centre of the umbilicus to the inferior and inner border of each patella, the body and limbs lying perfectly straight.

3d. A slightly *everted* condition of the limb being that which is most natural when the body is dorsally recumbent, the surgeon should aim to maintain it in that position during the period necessary to obtain reunion of the ends of the broken bone.

4th. The *heel* must be seen to; for if it be neglected it will be sure to inflame and ulcerate, if not slough. Too much care, therefore, cannot be taken to ward off pressure by filling up the hollow on each side of the tendo Achillis with cotton, or employing, if necessary, a small air-bag, or a bladder partially filled with water.

5th. *Extension* must be maintained with two broad strips of adhesive plaster, stretched along the sides of the leg nearly as high as the knee, secured by cross-pieces, and fastened to the foot-board of the splints or fracture-box; the surface being carefully shaved prior to their application. Or, instead of this, two long and broad strips of linen or muslin are secured to the limb by means of a roller, the upper extremity of each being turned loop-like down upon itself, over the bandage, and fastened by carrying the roller downwards. The gaiter and handkerchief should not be used in any case, for reasons previously mentioned.

The *perineal band* must also receive due attention, otherwise it will be sure to gall and fret the parts, and thus greatly distress the patient. Besides, if not properly managed, it will be extremely apt to displace the upper fragment, by pushing it outwards, away from the inferior.

6th. In *compound fractures*, one of the splints may be bracketed, as originally recommended by Dr. Hayes, of Indiana, the method having been adopted by him during our war with England, in 1813 and 1814. The opening which is thus left affords ready access to the wound, and, consequently, great convenience for the application of the necessary dressing.

7th. Much objection has been urged by certain writers against the *bandage* in the treatment of fractures of the thigh, on the ground not only that it is inconvenient, but absolutely useless. My experience does not corroborate this statement. On the contrary, I have always derived the most marked benefit from it, and would not, therefore, on any account, omit it. While I should hardly know how to control muscular spasm without it, it is one of the most powerful means we can employ to counteract the tendency to shortening, so common in nearly all fractures of the thigh. To answer the purpose, however, it must be applied with great care; otherwise harm, not benefit, will result.

In simple fractures of the thigh, the ordinary roller is sufficient, but in compound fractures preference is given to the bandage of Scultetus, inasmuch as, being composed of separate strips, it admits of more easy removal and reapplication.

The *starch bandage* may often be employed with great advantage, giving adequate support to the broken limb, and enabling the patient to take exercise in the open air, or about the house, upon crutches, a matter frequently of great importance. My experience, however, is averse to its use in the early stage of the treatment; applied too soon after the accident, before there is pretty complete subsidence of inflammation and swelling, it may do incalculable harm, not only greatly aggravating the local trouble, but endangering the safety of the limb by the induction of gangrene. For these reasons, therefore, I seldom resort to it before the end of a fortnight or the beginning of the third week.

8th. Care must be taken to keep off the bedclothes from the fractured

limb, as their weight would not only be oppressive, but tend to derange the ends of the fragments. A good and ready mode of accomplishing this is to cut a stout barrel hoop through at the middle, and to place the two halves, tied firmly together, crosswise, over the injured extremity. Or, instead of this apparatus, the surgeon may use, what is much better, the frame depicted at page 937.

Mr. Pott, of England, conceived the idea that the best mode of treating fractures of the femur was to place the affected limb upon its outside, the body inclining in the same direction, and the knee being in a semi-flexed state. The leg and foot, supported upon smooth pillows, were elevated somewhat above the level of the thigh, which was enveloped by a many-tailed bandage, and covered in by two broad, carved wooden splints. This plan, which Mr. Pott recommended with all the enthusiasm of a man of genius, was founded upon the erroneous notion that it would completely relax the different sets of muscles connected with the broken bone, thus preventing them from acting injuriously upon its fragments; forgetting that, in proportion as he took off the tension from one class, he necessarily increased that of another. It has been found altogether impossible to carry out this plan successfully in practice, experience having shown that the patient is utterly unable to remain so long in one position without suffering greatly from bed-sores, and that the apparatus, with all the care that can be taken to keep it in place, is wholly inadequate to answer the purpose of an accurate adjuster.

Another mode of treating fractures of the body of the femur, quite different from any hitherto described, was much in vogue at one time, both in England and in this country, chiefly in consequence of the influence of the late Sir Charles Bell, by whom, if it was not originated by him, it was extensively employed for a long time at the Middlesex Hospital, London. It consists in placing the limb upon two grooved cushions, resting upon two pieces of board, united by hinges in the form of a double inclined plane, as seen in fig. 439, and long enough to extend from the tuberosity of the ischium to the

Fig. 439.

Double inclined plane of Sir Charles Bell.

back part of the heel. A roller having been previously applied from the toes to the groin, two light, but firm binder's board splints, carefully softened in hot water, are secured to the outer and inner parts of the thigh, meeting nearly in front, and reaching from the groin to the knee. The extremity is now laid over the inclined plane, in an easy, comfortable position, the angle of flexion having special reference to this point; the foot is attached to the foot-board, and the limb and plane being tied firmly together by tapes, or, what is better, a bandage, the dressing is completed.

The method of treatment by the double inclined plane ought not to be too lightly condemned, for it cannot be denied that very excellent cures are occasionally effected with it. Much less frequently employed now than formerly, it is more particularly applicable to the treatment of fractures of the condyles of the femur and of the upper extremity of this bone, attended with a

constant disposition to displacement of the lower extremity of the superior fragment. It may also be advantageously employed in compound fractures, attended with severe contusion and laceration of the integuments, where confinement in the extended position would be productive of violent pain and extreme discomfort. The extension is made mainly by the weight of the leg and foot, while the counter-extension is made by the pressure of the apparatus against the tuberosity of the ischium. The annexed drawing, fig. 440, represents M'Intyre's splint, or double inclined plane, modified by Liston. Fig. 441 exhibits it as it is applied to the limb.

Fig. 440.

M'Intyre's splint, simplified and improved by Liston.

Fig. 441.

M'Intyre's splint applied to the limb.

Finally, when *both thighs* are broken the case may be treated with a double inclined plane, or a fracture-bed, the hinges being arranged in such a manner as to permit the trunk to be raised or lowered at pleasure, without causing any motion of the hips. The limbs should be well protected with side and front splints, and be immovably tied together.

The period required for the consolidation of fractures of the shaft of the femur must necessarily be greatly influenced by circumstances, as the age and health of the patient, and the care with which the ends of the fragments are kept together. In children of from five to fifteen years, complete union may usually be looked for in from twenty-four to twenty-eight days. In eighteen cases, analyzed by Dr. A. L. Peirson, of Massachusetts, the cure in persons of thirty years of age and under, occupied 35.88 days; while in seventeen, where the age was upwards of thirty, the average period was 36.64 days; thus showing only a very trifling difference in the two series.

It has been asserted by many highly respectable practitioners that it is always extremely difficult, if not impossible, to effect a cure in fractures of the shaft of the thigh-bone without some degree of shortening, and my opinion is that this conclusion is only too well founded. There can be no question at all that in many cases a certain degree of shortening is absolutely and positively unavoidable, not on account of any defect in the treatment, but from the very nature of the fracture itself. How is it possible it should be otherwise, when the ends of the fragments are driven the one into the other? The best skill and the most devoted attention would utterly fail, under such

circumstances, to make a good limb. So, also, when the fracture is compound or comminuted, more or less deformity and shortening will almost be inevitable. In the New York Hospital, where fractures of the shaft of the thigh-bone are very common, and where this accident is probably treated with as much adroitness and care as anywhere in the world, from a third to half an inch of shortening is generally looked for, as a natural consequence, by the surgeons of the Institution, and it is questionable whether the statistics of other similar establishments, if they could be ascertained, would exhibit a more favorable result.

2. FRACTURES OF THE INFERIOR EXTREMITY.

Fracture of the condyles of the femur is, in comparison with that of the humerus, an extremely infrequent occurrence. Indeed, it is very uncommon, not only relatively, but absolutely speaking. Sir Astley Cooper mentions only two instances of the kind in his work on Dislocations and Fractures; the Dupuytren Museum at Paris, so rich in osteological preparations, contains but five specimens of the lesion; and in the Mütter collection, not a single bone, illustrative of the occurrence, is met with. The cabinet of Professor Gibson, the elder, now at Richmond, has, however, several beautiful specimens of fracture of the condyles; and among my own preparations is a very rare one, in which these eminences are broken off vertically, leaving the trochlea attached to the lower end of the shaft which exhibits a remarkably comminuted appearance, consisting of not less than five distinct fragments.

The fracture may be limited to one of the condyles, which, however, is extremely rare, or it may implicate both, the fissure in the latter case extending between the two prominences, and terminating above in an oblique fracture of the shaft, so as to give rise to three distinct fragments. From the amount of force required to produce this fracture, it is generally attended with a great deal of injury to the soft parts, and, for the same reason, it is not unfrequently of a compound and comminuted character, the ends of the fragments protruding either externally or projecting into the cavity of the knee-joint. A partial fracture of one of the condyles occasionally occurs. In rare cases, the fracture presents the character of impaction, the lower end of the shaft being forcibly impelled into the cancellous structure of the condyles, which are completely severed in their entire length. Fig. 442 conveys an excellent idea of a fracture of the external condyle from a drawing of Sir Astley Cooper.

Whatever form the fracture may assume, it is nearly always the result of direct violence; generally of a fall upon the knee, the passage of the wheel of a carriage, or the kick of a horse. In one of the three cases that have fallen under my observation, it was occasioned by a fall from a high scaffolding, the individual, a man upwards of fifty years of age, alighting upon his feet, but striking, before he could recover himself, his knee against a large stone. The subjects of these fractures are usually old persons, in whom the condyles of the femur have become atrophied and brittle from the effects of interstitial absorption and fatty degeneration.

The *symptoms* of fracture of the condyles are not always well characterized, owing to the fact that the fragments are generally held in place by the

Fig. 442.

Fracture of the external condyle.

ligaments of the knee, thus preventing marked deformity, and rendering the production of crepitus difficult. The joint appears to be wider and flatter in front than usual, and if the patella be pressed backwards, the condyles may be considerably separated, so as to increase the transverse diameter of the limb. The joint is much swollen and bruised, the member is completely powerless, and, when the fracture affects both prominences, there is nearly always marked shortening, often amounting to from one to two inches, the lower fragment being drawn up behind the superior by the action of the hamstring muscles. When only one condyle is broken, the deformity, other things being equal, will be less than when both suffer, and there will also, of course, be less shortening.

In the specimen of vertical fracture of the condyles in my cabinet, previously alluded to, the short fragment is drawn upwards against the posterior surface of the shaft of the femur, to the distance of at least two inches, its upper surface looking towards the trochlea, with which it forms an obtuse angle, thus greatly increasing the antero-posterior diameter of the joint. The various appearances of this rare specimen are well represented in fig. 443.

Fig. 443.

Comminuted fracture of the lower extremity of the femur.

Fracture of both condyles occasionally simulates a partial luxation of the head of the tibia backwards. In a case reported by Professor Neill, the symptoms resemble much more those of an accident of this kind than those of a fracture of the condyles. The leg being thrown backwards, rendered the patella remarkably prominent in front, but there was no increased breadth of the knee, no crepitus, and no contortion of the foot, at the same time that it was easy to flex and extend the joint. The best diagnostic consists in taking hold of the condyles, and attempting to press them in opposite directions, which cannot, of course, be done, if there be no fracture. The same procedure can hardly fail to elicit crepitation, although this may be rather slight, especially if the fragments are held pretty firmly together by the ligaments.

The *prognosis* of this fracture is especially grave, on account both of the injury done to the soft parts, and of its connection with the joint, which may be involved in an alarming degree. The fracture may, as already stated, be compound or comminuted, and when this is the case the danger will, of course, be greatly increased, perhaps to such an extent as to require amputation, or, when this is not deemed advisable, in such a manner as to jeopard life by mortification, pyemia, erysipelas, or congestive pneumonia.

The *treatment* will usually require, in the first instance, to be strictly antiphlogistic, leeches and evaporating lotions being necessary, on account of the injury done to the soft parts. The limb, enveloped in a bandage, is laid in an easy position, and free use is made of anodynes in order to prevent spasm, so common and annoying after these accidents. As soon as the inflammation

has been sufficiently subdued, the fragments are restored to their proper position, and maintained by appropriate apparatus, the limb being extended, if the fracture be transverse, or nearly so, or placed over a double inclined plane, if it be very oblique, with a strong tendency to displacement of the broken ends. Passive motion is instituted at the expiration of a month, but, despite the attention of the surgeon, a good and unexceptionable cure will be extremely difficult, if not impossible, especially when both condyles are implicated.

Complicated fractures of the condyles are occasionally met with, principally as the result of direct violence, such as the passage of the wheel of a carriage, or of gunshot injury, and are among the most dangerous of accidents, bringing life in jeopardy by tetanus, erysipelas, pyemia, and profuse suppuration and hectic irritation. The danger is proportionately increased when the lesion is attended with extensive wound of the knee-joint, or a comminuted condition of the bone. An attempt may be made to preserve the limb when the patient is young and in good health at the time of the fracture, when the weather is not too hot and exhausting, and when the injury in the soft parts is comparatively slight; under opposite circumstances, on the contrary, the best plan will be to amputate on the spot, immediately after the occurrence of reaction. To hesitate, in such a case, would only be to trifle with the patient's life, which could hardly fail to be the forfeit of the surgeon's timidity.

3. FRACTURES OF THE SUPERIOR EXTREMITY OF THE FEMUR.

The superior extremity of the femur comprises the head and neck of that bone, together with the two trochanters, so that in an individual of ordinary stature it is from three inches and a quarter to three inches and a half in length, there being, however, no distinct boundary line between it and the shaft. The head composes nearly two-thirds of a sphere, and rests upon the

Fig. 444.

Natural appearances of the head and neck of the femur.

Fig. 445.

Alterations of the head and neck of the femur from the effects of old age.

neck, which is inclined obliquely upwards and inwards, so as to form an obtuse angle with it; they are surrounded by the capsular ligament, the

strongest membrane of the kind in the body, and consist of a large amount of spongy tissue, inclosed by a thin lamella of compact substance. Both these structures undergo important changes in consequence of advancing age, the former becoming greatly rarefied, light, and porous, while the latter is so attenuated as to be, in some places, hardly as thick as common letter paper. These changes, the necessary effect of which is to render the bony texture frail and brittle, are particularly conspicuous after the fiftieth year, and are a principal cause of the frequency of fracture of the neck of the femur at and after this period of life. There is another circumstance, also, which powerfully contributes to this occurrence, and that is the alteration which the position of the neck of the femur undergoes, causing it, in many cases, to stand off almost at a right angle with the shaft of the bone, or even to sink below this level. This change in the obliquity of this portion of the bone is, as a general rule, more common, as well as more marked, in women than in men, and hence it is that the former are always more liable to fracture of the neck of the femur than the latter. These various appearances are well illustrated in the adjoining sketches. Fig. 444 represents the ordinary normal shape of the head and neck, together with its spongy and compact structures. Fig. 445, from a preparation in my collection, affords a good idea of the changes which these parts experience in consequence of the effects of age.

A thorough knowledge of the disposition and strength of the two ligaments of the hip-joint is of great consequence in the study of fractures of the superior extremity of the femur, both as it respects their symptoms and mode of reparation.

Fig. 446.

Head and neck of the femur with capsular ligament laid open.

The capsular ligament, fig. 446, represents a kind of shut sac, which is attached, on the one hand, to the periphery of the cotyloid cavity, and, on the other, to the prominent lines which extend, in front and behind, from one trochanter to the other, thus including both the head and neck of the bone. It descends further down on the anterior than on the posterior surface of the neck, and is thicker and stronger above and behind than in any other portion of its extent. Anteriorly, it is strengthened by the psoas, iliac, and crural muscles, together with a band of ligamentous fibres; posteriorly, by the geminal, pyramidal, and inner obturator muscles; internally, by the pectineal and outer obturator muscles; and superiorly, by the small gluteal.

The inter-articular ligament—the round ligament of anatomists—is a dense, triangular bundle of fibres, which arises from the depression upon the head of the femur, just below its centre, and is inserted by two divergent processes into the margins of the cotyloid notch of the acetabulum.

These two ligaments, maintaining the head and neck of the femur in their proper position, generally sustain serious injury in fracture of the superior extremity of the bone. When the lesion is intra-capsular, the capsular ligament is usually completely torn across so as frequently to admit of the escape of the upper extremity of the inferior fragment through the rent, either on the spot, or soon afterwards, thus accounting, in some degree, for the shortening experienced by the limb. The upper fragment, on the contrary, hangs

on, as it were, to the round ligament, which thus supports and nourishes it, its vascular and nervous supplies being cut off in every other direction.

There is another point of great practical interest in the anatomy of the neck of the femur, which, from the influence it exercises over the repair of fractures, deserves brief mention here. I allude to the fact that this portion of the bone is nearly destitute of periosteum, thereby disqualifying it, in great degree, for the formation of callus, an occurrence which is still further opposed by the circumstance that this part is invested by a synovial membrane, which, in case of accident, always pours out a large quantity of fluid, the interposition of which between the ends of the fragments becomes thus a powerful obstacle to their reunion. Occasion will be afforded of speaking again of these various points as we proceed with the discussion of the nature and treatment of fractures of the neck of the femur.

Fractures of the neck of the femur are divisible into two classes, those, namely, which occur within the capsular ligament, and those which take place exterior to it; the former being now usually termed intra-capsular, and the latter extra-capsular. The distinction, as will be seen by and by, is one of great pathological as well as practical importance, and is, therefore, worthy of profound consideration.

INTRA-CAPSULAR FRACTURES.

Fracture of the neck of the femur within the capsular ligament may occur at any portion of this part of the bone, as exhibited in the accompanying figures, 447, 448, and 449; but, in general, it is met with at a short distance

Fig. 447.

Fig. 448.

Illustrations of intra-capsular fracture.

below the head, or between the head and centre of the neck, where the compact structure appears to be unusually weak, and where, consequently, the slightest force frequently produces the accident. Sometimes the line of fracture is on a level with the globular head, which, therefore, alone constitutes the upper fragment; and, on the other hand, cases are observed where the bone yields just above the attachment of the capsular ligament. Finally, the fracture is sometimes partly within and partly without the ligament, forming an interesting variety, especially in reference to the question of the process of consolidation. The direction of the fracture is usually oblique; but it

may be perfectly perpendicular, especially when the neck, in consequence of age or disease, forms a right angle with the shaft of the bone.

Fig. 449.

Intra-capsular fracture of the femur.

Fig. 450.

Vertical fracture of the neck of the femur.

An incomplete variety of intra-capsular fracture has been from time to time recognized by surgical observers, but much doubt has always been entertained by many in relation to the possibility of such an occurrence. I have myself never met with an example in the numerous dried specimens that I have examined in different collections, and I, therefore, assume that the accident must be extremely uncommon. A well-marked instance of the kind occurred in 1856 to Dr. J. B. S. Jackson, of Boston, in a man, aged forty-two years, in consequence of a fall through two stories of a building upon a hard floor, breaking his spine and the femur at several points. The fracture of the neck, commencing at its junction with the head, reached, as is seen in fig. 450, in a nearly perpendicular direction, to within about a quarter of an inch of the inferior and internal wall of the bone, the fissure being so extensive as that, if the man had been able to walk, the unbroken part could probably not have supported the weight of his body.

The cause of intra-capsular fractures is generally some trivial accident; most commonly a fall upon the great trochanter, or a blow upon the hip when the thigh is fixed and separated from its fellow, thus increasing the strain upon the upper portion of the bone. I have known the injury to be produced by the great toe catching in a fold of the carpet, while the person, an old lady of seventy-six, was walking across the floor. In London, according to Sir Astley Cooper, it most frequently occurs from the foot suddenly slipping off the edge of the side-walk over the curb-stone, upon the carriage pavement, the weight of the body being thus thrown forcibly upon the neck of the bone in a perpendicular direction, when it is unprepared for such an event. Cases are recorded of the fracture having happened in consequence of the individual having turned awkwardly in bed, or of having stepped carelessly out of the bed upon the floor, in either case powerfully twisting the thigh-bone. The fact that so serious a lesion may occur from so trivial a cause, while it is of great value in a diagnostic point of view, affords the clearest possible proof that a bone, liable to be so affected, cannot be very sound, but, on the contrary, that its structure must have undergone serious

changes to render it capable of an accident, which, in other pieces of the skeleton, requires an extraordinary degree of force. That this is the case, as a general principle, has already been shown, the immediate cause being the fatty, atrophied, and rarefied condition of the compact and spongy tissues of the neck of the bone, the animal matter being absorbed, and the earthy alone left, the result of the whole being a weakened condition of the affected parts, and, consequently, a predisposition to fracture. Although the lesion is usually occasioned by slight accidents, yet instances are observed where the reverse is the case, but then it is worthy of remark that it is ordinarily of a complicated character.

The *age* at which this variety of fracture occurs is, diagnostically considered, a matter of great importance. A fracture in other bones, or parts of a bone, may take place at any period of life, even in infancy and early childhood. Thus, I have seen the shaft of the femur itself broken in an infant of four weeks. But it is very different with the neck of this bone within the capsular ligament, experience having shown that it is subject to fracture only, as a general rule, after the age of fifty, when, as already stated, its spongy and compact tissues suffer from atrophy and fatty degeneration, thus rendering it more or less brittle, and incapable of withstanding injury. The youngest subject in whom this fracture has been observed was a lady of eighteen, whose case has been reported by Mr. Stanley, of London. Sir Astley Cooper saw an instance at thirty-eight. Doubtless other examples have occurred, but they do not disprove the rule that this variety of fracture is an occurrence of advanced life.

Sex also exerts a considerable influence upon the production of intra-capsular fracture. Of its precise relative frequency in males and females, no reliable statistics, at least none upon a large scale, have been placed before the profession; but a sufficient amount of information has been obtained to justify the assertion that it is much more common in the latter than in the former. In the Tables of Mr. R. W. Smith, of Dublin, in his Treatise on Fractures, the sex is given in twenty-eight cases, of which seventeen were women and eleven were men. The cause of this difference appears to be twofold, the more horizontal position of the neck of the thigh-bone and the greater amount of atrophy and fatty degeneration of this portion of bone in old females than in old males.

The intra-capsular fracture may be *complicated* with fracture of the neck on the outside of the capsular ligament, the lines of disjunction running into each other. Such an occurrence, indeed, is not infrequent. Again, an intra-capsular fracture may be associated with a fracture of the great trochanter; but this is extremely rare. In twenty-three specimens of this lesion in the Dupuytren Museum at Paris, there is not a solitary example of such a coincidence.

The *symptoms* of intra-capsular fracture are deserving of particular attention. They are: 1. Shortening of the thigh. 2. Eversion of the foot. 3. Preternatural mobility. 4. Crepitation. 5. Change of position in the great trochanter. 6. Pain at the site of injury. 7. Peculiarity of the patient's body in the erect position. Each of these symptoms, except, perhaps, the last, possesses a positive value, and must, therefore, be considered somewhat at length.

The *shortening of the thigh*, or of the limb through the thigh, is one of the most striking phenomena of this variety of fracture, and is the more valuable because of its almost universal occurrence. It is usually the first circumstance that attracts the attention of the surgeon, whether the patient be lying on his back, or standing up. As might be expected, it varies in different cases and in different conditions of the same patient, its extent being greatly influenced by the state of the capsular ligament, being generally less

in proportion to the integrity of this membrane, and conversely. It is always less immediately after the occurrence of the injury than it is after the lapse of several days, and also in impacted fracture than in the ordinary form of the accident. The amount of immediate shortening ranges from half an inch to an inch; but it may be considerably less than this, not, perhaps, exceeding three lines; and, on the other hand, it may reach an inch and a quarter, and even an inch and a half, especially if there be extensive laceration of the capsular ligament. During the progress of the case, the shortening will not unfrequently amount to upwards of two inches, while in rare cases it has been known to exceed three.

The diminution in the length of the limb, although generally immediate, is not always so, depending, perhaps, not so much, as has usually been supposed, upon the integrity of the capsular ligament, as upon the want of separation of the ends of the fragments, in consequence of the peculiar arrangement of their surfaces favoring their temporary contact. It is hardly reasonable to imagine that, if the integrity of the capsular ligament were the only cause of it, this ligament would become so stretched or torn within so short a time after the accident as to admit of the amount of shortening above mentioned. We must, therefore, seek for some other cause, and I know of none that is so plausible as the one here suggested. Under such circumstances, the shortening generally takes place suddenly; perhaps after the patient has made considerable exertion with his limb, several days, it may be, after the accident, in consequence of the instantaneous unlocking, as it were, of the ends of the fragments. When the fracture is impacted, the shortening will, of course, be immediate, and will also be likely to be permanent, unless the broken pieces are pulled forcibly asunder by the surgeon in the examination of the limb, or by the patient in his efforts at walking or turning about in bed.

Eversion of the foot, or, rather, of the whole limb, is another striking and constant symptom, being seldom absent in any case. When the patient stands up, it is such as to cause the heel of the affected side to point towards the hollow between the ankle and tendo Achillis of the sound limb; while, when he is recumbent, the foot inclines outwards almost horizontally, dropping involuntarily upon its external surface, nearly, or quite, in contact with the floor. The eversion, although generally an immediate effect of the accident, does not always reach its maximum until some time after, depending upon the manner in which the ends of the fragments are held together. When the fracture is impacted, it may be entirely absent, or the foot and knee, instead of being everted, may be more or less turned in the opposite direction.

The cause of the eversion of the limb, in this accident, has been differently explained. Most writers ascribe it to the action of the external rotator muscles, which, being connected with the superior extremity of the bone, thus readily roll the thigh outwards when it has lost its support above, the irritation consequent upon the fracture being an additional incentive to contraction. Others, on the contrary, and I include myself among the number, attribute it altogether to the weight of the limb, which has a natural tendency to eversion whenever the internal rotators are thrown off their guard, as is observed during sleep, when, the extremity being perfectly passive, the foot invariably inclines outwards.

Preternatural mobility, common to all fractures, is particularly observable in the intra-capsular variety, and therefore serves as an important diagnostic sign of the accident. There are cases, however, in which it is absent; in some entirely, as in the impacted fracture, and in others only in the early stage of the injury, as when the ends of the bone are held partially together by the interlocking of their fibres, by the incompleteness of the solution of

continuity, or by some other cause. Its existence, as well as its degree, is always readily ascertained by taking hold of the limb and rotating it upon its axis, or flexing it upon the pelvis, extending it behind the line of the sound limb, or carrying it inwards or outwards; movements which cannot be executed when there is a dislocation of the head of the femur. Extension and counter-extension will have the effect of restoring the limb promptly to its proper length, but as soon as the forces are discontinued the original shortening is reproduced.

Crepitation, the most valuable sign of all in fractures generally, is rarely wanting in this. Indeed, it can only be absent in the impacted form of the lesion, or in those cases where the ends of the fragments remain still partially in apposition with one another. In general, it is discoverable immediately after the accident, and may, of course, be produced as long as the fracture continues ununited. In order to determine its existence, it is necessary to bring the ends of the broken bone fully in contact by extension and counter-extension, when, upon rotating the limb, it will at once declare itself.

Change of position in the great trochanter is always a symptom of importance in intra-capsular fracture. This bony prominence is not only drawn upwards towards the ilium, in this accident, but it is brought in close contact with the border of the acetabulum, and is, therefore, much less easily felt and seen than in the normal state, in which it is always so conspicuous. Moreover, when the thigh is rotated upon its axis by taking hold of the foot, the great trochanter will be found to turn, as it were, upon a pivot, or to move in a segment of a lesser circle than natural. From the circumstance of the limb being generally strongly everted, the portion of the broken neck attached to the trochanter is directed inwards and upwards, being thus placed in closer proximity with the anterior superior spinous process of the ilium than the trochanter itself.

Pain at the site of injury, being common to all fractures, is of special value only in connection with the other symptoms already described. It derives its chief importance from the fact that it is located at the upper and inner part of the thigh, in the direction of the small trochanter, and that it is always greatly increased whenever an attempt is made to rotate the limb, to bend it upon the pelvis, or to carry it inwards over the sound one. When the patient is perfectly quiet, the limb being placed in a relaxed position, the suffering is usually very trivial, except in cases where the bone has received, in addition to the fracture, a severe degree of concussion, when the pain will frequently be excessive. It is generally worse, too, at night than in the day, and in wet weather than in dry.

There is a peculiarity in the *patient's attitude* as he stands up, which cannot fail to strike the most careless observer. The body, in this position, is inclined forwards in such a manner as to throw its weight upon the sound limb, which is firmly planted upon the floor, while the other hangs off in a constrained, unseemly, and awkward manner; the foot and knee are strongly everted; the leg is supported upon the ball of the toes, while the heel, resting in the interval between the ankle and tendo Achillis, is elevated from two to three inches from the surface; the natural prominence of the hip is destroyed; and the least attempt to walk or raise the limb not only proves abortive, but is productive of exquisite pain.

Finally, there is seldom much *swelling* in this variety of fracture; it is only when the hip has been struck a severe blow that the superficial parts are likely to be the seat of any considerable effusion, ecchymosis, discoloration, or contusion, and even then the symptoms are usually very evanescent.

The *pathological appearances* in intra-capsular fracture vary very much, according to the period of the examination, as well as the character of the original injury. In recent cases there is usually some sanguineous effusion,

although the quantity of blood is generally very small, unless, as occasionally happens, there is a rupture of the capsular ligament, when it may be considerable. Most commonly the ligament preserves its integrity, but if the accident has been unusually severe it may be torn at one or more points, so as to admit of the partial escape of the inferior fragment, the soft covering of which is often partially detached, hanging off in loose, irregular shreds. If several days have elapsed since the receipt of the injury, the changes will be such as are evincive of inflammation. The synovial membrane will be observed to be unnaturally vascular, and to be slightly coated with plastic matter, a small quantity of which is also sometimes found upon the ends of the fragments. There is likewise, at this stage, a marked increase of synovial fluid, and the structures around the joint frequently exhibit a contused appearance, with more or less infiltration of blood and serum.

If the dissection be made after the lapse of some months, the capsular ligament will be found to be much thickened by interstitial deposits, as well as by the addition of plastic matter to its synovial lining; the head and neck of the bone are also incrustated with lymph; and the ends of the fragments are softened, unnaturally vascular, and rounded off, or partially connected by fibro-ligamentous bands. The inter-articular ligament retains its normal structure, except in rare cases, in which it is inflamed and changed into fibrous tissue.

In old cases, or such as have been on hand for some years, there are not only great thickening and induration of the capsular ligament, but extraordinary alterations in the broken bone, the neck of which is often completely annihilated, the shaft terminating abruptly on a line with the two trochanters. At other times the neck is converted into a short, conical knob, partially incrustated with cartilage, or scooped out, as it were, into a sort of cup-like depression. The trochanters themselves are occasionally a good deal changed in their appearance, especially the great, which is liable to be diminished in size and altered in configuration. The head of the bone generally retains its position in the acetabulum, but that portion of the neck which remained attached to it at the time of the accident is usually totally absorbed; and cases occur, though they are rare, where the entire fragment is destroyed, or where it is represented by the merest possible remnant held in place by the round ligament. When the head is left, its lower surface is occasionally hollowed out into a kind of socket for the reception of the rounded conical end of the lower fragment; or the reverse obtains, the head being rounded off, and the lower fragment scooped out. In either event, the two extremities, continually moving upon each other, in time acquire a smooth, polished, eburnized character, the better qualifying them for the performance of their various functions.

The changes now described are sometimes closely imitated by those produced in the head and neck of the femur by a fall or blow on the hip, leading to interstitial absorption of the osseous tissue, and shortening of the limb, with destruction of the articular cartilage and eburnization of the resulting stump, very much as in arthritic rheumatism. There is reason to believe that cases of this kind are not unfrequently mistaken, both during life and after death, for fractures of the neck of this bone. The appearances here alluded to are well illustrated in figs. 451 and 452.

The mode of *repair* of intra-capsular fractures is peculiar, and, therefore, deserving of special attention. Injuries of this description generally unite by osseous matter, which passes through the same phases as the primitive osseous tissue, a considerable period invariably elapsing before the final completion of the process; but in this variety of fracture the connecting medium is constantly of a fibro-ligamentous nature, similar to that which is observed in fracture of the olecranon process, the patella, and skull. But it is not

always that the surgeon is to look even for such a union, imperfect as it is; in many cases the ends of the broken bone refuse altogether to unite, being gradually rounded off, and, perhaps, slightly incrustated with cartilage, or, as not unfrequently happens, especially in very aged and decrepit subjects, be-

Fig. 451.

Senile atrophy of the neck of the femur.

Fig. 452.

Atrophy which might be mistaken for united fracture.

coming, in time, completely absorbed, the lower fragment disappearing as far down as the two trochanters, and the upper as high up as the brim of the acetabulum. In rare cases, indeed, we see even the entire head removed, together with the greater portion both of the round and capsular ligaments.

A very excellent idea of the fibro-ligamentous union of this variety of fracture is afforded by fig. 453, borrowed from Sir Astley Cooper. It was taken nine months after the accident, the patient being between thirty and forty years of age.

The causes of this want of union are of easy recognition. In the first place, the parts have to encounter the prejudicial influence which results from the difficulty of maintaining accurate apposition of the broken ends of the bone; a circumstance which is so essential to the successful reparation of fractures in other pieces of the skeleton, but which it is almost impossible to effect here, in consequence of the want of proper leverage in the upper fragment. All the apparatus that has yet been devised for the purpose has utterly failed to accomplish the object; whatever may be done, more or less motion is inevitable. Secondly, the accident is always followed by a considerable degree of synovitis, and, as a necessary consequence, by an increased quantity of synovial fluid, which, bathing the ends of the bone, may be supposed to act inimically to the consolidating process. Thirdly, the most important reason, however, of all, why the intra-

Fig. 453.

Fracture of the neck of the thigh bone, united by fibroid matter.

capsular fracture does not unite by osseous matter, is because the extremities of the fragments have not a sufficient amount of strength to furnish the requisite plastic and organizable deposit, their vessels and nerves being torn and destroyed at the time of the accident. The superior and smaller fragment, represented by the globular head of the bone, or the head and a little remnant of the neck, is dependent solely for its vascular and nervous supplies upon the round ligament, and every one who knows how small this ligament is, and how insignificant its vessels are in the natural state, must be aware how utterly inadequate it must be for the nourishment of the bone to which it is attached. It need not then be wondered at that there is never any show of new osseous matter on the part of this fragment. Nor does the inferior fragment fare much, if any better, in this respect. Destitute, in great measure, of fibrous covering or periosteum, with many of its vessels in a hopelessly lacerated condition, its powers are too feeble to afford any substantial aid in the process of osseous union. Hence the result must necessarily always be as above stated; that is, there will either be no reparation at all, or, if an attempt be made at establishing a connection between the two fragments, that attempt will go no farther than the formation of a fibro-ligamentous substance.

When no effort whatever at repair occurs, it is highly probable that the ends of the fragments speedily undergo the fatty degeneration, and that then they become an easy prey to the action of the absorbent vessels, eventuating in their final annihilation.

It would, perhaps, be going too far to deny altogether the possibility of bony union in intra-capsular fracture of the thigh-bone, and yet I have no hesitation in asserting that I have never seen what I could regard as an unequivocal example of the kind. I have examined most of the specimens in this country, purporting to be cases of osseous consolidation, and in no instance have the appearances been such as, in my opinion, to justify such a conclusion. In general, the history of these cases has either been so exceedingly defective, or the necroscopic characters have so closely resembled those witnessed in the changes which the head and neck of the femur undergo in consequence of old age or disease, as to destroy all confidence in their authenticity as genuine cases of intra-capsular fracture. I need not insist here upon the great difficulty which the practitioner frequently encounters in establishing a correct diagnosis in injuries about the hip; what skill and care it generally requires to discriminate accurately between a mere sprain and a fracture, or a fracture and a dislocation; or how frequently even slight lesions of the ileo-femoral articulation, and of the head and neck of the femur, are followed by changes in the structure and conformation of these portions of bone which might so closely simulate those produced by fracture as to deceive the most enlightened and cautious observer.

The question, then, in regard to the repair of intra-capsular fracture, resolves itself into four groups of facts, which may thus be stated: 1. Under favorable circumstances, both as it respects the patient and the treatment, there may be fibro-ligamentous union, answering the purpose of a sufficiently strong bond to admit of tolerable progression after recovery from the more immediate effects of the accident. 2. Under adverse circumstances, that is, when the patient is old, decrepit, or worn out by disease, and cannot, in consequence, submit to the proper treatment, or when, although the system is sufficiently vigorous, the case has been injudiciously managed, no consolidation whatever will take place, and not only so, but the neck of the bone, or both neck and head, will be absorbed, the limb remaining, of course, permanently shortened and deformed. 3. Osseous union, although perhaps not wholly impossible, is yet so exceedingly infrequent as that it cannot reasonably be looked for in any case, however propitious the circumstances attending it, both as it respects the patient and the skill and attention of his

attendant. The event, other things being equal, will be most likely to happen in the impacted form of the injury, and in the ordinary fracture in comparatively young and robust persons. 4. When the fracture is of a mixed character, that is, partly within and partly without the capsular ligament, the mode of repair will be similar to that of ordinary fracture, although the process will require more time and care for its successful completion.

The *prognosis* in this variety of fracture is embraced in the above discussion respecting its repair, and need not, therefore, engage further attention here. In regard to life, the danger is generally inconsiderable, as the lesion is usually the result of very trivial accidents, involving no serious injury to the soft parts, or any comminution of the bone. In respect, however, to the limb, as the consolidation of the fracture is always more or less imperfect, its usefulness will necessarily be impaired in a degree proportionate to the defective character of the connecting medium. For a long time, the patient is obliged to employ a crutch, but eventually he is able to walk with the aid of a stick and a high-heeled shoe, the parts strengthening by exercise, notwithstanding there is a strong tendency to atrophy of the muscles.

Treatment.—Fractures of the neck of the femur within the capsular ligament are not, I think, generally as well managed as they should be, owing chiefly, if not wholly, to the influence of the writings of Sir Astley Cooper, who taught that, inasmuch as there never is any osseous union in this variety of injury, it was not, therefore, proper to torture the patient with a protracted confinement in the recumbent posture, and the application of an extending apparatus. He considered such a proceeding the more necessary because a great majority of the subjects of this fracture are old and decrepit persons, many of whom bear confinement very badly, soon becoming affected with foul bed-sores, and eventually perishing from hectic irritation or congestive pneumonia. In accordance with this view, he was in the habit of placing the limb upon a long pillow, in an easy position, for about a fortnight, or until the pain and inflammation, consequent upon the accident, had in a great measure subsided. The patient was then allowed to leave his bed, and sit in a high chair, or exercise upon crutches, care being taken to bear, at first, very gently upon the foot for fear of disturbing and fretting the ends of the fragments. Subsequently, as the limb improved in strength, a high-heeled shoe was ordered, and a stick was substituted for the crutches.

If this treatment were the exception, and not the rule, every practitioner of sense and experience would concur in its propriety; but the English surgeon, in his desire to generalize it, has carried it much farther than the interests of our patients justify. It is unquestionably true that many of the subjects of intra-capsular fracture do not bear confinement well; they suffer from the slightest restraint, and soon become bedridden. Such cases are extremely difficult to manage, and are not likely to be benefited by the use of splints, or any other mechanical contrivances calculated to compress the limb and hold it in an uneasy and constrained position. To this class, the treatment of Sir Astley Cooper is peculiarly applicable; indeed, no other can be employed. All that can be done is to make the patient comfortable, and let the limb get on as best it may. But there is another class of subjects, who, though perhaps a good deal advanced in years, are, nevertheless, quite stout and robust, enjoying excellent health at the time of the accident, whose constitution has never been impaired by intemperance or excess of any kind, and who can bear the long confinement incident to such an accident with the most perfect impunity. The persons composing this class are, for the most part, residents of the country, and not the poor, broken-down inhabitants of crowded cities, without any bodily vigor, and, therefore, without any recuperative power. Hence, an exclusive plan of treatment should not be adopted; on the contrary, it should be varied according to the exigencies

of each particular case. Such a course is the more necessary because it is utterly impossible always to determine positively, by the most careful examination, whether the case is one purely of intra-capsular or extra-capsular fracture, or whether it partakes, as, indeed, it not unfrequently does, of the character of both, the two being conjoined.

Acting upon the above principles, I have, for many years, treated most of the cases of intra-capsular fracture that have come under my notice as any other fracture of the femur, by permanent extension and counter-extension, not with the hope, as already stated, of obtaining bony consolidation, but with the view simply of keeping the ends of the fragments more accurately in contact, and thus affording them an opportunity of becoming united by fibro-ligamentous tissue. It is obvious that such a result can only reasonably be anticipated when this condition is fully complied with. When the broken pieces are permitted to overlap each other constantly, hardly any union will be possible, certainly none of a useful kind; and there is, moreover, under such circumstances, always great risk that at least the neck, if not also the greater portion of the head of the bone, will be absorbed, and the patient, in consequence, never regain the functions of his limb. Should the treatment fail, the surgeon has the consolation to know that he has discharged his duty, by having kept the parts in the only position in which it is ever possible for them to become united in any way. The limb may be maintained in the extended position, and the apparatus which best fulfils this indication is that depicted at page 1031; or, instead of this, the limb may be placed in an easy position over a double inclined plane; or, what is better, when it can be procured, the patient may be put upon a Daniel's fracture-bed, represented in fig. 454. The latter contrivance, which, unfortunately, however, is too

Fig. 454.

Daniel's fracture-bed.

expensive for general private use, is particularly adapted to cases of old persons likely to require protracted confinement. The bed is so arranged that, while the patient can sit up, or vary his position, efficient extension and counter-extension may be maintained with adhesive strips. An elaborate description of the apparatus will be found in the tenth volume of the Transactions of the American Medical Association.

Whatever plan of treatment be adopted, its effects should be most carefully watched, so that it may not prove irksome, much less injurious. The length of time during which the patient should be confined must vary, on an

average, from ten weeks to three months and a half. During all this trying period he should be on a full allowance of meat and porter; at all events, upon a generous diet, in order to sustain the system and promote reparation. Purgative medicines and all other depressing means should be used as sparingly as possible. Anodynes must be freely given in the evening to allay pain and procure sleep.

EXTRA-CAPSULAR FRACTURES.

The extra-capsular fracture is situated at the base of the neck of the femur, extending from above downwards and from behind forwards in the direction of the intertrochanteric line. It is not always, however, as the name declares, strictly exterior to the capsular ligament; on the contrary, it not unfrequently passes above the attachment of the ligament, so as to partake of the character both of an inner and an outer fracture of the neck. Moreover, the injury is always associated with fracture of the trochanters, sometimes with one, at other times with both, thus leaving in the former case three fragments, and four in the latter. Again, the fracture is often comminuted independently of its connection with the trochanters; and in the great majority of instances it is attended with more or less penetration of the superior piece into the inferior. My own observation, however, induces me to believe that, generally speaking, the penetration is very trivial, hardly ever exceeding three lines, and often not reaching even so high as that. The two accompanying cuts, figs. 455 and 456, afford a good idea of the situation and direction of the extra-capsular fracture.

The extra-capsular fracture is not as common as the intra-capsular; the

Fig. 455.

Extra-capsular fracture of the femur.

Fig. 456.

Comminuted fracture of the upper extremity of the femur.

difference, however, is trivial. Men are somewhat more subject to it than women, and, while it may take place at any period of life, experience teaches that it is met with almost exclusively after the age of fifty, by far the greater number of cases occurring after the sixtieth year. It is generally supposed, and, no doubt, correctly, that a much greater amount of violence is required

to produce this fracture than the intra-capsular, but the rule admits of many exceptions. The most common exciting cause is a fall or blow upon the hip; it may also follow a fall upon the foot or knee and the passage of the wheel of a carriage across the pelvis or upper part of the limb. Finally, cases occur where it happens from the body being crushed by a heavy load descending upon the back, the lower extremities being in a fixed state at the moment of the accident. In not a few instances, however, the fracture is occasioned by very slight causes, while in most there is reason to believe that the bone where the lesion occurs is in a remarkably brittle condition, predisposing it to the disruption of its fibres. In some of the preparations that I have examined in different osteological collections the compact structure, although not very seriously diminished in thickness, was almost of a vitreous consistence, while the spongy was extremely rarefied and expanded, thus occasioning great weakness of the part. The inter-cervical portion of the bone frequently retains, under such circumstances, a remarkably healthy appearance. When the osseous tissue is so very fragile at this point, it is not improbable that it may occasionally give way under mere muscular contraction, as has happened in at least one well authenticated case, the patient, a woman, aged eighty-three, having met with the accident in an effort to preserve her equilibrium when in the act of falling.

The *symptoms* of this variety of fracture bear a strong resemblance to those of the intra-capsular, some existing in a less and others in a greater degree, but none of them, considered separately, possessing any diagnostic value. In describing these symptoms it will be most satisfactory if they be presented in the same order as in the preceding case.

The *shortening*, which is a constant occurrence, varies from half an inch to an inch, as its minimum, to an inch and a half, as its maximum. In exceptional cases it may, however, amount to two inches and upwards. It is usually most distinct when there is a badly comminuted state of the bone, or when the great trochanter, forming a part of the upper fragment, is drawn uncommonly far outwards, so as to permit the lower fragment to ride considerably over the upper. Moreover, it possesses this peculiarity, that it is generally as great immediately after the fracture as at any period afterwards.

The knee and foot are generally *everted*, the limb lying as if it were perfectly powerless, the muscles having apparently lost all influence over it. This symptom is even more striking than in the intra-capsular fracture. Eversion, however, is not so constant an occurrence as in the latter accident; in a considerable number of cases the limb is strongly rotated inwards, and in both varieties, but especially in the former, the displacement is occasionally so obstinate as to require an unusual degree of force to rectify it, depending, doubtless, upon the interlocking of the fragments.

The extra-capsular fracture is characterized by complete *mobility* of its fragments, except when they are impacted, an occurrence which, as already stated, is more common here than in fracture within the capsule. The loss of function is also complete, the patient being unable to lift the limb by the effort of his muscles, or to execute any of its natural functions.

The *crepitation* is generally very distinct, being often loud and cracking, and is readily perceived by the hand and ear, applied to the hip when the limb is rotated upon its axis. It is usually more marked than in intra-capsular fracture, and does not, as in the latter, require extension and counter-extension for its production. When the fracture is badly comminuted, the fragments may often be readily detected with the fingers, and be made to move upon each other so as to emit a grating sound not unlike that caused by rubbing together several pieces of broken china.

The position of the great *trochanter* may be the same as in the intra-capsular fracture, obeying the movements of the limb, and turning as it were

upon a pivot, instead of describing the segment of a lesser circle, as it does in the natural state. In many cases, however, it is completely detached, and then, of course, it either remains stationary on rotating the foot, or it follows the inferior fragment as a separate body. In general, it will be found to be somewhat further off from the spine of the ilium than in the intra-capsular fracture, depending upon the smaller amount of retraction of the limb.

The *pain* is always unusually severe, and is greatly increased by every attempt at motion and manipulation; it is more superficial than in intra-capsular fracture, and is concentrated, as it were, upon the two trochanters.

The *swelling* is also uncommonly extensive, and there is nearly always considerable discoloration of the surface, owing to the contused and ecchymosed condition of the skin and subcutaneous cellular tissue, the latter of which is often extensively infiltrated with blood.

The *attitude* of the patient has nothing in it that is peculiar; it partakes of the same general character as that which is met with in intra-capsular fracture, and, in fact, so closely simulates it as to be distinguished from it with difficulty.

Finally, along with the symptoms now described, there is generally, in extra-capsular fracture, evidence of severe shock immediately after the occurrence of the accident, and the resulting reaction is not unfrequently followed by high fever, lasting often for a number of days, and requiring great attention on the part of the professional attendant. In intra-capsular fracture the patient may feel very faint, but he soon recovers, and seldom has much constitutional disturbance afterwards.

The *reparation* of the extra-capsular fracture is effected in the same manner precisely as fracture of any other piece of the skeleton provided with periosteum. It differs, therefore, wholly, in this respect, from that of the intra-capsular form of the lesion. Here osseous union is the rule, the want of it the exception, the reverse being the case in intra-capsular fracture. The period at which the consolidation will be completed will, of course, depend, as a general rule, upon the age and health of the patient, the presence or absence of complications, and, above all, upon the care which is observed in keeping the ends of the fragments in accurate apposition.

Although the extra-capsular fracture invariably unites by osseous matter, yet the *prognosis* is very far from being always favorable either as it respects the possibility of avoiding deformity and lameness, or our ability to save the patient. When the fracture is comminuted, or the bone is broken into a number of pieces, including the two trochanters, a good result is hardly to be anticipated under the most judicious management that the case can receive. Under such circumstances the neck of the bone, having lost its support, is pushed downwards and inwards below its natural level, and the consequence is that a certain degree of shortening with deformity of the upper part of the thigh will be inevitable. The same result will necessarily follow when the fracture is impacted. These facts should be well studied and appreciated, and should always be promptly communicated to the patient, lest, when the cure is completed, he might blame his attendant for making him a bad limb when it was impossible to make a good one.

From the great violence that is so frequently inflicted upon the parts, both soft and hard, the extra-capsular fracture often proves hazardous both to limb and life. Occasionally, though rarely, the patient dies from shock; in some instances he suffers greatly from the effects of excessive reaction. Most generally, however, when there is danger, life is put in jeopardy by the super-vention of erysipelas, or pyemia, the former commonly setting in within the first forty-eight hours from the occurrence of the fracture, and the latter towards the end of the first week or the beginning of the second. Some idea of the danger of extra-capsular fracture may be formed when it is stated that,

of eighteen cases treated in the Richmond Hospital at Dublin, nine proved fatal, the period of death ranging from the fifth to the fifteenth day. In some cases the patient sinks from the exhaustion consequent upon extensive suppuration or the formation of large sloughs over the sacrum and buttocks from protracted confinement in one position.

The *treatment* of extra-capsular fracture differs in no wise from that which is necessary in fracture of the shaft of the bone. The limb, being placed in the straight position, is kept perfectly at rest by means of splints, stretched along its outer and inner surfaces, and connected below in such a manner as to admit of the requisite extension and counter-extension until a cure is effected. The foot should incline *slightly* outwards to favor relaxation of the external rotator muscles, and special care should be taken to prevent overlapping of the fragments, or angular deformity, by the use of a gutta-percha splint, accurately moulded to the outer and anterior part of the thigh, and well secured by the bandage. The dressing should be continued for at least five weeks.

IMPACTED FRACTURES OF THE NECK OF THE FEMUR.

Fracture of the neck of the femur occasionally presents itself as an impacted lesion, the lower extremity of the upper fragment being forcibly impelled into the cancellated structure of the upper end of the lower fragment, the great trochanter being usually carried along with the descending portion. The accident, which is sufficiently rare, and of which fig. 457, from a specimen in the Mütter collection, affords a beautiful illustration, is nearly always associated with extra-capsular fracture, and occurs under two varieties of form, the complete and incomplete, of which the latter is by far the more frequent. Old persons only are subject to it, and it is most common in those in whom the neck of the femur is of inordinate volume in consequence of the expansion of its spongy structure. The line of fracture is generally at the

base of the neck, or at the junction of the neck with the shaft, the penetration occurring in the direction of the anterior surface of the bone, with which the neck is more immediately continuous, being separated from it behind by a well-marked depression, and by the large ridge connecting the two trochanters. The fracture

Fig. 457.

Impacted fracture of the neck of the femur.

Fig. 458.

Impacted fracture, through the trochanters, the upper fragment being wedged into the lower.

usually happens from the body being crushed by the falling of a heavy substance upon the trunk, while the chest is inclined forwards, and the knee rests upon a solid surface, the hip at the same time receiving a severe blow, as when a person is buried by the caving in of a coal bank; or, it may be produced by a fall from a height upon the knee, in which the weight of the body is violently impelled in the opposite direction, the two forces continuing to act after the bony tissues have given way. The direction of the fracture is generally oblique, extending from above downwards, from the great to the small trochanter, both of which are not unfrequently included in the injury, as seen in fig. 458.

The distance at which the upper fragment is buried in the lower varies from a few lines to half an inch, three-quarters of an inch, or even an inch, depending upon the degree of the impelling force and the amount of expansion of the cancellated structure at the base of the cervix. The compact substance of both fragments is often extensively comminuted, and the fragments themselves are usually interlocked in such a manner as to give the thigh-bone the appearance of being twisted upon its axis, the limb after the accident being generally everted, as in fracture without impaction, though in a less marked degree.

There is a variety of impacted fracture of the neck of the femur in which the lower fragment is impelled into the reticulated structure of the upper. The occurrence is very rare, and the amount of shortening a good deal less than in the more common form of the injury.

The *symptoms* of impacted fracture of the neck of the femur are in general quite characteristic, though a good deal of care is necessary, in every case, in order to make a correct diagnosis. The most valuable and reliable phenomena are the shortening of the thigh, eversion of the foot, the ability of the patient to walk, or to bear the weight of the body upon the thigh, after the accident, and the resistance which the fragments offer to extension and counter-extension when an attempt is made to restore the limb to its natural position. The pain is usually very intense, generally much more so than in ordinary cervical fracture, and there is not unfrequently extensive ecchymosis over the great trochanter, causing unwonted swelling and discoloration.

The degree of shortening varies, as already stated, from a few lines to an inch or more, the average ranging from a quarter of an inch to half an inch, which it rarely exceeds. The eversion of the foot, although well marked, generally exists in a slighter degree than in fracture of the neck of the bone without penetration, whether the injury be seated on the outside or within the capsular ligament. The occurrence is the more valuable as a diagnostic from the fact that it is rarely, if ever, entirely absent. Owing to the fact that the continuity of the femur is preserved, the patient is generally able to walk after the accident, although not without much suffering, or, at all events, to bear the weight of his body upon the affected member. For the same reason, the limb is easily rotated upon its axis, bent upon the pelvis, extended, abducted, or adducted; and when an attempt is made to restore it to its normal length, the effort, unless very powerful, ordinarily fails, the ends of the fragments retaining their interlocked position, despite the extension and counter-extension. Finally, there is generally, in addition to the symptoms now described, more or less deformity, although this cannot always be easily detected on account of the excessive swelling, and, when present, is not, of course, characteristic.

What, then, are the most important phenomena in a diagnostic point of view? Beyond all doubt the shortening of the thigh, the immobility of the limb, the existence of deformity at the hip, in the situation of the great trochanter, and the absence of crepitation. When these signs are present, it may be assumed that there is no dislocation of the ileo-femoral joint, nor any

ordinary fracture of the neck of the femur, but fracture of this portion of the bone with impaction of the upper fragment.

The *prognosis* of this variety of fracture is much more favorable than that of ordinary fracture of the cervix; for inasmuch as the fragments are firmly wedged together, it usually requires but little callus to effect their consolidation. Besides, very little retentive apparatus is usually necessary, the two fragments serving as their own splints. On the other hand, however, there must always remain a certain degree of deformity, consisting of slight shortening of the limb, and of an incurvated state of the thigh just below the hip. Some permanent lameness may, therefore, reasonably be looked for after the accident, even under the most favorable circumstances. I have seen several specimens of impacted fracture of the neck of the femur where great and irremediable ankylosis was produced by osseous matter being extended, in the form of bridges, from the seat of the injury to the innominate bone, immediately around the acetabulum, connecting the two together in a solid mass.

These protective means are displayed in a remarkable manner in a specimen, above depicted, of impacted fracture of the neck of the left femur in the Mütter collection. The head and neck of the bone, being two inches and nearly three-quarters in length, occupy a horizontal position in regard to the shaft, the neck being driven into the cancellated structure of the latter some distance below the trochanters. The superior third, or more, of the shaft is bent strongly forwards and outwards, and is surrounded by a casing of new osseous matter, more than half an inch in thickness at the concavity of the curve, or weakest portion of the femur, and at a point, consequently, where, after such an accident, the greatest amount of support is required. A large ledge of bone, two inches long, and very broad, thick, and firm, projects from the anterior and inner aspect of the superior extremity over towards the hip-joint, being connected by a strong, round ligament, upwards of two inches in length, with the anterior inferior spinous process of the ilium, which juts out as a remarkably long, slender prominence, more than twice the normal size. An idea of the amount of shortening of the femur may be formed, when it is stated that the summit of the great trochanter projected fully one inch above the upper border of the acetabulum. Nothing is known of the history of the case; but, judging from the completeness of the reparation, the accident must have occurred many years before death. Some degree of motion, certainly very slight, must have existed both in the acetabulum and at the junction of the two fragments, the upper end of the lower of which was converted into a socket into which the lower end of the upper was received, a kind of adventitious membrane having been interposed between the contiguous surfaces.

In the *treatment* of this fracture, one important point is not to pull the ends of the broken bone asunder in our attempts to examine the case. Hence, whenever impaction is suspected, the rule is to refrain from all rotation and extension. The nature of the accident being properly diagnosticated, the limb is to be placed in an easy position in bed, a pillow lying under the ham, and gentle, but steady pressure being made, by means of a compress and bandage, in the direction of the great trochanter, with a view of rectifying any deformity that may exist in that situation. Generally, no splint will be required, and in ordinary cases the patient will be able to move about on crutches in three or four weeks.

General Diagnosis.—Fractures of the neck of the thigh-bone are liable to be mistaken for other lesions, and it becomes, therefore, a matter of importance to the practitioner to have accurate conceptions of their real nature, errors of diagnosis here being always particularly prejudicial, both to the patient and the practitioner. The affections with which they are most apt

to be confounded are sprains and dislocations of the hip-joint, and, in many cases, great difficulty is also experienced in deciding whether the injury is one of fracture within the capsular ligament, or of fracture exterior to it.

The symptoms of fracture of the neck of the femur, especially the intra-capsular, are sometimes closely simulated by sprains and contusions of the hip, causing involuntary obliquity of the pelvis with apparent shortening of the limb, and eversion of the knee and foot, along with excessive pain and difficulty of motion. The resemblance is occasionally so perplexing as to create doubt in the mind of the most skilful diagnostician, and, among the less informed, has often led to the most serious errors of practice, by the employment of harsh means when the most mild and soothing alone were necessary. The signs of distinction are the following: 1. In fracture the shortening is real, and can be effaced only by extension and counter-extension; in sprains and contusions, on the contrary, it is not real, but apparent, as may be proved by placing the limbs parallel with each other, and bringing the two iliac crests on the same level. 2. In fracture the eversion of the foot is complete, the extremity presenting an appearance characteristic of total loss of power; in ordinary injuries of the hip and upper part of the thigh, the eversion is comparatively slight, and the patient can, in general, rectify it by his own efforts, although they may be productive of severe distress. 3. In fracture there is usually complete abolition of muscular action; so that the thigh can neither be flexed, extended, nor rotated, however determined the attempt. It is only in the impacted fracture that the individual has still some control over the limb, and then the best guide for avoiding mistake is the existence of actual shortening. In sprains and contusions motion is diminished, perhaps very greatly, but not abolished.

One would suppose, at first sight, that it would be very difficult, even for an experienced practitioner, to mistake a fracture of the neck of the thigh-bones for a dislocation of its head upon the dorsal surface of the ilium, yet numerous cases are upon record testifying not only to the possibility of such an accident, but to its actual occurrence in the hands of distinguished surgeons. The only way to avoid error is to remember clearly the most prominent signs of each lesion. The subjoined tabular arrangement will serve to place the subject in its proper light, at the same time rendering a comparison of these symptoms an easy task:—

INTRA-CAPSULAR FRACTURE.	ILIAC DISLOCATION.
1. Occurs nearly always in old persons.	1. Is most common in adult and middle life.
2. Is most common in women.	2. Occurs with equal frequency in both sexes.
3. Usually the result of slight causes.	3. Always produced by severe force.
4. The foot is strongly everted.	4. The foot is inverted.
5. There is great shortening, readily effaceable by extension and counter-extension, but recurring the moment the force is discontinued.	5. The shortening is also great, but can be effaced only by restoring the bone to its natural position, when it will not return.
6. Marked crepitation exists.	6. There is no crepitation.
7. There is preternatural mobility, the ends of the fragments being movable upon each other.	7. The bone is in a fixed and constrained position.

But the greatest difficulty in the diagnosis of these affections of the thigh and hip arises from the embarrassment which the surgeon experiences in determining whether the case be one of intra-capsular fracture, or fracture exterior to the capsular ligament. As the subject is one of great practical consequence, it deserves to be studied with unusual care; and I shall, therefore, arrange the principal points in tabular form:—

INTRA-CAPSULAR FRACTURE.

1. The shortening, slight at first, generally not exceeding a third or half an inch, gradually increases to two inches and upwards.

2. The crepitation is indistinct, and can only be fully elicited by extension and counter-extension.

3. Function is much impaired, but not wholly abolished.

4. The great trochanter, on rotating the limb, moves, as it were, upon a pivot.

5. The pain is unreliable, both as it respects site and intensity, being generally most severe at the upper and inner part of the thigh, in the direction of the small trochanter.

6. There is generally little or no contusion, swelling, or discoloration.

EXTRA-CAPSULAR FRACTURE.

1. The shortening is as great immediately after the accident as it is at any time afterwards, and its extent also is usually less than in the intra-capsular fracture.

2. Crepitation is uncommonly distinct, being often loud and ringing, and is readily perceived on laying the hand on the trochanter and rotating the limb.

3. The loss of power is complete, the limb lying in a helpless, paralyzed condition.

4. The great trochanter is often partially separated from the shaft of the bone, and then but imperfectly obeys the movements of the limb.

5. Pain is unreliable, but generally very severe, especially on manipulation or motion, and seated more in the direction of the great trochanter.

6. Usually severe contusion, with considerable swelling, ecchymosis, and discoloration.

Nothing of any diagnostic value can be deduced from a consideration of the age at which these two fractures occur, since, as was previously stated, both are met with almost exclusively after the fiftieth year, there being only a few well authenticated cases on record of its occurrence prior to that period. The same is true in relation to sex, experience having shown that this exercises much less influence upon the production of these two varieties of fracture than was formerly imagined. I am inclined, from a careful study of the subject, to place more reliance, in this respect, upon the existence of severe external injury, as contusion, swelling, and ecchymosis, and upon the presence of shortening, than upon any other phenomena. In the intra-capsular fracture, the external signs of injury are certainly, as a general rule, exceedingly slight, while the reverse is usually the case in the extra-capsular, the parts being nearly always much bruised and discolored. In regard to shortening, it possesses, I think, great value as a diagnostic of the two lesions; for it may be assumed, on the one hand, that when it is very slight immediately after the receipt of the injury, and gradually increases afterwards, it depends upon intra-capsular fracture; and, on the other, that when it is very considerable immediately after the accident, it is caused by extra-capsular fracture. Rodet, who studied the subject with much attention, arrived at the conclusion that every fracture of the neck of the femur, produced by a fall or blow upon the great trochanter, was of an extra-capsular nature; whereas, every one occasioned by a fall upon the feet, or by muscular action, must be seated within the ligament. This conclusion, however, is altogether unfounded; in adopting it we should be compelled to assume that all intra-capsular fractures are the result of falls upon the feet, when all experience teaches that they are almost invariably produced by force applied directly to the hip.

The most important diagnostic characters of the *impacted* fracture of the neck of the femur, whether within or without the capsule, are, as has already been stated, shortening of the limb, the absence of crepitation, and the comparative or complete immobility of the fragments. The shortening is always immediate, and remains permanent in its original degree, unless the ends of the bone are rudely drawn asunder; hence it is a sign of an unequivocal character; the absence of crepitus is also very significant, and the trivial mobility, or complete absence of motion, is another circumstance of importance. The great danger in such a case is that the fracture may be mistaken for a dislocation; but from this it may usually be readily distinguished by a

careful study of its history, and a thorough examination and comparison of the symptoms characteristic of the two lesions.

FRACTURES OF THE GREAT TROCHANTER.

Fracture of this bony apophysis may take place as an independent lesion, or as a concomitant of fracture of the neck of the femur, outside of the capsular ligament, as mentioned previously, and as exhibited in fig. 459, from a specimen in my collection. As an independent fracture, it is very infrequent in comparison with the other variety. It may occur at any period of life, but is chiefly observed in elderly subjects, as a consequence of direct violence, as a fall, blow, or kick, breaking off the trochanter in an oblique direction from above downwards. The fracture is sometimes comminuted, the trochanter being broken into several pieces, of irregular size and shape, the fragments grating under the fingers like a number of pieces of china. It may also be compound, although, in general, it is unaccompanied by any wound of the soft parts.

The *symptoms* of fracture of the great trochanter are generally well marked, the most important consisting in eversion of the limb, with separation of the fragments, inability on the part of the patient to sit down, and difficulty of obtaining crepitation. The eversion is unusually distinct, and is probably due, at least in great degree, to the loss of power in the external rotator muscles; the limb lies in a helpless condition, and no effort that the patient can make can change its position. The broken trochanter is commonly widely separated from the shaft of the bone, and hence the difficulty which is generally experienced in eliciting crepitus, this being only practicable by placing the parts in apposition with each other. The displacement is either upwards towards the ilium, or downwards towards the tuberosity of the ischium, the former being the more frequent. When the patient attempts to sit down he is completely foiled, and immediately experiences great increase of pain, compelling him to desist. Most authors speak of shortening of the limb as a symptom of this fracture, but, if shortening really exist, it can only be in a very slight degree. More or less contusion and ecchymosis of the soft parts are usually present.

The *diagnostic* signs are the eversion of the limb, the loss of prominence at the natural site of the trochanter, the fixed position of the small fragment on moving the shaft of the femur, and crepitus on approximation of the broken ends.

The *union* of this fracture is by osseous matter, and, unless the bone is comminuted, a cure may reasonably be expected without any deformity of the hip or impairment of the functions of the limb. Considerable difficulty, however, is generally experienced in maintaining apposition of the fragments, and hence such an injury always requires more than ordinary vigilance on the part of the attendant.

The *treatment* consists in maintaining the limb in a perfect state of quietude by means of two long splints, the foot being supported in a perpendicular direction, with a slight tendency to eversion, which is the most natural position for a person when he lies on his back, and, therefore, the most eligible for relaxing the external rotator muscles when there is a fracture of the tro-

Fig. 459.

Fracture of the great trochanter.

chanter. The broken trochanter, being drawn into its natural situation, is confined there by a soft leather belt, long enough to extend round the pelvis, and furnished with a sort of hollow pad, from three to four inches in diameter, for the purpose of embracing more effectually the prominence of the hip. Hardly any extension will be necessary. If the soft parts are much contused, leeches and fomentations should be applied before putting on the permanent dressings. After the patient has been confined for a month, he may be permitted to exercise on crutches. The annexed cut, fig. 460, represents the

Fig. 460.

Sir Astley Cooper's mode of treating fractures of the great trochanter.

mode of treating fractures of the great trochanter, recommended by Sir Astley Cooper.

The great trochanter is occasionally detached from the neck and shaft of the femur, in consequence of the forcible laceration of the fibro-cartilage by which it is connected to these parts during its *epiphysary* state in early life, before the completion of the process of ossification. The accident, which is one of uncommon occurrence, is usually produced by a severe fall upon the hip, and is always extremely difficult of diagnosis, owing to the fact that there is seldom much, if any, appreciable displacement. In most of the recorded cases there has been much diversity in the symptoms; in some, the patient was able to walk immediately after the accident, while in others he had lost all control over the muscles of his limb; in some, the foot was everted, while in others it preserved its natural position, or was even inverted; in all there was severe pain, with considerable swelling, either alone or conjoined with ecchymosis, at the site of injury, and, during their progress, more or less constitutional disturbance.

The best manner of determining the diagnosis, in this accident, is to make the patient lie on his back and incline the pelvis over the injured side, while the affected limb is thoroughly abducted, or carried away from the sound one. The glutæo-femoral muscles being thus completely relaxed, the trochanter, if detached, may easily be pushed into its natural position, and crepitation elicited by rubbing it against the neck and shaft of the femur.

The occurrence of this accident is not without danger, several cases having been recorded in which it proved fatal, death having been caused by extensive suppuration and constitutional disturbance. When recovery takes place, the limb remains for a long time weak and painful. The union, under such circumstances, is fibro-cartilaginous, or partly cartilaginous and partly osseous. The treatment must be conducted upon the same principles as in ordinary fracture of the trochanter.

BLANCHARD & LEA'S MEDICAL AND SURGICAL PUBLICATIONS.

TO THE MEDICAL PROFESSION.

The prices on the present catalogue are those at which our books can generally be furnished by booksellers throughout the United States, who can readily procure any which they may not have on hand. To physicians who have not convenient access to bookstores, we will, as long as the existing rates of postage remain unchanged, forward them at these prices, *free* by mail, to any post-office in the United States under 1,500 miles. As we open accounts only with booksellers, the amount must in every case, without exception, accompany the order, and we assume no risks of the mail, either on the money or on the books; and as we deal only in our own publications, we can supply no others. Gentlemen desirous of purchasing will, therefore, find it more advantageous to deal with the nearest booksellers whenever practicable.

BLANCHARD & LEA.

PHILADELPHIA, October, 1862.

* * We have now ready a new edition of our ILLUSTRATED CATALOGUE of Medical and Scientific Publications, forming an octavo pamphlet of 80 large pages, containing specimens of illustrations, notices of the medical press, &c. &c. It has been prepared without regard to expense, and will be found one of the handsomest specimens of typographical execution as yet presented in this country. Copies will be sent to any address, by mail, free of postage, on receipt of nine cents in stamps.

Catalogues of our numerous publications in miscellaneous and educational literature forwarded on application.

☞ The attention of physicians is especially solicited to the following important new works and new editions, just issued or nearly ready:—

Ashton on the Rectum,	See page	3

TWO MEDICAL PERIODICALS, FREE OF POSTAGE,

Containing over Fifteen Hundred large octavo pages,

FOR FIVE DOLLARS PER ANNUM.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, subject to postage, when not paid for in advance, \$5 00
 THE MEDICAL NEWS AND LIBRARY, invariably in advance, 1 00
 or, BOTH PERIODICALS mailed, FREE OF POSTAGE (as long as the existing rates are maintained), to any post-office in the United States, for Five Dollars remitted in advance.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, EDITED BY ISAAC HAYS, M. D.,

is published Quarterly, on the first of January, April, July, and October. Each number contains at least two hundred and eighty large octavo pages, handsomely and appropriately illustrated.

wherever necessary. It has now been issued regularly for more than FORTY years, and it has been under the control of the present editor for more than a quarter of a century. Throughout this long period, it has maintained its position in the highest rank of medical periodicals both at home and abroad, and has received the cordial support of the entire profession in this country. Its list of Collaborators will be found to contain a large number of the most distinguished names of the profession in every section of the United States, rendering the department devoted to

ORIGINAL COMMUNICATIONS

full of varied and important matter, of great interest to all practitioners.

As the aim of the Journal, however, is to combine the advantages presented by all the different varieties of periodicals, in its

REVIEW DEPARTMENT

will be found extended and impartial reviews of all important new works, presenting subjects of novelty and interest, together with very numerous

BIBLIOGRAPHICAL NOTICES,

including nearly all the medical publications of the day, both in this country and Great Britain, with a choice selection of the more important continental works. This is followed by the

QUARTERLY SUMMARY,

being a very full and complete abstract, methodically arranged, of the

IMPROVEMENTS AND DISCOVERIES IN THE MEDICAL SCIENCES.

This department of the Journal, so important to the practising physician, is the object of especial care on the part of the editor. It is classified and arranged under different heads, thus facilitating the researches of the reader in pursuit of particular subjects, and will be found to present a very full and accurate digest of all observations, discoveries, and inventions recorded in every branch of medical science. The very extensive arrangements of the publishers are such as to afford to the editor complete materials for this purpose, as he not only regularly receives

ALL THE AMERICAN MEDICAL AND SCIENTIFIC PERIODICALS,

but also twenty or thirty of the more important Journals issued in Great Britain and on the Continent, thus enabling him to present in a convenient compass a thorough and complete abstract of everything interesting or important to the physician occurring in any part of the civilized world.

To their old subscribers, many of whom have been on their list for twenty or thirty years, the publishers feel that no promises for the future are necessary; but those who may desire for the first time to subscribe, can rest assured that no exertion will be spared to maintain the Journal in the high position which it has occupied for so long a period.

By reference to the terms it will be seen that, in addition to this large amount of valuable and practical information on every branch of medical science, the subscriber, by paying in advance, becomes entitled, without further charge, to

THE MEDICAL NEWS AND LIBRARY,

a monthly periodical of thirty-two large octavo pages. Its "NEWS DEPARTMENT" presents the current information of the day, while the "LIBRARY DEPARTMENT" is devoted to presenting standard works on various branches of medicine. Within a few years, subscribers have thus received, without expense, many works of the highest character and practical value, such as "Watson's Practice," "Todd and Bowman's Physiology," "Malgaigne's Surgery," "West on Children," "West on Females, Part I.," "Habershon on the Alimentary Canal," &c.

While the work at present appearing in its columns is

CLINICAL LECTURES ON THE DISEASES OF WOMEN.

BY PROFESSOR J. Y. SIMPSON, of Edinburgh.

WITH NUMEROUS HANDSOME ILLUSTRATIONS.

These Lectures, published in England under the supervision of the Author, carry with them all the weight of his wide experience and distinguished reputation. Their eminently practical nature, and the importance of the subject treated, cannot fail to render them in the highest degree satisfactory to subscribers, who can thus secure them without cost. These Lectures are continued in the "News" for 1862.

It will thus be seen that for the small sum of FIVE DOLLARS, paid in advance, the subscriber will obtain a Quarterly and a Monthly periodical,

EMBRACING NEARLY SIXTEEN HUNDRED LARGE OCTAVO PAGES.

Those subscribers who do not pay in advance will bear in mind that their subscription of Five Dollars will entitle them to the Journal only, without the News, and that they will be at the expense of their own postage on the receipt of each number. The advantage of a remittance when ordering the Journal will thus be apparent.

Remittances of subscriptions can be mailed at our risk, when a certificate is taken from the Postmaster that the money is duly inclosed and forwarded.

Address

BLANCHARD & LEA, PHILADELPHIA.

ASHTON (T. J.),

Surgeon to the Blenheim Dispensary, &c.

ON THE DISEASES, INJURIES, AND MALFORMATIONS OF THE RECTUM AND ANUS; with remarks on Habitual Constipation. From the third and enlarged London edition. With handsome illustrations. In one very beautifully printed octavo volume, of about 300 pages. (*Just Issued.*) \$2 00.

The most complete one we possess on the subject. *Medico-Chirurgical Review.*

We are satisfied, after a careful examination of the volume, and a comparison of its contents with those of its leading predecessors and contemporaries, that the best way for the reader to avail himself of

the excellent advice given in the concluding paragraph above, would be to provide himself with a copy of the book from which it has been taken, and diligently to con its instructive pages. They may secure to him many a triumph and fervent blessing.—*Am. Journal Med. Sciences.*

ALLEN (J. M.), M. D.,

Professor of Anatomy in the Pennsylvania Medical College, &c.

THE PRACTICAL ANATOMIST; or, The Student's Guide in the Dissecting-Room. With 266 illustrations. In one handsome royal 12mo. volume, of over 600 pages, leather. \$2 25.

We believe it to be one of the most useful works upon the subject ever written. It is handsomely illustrated, well printed, and will be found of convenient size for use in the dissecting-room.—*Med. Examiner.*

However valuable may be the "Dissector's Guides" which we, of late, have had occasion to

notice, we feel confident that the work of Dr. Allen is superior to any of them. We believe with the author, that none is so fully illustrated as this, and the arrangement of the work is such as to facilitate the labors of the student. We most cordially recommend it to their attention.—*Western Lancet.*

ANATOMICAL ATLAS.

By Professors H. H. SMITH and W. E. HORNER, of the University of Pennsylvania. 1 vol. 8vo., extra cloth, with nearly 650 illustrations. See SMITH, p. 331.

ABEL (F. A.), F. C. S. AND C. L. BLOXAM.

HANDBOOK OF CHEMISTRY, Theoretical, Practical, and Technical; with a Recommendatory Preface by Dr. Hofmann. In one large octavo volume, extra cloth, of 662 pages, with illustrations. \$3 25.

ASHWELL (SAMUEL), M. D.,

Obstetric Physician and Lecturer to Guy's Hospital, London.

A PRACTICAL TREATISE ON THE DISEASES PECULIAR TO WOMEN.

Illustrated by Cases derived from Hospital and Private Practice. Third American, from the Third and revised London edition. In one octavo volume, extra cloth, of 528 pages. \$3 00.

The most useful practical work on the subject in the English language.—*Boston Med. and Surg. Journal.*

The most able, and certainly the most standard and practical, work on female diseases that we have yet seen.—*Medico-Chirurgical Review.*

ARNOTT (NEILL), M. D.

ELEMENTS OF PHYSICS; or Natural Philosophy, General and Medical.

Written for universal use, in plain or non-technical language. A new edition, by ISAAC HAYS, M. D. Complete in one octavo volume, leather, of 484 pages, with about two hundred illustrations. \$2 50.

BIRD (GOLDING), A. M., M. D., &c.

URINARY DEPOSITS: THEIR DIAGNOSIS, PATHOLOGY, AND THERAPEUTICAL INDICATIONS. Edited by EDMUND LLOYD BIRKETT, M. D. A new American, from the fifth and enlarged London edition. With eighty illustrations on wood. In one handsome octavo volume, of about 400 pages, extra cloth. \$2 00. (*Just Issued.*)

The death of Dr. Bird has rendered it necessary to entrust the revision of the present edition to other hands, and in his performance of the duty thus devolving on him, Dr. Birkett has sedulously endeavored to carry out the author's plan by introducing such new matter and modifications of the text as the progress of science has called for. Notwithstanding the utmost care to keep the work within a reasonable compass, these additions have resulted in a considerable enlargement. It is, therefore, hoped that it will be found fully up to the present condition of the subject, and that the reputation of the volume as a clear, complete, and compendious manual, will be fully maintained.

BENNETT (J. HUGHES), M. D., F. R. S. E.,

Professor of Clinical Medicine in the University of Edinburgh, &c.

THE PATHOLOGY AND TREATMENT OF PULMONARY TUBERCULOSIS, and on the Local Medication of Pharyngeal and Laryngeal Diseases frequently mistaken for or associated with, Phthisis. One vol. 8vo., extra cloth, with wood-cuts. pp. 130. \$1 25.

BARLOW (GEORGE H.), M. D.

Physician to Guy's Hospital, London, &c.

A MANUAL OF THE PRACTICE OF MEDICINE. With Additions by D. F. CONDIE, M. D., author of "A Practical Treatise on Diseases of Children," &c. In one handsome octavo volume, leather, of over 600 pages. \$2 75.

We recommend Dr. Barlow's Manual in the warmest manner as a most valuable vade-mecum. We have had frequent occasion to consult it, and have

found it clear, concise, practical, and sound.—*Boston Med. and Surg. Journal.*

BUDD (GEORGE). M. D., F. R. S.,

Professor of Medicine in King's College, London.

ON DISEASES OF THE LIVER. Third American, from the third and enlarged London edition. In one very handsome octavo volume, extra cloth, with four beautifully colored plates, and numerous wood-cuts. pp. 500. \$3 00.

Has fairly established for itself a place among the classical medical literature of England.—*British and Foreign Medico-Chir. Review*.

Dr. Budd's Treatise on Diseases of the Liver is now a standard work in Medical literature, and during the intervals which have elapsed between the successive editions, the author has incorporated into the text the most striking novelties which have characterized the recent progress of hepatic physiology and pathology; so that although the size of the book

is not perceptibly changed, the history of liver diseases is made more complete, and is kept upon a level with the progress of modern science. It is the best work on Diseases of the Liver in any language.—*London Med. Times and Gazette*.

This work, now the standard book of reference on the diseases of which it treats, has been carefully revised, and many new illustrations of the views of the learned author added in the present edition.—*Dublin Quarterly Journal*.

BY THE SAME AUTHOR.

ON THE ORGANIC DISEASES AND FUNCTIONAL DISORDERS OF THE STOMACH. In one neat octavo volume, extra cloth. \$1 50.

BUCKNILL (J. C.), M. D., AND DANIEL H. TUKE, M. D.,

Medical Superintendent of the Devon Lunatic Asylum. Visiting Medical Officer to the York Retreat.

A MANUAL OF PSYCHOLOGICAL MEDICINE; containing the History, Nosology, Description, Statistics, Diagnosis, Pathology, and Treatment of INSANITY. With a Plate. In one handsome octavo volume, of 536 pages. \$3 00.

The increase of mental disease in its various forms, and the difficult questions to which it is constantly giving rise, render the subject one of daily enhanced interest, requiring on the part of the physician a constantly greater familiarity with this, the most perplexing branch of his profession. At the same time there has been for some years no work accessible in this country, presenting the results of recent investigations in the Diagnosis and Prognosis of Insanity, and the greatly improved methods of treatment which have done so much in alleviating the condition or restoring the health of the insane. To fill this vacancy the publishers present this volume, assured that the distinguished reputation and experience of the authors will entitle it at once to the confidence of both student and practitioner. Its scope may be gathered from the declaration of the authors that "their aim has been to supply a text book which may serve as a guide in the acquisition of such knowledge, sufficiently elementary to be adapted to the wants of the student, and sufficiently modern in its views and explicit in its teaching to suffice for the demands of the practitioner."

BENNETT (HENRY), M. D.

A PRACTICAL TREATISE ON INFLAMMATION OF THE UTERUS, ITS CERVIX AND APPENDAGES, and on its connection with Uterine Disease. To which is added, a Review of the present state of Uterine Pathology. Fifth American, from the third English edition. In one octavo volume, of about 500 pages, extra cloth. \$2 00.

BROWN (ISAAC BAKER),

Surgeon-Accoucheur to St. Mary's Hospital, &c.

ON SOME DISEASES OF WOMEN ADMITTING OF SURGICAL TREATMENT. With handsome illustrations. One vol. 8vo., extra cloth, pp. 276. \$1 60.

Mr. Brown has earned for himself a high reputation in the operative treatment of sundry diseases and injuries to which females are peculiarly subject. We can truly say of his work that it is an important addition to obstetrical literature. The operative suggestions and contrivances which Mr. Brown describes, exhibit much practical sagacity and skill,

and merit the careful attention of every surgeon accoucheur.—*Association Journal*.

We have no hesitation in recommending this book to the careful attention of all surgeons who make female complaints a part of their study and practice.—*Dublin Quarterly Journal*.

BOWMAN (JOHN E.), M. D.

PRACTICAL HANDBOOK OF MEDICAL CHEMISTRY. Second American, from the third and revised English Edition. In one neat volume, royal 12mo., extra cloth, with numerous illustrations. pp. 288. \$1 25.

BY THE SAME AUTHOR.

INTRODUCTION TO PRACTICAL CHEMISTRY, INCLUDING ANALYSIS. Second American, from the second and revised London edition. With numerous illustrations. In one neat vol., royal 12mo., extra cloth. pp. 350. \$1 25.

BEALE ON THE LAWS OF HEALTH IN RELATION TO MIND AND BODY. A Series of Letters from an old Practitioner to a Patient. In one volume, royal 12mo., extra cloth. pp. 296. 80 cents.

BUSHNAN'S PHYSIOLOGY OF ANIMAL AND VEGETABLE LIFE; a Popular Treatise on the Functions and Phenomena of Organic Life. In one handsome royal 12mo. volume, extra cloth, with over 100 illustrations. pp. 224. 80 cents.

BUCKLER ON THE ETIOLOGY, PATHOLOGY, AND TREATMENT OF FIBRO-BRONCHITIS AND RHEUMATIC PNEUMONIA. In one 8vo. volume, extra cloth. pp. 150. \$1 25.

BLOOD AND URINE (MANUALS ON). BY JOHN WILLIAM GRIFFITH, G. OWEN REESE, AND ALFRED MARKWICK. One thick volume, royal 12mo., extra cloth, with plates. pp. 460. \$1 25.

BRODIE'S CLINICAL LECTURES ON SURGERY. 1 vol. 8vo. cloth. 350 pp. \$1 25.

BUMSTEAD (FREEMAN J.) M. D.,

Lecturer on Venereal Diseases at the College of Physicians and Surgeons, New York, &c.

THE PATHOLOGY AND TREATMENT OF VENEREAL DISEASES,

including the results of recent investigations upon the subject. With illustrations on wood. In one very handsome octavo volume, of nearly 700 pages, extra cloth; \$3 75. (Now Ready.)

By far the most valuable contribution to this particular branch of practice that has seen the light within the last score of years. His clear and accurate descriptions of the various forms of venereal disease, and especially the methods of treatment he proposes, are worthy of the highest encomium. In these respects it is better adapted for the assistance of the every-day practitioner than any other with which we are acquainted. In variety of methods proposed, in minuteness of direction, guided by careful discrimination of varying forms and complications, we write down the book as unsurpassed. It is a work which should be in the possession of every practitioner.—*Chicago Med. Journal*. Nov. 1861.

The foregoing admirable volume comes to us, embracing the whole subject of syphilology, resolving many a doubt, correcting and confirming many an entertained opinion, and in our estimation the best, completest, fullest monograph on this subject in our language. As far as the author's labors themselves are concerned, we feel it a duty to say that he has not only exhausted his subject, but he has presented to us, without the slightest hyperbole, the best digested treatise on these diseases in our language. He has carried its literature down to the present moment, and has achieved his task in a manner which cannot but redound to his credit.—*British American Journal*, Oct. 1861.

We believe this treatise will come to be regarded as high authority in this branch of medical practice, and we cordially commend it to the favorable notice of our brethren in the profession. For our own part, we candidly confess that we have received many new ideas from its perusal, as well as modified many views which we have long, and, as we now think, erroneously entertained on the subject of syphilis.

To sum up all in a few words, this book is one which no practising physician or medical student can very well afford to do without.—*American Med. Times*, Nov. 2, 1861.

The whole work presents a complete history of venereal diseases, comprising much interesting and valuable material that has been spread through medical journals within the last twenty years—the period of many experiments and investigations on the subject—the whole carefully digested by the aid of the author's extensive personal experience, and offered to the profession in an admirable form. Its completeness is secured by good plates, which are especially full in the anatomy of the genital organs. We have examined it with great satisfaction, and congratulate the medical profession in America on the nationality of a work that may fairly be called original.—*Berkshire Med. Journal*, Dec. 1861.

One thing, however, we are impelled to say, that we have met with no other book on syphilis, in the English language, which gave so full, clear, and impartial views of the important subjects on which it treats. We cannot, however, refrain from expressing our satisfaction with the full and perspicuous manner in which the subject has been presented, and the careful attention to minute details, so useful—not to say indispensable—in a practical treatise. In conclusion, if we may be pardoned the use of a phrase now become stereotyped, but which we here employ in all seriousness and sincerity, we do not hesitate to express the opinion that Dr. Bumstead's Treatise on Venereal Diseases is a "work without which no medical library will hereafter be considered complete."—*Boston Med. and Surg. Journal*, Sept. 5, 1861.

BARCLAY (A. W.), M. D.,

Assistant Physician to St. George's Hospital, &c.

A MANUAL OF MEDICAL DIAGNOSIS; being an Analysis of the Signs

and Symptoms of Disease. Second American from the second and revised London edition. In one neat octavo volume, extra cloth, of 451 pages. \$2 25. (Now ready.)

The demand for a second edition of this work shows that the vacancy which it attempts to supply has been recognized by the profession, and that the efforts of the author to meet the want have been successful. The revision which it has enjoyed will render it better adapted than before to afford assistance to the learner in the prosecution of his studies, and to the practitioner who requires a convenient and accessible manual for speedy reference in the exigencies of his daily duties. For this latter purpose its complete and extensive Index renders it especially valuable, offering facilities for immediately turning to any class of symptoms, or any variety of disease.

The task of composing such a work is neither an easy nor a light one; but Dr. Barclay has performed it in a manner which meets our most unqualified approbation. He is no mere theorist; he knows his work thoroughly, and in attempting to perform it, has not exceeded his powers.—*British Med. Journal*.

We venture to predict that the work will be deservedly popular, and soon become, like Watson's Practice, an indispensable necessity to the practitioner.—*N. A. Med. Journal*.

An inestimable work of reference for the young practitioner and student.—*Nashville Med. Journal*.

We hope the volume will have an extensive circulation, not among students of medicine only, but practitioners also. They will never regret a faithful study of its pages.—*Cincinnati Lancet*.

An important acquisition to medical literature. It is a work of high merit, both from the vast importance of the subject upon which it treats, and also from the real ability displayed in its elaboration. In conclusion, let us bespeak for this volume that attention of every student of our art which it so richly deserves—that place in every medical library which it can so well adorn.—*Peninsular Medical Journal*.

BARTLETT (ELISHA), M. D.**THE HISTORY, DIAGNOSIS, AND TREATMENT OF THE FEVERS**

OF THE UNITED STATES. A new and revised edition. By ALONZO CLARK, M. D., Prof. of Pathology and Practical Medicine in the N. Y. College of Physicians and Surgeons, &c. In one octavo volume, of six hundred pages, extra cloth. Price \$3 00.

It is a work of great practical value and interest, containing much that is new relative to the several diseases of which it treats, and, with the additions of the editor, is fully up to the times. The distinctive features of the different forms of fever are plainly and forcibly portrayed, and the lines of demarcation carefully and accurately drawn, and to the American practitioner is a more valuable and safe guide than any work on fever extant.—*Ohio Med. and Surg. Journal*.

This excellent monograph on febrile disease, has

stood deservedly high since its first publication. It will be seen that it has now reached its fourth edition under the supervision of Prof. A. Clark, a gentleman who, from the nature of his studies and pursuits, is well calculated to appreciate and discuss the many intricate and difficult questions in pathology. His annotations add much to the interest of the work, and have brought it well up to the condition of the science as it exists at the present day in regard to this class of diseases.—*Southern Med. and Surg. Journal*.

BARWELL (RICHARD,) F. R. C. S.,

Assistant Surgeon Charing Cross Hospital, &c.

A TREATISE ON DISEASES OF THE JOINTS. Illustrated with engravings on wood. In one very handsome octavo volume, of about 500 pages, extra cloth; \$5 00. (Now Ready.)

"A treatise on Diseases of the Joints equal to, or rather beyond the current knowledge of the day, has long been required—my professional brethren must judge whether the ensuing pages may supply the deficiency. No author is fit to estimate his own work at the moment of its completion, but it may be permitted me to say that the study of joint diseases has very much occupied my attention, even from my studentship, and that for the last six or eight years my devotion to that subject has been almost unremitting. . . . The real weight of my work has been at the bedside, and the greatest labor devoted to interpreting symptoms and remedying their cause."—AUTHOR'S PREFACE.

At the outset we may state that the work is worthy of much praise, and bears evidence of much thoughtful and careful inquiry, and here and there of no slight originality. We have already carried this notice further than we intended to do, but not to the extent the work deserves. We can only add, that the perusal of it has afforded us great pleasure. The author has evidently worked very hard at his subject, and his investigations into the Physiology and Pathology of Joints have been carried on in a manner which entitles him to be listened to with attention and respect. We must not omit to mention the very admirable plates with which the volume is enriched. We seldom meet with such striking and faithful delineations of disease.—*London Med. Times and Gazette*, Feb. 9, 1861.

We cannot take leave, however, of Mr. Barwell, without congratulating him on the interesting amount of information which he has compressed into his book. The work appears to us calculated

to be of much use to the practising surgeon who may be in want of a treatise on diseases of the joints, and at the same time one which contains the latest information on articular affections and the operations for their cure.—*Dublin Med. Press*, Feb. 27, 1861.

This volume will be welcomed, both by the pathologist and the surgeon, as being the record of much honest research and careful investigation into the nature and treatment of a most important class of disorders. We cannot conclude this notice of a valuable and useful book without calling attention to the amount of *bonâ fide* work it contains. In the present day of universal book-making, it is no slight matter for a volume to show laborious investigation, and at the same time original thought, on the part of its author, whom we may congratulate on the successful completion of his arduous task.—*London Lancet*, March 9, 1861.

CARPENTER (WILLIAM B.), M. D., F. R. S., &c.,

Examiner in Physiology and Comparative Anatomy in the University of London.

PRINCIPLES OF HUMAN PHYSIOLOGY; with their chief applications to Psychology, Pathology, Therapeutics, Hygiene, and Forensic Medicine. A new American, from the last and revised London edition. With nearly three hundred illustrations. Edited, with additions, by FRANCIS GURNEY SMITH, M. D., Professor of the Institutes of Medicine in the Pennsylvania Medical College, &c. In one very large and beautiful octavo volume, of about nine hundred large pages, handsomely printed and strongly bound in leather, with raised bands. \$4 25.

In the preparation of this new edition, the author has spared no labor to render it, as heretofore, a complete and lucid exposition of the most advanced condition of its important subject. The amount of the additions required to effect this object thoroughly, joined to the former large size of the volume, presenting objections arising from the unwieldy bulk of the work, he has omitted all those portions not bearing directly upon HUMAN PHYSIOLOGY, designing to incorporate them in his forthcoming Treatise on GENERAL PHYSIOLOGY. As a full and accurate text-book on the Physiology of Man, the work in its present condition therefore presents even greater claims upon the student and physician than those which have heretofore won for it the very wide and distinguished favor which it has so long enjoyed. The additions of Prof. Smith will be found to supply whatever may have been wanting to the American student, while the introduction of many new illustrations, and the most careful mechanical execution, render the volume one of the most attractive as yet issued.

For upwards of thirteen years Dr. Carpenter's work has been considered by the profession generally, both in this country and England, as the most valuable compendium on the subject of physiology in our language. This distinction it owes to the high attainments and unwearied industry of its accomplished author. The present edition (which, like the last American one, was prepared by the author himself), is the result of such extensive revision, that it may almost be considered a new work. We need hardly say, in concluding this brief notice, that while the work is indispensable to every student of medicine in this country, it will amply repay the practitioner for its perusal by the interest and value of its contents.—*Boston Med. and Surg. Journal*.

This is a standard work—the text-book used by all medical students who read the English language. It has passed through several editions in order to keep pace with the rapidly growing science of Physiology. Nothing need be said in its praise, for its merits are universally known; we have nothing to say of its defects, for they only appear where the science of which it treats is incomplete.—*Western Lancet*.

The most complete exposition of physiology which any language can at present give.—*Brit. and For. Med.-Chirurg. Review*.

The greatest, the most reliable, and the best book on the subject which we know of in the English language.—*Stethoscope*.

To eulogize this great work would be superfluous. We should observe, however, that in this edition the author has remodelled a large portion of the former, and the editor has added much matter of interest, especially in the form of illustrations. We may confidently recommend it as the most complete work on Human Physiology in our language.—*Southern Med. and Surg. Journal*.

The most complete work on the science in our language.—*Am. Med. Journal*.

The most complete work now extant in our language.—*N. O. Med. Register*.

The best text-book in the language on this extensive subject.—*London Med. Times*.

A complete cyclopædia of this branch of science.—*N. Y. Med. Times*.

The profession of this country, and perhaps also of Europe, have anxiously and for sometime awaited the announcement of this new edition of Carpenter's Human Physiology. His former editions have for many years been almost the only text-book on Physiology in all our medical schools, and its circulation among the profession has been unsurpassed by any work in any department of medical science.

It is quite unnecessary for us to speak of this work as its merits would justify. The mere announcement of its appearance will afford the highest pleasure to every student of Physiology, while its perusal will be of infinite service in advancing physiological science.—*Ohio Med. and Surg. Journ.*

CARPENTER (WILLIAM B.), M. D., F. R. S.,

Examiner in Physiology and Comparative Anatomy in the University of London.

THE MICROSCOPE AND ITS REVELATIONS. With an Appendix containing the Applications of the Microscope to Clinical Medicine, &c. By F. G. SMITH, M. D. Illustrated by four hundred and thirty-four beautiful engravings on wood. In one large and very handsome octavo volume, of 724 pages, extra cloth, \$4 00; leather, \$4 50.

Dr. Carpenter's position as a microscopist and physiologist, and his great experience as a teacher, eminently qualify him to produce what has long been wanted—a good text-book on the practical use of the microscope. In the present volume his object has been, as stated in his Preface, “to combine, within a moderate compass, that information with regard to the use of his ‘tools,’ which is most essential to the working microscopist, with such an account of the objects best fitted for his study, as might qualify him to comprehend what he observes, and might thus prepare him to benefit science, whilst expanding and refreshing his own mind.” That he has succeeded in accomplishing this, no one acquainted with his previous labors can doubt.

The great importance of the microscope as a means of diagnosis, and the number of microscopists who are also physicians, have induced the American publishers, with the author's approval, to add an Appendix, carefully prepared by Professor Smith, on the applications of the instrument to clinical medicine, together with an account of American Microscopes, their modifications and accessories. This portion of the work is illustrated with nearly one hundred wood-cuts, and, it is hoped, will adapt the volume more particularly to the use of the American student.

Those who are acquainted with Dr. Carpenter's previous writings on Animal and Vegetable Physiology, will fully understand how vast a store of knowledge he is able to bring to bear upon so comprehensive a subject as the revelations of the microscope; and even those who have no previous acquaintance with the construction or uses of this instrument, will find abundance of information conveyed in clear and simple language.—*Med. Times and Gazette.*

Although originally not intended as a strictly

medical work, the additions by Prof. Smith give it a positive claim upon the profession, for which we doubt not he will receive their sincere thanks. Indeed, we know not where the student of medicine will find such a complete and satisfactory collection of microscopic facts bearing upon physiology and practical medicine as is contained in Prof. Smith's appendix; and this of itself, it seems to us, is fully worth the cost of the volume.—*Louisville Medical Review.*

BY THE SAME AUTHOR.

ELEMENTS (OR MANUAL) OF PHYSIOLOGY, INCLUDING PHYSIOLOGICAL ANATOMY. Second American, from a new and revised London edition. With one hundred and ninety illustrations. In one very handsome octavo volume, leather. pp. 566. \$3 00.

In publishing the first edition of this work, its title was altered from that of the London volume, by the substitution of the word “Elements” for that of “Manual,” and with the author's sanction the title of “Elements” is still retained as being more expressive of the scope of the treatise.

To say that it is the best manual of Physiology now before the public, would not do sufficient justice to the author.—*Buffalo Medical Journal.*

In his former works it would seem that he had exhausted the subject of Physiology. In the present, he gives the essence, as it were, of the whole.—*N. Y. Journal of Medicine.*

Those who have occasion for an elementary treatise on Physiology, cannot do better than to possess themselves of the manual of Dr. Carpenter.—*Medical Examiner.*

The best and most complete exposé of modern Physiology, in one volume, extant in the English language.—*St. Louis Medical Journal.*

BY THE SAME AUTHOR.

PRINCIPLES OF COMPARATIVE PHYSIOLOGY. New American, from the Fourth and Revised London edition. In one large and handsome octavo volume, with over three hundred beautiful illustrations. pp. 752. Extra cloth, \$4 80; leather, raised bands, \$5 25.

This book should not only be read but thoroughly studied by every member of the profession. None are too wise or old, to be benefited thereby. But especially to the younger class would we cordially commend it as best fitted of any work in the English language to qualify them for the reception and comprehension of those truths which are daily being developed in physiology.—*Medical Counsellor.*

Without pretending to it, it is an encyclopedia of the subject, accurate and complete in all respects—a truthful reflection of the advanced state at which the science has now arrived.—*Dublin Quarterly Journal of Medical Science.*

A truly magnificent work—in itself a perfect physiological study.—*Ranking's Abstract.*

This work stands without its fellow. It is one of the few men in Europe could have undertaken; it is one

no man, we believe, could have brought to so successful an issue as Dr. Carpenter. It required for its production a physiologist at once deeply read in the labors of others, capable of taking a general, critical, and unprejudiced view of those labors, and of combining the varied, heterogeneous materials at his disposal, so as to form an harmonious whole. We feel that this abstract can give the reader a very imperfect idea of the fulness of this work, and no idea of its unity, of the admirable manner in which material has been brought, from the most various sources, to conduce to its completeness, of the lucidity of the reasoning it contains, or of the clearness of language in which the whole is clothed. Not the profession only, but the scientific world at large, must feel deeply indebted to Dr. Carpenter for this great work. It must, indeed, add largely even, to his high reputation.—*Medical Times.*

BY THE SAME AUTHOR. (*Preparing.*)

PRINCIPLES OF GENERAL PHYSIOLOGY, INCLUDING ORGANIC CHEMISTRY AND HISTOLOGY. With a General Sketch of the Vegetable and Animal Kingdom. In one large and very handsome octavo volume, with several hundred illustrations.

BY THE SAME AUTHOR.

A PRIZE ESSAY ON THE USE OF ALCOHOLIC LIQUORS IN HEALTH AND DISEASE. New edition, with a Preface by D. F. CONDIE, M. D., and explanations of scientific words. In one neat 12mo. volume, extra cloth. pp. 178. 50 cents.

CONDIE (D. F.), M. D., &c.

A PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. Fifth edition, revised and augmented. In one large volume, 8vo., leather, of over 750 pages. \$3 25. (*Just Issued, 1899.*)

In presenting a new and revised edition of this favorite work, the publishers have only to state that the author has endeavored to render it in every respect "a complete and faithful exposition of the pathology and therapeutics of the maladies incident to the earlier stages of existence—a full and exact account of the diseases of infancy and childhood." To accomplish this he has subjected the whole work to a careful and thorough revision, rewriting a considerable portion, and adding several new chapters. In this manner it is hoped that any deficiencies which may have previously existed have been supplied, that the recent labors of practitioners and observers have been thoroughly incorporated, and that in every point the work will be found to maintain the high reputation it has enjoyed as a complete and thoroughly practical book of reference in infantile affections.

A few notices of previous editions are subjoined.

Dr. Condie's scholarship, acumen, industry, and practical sense are manifested in this, as in all his numerous contributions to science.—*Dr. Holmes's Report to the American Medical Association.*

Taken as a whole, in our judgment, Dr. Condie's Treatise is the one from the perusal of which the practitioner in this country will rise with the greatest satisfaction.—*Western Journal of Medicine and Surgery.*

One of the best works upon the Diseases of Children in the English language.—*Western Lancet.*

We feel assured from actual experience that no physician's library can be complete without a copy of this work.—*N. Y. Journal of Medicine.*

A veritable pædiatric encyclopædia, and an honor to American medical literature.—*Ohio Medical and Surgical Journal.*

We feel persuaded that the American medical profession will soon regard it not only as a very good, but as the VERY BEST "Practical Treatise on the Diseases of Children."—*American Medical Journal.*

In the department of infantile therapeutics, the work of Dr. Condie is considered one of the best which has been published in the English language.—*The Stethoscope.*

We pronounced the first edition to be the best work on the diseases of children in the English language, and, notwithstanding all that has been published, we still regard it in that light.—*Medical Examiner.*

The value of works by native authors on the diseases which the physician is called upon to combat, will be appreciated by all; and the work of Dr. Condie has gained for itself the character of a safe guide for students, and a useful work for consultation by those engaged in practice.—*N. Y. Med. Times.*

This is the fourth edition of this deservedly popular treatise. During the interval since the last edition, it has been subjected to a thorough revision by the author; and all new observations in the pathology and therapeutics of children have been included in the present volume. As we said before, we do not know of a better book on diseases of children, and to a large part of its recommendations we yield an unhesitating concurrence.—*Buffalo Med. Journal.*

Perhaps the most full and complete work now before the profession of the United States; indeed, we may say in the English language. It is vastly superior to most of its predecessors.—*Transylvania Med. Journal.*

CHRISTISON (ROBERT), M. D., V. P. R. S. E., &c.

A DISPENSATORY; or, Commentary on the Pharmacopœias of Great Britain and the United States; comprising the Natural History, Description, Chemistry, Pharmacy, Actions, Uses, and Doses of the Articles of the Materia Medica. Second edition, revised and improved, with a Supplement containing the most important New Remedies. With copious Additions, and two hundred and thirteen large wood-engravings. By R. EGLESFELD GRIFFITH, M. D. In one very large and handsome octavo volume, leather, raised bands, of over 1000 pages. \$3 50.

COOPER (BRANSBY B.), F. R. S.

LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY.

In one very large octavo volume, extra cloth, of 750 pages. \$3 00.

COOPER ON DISLOCATIONS AND FRACTURES OF THE JOINTS.—Edited by BRANSBY B. COOPER, F. R. S., &c. With additional Observations by Prof. J. C. WARREN. A new American edition. In one handsome octavo volume, extra cloth, of about 500 pages, with numerous illustrations on wood. \$3 25.

COOPER ON THE ANATOMY AND DISEASES OF THE BREAST, with twenty-five Miscellaneous and Surgical Papers. One large volume, imperial 8vo., extra cloth, with 252 figures, on 36 plates. \$2 50.

COOPER ON THE STRUCTURE AND DISEASES OF THE TESTIS, AND ON THE THYMUS GLAND. One vol. imperial 8vo., extra cloth, with 177 figures on 29 plates. \$2 00.

COPLAND ON THE CAUSES, NATURE, AND TREATMENT OF PALSY AND APOPLEXY. In one volume, royal 12mo., extra cloth. pp. 326. 80 cents.

CLYMER ON FEVERS; THEIR DIAGNOSIS, PATHOLOGY, AND TREATMENT In one octavo volume, leather, of 600 pages. \$1 50.

COLOMBAT DE L'ISERE ON THE DISEASES OF FEMALES, and on the special Hygiene of their Sex. Translated, with many Notes and Additions, by C. D. MEIGS, M. D. Second edition, revised and improved. In one large volume, octavo, leather, with numerous wood-cuts. pp. 720. \$3 50.

CARSON (JOSEPH), M. D.,

Professor of Materia Medica and Pharmacy in the University of Pennsylvania.

SYNOPSIS OF THE COURSE OF LECTURES ON MATERIA MEDICA AND PHARMACY, delivered in the University of Pennsylvania. Second and revised edition. In one very neat octavo volume, extra cloth, of 208 pages. \$1 50.

CURLING (T. B.), F. R. S.,

Surgeon to the London Hospital, President of the Hunterian Society, &c.

A PRACTICAL TREATISE ON DISEASES OF THE TESTIS, SPERMATIC CORD, AND SCROTUM. Second American, from the second and enlarged English edition. In one handsome octavo volume, extra cloth, with numerous illustrations. pp. 420. \$2 00.

CHURCHILL (FLEETWOOD), M. D., M. R. I. A.
ON THE THEORY AND PRACTICE OF MIDWIFERY. A new American from the fourth revised and enlarged London edition. With Notes and Additions, by D. FRANCIS CONDIE, M. D., author of a "Practical Treatise on the Diseases of Children," &c. With 194 illustrations. In one very handsome octavo volume, leather, of nearly 700 large pages. \$3 50. (Just Issued.)

This work has been so long an established favorite, both as a text-book for the learner and as a reliable aid in consultation for the practitioner, that in presenting a new edition it is only necessary to call attention to the very extended improvements which it has received. Having had the benefit of two revisions by the author since the last American reprint, it has been materially enlarged, and Dr. Churchill's well-known conscientious industry is a guarantee that every portion has been thoroughly brought up with the latest results of European investigation in all departments of the science and art of obstetrics. The recent date of the last Dublin edition has not left much of novelty for the American editor to introduce, but he has endeavored to insert whatever has since appeared, together with such matters as his experience has shown him would be desirable for the American student, including a large number of illustrations. With the sanction of the author he has added in the form of an appendix, some chapters from a little "Manual for Midwives and Nurses," recently issued by Dr. Churchill, believing that the details there presented can hardly fail to prove of advantage to the junior practitioner. The result of all these additions is that the work now contains fully one-half more matter than the last American edition, with nearly one-half more illustrations, so that notwithstanding the use of a smaller type, the volume contains almost two hundred pages more than before.

No effort has been spared to secure an improvement in the mechanical execution of the work equal to that which the text has received, and the volume is confidently presented as one of the handsomest that has thus far been laid before the American profession; while the very low price at which it is offered should secure for it a place in every lecture-room and on every office table.

A better book in which to learn these important points we have not met than Dr. Churchill's. Every page of it is full of instruction; the opinion of all writers of authority is given on questions of difficulty, as well as the directions and advice of the learned author himself, to which he adds the result of statistical inquiry, putting statistics in their proper place and giving them their due weight, and no more. We have never read a book more free from professional jealousy than Dr. Churchill's. It appears to be written with the true design of a book on medicine, viz: to give all that is known on the subject of which he treats, both theoretically and practically, and to advance such opinions of his own as he believes will benefit medical science, and insure the safety of the patient. We have said enough to convey to the profession that this book of Dr. Churchill's is admirably suited for a book of reference for the practitioner, as well as a text-book for the student, and we hope it may be extensively purchased amongst our readers. To them we most strongly recommend it.—*Dublin Medical Press*, June 20, 1860.

To bestow praise on a book that has received such marked approbation would be superfluous. We need only say, therefore, that if the first edition was thought worthy of a favorable reception by the medical public, we can confidently affirm that this will be found much more so. The lecturer, the practitioner, and the student, may all have recourse to its pages, and derive from their perusal much interest and instruction in everything relating to theoretical and practical midwifery.—*Dublin Quarterly Journal of Medical Science*.

A work of very great merit, and such as we can confidently recommend to the study of every obstetric practitioner.—*London Medical Gazette*.

This is certainly the most perfect system extant. It is the best adapted for the purposes of a text-book, and that which he whose necessities confine him to one book, should select in preference to all others.—*Southern Medical and Surgical Journal*.

BY THE SAME AUTHOR. (Lately Published.)

ON THE DISEASES OF INFANTS AND CHILDREN. Second American Edition, revised and enlarged by the author. Edited, with Notes, by W. V. KEATING, M. D. In one large and handsome volume, extra cloth, of over 700 pages. \$3 00, or in leather, \$3 25.

In preparing this work a second time for the American profession, the author has spared no labor in giving it a very thorough revision, introducing several new chapters, and rewriting others, while every portion of the volume has been subjected to a severe scrutiny. The efforts of the American editor have been directed to supplying such information relative to matters peculiar to this country as might have escaped the attention of the author, and the whole may, therefore, be safely pronounced one of the most complete works on the subject accessible to the American Profession. By an alteration in the size of the page, these very extensive additions have been accommodated without unduly increasing the size of the work.

BY THE SAME AUTHOR.

ESSAYS ON THE PUERPERAL FEVER, AND OTHER DISEASES PECULIAR TO WOMEN. Selected from the writings of British Authors previous to the close of the Eighteenth Century. In one neat octavo volume, extra cloth, of about 450 pages. \$2 50.

The most popular work on midwifery ever issued from the American press.—*Charleston Med. Journal*.

Were we reduced to the necessity of having but one work on midwifery, and permitted to choose, we would unhesitatingly take Churchill.—*Western Med. and Surg. Journal*.

It is impossible to conceive a more useful and elegant manual than Dr. Churchill's Practice of Midwifery.—*Provincial Medical Journal*.

Certainly, in our opinion, the very best work on the subject which exists.—*N. Y. Annalist*.

No work holds a higher position, or is more deserving of being placed in the hands of the tyro, the advanced student, or the practitioner.—*Medical Examiner*.

Previous editions, under the editorial supervision of Prof. R. M. Huston, have been received with marked favor, and they deserved it; but this, reprinted from a very late Dublin edition, carefully revised and brought up by the author to the present time, does present an unusually accurate and able exposition of every important particular embraced in the department of midwifery. * * The clearness, directness, and precision of its teachings, together with the great amount of statistical research which its text exhibits, have served to place it already in the foremost rank of works in this department of medical science.—*N. O. Med. and Surg. Journal*.

In our opinion, it forms one of the best if not the very best text-book and epitome of obstetric science which we at present possess in the English language.—*Monthly Journal of Medical Science*.

The clearness and precision of style in which it is written, and the great amount of statistical research which it contains, have served to place it in the first rank of works in this department of medical science.—*N. Y. Journal of Medicine*.

Few treatises will be found better adapted as a text-book for the student, or as a manual for the frequent consultation of the young practitioner.—*American Medical Journal*.

CHURCHILL (FLEETWOOD), M. D., M. R. I. A., &c.
ON THE DISEASES OF WOMEN; including those of Pregnancy and Child-bed. A new American edition, revised by the Author. With Notes and Additions, by D. FRANCIS CONDIE, M. D., author of "A Practical Treatise on the Diseases of Children." With numerous illustrations. In one large and handsome octavo volume, leather, of 768 pages. \$3 00.

This edition of Dr. Churchill's very popular treatise may almost be termed a new work, so thoroughly has he revised it in every portion. It will be found greatly enlarged, and completely brought up to the most recent condition of the subject, while the very handsome series of illustrations introduced, representing such pathological conditions as can be accurately portrayed, present a novel feature, and afford valuable assistance to the young practitioner. Such additions as appeared desirable for the American student have been made by the editor, Dr. Condie, while a marked improvement in the mechanical execution keeps pace with the advance in all other respects which the volume has undergone, while the price has been kept at the former very moderate rate.

It comprises, unquestionably, one of the most exact and comprehensive expositions of the present state of medical knowledge in respect to the diseases of women that has yet been published.—*Am. Journ. Med. Sciences.*

This work is the most reliable which we possess on this subject; and is deservedly popular with the profession.—*Charleston Med. Journal*, July, 1857.

We know of no author who deserves that approbation, on "the diseases of females," to the same

extent that Dr. Churchill does. His, indeed, is the only thorough treatise we know of on the subject; and it may be commended to practitioners and students as a masterpiece in its particular department.—*The Western Journal of Medicine and Surgery.*

As a comprehensive manual for students, or a work of reference for practitioners, it surpasses any other that has ever issued on the same subject from the British press.—*Dublin Quart. Journal.*

DICKSON (S. H.), M. D.,

Professor of Practice of Medicine in the Jefferson Medical College, Philadelphia.

ELEMENTS OF MEDICINE; a Compendious View of Pathology and Therapeutics, or the History and Treatment of Diseases. Second edition, revised. In one large and handsome octavo volume, of 750 pages, leather. \$3 75. (*Just Issued.*)

The steady demand which has so soon exhausted the first edition of this work, sufficiently shows that the author was not mistaken in supposing that a volume of this character was needed—an elementary manual of practice, which should present the leading principles of medicine with the practical results, in a condensed and perspicuous manner. Disencumbered of unnecessary detail and fruitless speculations, it embodies what is most requisite for the student to learn, and at the same time what the active practitioner wants when obliged, in the daily calls of his profession, to refresh his memory on special points. The clear and attractive style of the author renders the whole easy of comprehension, while his long experience gives to his teachings an authority everywhere acknowledged. Few physicians, indeed, have had wider opportunities for observation and experience, and few, perhaps, have used them to better purpose. As the result of a long life devoted to study and practice, the present edition, revised and brought up to the date of publication, will doubtless maintain the reputation already acquired as a condensed and convenient American text-book on the Practice of Medicine.

DRUITT (ROBERT), M. R. C. S., &c.

THE PRINCIPLES AND PRACTICE OF MODERN SURGERY. A new and revised American from the eighth enlarged and improved London edition. Illustrated with four hundred and thirty-two wood-engravings. In one very handsomely printed octavo volume, leather, of nearly 700 large pages. \$3 50. (*Just Issued.*)

A work which like DRUITT'S SURGERY has for so many years maintained the position of a leading favorite with all classes of the profession, needs no special recommendation to attract attention to a revised edition. It is only necessary to state that the author has spared no pains to keep the work up to its well earned reputation of presenting in a small and convenient compass the latest condition of every department of surgery, considered both as a science and as an art; and that the services of a competent American editor have been employed to introduce whatever novelties may have escaped the author's attention, or may prove of service to the American practitioner. As several editions have appeared in London since the issue of the last American reprint, the volume has had the benefit of repeated revisions by the author, resulting in a very thorough alteration and improvement. The extent of these additions may be estimated from the fact that it now contains about one-third more matter than the previous American edition, and that notwithstanding the adoption of a smaller type, the pages have been increased by about one hundred, while nearly two hundred and fifty wood-cuts have been added to the former list of illustrations.

A marked improvement will also be perceived in the mechanical and artistic execution of the work, which, printed in the best style, on new type, and fine paper, leaves little to be desired as regards external finish; while at the very low price affixed it will be found one of the cheapest volumes accessible to the profession.

This popular volume, now a most comprehensive work on surgery, has undergone many corrections, improvements, and additions, and the principles and the practice of the art have been brought down to the latest record and observation. Of the operations in surgery it is impossible to speak too highly. The descriptions are so clear and concise, and the illustrations so accurate and numerous, that the student can have no difficulty, with instrument in hand, and book by his side, over the dead body, in obtaining a proper knowledge and sufficient tact in this much neglected department of medical education.—*British and Foreign Medico-Chirurg. Review*, Jan. 1860.

In the present edition the author has entirely rewritten many of the chapters, and has incorporated the various improvements and additions in modern surgery. On carefully going over it, we find that

nothing of real practical importance has been omitted; it presents a faithful epitome of everything relating to surgery up to the present hour. It is deservedly a popular manual, both with the student and practitioner.—*London Lancet*, Nov. 19, 1859.

In closing this brief notice, we recommend as cordially as ever this most useful and comprehensive hand-book. It must prove a vast assistance, not only to the student of surgery, but also to the busy practitioner who may not have the leisure to devote himself to the study of more lengthy volumes.—*London Med. Times and Gazette*, Oct. 22, 1859.

In a word, this eighth edition of Dr. Drutt's Manual of Surgery is all that the surgical student or practitioner could desire.—*Dublin Quarterly Journal of Med. Sciences*, Nov. 1859.

DALTON, JR. (J. C.), M. D.

Professor of Physiology in the College of Physicians, New York.

A TREATISE ON HUMAN PHYSIOLOGY, designed for the use of Students and Practitioners of Medicine. Second edition, revised and enlarged, with two hundred and seventy-one illustrations on wood. In one very beautiful octavo volume, of 700 pages, extra cloth, \$4 00; leather, raised bands, \$4 50. (*Just Issued*, 1861.)

The general favor which has so soon exhausted an edition of this work has afforded the author an opportunity in its revision of supplying the deficiencies which existed in the former volume. This has caused the insertion of two new chapters—one on the Special Senses, the other on Imbibition, Exhalation, and the Functions of the Lymphatic System—besides numerous additions of smaller amount scattered through the work, and a general revision designed to bring it thoroughly up to the present condition of the science with regard to all points which may be considered as definitely settled. A number of new illustrations has been introduced, and the work, it is hoped, in its improved form, may continue to command the confidence of those for whose use it is intended.

It will be seen, therefore, that Dr. Dalton's best efforts have been directed towards perfecting his work. The additions are marked by the same features which characterize the remainder of the volume, and render it by far the most desirable text-book on physiology to place in the hands of the student which, so far as we are aware, exists in the English language, or perhaps in any other. We therefore have no hesitation in recommending Dr. Dalton's book for the classes for which it is intended, satisfied as we are that it is better adapted to their use than any other work of the kind to which they have access.—*American Journal of the Medical Sciences*, April, 1861.

It is, therefore, no disparagement to the many books upon physiology, most excellent in their day, to say that Dalton's is the only one that gives us the science as it was known to the best philosophers throughout the world, at the beginning of the current year. It states in comprehensive but concise diction, the facts established by experiment, or other method of demonstration, and details, in an understandable manner, how it is done, but abstains from the discussion of unsettled or theoretical points. Herein it is unique; and these characteristics render it a text-book without a rival, for those who desire to study physiological science as it is known to its most successful cultivators. And it is physiology thus presented that lies at the foundation of correct pathological knowledge; and this in turn is the basis of rational therapeutics; so that pathology, in fact, becomes of prime importance in the proper discharge of our every-day practical duties.—*Cincinnati Lancet*, May, 1861.

Dr. Dalton needs no word of praise from us. He is universally recognized as among the first, if not the very first, of American physiologists now living. The first edition of his admirable work appeared but two years since, and the advance of science, his

own original views and experiments, together with a desire to supply what he considered some deficiencies in the first edition, have already made the present one a necessity, and it will no doubt be even more eagerly sought for than the first. That it is not merely a reprint, will be seen from the author's statement of the following principal additions and alterations which he has made. The present, like the first edition, is printed in the highest style of the printer's art, and the illustrations are truly admirable for their clearness in expressing exactly what their author intended.—*Boston Medical and Surgical Journal*, March 28, 1861.

It is unnecessary to give a detail of the additions; suffice it to say, that they are numerous and important, and such as will render the work still more valuable and acceptable to the profession as a learned and original treatise on this all-important branch of medicine. All that was said in commendation of the getting up of the first edition, and the superior style of the illustrations, apply with equal force to this. No better work on physiology can be placed in the hand of the student.—*St. Louis Medical and Surgical Journal*, May, 1861.

These additions, while testifying to the learning and industry of the author, render the book exceedingly useful, as the most complete exposé of a science, of which Dr. Dalton is doubtless the ablest representative on this side of the Atlantic.—*New Orleans Med. Times*, May, 1861.

A second edition of this deservedly popular work having been called for in the short space of two years, the author has supplied deficiencies, which existed in the former volume, and has thus more completely fulfilled his design of presenting to the profession a reliable and precise text-book, and one which we consider the best outline on the subject of which it treats, in any language.—*N. American Medico-Chirurg. Review*, May, 1861.

DUNGLISON, FORBES, TWEEDIE, AND CONOLLY.

THE CYCLOPÆDIA OF PRACTICAL MEDICINE: comprising Treatises on the Nature and Treatment of Diseases, Materia Medica, and Therapeutics, Diseases of Women and Children, Medical Jurisprudence, &c. &c. In four large super-royal octavo volumes, of 3254 double-columned pages, strongly and handsomely bound, with raised bands. \$12 00.

*** This work contains no less than four hundred and eighteen distinct treatises, contributed by sixty-eight distinguished physicians, rendering it a complete library of reference for the country practitioner.

The most complete work on Practical Medicine extant; or, at least, in our language.—*Buffalo Medical and Surgical Journal*.

For reference, it is above all price to every practitioner.—*Western Lancet*.

One of the most valuable medical publications of the day—as a work of reference it is invaluable.—*Western Journal of Medicine and Surgery*.

It has been to us, both as learner and teacher, a work for ready and frequent reference, one in which modern English medicine is exhibited in the most advantageous light.—*Medical Examiner*.

The editors are practitioners of established reputation, and the list of contributors embraces many of the most eminent professors and teachers of London, Edinburgh, Dublin, and Glasgow. It is, indeed, the great merit of this work that the principal articles have been furnished by practitioners who have not only devoted especial attention to the diseases about which they have written, but have also enjoyed opportunities for an extensive practical acquaintance with them and whose reputation carries the assurance of their competency justly to appreciate the opinions of others, while it stamps their own doctrines with high and just authority.—*American Medical Journal*.

DEWEES'S COMPREHENSIVE SYSTEM OF MIDWIFERY. Illustrated by occasional cases and many engravings. Twelfth edition, with the author's last improvements and corrections. In one octavo volume, extra cloth, of 600 pages. \$3 20.

DEWEES'S TREATISE ON THE PHYSICAL

AND MEDICAL TREATMENT OF CHILDREN. The last edition. In one volume, octavo, extra cloth, 548 pages. \$2 80.

DEWEES'S TREATISE ON THE DISEASES OF FEMALES. Tenth edition. In one volume, octavo extra cloth, 532 pages, with plates. \$3 00.

DUNGLISON (ROBLEY), M. D.,

Professor of Institutes of Medicine in the Jefferson Medical College, Philadelphia.

NEW AND ENLARGED EDITION.

MEDICAL LEXICON; a Dictionary of Medical Science, containing a concise Explanation of the various Subjects and Terms of Anatomy, Physiology, Pathology, Hygiene, Therapeutics, Pharmacology, Pharmacy, Surgery, Obstetrics, Medical Jurisprudence, Dentistry, &c. Notices of Climate and of Mineral Waters; Formulæ for Official, Empirical, and Dietetic Preparations, &c. With French and other Synonymes. Revised and very greatly enlarged. In one very large and handsome octavo volume, of 992 double-columned pages, in small type; strongly bound in leather, with raised bands. Price \$4 00.

Especial care has been devoted in the preparation of this edition to render it in every respect worthy a continuance of the very remarkable favor which it has hitherto enjoyed. The rapid sale of FIFTEEN large editions, and the constantly increasing demand, show that it is regarded by the profession as the standard authority. Stimulated by this fact, the author has endeavored in the present revision to introduce whatever might be necessary "to make it a satisfactory and desirable—if not indispensable—lexicon, in which the student may search without disappointment for every term that has been legitimated in the nomenclature of the science." To accomplish this, large additions have been found requisite, and the extent of the author's labors may be estimated from the fact that about SIX THOUSAND subjects and terms have been introduced throughout, rendering the whole number of definitions about SIXTY THOUSAND, to accommodate which, the number of pages has been increased by nearly a hundred, notwithstanding an enlargement in the size of the page. The medical press, both in this country and in England, has pronounced the work indispensable to all medical students and practitioners, and the present improved edition will not lose that enviable reputation.

The publishers have endeavored to render the mechanical execution worthy of a volume of such universal use in daily reference. The greatest care has been exercised to obtain the typographical accuracy so necessary in a work of the kind. By the small but exceedingly clear type employed, an immense amount of matter is condensed in its thousand ample pages, while the binding will be found strong and durable. With all these improvements and enlargements, the price has been kept at the former very moderate rate, placing it within the reach of all.

This work, the appearance of the fifteenth edition of which, it has become our duty and pleasure to announce, is perhaps the most stupendous monument of labor and erudition in medical literature. One would hardly suppose after constant use of the preceding editions, where we have never failed to find a sufficiently full explanation of every medical term, that in this edition "about six thousand subjects and terms have been added," with a careful revision and correction of the entire work. It is only necessary to announce the advent of this edition to make it occupy the place of the preceding one on the table of every medical man, as it is without doubt the best and most comprehensive work of the kind which has ever appeared.—*Buffalo Med. Journ.*, Jan. 1858.

The work is a monument of patient research, skilful judgment, and vast physical labor, that will perpetuate the name of the author more effectually than any possible device of stone or metal. Dr. Dunglison deserves the thanks not only of the American profession, but of the whole medical world.—*North Am. Medico-Chir. Review*, Jan. 1858.

A Medical Dictionary better adapted for the wants of the profession than any other with which we are acquainted, and of a character which places it far above comparison and competition.—*Am. Journ. Med. Sciences*, Jan. 1858.

We need only say, that the addition of 6,000 new terms, with their accompanying definitions, may be said to constitute a new work, by itself. We have examined the Dictionary attentively, and are most happy to pronounce it unrivalled of its kind. The erudition displayed, and the extraordinary industry which must have been demanded, in its preparation and perfection, redound to the lasting credit of its author, and have furnished us with a volume indispensable at the present day, to all who would find themselves *au niveau* with the highest standards of medical information.—*Boston Medical and Surgical Journal*, Dec. 31, 1857.

Good lexicons and encyclopedic works generally, are the most labor-saving contrivances which literary men enjoy; and the labor which is required to produce them in the perfect manner of this example is something appalling to contemplate. The author

tells us in his preface that he has added about six thousand terms and subjects to this edition, which, before, was considered universally as the best work of the kind in any language.—*Silliman's Journal*, March, 1858.

He has razed his gigantic structure to the foundations, and remodelled and reconstructed the entire pile. No less than six thousand additional subjects and terms are illustrated and analyzed in this new edition, swelling the grand aggregate to beyond sixty thousand! Thus is placed before the profession a complete and thorough exponent of medical terminology, without rival or possibility of rivalry.—*Nashville Journ. of Med. and Surg.*, Jan. 1858.

It is universally acknowledged, we believe, that this work is incomparably the best and most complete Medical Lexicon in the English language. The amount of labor which the distinguished author has bestowed upon it is truly wonderful, and the learning and research displayed in its preparation are equally remarkable. Comment and commendation are unnecessary, as no one at the present day thinks of purchasing any other Medical Dictionary than this.—*St. Louis Med. and Surg. Journ.*, Jan. 1858.

It is the foundation stone of a good medical library, and should always be included in the first list of books purchased by the medical student.—*Am. Med. Monthly*, Jan. 1858.

A very perfect work of the kind, undoubtedly the most perfect in the English language.—*Med. and Surg. Reporter*, Jan. 1858.

It is now emphatically the Medical Dictionary of the English language, and for it there is no substitute.—*N. H. Med. Journ.*, Jan. 1858.

It is scarcely necessary to remark that any medical library wanting a copy of Dunglison's Lexicon must be imperfect.—*Cin. Lancet*, Jan. 1858.

We have ever considered it the best authority published, and the present edition we may safely say has no equal in the world.—*Peninsular Med. Journal*, Jan. 1858.

The most complete authority on the subject to be found in any language.—*Va. Med. Journal*, Feb. '58.

BY THE SAME AUTHOR.

THE PRACTICE OF MEDICINE. A Treatise on Special Pathology and Therapeutics. Third Edition. In two large octavo volumes, leather, of 1,500 pages. \$6 25.

DUNGLISON (ROBLEY), M. D.,

Professor of Institutes of Medicine in the Jefferson Medical College, Philadelphia.

HUMAN PHYSIOLOGY. Eighth edition. Thoroughly revised and extensively modified and enlarged, with five hundred and thirty-two illustrations. In two large and handsomely printed octavo volumes, leather, of about 1500 pages. \$7 00.

In revising this work for its eighth appearance, the author has spared no labor to render it worthy a continuance of the very great favor which has been extended to it by the profession. The whole contents have been rearranged, and to a great extent remodelled; the investigations which of late years have been so numerous and so important, have been carefully examined and incorporated, and the work in every respect has been brought up to a level with the present state of the subject. The object of the author has been to render it a concise but comprehensive treatise, containing the whole body of physiological science, to which the student and man of science can at all times refer with the certainty of finding whatever they are in search of, fully presented in all its aspects; and on no former edition has the author bestowed more labor to secure this result.

We believe that it can truly be said, no more complete repertory of facts upon the subject treated, can anywhere be found. The author has, moreover, that enviable tact at description and that facility and ease of expression which render him peculiarly acceptable to the casual, or the studious reader. This faculty, so requisite in setting forth many graver and less attractive subjects, lends additional charms to one always fascinating.—*Boston Med. and Surg. Journal*.

The most complete and satisfactory system of Physiology in the English language.—*Amer. Med. Journal*.

The best work of the kind in the English language.—*Silliman's Journal*.

The present edition the author has made a perfect mirror of the science as it is at the present hour. As a work upon physiology proper, the science of the functions performed by the body, the student will find it all he wishes.—*Nashville Journ. of Med.*

That he has succeeded, most admirably succeeded in his purpose, is apparent from the appearance of an eighth edition. It is now the great encyclopædia on the subject, and worthy of a place in every physician's library.—*Western Lancet*.

BY THE SAME AUTHOR. (A new edition.)

GENERAL THERAPEUTICS AND MATERIA MEDICA; adapted for a Medical Text-book. With Indexes of Remedies and of Diseases and their Remedies. SIXTH EDITION, revised and improved. With one hundred and ninety-three illustrations. In two large and handsomely printed octavo vols., leather, of about 1100 pages. \$6 00.

In announcing a new edition of Dr. Dunglison's General Therapeutics and Materia Medica, we have no words of commendation to bestow upon a work whose merits have been heretofore so often and so justly extolled. It must not be supposed, however, that the present is a mere reprint of the previous edition; the character of the author for laborious research, judicious analysis, and clearness of expression, is fully sustained by the numerous additions he has made to the work, and the careful revision to which he has subjected the whole.—*N. A. Medico-Chir. Review*, Jan. 1858.

The work will, we have little doubt, be bought and read by the majority of medical students; its size, arrangement, and reliability recommend it to all; no one, we venture to predict, will study it without profit, and there are few to whom it will not be in some measure useful as a work of reference. The young practitioner, more especially, will find the copious indexes appended to this edition of great assistance in the selection and preparation of suitable formulæ.—*Charleston Med. Journ. and Review*, Jan. 1858.

BY THE SAME AUTHOR. (A new Edition.)

NEW REMEDIES, WITH FORMULÆ FOR THEIR PREPARATION AND ADMINISTRATION. Seventh edition, with extensive Additions. In one very large octavo volume, leather, of 770 pages. \$3 75.

Another edition of the "New Remedies" having been called for, the author has endeavored to add everything of moment that has appeared since the publication of the last edition.

The articles treated of in the former editions will be found to have undergone considerable expansion in this, in order that the author might be enabled to introduce, as far as practicable, the results of the subsequent experience of others, as well as of his own observation and reflection; and to make the work still more deserving of the extended circulation with which the preceding editions have been favored by the profession. By an enlargement of the page, the numerous additions have been incorporated without greatly increasing the bulk of the volume.—*Preface*.

One of the most useful of the author's works.—*Southern Medical and Surgical Journal*.

This elaborate and useful volume should be found in every medical library, for as a book of reference, for physicians, it is unsurpassed by any other work in existence, and the double index for diseases and for remedies, will be found greatly to enhance its value.—*New York Med. Gazette*.

The great learning of the author, and his remarkable industry in pushing his researches into every source whence information is derivable, have enabled him to throw together an extensive mass of facts and statements, accompanied by full reference to authorities; which last feature renders the work practically valuable to investigators who desire to examine the original papers.—*The American Journal of Pharmacy*.

ELLIS (BENJAMIN), M. D.

THE MEDICAL FORMULARY: being a Collection of Prescriptions, derived from the writings and practice of many of the most eminent physicians of America and Europe. Together with the usual Dietetic Preparations and Antidotes for Poisons. To which is added an Appendix, on the Endermic use of Medicines, and on the use of Ether and Chloroform. The whole accompanied with a few brief Pharmaceutical and Medical Observations. Eleventh edition, revised and much extended by ROBERT P. THOMAS, M. D., Professor of Materia Medica in the Philadelphia College of Pharmacy. (*Preparing*.)

ERICHSEN (JOHN),

Professor of Surgery in University College, London, &c.

THE SCIENCE AND ART OF SURGERY; BEING A TREATISE ON SURGICAL

INJURIES, DISEASES, AND OPERATIONS. New and improved American, from the second enlarged and carefully revised London edition. Illustrated with over four hundred engravings on wood. In one large and handsome octavo volume, of one thousand closely printed pages, leather, raised bands. \$4 50. (*Just Issued.*)

The very distinguished favor with which this work has been received on both sides of the Atlantic has stimulated the author to render it even more worthy of the position which it has so rapidly attained as a standard authority. Every portion has been carefully revised, numerous additions have been made, and the most watchful care has been exercised to render it a complete exponent of the most advanced condition of surgical science. In this manner the work has been enlarged by about a hundred pages, while the series of engravings has been increased by more than a hundred, rendering it one of the most thoroughly illustrated volumes before the profession. The additions of the author having rendered unnecessary most of the notes of the former American editor, but little has been added in this country; some few notes and occasional illustrations have, however, been introduced to elucidate American modes of practice.

It is, in our humble judgment, decidedly the best book of the kind in the English language. Strange that just such books are not oftener produced by public teachers of surgery in this country and Great Britain. Indeed, it is a matter of great astonishment, but no less true than astonishing, that of the many works on surgery republished in this country within the last fifteen or twenty years as text-books for medical students, this is the only one that even approximates to the fulfilment of the peculiar wants of young men just entering upon the study of this branch of the profession.—*Western Jour. of Med. and Surgery.*

Its value is greatly enhanced by a very copious well-arranged index. We regard this as one of the most valuable contributions to modern surgery. To one entering his novitiate of practice, we regard it the most serviceable guide which he can consult. He will find a fulness of detail leading him through every

step of the operation, and not deserting him until the final issue of the case is decided.—*Sethoscope.*

Embracing, as will be perceived, the whole surgical domain, and each division of itself almost complete and perfect, each chapter full and explicit, each subject faithfully exhibited, we can only express our estimate of it in the aggregate. We consider it an excellent contribution to surgery, as probably the best single volume now extant on the subject, and with great pleasure we add it to our text-books.—*Nashville Journal of Medicine and Surgery.*

Prof. Erichsen's work, for its size, has not been surpassed; his nine hundred and eight pages, profusely illustrated, are rich in physiological, pathological, and operative suggestions, doctrines, details, and processes; and will prove a reliable resource for information, both to physician and surgeon, in the hour of peril.—*N. O. Med. and Surg. Journal.*

FLINT (AUSTIN), M. D.,

Professor of the Theory and Practice of Medicine in the University of Louisville, &c.

PHYSICAL EXPLORATION AND DIAGNOSIS OF DISEASES AFFECTING THE RESPIRATORY ORGANS.

In one large and handsome octavo volume, extra cloth, 636 pages. \$3 00.

We regard it, in point both of arrangement and of the marked ability of its treatment of the subjects, as destined to take the first rank in works of this class. So far as our information extends, it has at present no equal. To the practitioner, as well as the student, it will be invaluable in clearing up the diagnosis of doubtful cases, and in shedding light upon difficult phenomena.—*Buffalo Med. Journal.*

A work of original observation of the highest merit. We recommend the treatise to every one who wishes to become a correct auscultator. Based to a very large extent upon cases numerically examined, it carries the evidence of careful study and discrimination upon every page. It does credit to the author, and, through him, to the profession in this country. It is, what we cannot call every book upon auscultation, a readable book.—*Am. Jour. Med. Sciences.*

BY THE SAME AUTHOR. (*Now Ready.*)**A PRACTICAL TREATISE ON THE DIAGNOSIS, PATHOLOGY, AND TREATMENT OF DISEASES OF THE HEART.**

In one neat octavo volume, of about 500 pages, extra cloth. \$2 75.

We do not know that Dr. Flint has written anything which is not first rate; but this, his latest contribution to medical literature, in our opinion, surpasses all the others. The work is most comprehensive in its scope, and most sound in the views it enunciates. The descriptions are clear and methodical; the statements are substantiated by facts, and are made with such simplicity and sincerity, that without them they would carry conviction. The style is admirably clear, direct, and free from dryness. With Dr. Walshe's excellent treatise before us, we have no hesitation in saying that Dr. Flint's book is the best work on the heart in the English language.—*Boston Med. and Surg. Journal.*

We have thus endeavored to present our readers with a fair analysis of this remarkable work. Preferring to employ the very words of the distinguished author, wherever it was possible, we have essayed to condense into the briefest space a general view of his observations and suggestions, and to direct the attention of our brethren to the abounding stores of valuable matter here collected and arranged for their use and instruction. No medical library will hereafter be considered complete without this volume; and we trust it will promptly find its way into the hands of every American student and physician.—*N. Am. Med. Chir. Review.*

This last work of Prof. Flint will add much to his previous well-earned celebrity, as a writer of

great force and beauty, and, with his previous work, places him at the head of American writers upon diseases of the chest. We have adopted his work upon the heart as a text-book, believing it to be more valuable for that purpose than any work of the kind that has yet appeared.—*Nashville Med. Journ.*

With more than pleasure do we hail the advent of this work, for it fills a wide gap on the list of text-books for our schools, and is, for the practitioner, the most valuable practical work of its kind.—*N. O. Med. News.*

In regard to the merits of the work, we have no hesitation in pronouncing it full, accurate, and judicious. Considering the present state of science, such a work was much needed. It should be in the hands of every practitioner.—*Chicago Med. Journal.*

But these are very trivial spots, and in no wise prevent us from declaring our most hearty approval of the author's ability, industry, and conscientiousness.—*Dublin Quarterly Journal of Med. Sciences.*

He has labored on with the same industry and care, and his place among the first authors of our country is becoming fully established. To this end, the work whose title is given above, contributes in no small degree. Our space will not admit of an extended analysis, and we will close this brief notice by commending it without reserve to every class of readers in the profession.—*Peninsular Med. Journ.*

FOWNES (GEORGE), PH. D., &c.

A MANUAL OF ELEMENTARY CHEMISTRY; Theoretical and Practical.

From the seventh revised and corrected London edition. With one hundred and ninety-seven illustrations. Edited by ROBERT BRIDGES, M. D. In one large royal 12mo volume, of 600 pages. In leather, \$1 65; extra cloth, \$1 50. (*Just Issued.*)

The death of the author having placed the editorial care of this work in the practised hands of Drs. Bence Jones and A. W. Hoffman, everything has been done in its revision which experience could suggest to keep it on a level with the rapid advance of chemical science. The additions requisite to this purpose have necessitated an enlargement of the page, notwithstanding which the work has been increased by about fifty pages. At the same time every care has been used to maintain its distinctive character as a condensed manual for the student, divested of all unnecessary detail or mere theoretical speculation. The additions have, of course, been mainly in the department of Organic Chemistry, which has made such rapid progress within the last few years, but yet equal attention has been bestowed on the other branches of the subject—Chemical Physics and Inorganic Chemistry—to present all investigations and discoveries of importance, and to keep up the reputation of the volume as a complete manual of the whole science, admirably adapted for the learner. By the use of a small but exceedingly clear type the matter of a large octavo is compressed within the convenient and portable limits of a moderate sized duodecimo, and at the very low price affixed, it is offered as one of the cheapest volumes before the profession.

Dr. Fownes' excellent work has been universally recognized everywhere in his own and this country, as the best elementary treatise on chemistry in the English tongue, and is very generally adopted, we believe, as the standard text-book in all our colleges, both literary and scientific.—*Charleston Med. Journ. and Review.*

A standard manual, which has long enjoyed the reputation of embodying much knowledge in a small space. The author has achieved the difficult task of condensation with masterly tact. His book is concise without being dry, and brief without being too dogmatical or general.—*Virginia Med. and Surgical Journal.*

The work of Dr. Fownes has long been before the public, and its merits have been fully appreciated as the best text-book on chemistry now in existence. We do not, of course, place it in a rank superior to the works of Brande, Graham, Turner, Gregory, or Gmelin, but we say that, as a work for students, it is preferable to any of them.—*London Journal of Medicine.*

A work well adapted to the wants of the student. It is an excellent exposition of the chief doctrines and facts of modern chemistry. The size of the work, and still more the condensed yet perspicuous style in which it is written, absolve it from the charges very properly urged against most manuals termed popular.—*Edinburgh Journal of Medical Science.*

FISKE FUND PRIZE ESSAYS.—THE EFFECTS OF CLIMATE ON TUBERCULOUS DISEASE. By EDWIN LEE, M. R. C. S., London, and THE INFLUENCE OF PREGNANCY ON THE DEVELOPMENT OF TUBERCLES. By

EDWARD WARREN, M. D., of Edenton, N. C. Together in one neat 8vo volume, extra cloth, \$1 00. **FRICK ON RENAL AFFECTIONS;** their Diagnosis and Pathology. With illustrations. One volume, royal 12mo., extra cloth. 75 cents.

FERGUSON (WILLIAM), F. R. S.,

Professor of Surgery in King's College, London, &c.

A SYSTEM OF PRACTICAL SURGERY. Fourth American, from the third and enlarged London edition. In one large and beautifully printed octavo volume, of about 700 pages, with 393 handsome illustrations, leather. \$3 00.

GRAHAM (THOMAS), F. R. S.

THE ELEMENTS OF INORGANIC CHEMISTRY, including the Applications of the Science in the Arts. New and much enlarged edition, by HENRY WATTS and ROBERT BRIDGES, M. D. Complete in one large and handsome octavo volume, of over 800 very large pages, with two hundred and thirty-two wood-cuts, extra cloth. \$4 00.

*** Part II., completing the work from p. 431 to end, with Index, Title Matter, &c., may be had separate, cloth backs and paper sides. Price \$2 50.

From Prof. E. N. Horsford, Harvard College.

It has, in its earlier and less perfect editions, been familiar to me, and the excellence of its plan and the clearness and completeness of its discussions, have long been my admiration.

No reader of English works on this science can

afford to be without this edition of Prof. Graham's Elements.—*Silliman's Journal*, March, 1853.

From Prof. Wolcott Gibbs, N. Y. Free Academy.

The work is an admirable one in all respects, and its republication here cannot fail to exert a positive influence upon the progress of science in this country.

GRIFFITH (ROBERT E.), M. D., &c.

A UNIVERSAL FORMULARY, containing the methods of Preparing and Administering Official and other Medicines. The whole adapted to Physicians and Pharmacutists. SECOND EDITION, thoroughly revised, with numerous additions, by ROBERT P. THOMAS, M. D., Professor of Materia Medica in the Philadelphia College of Pharmacy. In one large and handsome octavo volume, extra cloth, of 650 pages, double columns. \$3 00; or in sheep, \$3 25.

It was a work requiring much perseverance, and when published was looked upon as by far the best work of its kind that had issued from the American press. Prof. Thomas has certainly "improved," as well as added to this Formulary, and has rendered it additionally deserving of the confidence of pharmacutists and physicians.—*Am. Journal of Pharmacy.*

We are happy to announce a new and improved edition of this, one of the most valuable and useful works that have emanated from an American pen. It would do credit to any country, and will be found of daily usefulness to practitioners of medicine; it is better adapted to their purposes than the dispensatories.—*Southern Med. and Surg. Journal.*

It is one of the most useful books a country practitioner can possibly have.—*Medical Chronicle.*

This is a work of six hundred and fifty-one pages, embracing all on the subject of preparing and administering medicines that can be desired by the physician and pharmacist.—*Western Lancet.*

The amount of useful, every-day matter for a practicing physician, is really immense.—*Boston Med. and Surg. Journal.*

This edition has been greatly improved by the revision and ample additions of Dr. Thomas, and is now, we believe, one of the most complete works of its kind in any language. The additions amount to about seventy pages, and no effort has been spared to include in them all the recent improvements. A work of this kind appears to us indispensable to the physician, and there is none we can more cordially recommend. *N. Y. Journal of Medicine.*

GROSS (SAMUEL D.), M. D.,

Professor of Surgery in the Jefferson Medical College of Philadelphia, &c.

Enlarged Edition—Now Ready, January, 1862.

A SYSTEM OF SURGERY: Pathological, Diagnostic, Therapeutic, and Operative. Illustrated by TWELVE HUNDRED AND TWENTY-SEVEN ENGRAVINGS. Second edition, much enlarged and carefully revised. In two large and beautifully printed octavo volumes, of about twenty-two hundred pages; strongly bound in leather, with raised bands. Price \$12.

The exhaustion in little more than two years of a large edition of so elaborate and comprehensive a work as this is the best evidence that the author was not mistaken in his estimate of the want which existed of a complete American System of Surgery, presenting the science in all its necessary details and in all its branches. That he has succeeded in the attempt to supply this want is shown not only by the rapid sale of the work, but also by the very favorable manner in which it has been received by the organs of the profession in this country and in Europe, and by the fact that a translation is now preparing in Holland—a mark of appreciation not often bestowed on any scientific work so extended in size.

The author has not been insensible to the kindness thus bestowed upon his labors, and in revising the work for a new edition he has spared no pains to render it worthy of the favor with which it has been received. Every portion has been subjected to close examination and revision; any deficiencies apparent have been supplied, and the results of recent progress in the science and art of surgery have been everywhere introduced; while the series of illustrations has been enlarged by the addition of nearly three hundred wood-cuts, rendering it one of the most thoroughly illustrated works ever laid before the profession. To accommodate these very extensive additions, the work has been printed upon a smaller type, so that notwithstanding the very large increase in the matter and value of the book, its size is more convenient and less cumbersome than before. Every care has been taken in the printing to render the typographical execution unexceptionable, and it is confidently presented as a work in every way worthy of a place in even the most limited library of the practitioner or student.

A few testimonials of the value of the former edition are appended.

Has Dr. Gross satisfactorily fulfilled this object? A careful perusal of his volumes enables us to give an answer in the affirmative. Not only has he given to the reader an elaborate and well-written account of his own vast experience, but he has not failed to embody in his pages the opinions and practice of surgeons in this and other countries of Europe. The result has been a work of such completeness, that it has no superior in the systematic treatises on surgery which have emanated from English or Continental authors. It has been justly objected that these have been far from complete in many essential particulars, many of them having been deficient in some of the most important points which should characterize such works. Some of them have been elaborate—too elaborate—with respect to certain diseases, while they have merely glanced at, or given an unsatisfactory account of, others equally important to the surgeon. Dr. Gross has avoided this error, and has produced the most complete work that has yet issued from the press on the science and practice of surgery. It is not, strictly speaking, a Dictionary of Surgery, but it gives to the reader all the information that he may require for his treatment of surgical diseases. Having said so much, it might appear superfluous to add another word; but it is only due to Dr. Gross to state that he has embraced the opportunity of transferring to his pages a vast number of engravings from English and other authors, illustrative of the pathology and treatment of surgical diseases. To these are added several hundred original wood-cuts. The work altogether commends itself to the attention of British surgeons, from whom it cannot fail to meet with extensive patronage.—*London Lancet*, Sept. 1, 1860.

Of Dr. Gross's treatise on Surgery we can say no more than that it is the most elaborate and complete work on this branch of the healing art which has ever been published in any country. A systematic work, it admits of no analytical review; but, did our space permit, we should gladly give some extracts from it, to enable our readers to judge of the classical style of the author, and the exhausting way in which each subject is treated.—*Dublin Quarterly Journal of Med. Science*.

The work is so superior to its predecessors in matter and extent, as well as in illustrations and style of publication, that we can honestly recommend it as the best work of the kind to be taken home by the young practitioner.—*Am. Med. Journ.*

With pleasure we record the completion of this long-anticipated work. The reputation which the author has for many years sustained, both as a surgeon and as a writer, had prepared us to expect a treatise of great excellence and originality; but we confess we were by no means prepared for the work which is before us—the most complete treatise upon surgery ever published, either in this or any other country, and we might, perhaps, safely say, the most original. There is no subject belonging properly to surgery which has not received from the author a due share of attention. Dr. Gross has supplied a want in surgical literature which has long been felt by practitioners; he has furnished us with a complete practical treatise upon surgery in all its departments. As Americans, we are proud of the achievement; as surgeons, we are most sincerely thankful to him for his extraordinary labors in our behalf.—*N. Y. Monthly Review and Buffalo Med. Journal*.

BY THE SAME AUTHOR.

ELEMENTS OF PATHOLOGICAL ANATOMY. Third edition, thoroughly revised and greatly improved. In one large and very handsome octavo volume, with about three hundred and fifty beautiful illustrations, of which a large number are from original drawings. Price in extra cloth, \$4 75; leather, raised bands, \$5 25. (*Lately Published.*)

The very rapid advances in the Science of Pathological Anatomy during the last few years have rendered essential a thorough modification of this work, with a view of making it a correct exponent of the present state of the subject. The very careful manner in which this task has been executed, and the amount of alteration which it has undergone, have enabled the author to say that "with the many changes and improvements now introduced, the work may be regarded almost as a new treatise," while the efforts of the author have been seconded as regards the mechanical execution of the volume, rendering it one of the handsomest productions of the American press.

We most sincerely congratulate the author on the successful manner in which he has accomplished his proposed object. His book is most admirably calculated to fill up a blank which has long been felt to exist in this department of medical literature, and as such must become very widely circulated amongst all classes of the profession.—*Dublin Quarterly Journ. of Med. Science*, Nov. 1857.

We have been favorably impressed with the general manner in which Dr. Gross has executed his task of affording a comprehensive digest of the present state of the literature of Pathological Anatomy, and have much pleasure in recommending his work to our readers, as we believe one well deserving of diligent perusal and careful study.—*Montreal Med. Chron.*, Sept. 1857.

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON FOREIGN BODIES IN THE AIR-PASSAGES. In one handsome octavo volume, extra cloth, with illustrations. pp. 468. \$2 75.

GROSS (SAMUEL D.), M. D.,

Professor of Surgery in the Jefferson Medical College of Philadelphia, &c.

A PRACTICAL TREATISE ON THE DISEASES, INJURIES, AND MALFORMATIONS OF THE URINARY BLADDER, THE PROSTATE GLAND, AND THE URETHRA. Second Edition, revised and much enlarged, with one hundred and eighty-four illustrations. In one large and very handsome octavo volume, of over nine hundred pages. In leather, raised bands, \$5 25; extra cloth, \$4 75.

Philosophical in its design, methodical in its arrangement, ample and sound in its practical details, it may in truth be said to leave scarcely anything to be desired on so important a subject.—*Boston Med. and Surg. Journal*.

Whoever will peruse the vast amount of valuable practical information it contains, will, we think,

agree with us, that there is no work in the English language which can make any just pretensions to be its equal.—*N. Y. Journal of Medicine*.

A volume replete with truths and principles of the utmost value in the investigation of these diseases.—*American Medical Journal*.

GRAY (HENRY), F. R. S.,

Lecturer on Anatomy at St. George's Hospital, London, &c.

ANATOMY, DESCRIPTIVE AND SURGICAL. The Drawings by H. V. CARTER, M. D., late Demonstrator on Anatomy at St. George's Hospital; the Dissections jointly by the AUTHOR and Dr. CARTER. Second American, from the second revised and improved London edition. In one magnificent imperial octavo volume, of over 800 pages, with 388 large and elaborate engravings on wood. Price in extra cloth, \$6 25; leather, raised bands, \$7 00. (*Now Ready*, 1852.)

The speedy exhaustion of a large edition of this work is sufficient evidence that its plan and execution have been found to present superior practical advantages in facilitating the study of Anatomy. In presenting it to the profession a second time, the author has availed himself of the opportunity to supply any deficiencies which experience in its use had shown to exist, and to correct any errors of detail, to which the first edition of a scientific work on so extensive and complicated a science is liable. These improvements have resulted in some increase in the size of the volume, while twenty-six new wood-cuts have been added to the beautiful series of illustrations which form so distinctive a feature of the work. The American edition has been passed through the press under the supervision of a competent professional man, who has taken every care to render it in all respects accurate, and it is now presented, without any increase of price, as fitted to maintain and extend the popularity which it has everywhere acquired.

With little trouble, the busy practitioner whose knowledge of anatomy may have become obscured by want of practice, may now resuscitate his former anatomical lore, and be ready for any emergency. It is to this class of individuals, and not to the student alone, that this work will ultimately tend to be of most incalculable advantage, and we feel satisfied that the library of the medical man will soon be considered incomplete in which a copy of this work does not exist.—*Madras Quarterly Journal of Med. Science*, July, 1861.

This edition is much improved and enlarged, and contains several new illustrations by Dr. Westmacott. The volume is a complete companion to the dissecting-room, and saves the necessity of the student possessing a variety of "Manuals."—*The London Lancet*, Feb. 9, 1861.

The work before us is one entitled to the highest praise, and we accordingly welcome it as a valuable addition to medical literature. Intermediate in fulness of detail between the treatises of Saarep and of Wilson, its characteristic merit lies in the number and excellence of the engravings it contains. Most of these are original, of much larger than ordinary size, and admirably executed. The various parts are also lettered after the plan adopted in Holden's *Osteology*. It would be difficult to over-estimate the advantages offered by this mode of pictorial illustration. Bones, ligaments, muscles, bloodvessels, and nerves are each in turn figured, and marked with their appropriate names; thus enabling the student to comprehend, at a glance, what would otherwise often be ignored, or at any rate, acquired only by prolonged and irksome application. In conclusion, we heartily commend the work of Mr. Gray to the attention of the medical profession, feeling certain that it should be regarded as one of the most valuable contributions ever made to educational literature.—*N. Y. Monthly Review*, Dec. 1859.

In this view, we regard the work of Mr. Gray as far better adapted to the wants of the profession, and especially of the student, than any treatise on anatomy yet published in this country. It is destined, we believe, to supersede all others, both as a manual of dissections, and a standard of reference to the student of general or relative anatomy.—*N. Y. Journal of Medicine*, Nov. 1859.

For this truly admirable work the profession is indebted to the distinguished author of "Gray on the Spleen." The vacancy it fills has been long felt

to exist in this country. Mr. Gray writes throughout with both branches of his subject in view. His description of each particular part is followed by a notice of its relations to the parts with which it is connected, and this, too, sufficiently ample for all the purposes of the operative surgeon. After describing the bones and muscles, he gives a concise statement of the fractures to which the bones of the extremities are most liable, together with the amount and direction of the displacement to which the fragments are subjected by muscular action. The section on arteries is remarkably full and accurate. Not only is the surgical anatomy given to every important vessel, with directions for its ligation, but at the end of the description of each arterial trunk we have a useful summary of the irregularities which may occur in its origin, course, and termination.—*N. A. Med. Chir. Review*, Mar. 1859.

Mr. Gray's book, in excellency of arrangement and completeness of execution, exceeds any work on anatomy hitherto published in the English language, affording a complete view of the structure of the human body, with especial reference to practical surgery. Thus the volume constitutes a perfect book of reference for the practitioner, demanding a place in even the most limited library of the physician or surgeon, and a work of necessity for the student to fix in his mind what he has learned by the dissecting knife from the book of nature.—*The Dublin Quarterly Journal of Med. Sciences*, Nov. 1858.

In our judgment, the mode of illustration adopted in the present volume cannot but present many advantages to the student of anatomy. To the zealous disciple of Vesalius, earnestly desirous of real improvement, the book will certainly be of immense value; but, at the same time, we must also confess that to those simply desirous of "cramming" it will be an undoubted godsend. The peculiar value of Mr. Gray's mode of illustration is nowhere more markedly evident than in the chapter on osteology, and especially in those portions which treat of the bones of the head and of their development. The study of these parts is thus made one of comparative ease, if not of positive pleasure; and those bugbears of the student, the temporal and sphenoid bones, are shorn of half their terrors. It is, in our estimation, an admirable and complete text-book for the student, and a useful work of reference for the practitioner; its pictorial character forming a novel element, to which we have already sufficiently alluded.—*Am. Journ. Med. Sci.*, July, 1859.

GIBSON'S INSTITUTES AND PRACTICE OF SURGERY. Eighth edition, improved and altered. With thirty-four plates. In two handsome octavo volumes, containing about 1,000 pages, leather, raised bands. \$6 50.

GARDNER'S MEDICAL CHEMISTRY, for the use of Students and the Profession. In one royal 12mo. vol., cloth, pp. 396, with wood cuts. \$1.

GLUGE'S ATLAS OF PATHOLOGICAL HISTOLOGY. Translated, with Notes and Addi-

tions, by JOSEPH LEIDY, M. D. In one volume, very large imperial quarto, extra cloth, with 320 copper plate figures, plain and colored, \$5 00.

HUGHES' INTRODUCTION TO THE PRACTICE OF AUSCULTATION AND OTHER MODES OF PHYSICAL DIAGNOSIS. IN DISEASES OF THE LUNGS AND HEART. Second edition. 1 vol. royal 12mo., ex. cloth, pp. 304. \$1 00.

HAMILTON (FRANK H.), M. D.,

Professor of Surgery in the Long Island College Hospital.

A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS. In one large and handsome octavo volume, of over 750 pages, with 289 illustrations. \$4 25. (*Now Ready, January, 1860.*)

Among the many good workers at surgery of whom America may now boast not the least is Frank Hamilton; and the volume before us is (we say it with a pang of wounded patriotism) the best and handiest book on the subject in the English language. It is in vain to attempt a review of it; nearly as vain to seek for any sins, either of commission or omission. We have seen no work on practical surgery which we would sooner recommend to our brother surgeons, especially those of "the services," or those whose practice lies in districts where a man has necessarily to rely on his own unaided resources. The practitioner will find in it directions for nearly every possible accident, easily found and comprehended; and much pleasant reading for him to muse over in the after consideration of his cases.—*Edinburgh Med. Journ.* Feb. 1861.

This is a valuable contribution to the surgery of most important affections, and is the more welcome, inasmuch as at the present time we do not possess a single complete treatise on Fractures and Dislocations in the English language. It has remained for our American brother to produce a complete treatise upon the subject, and bring together in a convenient form those alterations and improvements that have been made from time to time in the treatment of these affections. One great and valuable feature in the work before us is the fact that it comprises all the improvements introduced into the practice of both English and American surgery, and though far from omitting mention of our continental neighbors, the author by no means encourages the notion—but too prevalent in some quarters—that nothing is good unless imported from France or Germany. The latter half of the work is devoted to the consideration of the various dislocations and their appropriate treatment, and its merit is fully equal to that of the preceding portion.—*The London Lancet*, May 5, 1860.

It is emphatically the book upon the subjects of which it treats, and we cannot doubt that it will continue so to be for an indefinite period of time. When we say, however, that we believe it will at once take its place as the best book for consultation by the practitioner; and that it will form the most complete, available, and reliable guide in emergencies of every nature connected with its subjects; and also that the student of surgery may make it his textbook with entire confidence, and with pleasure also, from its agreeable and easy style—we think our own

opinion may be gathered as to its value.—*Boston Medical and Surgical Journal*, March 1, 1860.

The work is concise, judicious, and accurate, and adapted to the wants of the student, practitioner, and investigator, honorable to the author and to the profession.—*Chicago Med. Journal*, March, 1860.

We regard this work as an honor not only to its author, but to the profession of our country. Were we to review it thoroughly, we could not convey to the mind of the reader more forcibly our honest opinion expressed in the few words—we think it the best book of its kind extant. Every man interested in surgery will soon have this work on his desk. He who does not, will be the loser.—*New Orleans Medical News*, March, 1860.

Now that it is before us, we feel bound to say that much as was expected from it, and onerous as was the undertaking, it has surpassed expectation, and achieved more than was pledged in its behalf; for its title does not express in full the richness of its contents. On the whole, we are prouder of this work than of any which has for years emanated from the American medical press; its sale will certainly be very large in this country, and we anticipate its eliciting much attention in Europe.—*Nashville Medical Record*, Mar. 1860.

Every surgeon, young and old, should possess himself of it, and give it a careful perusal, in doing which he will be richly repaid.—*St. Louis Med. and Surg. Journal*, March, 1860.

Dr. Hamilton is fortunate in having succeeded in filling the void, so long felt, with what cannot fail to be at once accepted as a model monograph in some respects, and a work of classical authority. We sincerely congratulate the profession of the United States on the appearance of such a publication from one of their number. We have reason to be proud of it as an original work, both in a literary and scientific point of view, and to esteem it as a valuable guide in a most difficult and important branch of study and practice. On every account, therefore, we hope that it may soon be widely known abroad as an evidence of genuine progress on this side of the Atlantic, and further, that it may be still more widely known at home as an authoritative teacher from which every one may profitably learn, and as affording an example of honest, well-directed, and untiring industry in authorship which every surgeon may emulate.—*Am. Med. Journal*, April, 1860.

HOBLYN (RICHARD D.), M. D.

A DICTIONARY OF THE TERMS USED IN MEDICINE AND THE COLLATERAL SCIENCES. A new American edition. Revised, with numerous Additions, by ISAAC HAYS, M. D., editor of the "American Journal of the Medical Sciences." In one large royal 12mo. volume, leather, of over 500 double columned pages. \$1 50.

To both practitioner and student, we recommend this dictionary as being convenient in size, accurate in definition, and sufficiently full and complete for ordinary consultation.—*Charleston Med. Journ.*

We know of no dictionary better arranged and adapted. It is not encumbered with the obsolete terms of a bygone age, but it contains all that are now in

use; embracing every department of medical science down to the very latest date.—*Western Lancet*.

Hoblyn's Dictionary has long been a favorite with us. It is the best book of definitions we have, and ought always to be upon the student's table.—*Southern Med. and Surg. Journal*.

HOLLAND'S MEDICAL NOTES AND REFLECTIONS. From the third London edition. In one handsome octavo volume, extra cloth. \$3.

HORNER'S SPECIAL ANATOMY AND HIS-

TOLOGY. Eighth edition. Extensively revised and modified. In two large octavo volumes, extra cloth, of more than 1000 pages, with over 300 illustrations. \$6 00.

HODGE (HUGH L.), M. D.,
Professor of Midwifery and the Diseases of Women and Children in the University of Pennsylvania, &c.

ON DISEASES PECULIAR TO WOMEN, including Displacements of the Uterus. With original illustrations. In one beautifully printed octavo volume, of nearly 500 pages, extra cloth. \$3 25. (*Now Ready.*)

We will say at once that the work fulfils its object capitally well; and we will moreover venture the assertion that it will inaugurate an improved practice throughout this whole country. The secrets of the author's success are so clearly revealed that the attentive student cannot fail to insure a goodly portion of similar success in his own practice. It is a credit to all medical literature; and we add, that the physician who does not place it in his library, and who does not faithfully con its pages, will lose a vast deal of knowledge that would be most useful to himself and beneficial to his patients. *It is a practical work of the highest order of merit; and it will take rank as such immediately.*—*Maryland and Virginia Medical Journal*, Feb. 1861.

This contribution towards the elucidation of the pathology and treatment of some of the diseases peculiar to women, cannot fail to meet with a favorable reception from the medical profession. The character of the particular maladies of which the work before us treats; their frequency, variety, and obscurity; the amount of malaise and even of actual suffering by which they are invariably attended; their obstinacy, the difficulty with which they are overcome, and their disposition again and again to recur—these, taken in connection with the entire competency of the author to render a correct account of their nature, their causes, and their appropriate management—his ample experience, his matured judgment, and his perfect conscientiousness—invest this publication with an interest and value to which few of the medical treatises of a recent date can lay a stronger, if, perchance, an equal claim.—*Am. Journ. Med. Sciences*, Jan. 1861.

Indeed, although no part of the volume is not eminently deserving of perusal and study, we think that the nine chapters devoted to this subject, are especially so, and we know of no more valuable monograph upon the symptoms, prognosis, and management of these annoying maladies than is constituted by this part of the work. We cannot but regard it as one of the most original and most practical works of the day; one which every accoucheur and physician should most carefully read; for we are persuaded that he will arise from its perusal with new ideas, which will induct him into a more rational practice in regard to many a suffering female, who may have placed her health in his hands.—*British American Journal*, Feb. 1861.

Of the many excellences of the work we will not speak at length. We advise all who would acquire a knowledge of the proper management of the maladies of which it treats, to study it with care. The second part is of itself a most valuable contribution to the practice of our art.—*Am. Med. Monthly and New York Review*, Feb. 1861.

The illustrations, which are all original, are drawn to a uniform scale of one-half the natural size.

HABERSHON (S. O.), M. D.,
Assistant Physician to and Lecturer on Materia Medica and Therapeutics at Guy's Hospital, &c.

PATHOLOGICAL AND PRACTICAL OBSERVATIONS ON DISEASES OF THE ALIMENTARY CANAL, OESOPHAGUS, STOMACH, CÆCUM, AND INTESTINES. With illustrations on wood. In one handsome octavo volume of 312 pages, extra cloth \$1 75. (*Now Ready.*)

JONES (T. WHARTON), F. R. S.,
Professor of Ophthalmic Medicine and Surgery in University College, London, &c.
THE PRINCIPLES AND PRACTICE OF OPHTHALMIC MEDICINE AND SURGERY. With one hundred and ten illustrations. Second American from the second and revised London edition, with additions by EDWARD HARTSHORNE, M. D., Surgeon to Wills' Hospital, &c. In one large, handsome royal 12mo. volume, extra cloth, of 500 pages. \$1 50.

JONES (C. HANDFIELD), F. R. S., & EDWARD H. SIEVEKING, M. D.,
Assistant Physicians and Lecturers in St. Mary's Hospital, London.
A MANUAL OF PATHOLOGICAL ANATOMY. First American Edition, Revised. With three hundred and ninety-seven handsome wood engravings. In one large and beautiful octavo volume of nearly 750 pages, leather. \$3 75.

As a concise text-book, containing, in a condensed form, a complete outline of what is known in the domain of Pathological Anatomy, it is perhaps the best work in the English language. Its great merit consists in its completeness and brevity, and in this respect it supplies a great desideratum in our literature. Heretofore the student of pathology was

obliged to glean from a great number of monographs, and the field was so extensive that but few cultivated it with any degree of success. As a simple work of reference, therefore, it is of great value to the student of pathological anatomy, and should be in every physician's library.—*Western Lancet*.

KIRKES (WILLIAM SENHOUSE), M. D.,
Demonstrator of Morbid Anatomy at St. Bartholomew's Hospital, &c.
A MANUAL OF PHYSIOLOGY. A new American, from the third and improved London edition. With two hundred illustrations. In one large and handsome royal 12mo. volume, leather. pp. 586. \$2 00. (*Lately Published.*)

This is a new and very much improved edition of Dr. Kirkes' well-known Handbook of Physiology. It combines conciseness with completeness, and is, therefore, admirably adapted for consultation by the busy practitioner.—*Dublin Quarterly Journal*.

One of the very best handbooks of Physiology we possess—presenting just such an outline of the science as the student requires during his attendance upon a course of lectures, or for reference whilst preparing for examination.—*Am. Medical Journal*.

Its excellence is in its compactness, its clearness,

and its carefully cited authorities. It is the most convenient of text-books. These gentlemen, Messrs. Kirkes and Paget, have the gift of telling us what we want to know, without thinking it necessary to tell us all they know.—*Boston Med and Surg. Journal*.

For the student beginning this study, and the practitioner who has but leisure to refresh his memory, this book is invaluable, as it contains all that it is important to know.—*Charleston Med. Journal*.

KNAPP'S TECHNOLOGY; or, Chemistry applied to the Arts and to Manufactures. Edited by Dr. RONALDS, Dr. RICHARDSON, and Prof. W. R. JOHNSON. In two handsome 8vo. vols., without 500 wood-engravings. \$6 00.

LAYCOCK'S LECTURES ON THE PRINCIPLES AND METHODS OF MEDICAL OBSERVATION AND RESEARCH. For the Use of Advanced Students and Junior Practitioners. In one royal 12mo. volume, extra cloth. Price \$1.

LALLEMAND AND WILSON.

A PRACTICAL TREATISE ON THE CAUSES, SYMPTOMS, AND TREATMENT OF SPERMATORRHOEA. By M. LALLEMAND. Translated and edited by HENRY J. McDougall. Third American edition. To which is added — **ON DISEASES OF THE VESICULÆ SEMINALES; AND THEIR ASSOCIATED ORGANS.** With special reference to the Morbid Secretions of the Prostatic and Urethral Mucous Membrane. By MARRIS WILSON, M. D. In one neat octavo volume, of about 400 pp., extra cloth. \$2 00. (*Just Issued.*)

LA ROCHE (R.), M. D., &c.

YELLOW FEVER, considered in its Historical, Pathological, Etiological, and Therapeutical Relations. Including a Sketch of the Disease as it has occurred in Philadelphia from 1699 to 1854, with an examination of the connections between it and the fevers known under the same name in other parts of temperate as well as in tropical regions. In two large and handsome octavo volumes of nearly 1500 pages, extra cloth. \$7 00.

From Professor S. H. Dickson, Charleston, S. C., September 18, 1855.

A monument of intelligent and well applied research, almost without example. It is, indeed, in itself, a large library, and is destined to constitute the special resort as a book of reference, in the subject of which it treats, to all future time.

We have not time at present, engaged as we are, by day and by night, in the work of combating this very disease, now prevailing in our city, to do more than give this cursory notice of what we consider as undoubtedly the most able and erudite medical publication our country has yet produced. But in view of the startling fact, that this, the most malig-

nant and unmanageable disease of modern times, has for several years been prevailing in our country to a greater extent than ever before; that it is no longer confined to either large or small cities, but penetrates country villages, plantations, and farm-houses; that it is treated with scarcely better success now than thirty or forty years ago; that there is vast mischief done by ignorant pretenders to knowledge in regard to the disease, and in view of the probability that a majority of southern physicians will be called upon to treat the disease, we trust that this able and comprehensive treatise will be very generally read in the south.—*Memphis Med. Recorder.*

BY THE SAME AUTHOR.

PNEUMONIA; its Supposed Connection, Pathological and Etiological, with Autumnal Fevers, including an Inquiry into the Existence and Morbid Agency of Malaria. In one handsome octavo volume, extra cloth, of 500 pages. \$3 00.

LAWRENCE (W.), F. R. S., &c.

A TREATISE ON DISEASES OF THE EYE. A new edition, edited, with numerous additions, and 243 illustrations, by ISAAC HAYS, M. D., Surgeon to Will's Hospital, &c. In one very large and handsome octavo volume, of 950 pages, strongly bound in leather with raised bands. \$5 00.

LUDLOW (J. L.), M. D.

A MANUAL OF EXAMINATIONS upon Anatomy, Physiology, Surgery, Practice of Medicine, Obstetrics, Materia Medica, Chemistry, Pharmacy, and Therapeutics. To which is added a Medical Formulary. Third edition, thoroughly revised and greatly extended and enlarged. With 370 illustrations. In one handsome royal 12mo. volume, leather, of 816 large pages. \$2 50.

We know of no better companion for the student during the hours spent in the lecture room, or to refresh, at a glance, his memory of the various topics

cramped into his head by the various professors to whom he is compelled to listen.—*Western Lancet*, May, 1857.

LEHMANN (C. G.)

PHYSIOLOGICAL CHEMISTRY. Translated from the second edition by GEORGE E. DAY, M. D., F. R. S., &c., edited by R. E. ROGERS, M. D., Professor of Chemistry in the Medical Department of the University of Pennsylvania, with illustrations selected from Funke's Atlas of Physiological Chemistry, and an Appendix of plates. Complete in two large and handsome octavo volumes, extra cloth, containing 1200 pages, with nearly two hundred illustrations. \$6 00.

The work of Lehmann stands unrivalled as the most comprehensive book of reference and information extant on every branch of the subject on which it treats.—*Edinburgh Journal of Medical Science.*

The most important contribution as yet made to Physiological Chemistry.—*Am. Journal Med. Sciences*, Jan. 1856.

BY THE SAME AUTHOR. (*Lately Published.*)

MANUAL OF CHEMICAL PHYSIOLOGY. Translated from the German, with Notes and Additions, by J. CHESTON MORRIS, M. D., with an Introductory Essay on Vital Force, by Professor SAMUEL JACKSON, M. D., of the University of Pennsylvania. With illustrations on wood. In one very handsome octavo volume, extra cloth, of 336 pages. \$2 25.

From Prof. Jackson's Introductory Essay.

In adopting the handbook of Dr. Lehmann as a manual of Organic Chemistry for the use of the students of the University, and in recommending his original work of **PHYSIOLOGICAL CHEMISTRY** for their more mature studies, the high value of his researches, and the great weight of his authority in that important department of medical science are fully recognized.

LYONS (ROBERT D.), K. C. C.,

Late Pathologist in-chief to the British Army in the Crimea, &c.

A TREATISE ON FEVER; or, selections from a course of Lectures on Fever. Being part of a course of Theory and Practice of Medicine. In one neat octavo volume, of 362 pages, extra cloth; \$2 00. (*Now Ready.*)

From the Author's Preface.

"I am induced to publish this work on Fever with a view to bring within the reach of the student and junior practitioner, in a convenient form, the more recent results of inquiries into the Pathology and Therapeutics of this formidable class of diseases.

"The works of the great writers on Fever are so numerous, and in the present day are scattered in so many languages, that they are difficult of access, not only to students but also to practitioners. I shall deem myself fortunate if I can in any measure supply the want which is felt in this respect.

We have great pleasure in recommending Dr. Lyons' work on *Fever* to the attention of the profession. It is a work which cannot fail to enhance the author's previous well-earned reputation, as a diligent, careful, and accurate observer.—*British Med. Journal*, March 2, 1861.

Taken as a whole we can recommend it in the highest terms as well worthy the careful perusal and study of every student and practitioner of medi-

cine. We consider the work a most valuable addition to medical literature, and one destined to wield no little influence over the mind of the profession.—*Med. and Surg. Reporter*, May 4, 1861.

This is an admirable work upon the most remarkable and most important class of diseases to which mankind are liable.—*Med. Journ. of N. Carolina*, May, 1861.

MEIGS (CHARLES D.), M. D.,

Professor of Obstetrics, &c. in the Jefferson Medical College, Philadelphia.

OBSTETRICS: THE SCIENCE AND THE ART. Third edition, revised and improved. With one hundred and twenty-nine illustrations. In one beautifully printed octavo volume, leather, of seven hundred and fifty-two large pages. \$3 75.

Though the work has received only five pages of enlargement, its chapters throughout wear the impress of careful revision. Expunging and rewriting, remodelling its sentences, with occasional new material, all evince a lively desire that it shall deserve to be regarded as improved in manner as well as matter. In the matter, every stroke of the pen has increased the value of the book, both in expungings and additions.—*Western Lancet*, Jan. 1857.

The best American work on Midwifery that is accessible to the student and practitioner.—*N. W. Med. and Surg. Journal*, Jan. 1857.

This is a standard work by a great American Obstetrician. It is the third and last edition, and, in the language of the preface, the author has "brought the subject up to the latest dates of real improvement in our art and Science."—*Nashville Journ. of Med. and Surg.*, May, 1857.

BY THE SAME AUTHOR. (*Just Issued.*)

WOMAN: HER DISEASES AND THEIR REMEDIES. A Series of Lectures to his Class. Fourth and Improved edition. In one large and beautifully printed octavo volume, leather, of over 700 pages. \$3 60.

In other respects, in our estimation, too much cannot be said in praise of this work. It abounds with beautiful passages, and for conciseness, for originality, and for all that is commendable in a work on the diseases of females, it is not excelled, and probably not equalled in the English language. On the whole, we know of no work on the diseases of women which we can so cordially commend to the student and practitioner as the one before us.—*Ohio Med. and Surg. Journal*.

The body of the book is worthy of attentive consideration, and is evidently the production of a clever, thoughtful, and sagacious physician. Dr. Meigs's letters on the diseases of the external organs, contain many interesting and rare cases, and many instructive observations. We take our leave of Dr. Meigs, with a high opinion of his talents and originality.—*The British and Foreign Medico-Chirurgical Review*.

Every chapter is replete with practical instruction, and bears the impress of being the composition of an acute and experienced mind. There is a terseness, and at the same time an accuracy in his description of symptoms, and in the rules for diagnosis,

which cannot fail to recommend the volume to the attention of the reader.—*Ranking's Abstract*.

It contains a vast amount of practical knowledge, by one who has accurately observed and retained the experience of many years.—*Dublin Quarterly Journal*.

Full of important matter, conveyed in a ready and agreeable manner.—*St. Louis Med. and Surg. Jour.*

There is an off-hand fervor, a glow, and a warm-heartedness infecting the effort of Dr. Meigs, which is entirely captivating, and which absolutely hurries the reader through from beginning to end. Besides, the book teems with solid instruction, and it shows the very highest evidence of ability, viz., the clearness with which the information is presented. We know of no better test of one's understanding a subject than the evidence of the power of lucidly explaining it. The most elementary, as well as the obscurest subjects, under the pencil of Prof. Meigs, are isolated and made to stand out in such bold relief, as to produce distinct impressions upon the mind and memory of the reader.—*The Charleston Med. Journal*.

BY THE SAME AUTHOR.

ON THE NATURE, SIGNS, AND TREATMENT OF CHILDBED FEVER. In a Series of Letters addressed to the Students of his Class. In one handsome octavo volume, extra cloth, of 365 pages. \$2 50.

The instructive and interesting author of this work, whose previous labors have placed his countrymen under deep and abiding obligations, again challenges their admiration in the fresh and vigorous, attractive and racy pages before us. It is a de-

lectable book. * * * This treatise upon childbed fevers will have an extensive sale, being destined, as it deserves, to find a place in the library of every practitioner who acorns to lag in the rear.—*Nashville Journal of Medicine and Surgery*.

BY THE SAME AUTHOR; WITH COLORED PLATES.

A TREATISE ON ACUTE AND CHRONIC DISEASES OF THE NECK OF THE UTERUS. With numerous plates, drawn and colored from nature in the highest style of art. In one handsome octavo volume, extra cloth. \$4 50.

MACLISE (JOSEPH), SURGEON.

SURGICAL ANATOMY. Forming one volume, very large imperial quarto.

With sixty-eight large and splendid Plates, drawn in the best style and beautifully colored. Containing one hundred and ninety Figures, many of them the size of life. Together with copious and explanatory letter-press. Strongly and handsomely bound in extra cloth, being one of the cheapest and best executed Surgical works as yet issued in this country. \$11 00.

* * The size of this work prevents its transmission through the post-office as a whole, but those who desire to have copies forwarded by mail, can receive them in five parts, done up in stout wrappers. Price \$9 00.

One of the greatest artistic triumphs of the age in Surgical Anatomy.—*British American Medical Journal*.

No practitioner whose means will admit should fail to possess it.—*Ranking's Abstract*.

Too much cannot be said in its praise; indeed, we have not language to do it justice.—*Ohio Medical and Surgical Journal*.

The most accurately engraved and beautifully colored plates we have ever seen in an American book—one of the best and cheapest surgical works ever published.—*Buffalo Medical Journal*.

It is very rare that so elegantly printed, so well illustrated, and so useful a work, is offered at so moderate a price.—*Charleston Medical Journal*.

Its plates can boast a superiority which places them almost beyond the reach of competition.—*Medical Examiner*.

Country practitioners will find these plates of immense value.—*N. Y. Medical Gazette*.

A work which has no parallel in point of accuracy and cheapness in the English language.—*N. Y. Journal of Medicine*.

We are extremely gratified to announce to the profession the completion of this truly magnificent work, which, as a whole, certainly stands unrivalled, both for accuracy of drawing, beauty of coloring, and all the requisite explanations of the subject in hand.—*The New Orleans Medical and Surgical Journal*.

This is by far the ablest work on Surgical Anatomy that has come under our observation. We know of no other work that would justify a student, in any degree, for neglect of actual dissection. In those sudden emergencies that so often arise, and which require the instantaneous command of minute anatomical knowledge, a work of this kind keeps the details of the dissecting-room perpetually fresh in the memory.—*The Western Journal of Medicine and Surgery*.

MILLER (HENRY), M. D.,

Professor of Obstetrics and Diseases of Women and Children in the University of Louisville.

PRINCIPLES AND PRACTICE OF OBSTETRICS, &c.; including the Treatment of Chronic Inflammation of the Cervix and Body of the Uterus considered as a frequent cause of Abortion. With about one hundred illustrations on wood. In one very handsome octavo volume, of over 600 pages. (Lately Published.) \$3 75.

We congratulate the author that the task is done. We congratulate him that he has given to the medical public a work which will secure for him a high and permanent position among the standard authorities on the principles and practice of obstetrics. Congratulations are not less due to the medical profession of this country, on the acquisition of a treatise embodying the results of the studies, reflections, and experience of Prof. Miller. Few men, if any, in this country, are more competent than he to write on this department of medicine. Engaged for thirty-five years in an extended practice of obstetrics, for many years a teacher of this branch of instruction in one of the largest of our institutions, a diligent student as well as a careful observer, an original and independent thinker, wedded to no hobbies, ever ready to consider without prejudice new views, and to adopt innovations if they are really improvements, and withal a clear, agreeable writer, a practical treatise from his pen could not fail to possess great value.—*Buffalo Med Journal*.

In fact, this volume must take its place among the standard systematic treatises on obstetrics; a posi-

tion to which its merits justly entitle it. The style is such that the descriptions are clear, and each subject is discussed and elucidated with due regard to its practical bearings, which cannot fail to make it acceptable and valuable to both students and practitioners. We cannot, however, close this brief notice without congratulating the author and the profession on the production of such an excellent treatise. The author is a western man of whom we feel proud, and we cannot but think that his book will find many readers and warm admirers wherever obstetrics is taught and studied as a science and an art.—*The Cincinnati Lancet and Observer*.

A most respectable and valuable addition to our home medical literature, and one reflecting credit alike on the author and the institution to which he is attached. The student will find in this work a most useful guide to his studies; the country practitioner, rusty in his reading, can obtain from its pages a fair resumé of the modern literature of the science; and we hope to see this American production generally consulted by the profession.—*Va. Med. Journal*.

MACKENZIE (W.), M. D.,

Surgeon Oculist in Scotland in ordinary to Her Majesty, &c. &c.

A PRACTICAL TREATISE ON DISEASES AND INJURIES OF THE

EYE. To which is prefixed an Anatomical Introduction explanatory of a Horizontal Section of the Human Eyeball, by THOMAS WHARTON JONES, F. R. S. From the Fourth Revised and Enlarged London Edition. With Notes and Additions by ADDINELL HEWSON, M. D., Surgeon to Wills Hospital, &c. &c. In one very large and handsome octavo volume, leather, raised bands, with plates and numerous wood-cuts. \$5 25.

The treatise of Dr. Mackenzie indisputably holds the first place, and forms, in respect of learning and research, an Encyclopædia unequalled in extent by any other work of the kind, either English or foreign.—*Dixon on Diseases of the Eye*.

Few modern books on any department of medicine or surgery have met with such extended circulation, or have procured for their authors a like amount of European celebrity. The immense research which it displayed, the thorough acquaintance with the subject, practically as well as theoretically, and the

able manner in which the author's stores of learning and experience were rendered available for general use, at once procured for the first edition, as well on the continent as in this country, that high position as a standard work which each successive edition has more firmly established. We consider it the duty of every one who has the love of his profession and the welfare of his patient at heart, to make himself familiar with this the most complete work in the English language upon the diseases of the eye.—*Med. Times and Gazette*.

MAYNE'S DISPENSATORY AND THERAPEUTICAL REMEMBRANCER. With every Practical Formula contained in the three British Pharmacopœias. Edited, with the addition of the Formulæ of the U. S. Pharmacopœia, by R. E. GRIFFITH, M. D. 12mo. vol. ex. cl., 300 pp. 75 c.

MALGAIGNE'S OPERATIVE SURGERY, based on Normal and Pathological Anatomy. Translated from the French by FREDERICK BRITTON, A. B., M. D. With numerous illustrations on wood. In one handsome octavo volume, extra cloth, of nearly six hundred pages. \$2 25.

MILLER (JAMES), F. R. S. E.,
Professor of Surgery in the University of Edinburgh, &c.

PRINCIPLES OF SURGERY. Fourth American, from the third and revised Edinburgh edition. In one large and very beautiful volume, leather, of 700 pages, with two hundred and forty illustrations on wood. \$3 75.

The work of Mr. Miller is too well and too favorably known among us, as one of our best text-books, to render any further notice of it necessary than the announcement of a new edition, the fourth in our country, a proof of its extensive circulation among us. As a concise and reliable exposition of the science of modern surgery, it stands deservedly high—we know not its superior.—*Boston Med. and Surg. Journal.*

The work takes rank with Watson's Practice of Physic; it certainly does not fall behind that great work in soundness of principle or depth of reasoning and research. No physician who values his reputation, or seeks the interests of his clients, can acquit himself before his God and the world without making himself familiar with the sound and philosophical views developed in the foregoing book.—*New Orleans Med. and Surg. Journal.*

BY THE SAME AUTHOR. (Just Issued.)

THE PRACTICE OF SURGERY. Fourth American from the last Edinburgh edition. Revised by the American editor. Illustrated by three hundred and sixty-four engravings on wood. In one large octavo volume, leather, of nearly 700 pages. \$3 75.

No encomium of ours could add to the popularity of Miller's Surgery. Its reputation in this country is unsurpassed by that of any other work, and, when taken in connection with the author's *Principles of Surgery*, constitutes a whole, without reference to which no conscientious surgeon would be willing to practice his art.—*Southern Med. and Surg. Journal.*

It is seldom that two volumes have ever made so profound an impression in so short a time as the "Principles" and the "Practice" of Surgery by Mr. Miller—or so richly merited the reputation they have acquired. The author is an eminently sensible, practical, and well-informed man, who knows exactly what he is talking about and exactly how to talk it.—*Kentucky Medical Recorder.*

By the almost unanimous voice of the profession,

his works, both on the principles and practice of surgery have been assigned the highest rank. If we were limited to but one work on surgery, that one should be Miller's, as we regard it as superior to all others.—*St. Louis Med. and Surg. Journal.*

The author has in this and his "Principles," presented to the profession one of the most complete and reliable systems of Surgery extant. His style of writing is original, impressive, and engaging, energetic, concise, and lucid. Few have the faculty of condensing so much in small space, and at the same time so persistently holding the attention. Whether as a text-book for students or a book of reference for practitioners, it cannot be too strongly recommended.—*Southern Journal of Med. and Physical Sciences.*

MORLAND (W. W.), M. D.,
Fellow of the Massachusetts Medical Society, &c.

DISEASES OF THE URINARY ORGANS; a Compendium of their Diagnosis, Pathology, and Treatment. With illustrations. In one large and handsome octavo volume, of about 600 pages, extra cloth. (Just Issued.) \$3 50.

Taken as a whole, we can recommend Dr. Morland's compendium as a very desirable addition to the library of every medical or surgical practitioner.—*Brit. and For. Med.-Chir. Rev.*, April, 1859.

Every medical practitioner whose attention has been to any extent attracted towards the class of diseases to which this treatise relates, must have often and sorely experienced the want of some full, yet concise recent compendium to which he could

refer. This desideratum has been supplied by Dr. Morland, and it has been ably done. He has placed before us a full, judicious, and reliable digest. Each subject is treated with sufficient minuteness, yet in a succinct, narrative style, such as to render the work one of great interest, and one which will prove in the highest degree useful to the general practitioner.—*N. Y. Journ. of Medicine.*

BY THE SAME AUTHOR —(Now Ready.)

THE MORBID EFFECTS OF THE RETENTION IN THE BLOOD OF THE ELEMENTS OF THE URINARY SECRETION. Being the Dissertation to which the Fiske Fund Prize was awarded, July 11, 1861. In one small octavo volume, 83 pages, extra cloth. 75 cents.

MONTGOMERY (W. F.), M. D., M. R. I. A., &c.,
Professor of Midwifery in the King and Queen's College of Physicians in Ireland, &c.

AN EXPOSITION OF THE SIGNS AND SYMPTOMS OF PREGNANCY. With some other Papers on Subjects connected with Midwifery. From the second and enlarged English edition. With two exquisite colored plates, and numerous wood-cuts. In one very handsome octavo volume, extra cloth, of nearly 600 pages. (Lately Published.) \$3 75.

A book unusually rich in practical suggestions.—*Am. Journal Med. Sciences*, Jan. 1857.

These several subjects so interesting in themselves, and so important, every one of them, to the most delicate and precious of social relations, controlling often the honor and domestic peace of a family, the legitimacy of offspring, or the life of its parent, are all treated with an elegance of diction, fulness of illustrations, acuteness and justice of reasoning, unparalleled in obstetrics, and unsurpassed in medicine. The reader's interest can never flag, so

fresh, and vigorous, and classical is our author's style; and one forgets, in the renewed charm of every page, that it, and every line, and every word has been weighed and reweighed through years of preparation; that this is of all others the book of Obstetric Law, on each of its several topics; on all points connected with pregnancy, to be everywhere received as a manual of special jurisprudence, at once announcing fact, affording argument, establishing precedent, and governing alike the juryman, advocate, and judge.—*N. A. Med.-Chir. Review.*

MOHR (FRANCIS), PH. D., AND REDWOOD (THEOPHILUS).
PRACTICAL PHARMACY. Comprising the Arrangements, Apparatus, and Manipulations of the Pharmaceutical Shop and Laboratory. Edited, with extensive Additions, by Prof. WILLIAM PROCTER, of the Philadelphia College of Pharmacy. In one handsomely printed octavo volume, extra cloth, of 570 pages, with over 500 engravings on wood. \$2 75.

NEILL (JOHN), M. D.,

Surgeon to the Pennsylvania Hospital, &c.; and

FRANCIS GURNEY SMITH, M. D.,

Professor of Institutes of Medicine in the Pennsylvania Medical College.

AN ANALYTICAL COMPENDIUM OF THE VARIOUS BRANCHES OF MEDICAL SCIENCE; for the Use and Examination of Students. A new edition, revised and improved. In one very large and handsomely printed royal 12mo. volume, of about one thousand pages, with 374 wood-cuts. Strongly bound in leather, with raised bands. \$3 00.

The very flattering reception which has been accorded to this work, and the high estimate placed upon it by the profession, as evinced by the constant and increasing demand which has rapidly exhausted two large editions, have stimulated the authors to render the volume in its present revision more worthy of the success which has attended it. It has accordingly been thoroughly examined, and such errors as had on former occasions escaped observation have been corrected, and whatever additions were necessary to maintain it on a level with the advance of science have been introduced. The extended series of illustrations has been still further increased and much improved, while, by a slight enlargement of the page, these various additions have been incorporated without increasing the bulk of the volume.

The work is, therefore, again presented as eminently worthy of the favor with which it has hitherto been received. As a book for daily reference by the student requiring a guide to his more elaborate text-books, as a manual for preceptors desiring to stimulate their students by frequent and accurate examination, or as a source from which the practitioners of older date may easily and cheaply acquire a knowledge of the changes and improvement in professional science, its reputation is permanently established.

The best work of the kind with which we are acquainted.—*Med. Examiner.*

Having made free use of this volume in our examinations of pupils, we can speak from experience in recommending it as an admirable compend for students, and as especially useful to preceptors who examine their pupils. It will save the teacher much labor by enabling him readily to recall all of the points upon which his pupils should be examined. A work of this sort should be in the hands of every one who takes pupils into his office with a view of examining them; and this is unquestionably the best of its class.—*Pennsylvania Med. Journal.*

In the rapid course of lectures, where work for

the students is heavy, and review necessary for an examination, a compend is not only valuable, but it is almost a *sine qua non*. The one before us is, in most of the divisions, the most unexceptionable of all books of the kind that we know of. The newest and soundest doctrines and the latest improvements and discoveries are explicitly, though concisely, laid before the student. There is a class to whom we very sincerely commend this cheap book as worth its weight in silver—that class is the graduates in medicine of more than ten years' standing, who have not studied medicine since. They will perhaps find out from it that the science is not exactly now what it was when they left it off.—*The Stethoscope.*

NELIGAN (J. MOORE), M. D., M. R. I. A., &c.

ATLAS OF CUTANEOUS DISEASES. In one beautiful quarto volume, extra cloth, with splendid colored plates, presenting nearly one hundred elaborate representations of disease. \$4 50.

This beautiful volume is intended as a complete and accurate representation of all the varieties of Diseases of the Skin. While it can be consulted in conjunction with any work on Practice, it has especial reference to the author's "Treatise on Diseases of the Skin," so favorably received by the profession some years since. The publishers feel justified in saying that few more beautifully executed plates have ever been presented to the profession of this country.

Neligan's Atlas of Cutaneous Diseases supplies a long existent desideratum much felt by the largest class of our profession. It presents, in quarto size, 16 plates, each containing from 3 to 6 figures, and forming in all a total of 90 distinct representations of the different species of skin affections, grouped together in genera or families. The illustrations have been taken from nature, and have been copied with such fidelity that they present a striking picture of life; in which the reduced scale aptly serves to

give, at a *coup d'œil*, the remarkable peculiarities of each individual variety. And while thus the disease is rendered more definable, there is yet no loss of proportion incurred by the necessary concentration. Each figure is highly colored, and so truthful has the artist been that the most fastidious observer could not justly take exception to the correctness of the execution of the pictures under his scrutiny.—*Montreal Med. Chronicle.*

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. Third American edition. In one neat royal 12mo. volume, extra cloth, of 334 pages. \$1 00.

 The two volumes will be sent by mail on receipt of *Five Dollars*.

OWEN ON THE DIFFERENT FORMS OF THE SKELETON, AND OF THE TEETH.

One vol. royal 12mo., extra cloth with numerous illustrations. \$1 25

PIRRIE (WILLIAM), F. R. S. E.,

Professor of Surgery in the University of Aberdeen.

THE PRINCIPLES AND PRACTICE OF SURGERY. Edited by JOHN NEILL, M. D., Professor of Surgery in the Penna. Medical College, Surgeon to the Pennsylvania Hospital, &c. In one very handsome octavo volume, leather, of 780 pages, with 316 illustrations. \$3 75.

We know of no other surgical work of a reasonable size, wherein there is so much theory and practice, or where subjects are more soundly or clearly taught.—*The Stethoscope.*

Prof. Pirrie, in the work before us, has elabo-

ately discussed the principles of surgery, and a safe and effectual practice predicated upon them. Perhaps no work upon this subject heretofore issued is so full upon the science of the art of surgery.—*Nashville Journal of Medicine and Surgery.*

PARRISH (EDWARD),

Lecturer on Practical Pharmacy and Materia Medica in the Pennsylvania Academy of Medicine, &c.

AN INTRODUCTION TO PRACTICAL PHARMACY. Designed as a Text-Book for the Student, and as a Guide for the Physician and Pharmacist. With many Formulæ and Prescriptions. Second edition, greatly enlarged and improved. In one handsome octavo volume of 720 pages, with several hundred illustrations, extra cloth. \$3 50. (*Just Issued.*)

During the short time in which this work has been before the profession, it has been received with very great favor, and in assuming the position of a standard authority, it has filled a vacancy which had been severely felt. Stimulated by this encouragement, the author, in availing himself of the opportunity of revision, has spared no pains to render it more worthy of the confidence bestowed upon it, and his assiduous labors have made it rather a new book than a new edition, many portions having been rewritten, and much new and important matter added. These alterations and improvements have been rendered necessary by the rapid progress made by pharmaceutical science during the last few years, and by the additional experience obtained in the practical use of the volume as a text-book and work of reference. To accommodate these improvements, the size of the page has been materially enlarged, and the number of pages considerably increased, presenting in all nearly *one-half more* matter than the last edition. The work is therefore now presented as a complete exponent of the subject in its most advanced condition. From the most ordinary matters in the dispensing office, to the most complicated details of the vegetable alkaloids, it is hoped that everything requisite to the practising physician, and to the apothecary, will be found fully and clearly set forth, and that the new matter alone will be worth more than the very moderate cost of the work to those who have been consulting the previous edition.

That Edward Parrish, in writing a book upon practical Pharmacy some few years ago—one eminently original and unique—did the medical and pharmaceutical professions a great and valuable service, no one, we think, who has had access to its pages will deny; doubly welcome, then, is this new edition, containing the added results of his recent and rich experience as an observer, teacher, and practical operator in the pharmaceutical laboratory. The excellent plan of the first is more thoroughly, and in detail, carried out in this edition.—*Peninsular Med. Journal*, Jan. 1860.

Of course, all apothecaries who have not already a copy of the first edition will procure one of this; it is, therefore, to physicians residing in the country and in small towns, who cannot avail themselves of the skill of an educated pharmacist, that we would especially commend this work. In it they

will find all that they desire to know, and should know, but very little of which they do really know in reference to this important collateral branch of their profession; for it is a well established fact, that, in the education of physicians, while the science of medicine is generally well taught, very little attention is paid to the art of preparing them for use, and we know not how this defect can be so well remedied as by procuring and consulting Dr. Parrish's excellent work.—*St. Louis Med. Journal*, Jan. 1860.

We know of no work on the subject which would be more indispensable to the physician or student desiring information on the subject of which it treats. With Griffith's "Medical Formulæ" and this, the practising physician would be supplied with nearly or quite all the most useful information on the subject.—*Charleston Med. Jour. and Review*, Jan. 1860.

PEASLEE (E. R.), M. D.,

Professor of Physiology and General Pathology in the New York Medical College.

HUMAN HISTOLOGY, in its relations to Anatomy, Physiology, and Pathology; for the use of Medical Students. With four hundred and thirty-four illustrations. In one handsome octavo volume, of over 600 pages. (*Lately Published.*) \$3 75.

It embraces a library upon the topics discussed within itself, and is just what the teacher and learner need. Another advantage, by no means to be overlooked, everything of real value in the wide range which it embraces, is with great skill compressed into an octavo volume of but little more than six hundred pages. We have not only the whole subject of Histology, interesting in itself, ably and fully discussed, but what is of infinitely greater interest to the student, because of greater practical value, are its relations to Anatomy, Physiology, and Pathology, which are here fully and satisfactorily set forth.—*Nashville Journ. of Med. and Surgery*.

We would recommend it to the medical student and practitioner, as containing a summary of all that is known of the important subjects which it treats; of all that is contained in the great works of Simon and Lehmann, and the organic chemists in general. Master this one volume, we would say to the medical student and practitioner—master this book and you know all that is known of the great fundamental principles of medicine, and we have no hesitation in saying that it is an honor to the American medical profession that one of its members should have produced it.—*St. Louis Med. and Surg. Journal*.

PEREIRA (JONATHAN), M. D., F. R. S., AND L. S.

THE ELEMENTS OF MATERIA MEDICA AND THERAPEUTICS.

Third American edition, enlarged and improved by the author; including Notices of most of the Medicinal Substances in use in the civilized world, and forming an Encyclopædia of Materia Medica. Edited, with Additions, by JOSEPH CARSON, M. D., Professor of Materia Medica and Pharmacy in the University of Pennsylvania. In two very large octavo volumes of 2100 pages, on small type, with about 500 illustrations on stone and wood, strongly bound in leather, with raised bands. \$9 00.

*** Vol. II. will no longer be sold separate.

PARKER (LANGSTON),

Surgeon to the Queen's Hospital, Birmingham.

THE MODERN TREATMENT OF SYPHILITIC DISEASES, BOTH PRIMARY AND SECONDARY; comprising the Treatment of Constitutional and Confirmed Syphilis, by a safe and successful method. With numerous Cases, Formulæ, and Clinical Observations. From the Third and entirely rewritten London edition. In one neat octavo volume, extra cloth, of 316 pages. \$1 75.

ROYLE'S MATERIA MEDICA AND THERAPEUTICS; including the Preparations of the Pharmacopœias of London, Edinburgh, Dublin, and of the United States. With many new medicines. Edited by JOSEPH CARSON, M. D. With ninety-eight illustrations. In one large octavo volume, extra cloth, of about 700 pages. \$3 00.

RAMSBOTHAM (FRANCIS H.), M. D.

THE PRINCIPLES AND PRACTICE OF OBSTETRIC MEDICINE AND

SURGERY, in reference to the Process of Parturition. A new and enlarged edition, thoroughly revised by the Author. With Additions by W. V. KEATING, M. D., Professor of Obstetrics, &c., in the Jefferson Medical College, Philadelphia. In one large and handsome imperial octavo volume, of 650 pages, strongly bound in leather, with raised bands; with sixty-four beautiful Plates, and numerous Wood-cuts in the text, containing in all nearly 200 large and beautiful figures. \$5 00.

From Prof. Hodge, of the University of Pa.

To the American public, it is most valuable, from its intrinsic undoubted excellence, and as being the best authorized exponent of British Midwifery. Its circulation will, I trust, be extensive throughout our country.

It is unnecessary to say anything in regard to the utility of this work. It is already appreciated in our country for the value of the matter, the clearness of its style, and the fulness of its illustrations. To the physician's library it is indispensable, while to the student as a text-book, from which to extract the material for laying the foundation of an education on obstetrical science, it has no superior.—*Ohio Med and Surg. Journal*.

The publishers have secured its success by the

truly elegant style in which they have brought it out, excelling themselves in its production, especially in its plates. It is dedicated to Prof. Meigs, and has the emphatic endorsement of Prof. Hodge, as the best exponent of British Midwifery. We know of no text-book which deserves in all respects to be more highly recommended to students, and we could wish to see it in the hands of every practitioner, for they will find it invaluable for reference.—*Med. Gazette*.

RICORD (P.), M. D.

A TREATISE ON THE VENEREAL DISEASE. By JOHN HUNTER, F. R. S.

With copious Additions, by PH. RICORD, M. D. Translated and Edited, with Notes, by FREEMAN J. BUMSTEAD, M. D., Lecturer on Venereal at the College of Physicians and Surgeons, New York. Second edition, revised, containing a *résumé* of RICORD'S RECENT LECTURES ON CHANCERE. In one handsome octavo volume, extra cloth, of 550 pages, with eight plates. \$3 25. (Just Issued.)

In revising this work, the editor has endeavored to introduce whatever matter of interest the recent investigations of syphilographers have added to our knowledge of the subject. The principal source from which this has been derived is the volume of "Lectures on Chancere," published a few months since by M. Ricord, which affords a large amount of new and instructive material on many controverted points. In the previous edition, M. Ricord's additions amounted to nearly one-third of the whole, and with the matter now introduced, the work may be considered to present his views and experience more thoroughly and completely than any other.

Every one will recognize the attractiveness and value which this work derives from thus presenting the opinions of these two masters side by side. But, it must be admitted, what has made the fortune of the book, is the fact that it contains the "most complete embodiment of the veritable doctrines of the Hôpital du Midi," which has ever been made public. The doctrinal ideas of M. Ricord, ideas which, if not universally adopted, are incontestably dominant, have heretofore only been interpreted by more or less skillful

secretaries, sometimes accredited and sometimes not.

In the notes to Hunter, the master substitutes himself for his interpreters, and gives his original thoughts to the world in a lucid and perfectly intelligible manner. In conclusion we can say that this is incontestably the best treatise on syphilis with which we are acquainted, and, as we do not often employ the phrase, we may be excused for expressing the hope that it may find a place in the library of every physician.—*Virginia Med. and Surg. Journal*.

BY THE SAME AUTHOR.

RICORD'S LETTERS ON SYPHILIS. Translated by W. P. LATTIMORE, M. D.

In one neat octavo volume, of 270 pages, extra cloth. \$2 00.

ROKITANSKY (CARL), M. D.,

Curator of the Imperial Pathological Museum, and Professor at the University of Vienna, &c.

A MANUAL OF PATHOLOGICAL ANATOMY. Four volumes, octavo,

bound in two, extra cloth, of about 1200 pages. Translated by W. E. SWAINE, EDWARD SIEVEKING, C. H. MOORE, and G. E. DAY. \$5 50.

The profession is too well acquainted with the reputation of Rokitansky's work to need our assurance that this is one of the most profound, thorough, and valuable books ever issued from the medical press. It is *sui generis*, and has no standard of comparison. It is only necessary to announce that it is issued in a form as cheap as is compatible with its size and preservation, and its sale follows as a matter of course. No library can be called complete without it.—*Buffalo Med. Journal*.

An attempt to give our readers any adequate idea of the vast amount of instruction accumulated in these volumes, would be feeble and hopeless. The effort of the distinguished author to concentrate in a small space his great fund of knowledge, has

so charged his text with valuable truths, that any attempt of a reviewer to epitomize is at once paralyzed, and must end in a failure.—*Western Lancet*.

As this is the highest source of knowledge upon the important subject of which it treats, no real student can afford to be without it. The American publishers have entitled themselves to the thanks of the profession of their country, for this timely and beautiful edition.—*Nashville Journal of Medicine*.

As a book of reference, therefore, this work must prove of inestimable value, and we cannot too highly recommend it to the profession.—*Charleston Med. Journal and Review*.

This book is a necessity to every practitioner.—*Am. Med. Monthly*.

RIGBY (EDWARD), M. D.,

Senior Physician to the General Lying-in Hospital, &c.

A SYSTEM OF MIDWIFERY. With Notes and Additional Illustrations.

Second American Edition. One volume octavo, extra cloth, 422 pages. \$2 50.

BY THE SAME AUTHOR. (Lately Published.)

ON THE CONSTITUTIONAL TREATMENT OF FEMALE DISEASES.

In one neat royal 12mo. volume, extra cloth, of about 250 pages. \$1 00.

STILLE (ALFRED), M. D.

THERAPEUTICS AND MATERIA MEDICA; a Systematic Treatise on the

Action and Uses of Medicinal Agents, including their Description and History. In two large and handsome octavo volumes, of 1789 pages. (Just Issued.) \$8 00.

This work is designed especially for the student and practitioner of medicine, and treats the various articles of the *Materia Medica* from the point of view of the bedside, and not of the shop or of the lecture-room. While thus endeavoring to give all practical information likely to be useful with respect to the employment of special remedies in special affections, and the results to be anticipated from their administration, a copious Index of Diseases and their Remedies renders the work eminently fitted for reference by showing at a glance the different means which have been employed, and enabling the practitioner to extend his resources in difficult cases with all that the experience of the profession has suggested.

Rarely, indeed, have we had submitted to us a work on medicine so ponderous in its dimensions as that now before us, and yet so fascinating in its contents. It is, therefore, with a peculiar gratification that we recognize in Dr. Stille the possession of many of those more distinguished qualifications which entitle him to approbation, and which justify him in coming before his medical brethren as an instructor. A comprehensive knowledge, tested by a sound and penetrating judgment, joined to a love of progress—which a discriminating spirit of inquiry has tempered so as to accept nothing new because it is new, and abandon nothing old because it is old, but which estimates either according to its relations to a just logic and experience—manifests itself everywhere, and gives to the guidance of the author all the assurance of safety which the difficulties of his subject can allow. In conclusion, we earnestly advise our readers to ascertain for themselves, by a study of Dr. Stille's volumes, the great value and interest of the stores of knowledge they present. We have pleasure in referring rather to the ample treasury of undoubted truths, the real and assured conquest of medicine, accumulated by Dr. Stille in his pages; and commend the sum of his labors to the attention of our readers, as alike honorable to our science, and creditable to the zeal, the candor, and the judgment of him who has garnered the whole so carefully.—*Edinburgh Med. Journal*.

Our expectations of the value of this work were based on the well-known reputation and character of the author as a man of scholarly attainments, an elegant writer, a candid inquirer after truth, and a philosophical thinker; we knew that the task would be conscientiously performed, and that few, if any, among the distinguished medical teachers in this country are better qualified than he to prepare a systematic treatise on therapeutics in accordance with the present requirements of medical science. Our preliminary examination of the work has satis-

fied us that we were not mistaken in our anticipations.—*New Orleans Medical News*, March, 1860.

The most recent authority is the one last mentioned, Stille. His great work on "*Materia Medica and Therapeutics*," published last year, in two octavo volumes, of some sixteen hundred pages, while it embodies the results of the labor of others up to the time of publication, is enriched with a great amount of original observation and research. We would draw attention, by the way, to the very convenient mode in which the *Index* is arranged in this work. There is first an "*Index of Remedies*;" next an "*Index of Diseases and their Remedies*." Such an arrangement of the Indices, in our opinion, greatly enhances the practical value of books of this kind. In tedious, obstinate cases of disease, where we have to try one remedy after another until our stock is pretty nearly exhausted, and we are almost driven to our wit's end, such an index as the second of the two just mentioned, is precisely what we want.—*London Med. Times and Gazette*, April, 1861.

We think this work will do much to obviate the reluctance to a thorough investigation of this branch of scientific study, for in the wide range of medical literature treasured in the English tongue, we shall hardly find a work written in a style more clear and simple, conveying forcibly the facts taught, and yet free from turgidity and redundancy. There is a fascination in its pages that will insure to it a wide popularity and attentive perusal, and a degree of usefulness not often attained through the influence of a single work. The author has much enhanced the practical utility of his book by passing briefly over the physical, botanical, and commercial history of medicines, and directing attention chiefly to their physiological action, and their application for the amelioration or cure of disease. He ignores hypothesis and theory which are so alluring to many medical writers, and so liable to lead them astray, and confines himself to such facts as have been tried in the crucible of experience.—*Chicago Medical Journal*.

SMITH (HENRY H.), M. D. AND HORNER (WILLIAM E.), M. D.

AN ANATOMICAL ATLAS, illustrative of the Structure of the Human Body.

In one volume, large imperial octavo, extra cloth, with about six hundred and fifty beautiful figures. \$3 00.

These figures are well selected, and present a complete and accurate representation of that wonderful fabric, the human body. The plan of this Atlas, which renders it so peculiarly convenient for the student, and its superb artistic execution, have been already pointed out. We must congratulate

late the student upon the completion of this Atlas as it is the most convenient work of the kind that has yet appeared; and we must add, the very beautiful manner in which it is "got up" is so creditable to the country as to be flattering to our national pride.—*American Medical Journal*.

SHARPEY (WILLIAM), M. D., JONES QUAIN, M. D., AND RICHARD QUAIN, F. R. S., &c.

HUMAN ANATOMY. Revised, with Notes and Additions, by JOSEPH LEIDY,

M. D., Professor of Anatomy in the University of Pennsylvania. Complete in two large octavo volumes, leather, of about thirteen hundred pages. Beautifully illustrated with over five hundred engravings on wood. \$6 00.

SIMPSON (J. Y.), M. D.,

Professor of Midwifery, &c., in the University of Edinburgh, &c.

CLINICAL LECTURES ON THE DISEASES OF FEMALES. With numerous illustrations.

This valuable series of practical Lectures is now appearing in the "*MEDICAL NEWS AND LIBRARY*" for 1860, 1861, and 1862, and can thus be had without cost by subscribers to the "*AMERICAN JOURNAL OF THE MEDICAL SCIENCES*." See p. 2.

SOLLY ON THE HUMAN BRAIN; its Structure, Physiology, and Diseases. From the Second and much enlarged London edition. In one octavo volume, extra cloth, of 500 pages, with 120 wood-cuts. \$2 00.

KEY'S OPERATIVE SURGERY. In one very

handsome octavo volume, extra cloth, of over 650 pages, with about one hundred wood-cuts. \$3 25.

SIMON'S GENERAL PATHOLOGY, as conducive to the Establishment of Rational Principles for the prevention and Cure of Disease. In one octavo volume, extra cloth, of 212 pages. \$1 25.

SARGENT (F. W.), M. D.

ON BANDAGING AND OTHER OPERATIONS OF MINOR SURGERY.

New edition, with an additional chapter on Military Surgery. One handsome royal 12mo. vol., of nearly 400 pages, with 184 wood cuts. Leather, \$1 50. (*Now Ready*)

The value of this work as a handy and convenient manual for surgeons engaged in active duty in the field and hospital, has induced the publishers to render it more complete for those purposes by the addition of a chapter on gun-shot wounds and other matters peculiar to military surgery. In its present form, therefore, with no increase in price, it will be found a very cheap and convenient vade-mecum for consultation and reference in the daily exigencies of military as well as civil practice.

We have read Bourgerie's Minor Surgery with pleasure and profit, but in many respects the volume now before us immeasurably transcends it. We consider that no better book could be placed in the hands of an hospital dresser, or the young surgeon, whose education in this respect has not been perfected. We most cordially commend this volume as one which the medical student should most closely study, to perfect himself in these minor surgical operations in which neatness and dexterity are so much required, and on which a great portion of his reputation as a future surgeon must evidently rest. And to the surgeon in practice it must prove itself a valuable volume, as instructive on many points which he may have forgotten.—*British American Journal*, May, 1862.

The instruction given upon the subject of *Bandaging*, is alone of great value, and while the author modestly proposes to instruct the students of medicine, and the younger physicians, we will say that experienced physicians will obtain many exceedingly valuable suggestions by its perusal. Without attempting to particularize further, we will conclude our brief notice by saying, that it will be found one of the most satisfactory manuals for reference in the field, or hospital yet published; thoroughly adapted to the wants of Military surgeons, and at the same time equally useful for ready and convenient reference by surgeons everywhere.—*Buffalo Med. and Surg. Journal*, June, 1862.

SMITH (W. TYLER), M. D.,

Physician Accoucheur to St. Mary's Hospital, &c.

ON PARTURITION, AND THE PRINCIPLES AND PRACTICE OF OBSTETRICS. In one royal 12mo. volume, extra cloth, of 400 pages. \$1 25.

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON THE PATHOLOGY AND TREATMENT OF LEUCORRHOEA. With numerous illustrations. In one very handsome octavo volume, extra cloth, of about 250 pages. \$1 50.

TANNER (T. H.), M. D.,

Physician to the Hospital for Women, &c.

A MANUAL OF CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS.

To which is added The Code of Ethics of the American Medical Association. Second American Edition. In one neat volume, small 12mo., extra cloth, 87½ cents.

TAYLOR (ALFRED S.), M. D., F. R. S.,

Lecturer on Medical Jurisprudence and Chemistry in Guy's Hospital.

MEDICAL JURISPRUDENCE. Fifth American, from the seventh improved and enlarged London edition. With Notes and References to American Decisions, by EDWARD HARTSHORNE, M. D. In one large 8vo. volume, leather, of over 700 pages. (*Now Ready*.) \$3 25.

This standard work having had the advantage of two revisions at the hands of the author since the appearance of the last American edition, will be found thoroughly revised and brought up completely to the present state of the science. As a work of authority, it must therefore maintain its position, both as a text-book for the student, and a compendious treatise to which the practitioner can at all times refer in cases of doubt or difficulty.

No work upon the subject can be put into the hands of students either of law or medicine which will engage them more closely or profitably; and none could be offered to the busy practitioner of either calling, for the purpose of casual or hasty reference, that would be more likely to afford the aid desired. We therefore recommend it as the best and safest manual for daily use.—*American Journal of Medical Sciences*.

It is not excess of praise to say that the volume before us is the very best treatise extant on Medical Jurisprudence. In saying this, we do not wish to be understood as detracting from the merits of the excellent works of Beck, Ryan, Traill, Guy, and others; but in interest and value we think it must be conceded that Taylor is superior to anything that has preceded it.—*N. W. Medical and Surg. Journal*.

It is at once comprehensive and eminently practical, and by universal consent stands at the head of

American and British legal medicine. It should be in the possession of every physician, as the subject is one of great and increasing importance to the public as well as to the profession.—*St. Louis Med. and Surg. Journal*.

This work of Dr. Taylor's is generally acknowledged to be one of the ablest extant on the subject of medical jurisprudence. It is certainly one of the most attractive books that we have met with; supplying so much both to interest and instruct, that we do not hesitate to affirm that after having once commenced its perusal, few could be prevailed upon to desist before completing it. In the last London edition, all the newly observed and accurately recorded facts have been inserted, including much that is recent of Chemical, Microscopical, and Pathological research, besides papers on numerous subjects never before published.—*Charleston Med. Journal and Review*.

BY THE SAME AUTHOR.

ON POISONS, IN RELATION TO MEDICAL JURISPRUDENCE AND MEDICINE. Second American, from a second and revised London edition. In one large octavo volume, of 755 pages, leather. \$3 50.

Mr. Taylor's position as the leading medical jurist of England, has conferred on him extraordinary advantages in acquiring experience on these subjects, nearly all cases of moment being referred to him for examination, as an expert whose testimony is generally accepted as final. The results of his labors, therefore, as gathered together in this volume, carefully weighed and sifted, and presented in the clear and intelligible style for which he is noted, may be received as an acknowledged authority, and as a guide to be followed with implicit confidence.

TODD (ROBERT BENTLEY), M. D., F. R. S.,
Professor of Physiology in King's College, London; and

WILLIAM BOWMAN, F. R. S.,
Demonstrator of Anatomy in King's College, London.

THE PHYSIOLOGICAL ANATOMY AND PHYSIOLOGY OF MAN. With about three hundred large and beautiful illustrations on wood. Complete in one large octavo volume, of 950 pages, leather. Price \$4 50.

Gentlemen who have received portions of this work, as published in the "MEDICAL NEWS AND LIBRARY," can now complete their copies, if immediate application be made. It will be furnished as follows, free by mail, in paper covers, with cloth backs.

PARTS I., II., III. (pp. 25 to 552), \$2 50.

PART IV. (pp. 553 to end, with Title, Preface, Contents, &c.), \$2 00.

Or, PART IV., SECTION II. (pp. 725 to end, with Title, Preface, Contents, &c.), \$1 25.

A magnificent contribution to British medicine, and the American physician who shall fail to peruse it, will have failed to read one of the most instructive books of the nineteenth century.—*N. O. Med. and Surg. Journal*.

It is more concise than Carpenter's Principles, and more modern than the accessible edition of Müller's Elements; its details are brief, but sufficient; its descriptions vivid; its illustrations exact and copious; and its language terse and perspicuous.—*Charleston Med. Journal*.

We know of no work on the subject of physiology

so well adapted to the wants of the medical student. Its completion has been thus long delayed, that the authors might secure accuracy by personal observation.—*St. Louis Med. and Surg. Journal*.

Our notice, though it conveys but a very feeble and imperfect idea of the magnitude and importance of the work now under consideration, already transcends our limits; and, with the indulgence of our readers, and the hope that they will peruse the book for themselves, as we feel we can with confidence recommend it, we leave it in their hands.—*The Northwestern Med. and Surg. Journal*.

TODD (R. B.) M. D., F. R. S., &c.

CLINICAL LECTURES ON CERTAIN DISEASES OF THE URINARY ORGANS AND ON DROPSIES. In one octavo volume, 284 pages. \$1 50.

BY THE SAME AUTHOR. (*New Ready.*)

CLINICAL LECTURES ON CERTAIN ACUTE DISEASES. In one neat octavo volume, of 320 pages, extra cloth. \$1 75.

TOYNBEE (JOSEPH), F. R. S.,

Aural Surgeon to, and Lecturer on Surgery at, St. Mary's Hospital.

A PRACTICAL TREATISE ON DISEASES OF THE EAR; their Diagnosis, Pathology, and Treatment. Illustrated with one hundred engravings on wood. In one very handsome octavo volume, extra cloth, \$3 00. (*Just Issued.*)

The work, as was stated at the outset of our notice, is a model of its kind, and every page and paragraph of it are worthy of the most thorough study. Considered all in all—as an original work, well written, philosophically elaborated, and happily illustrated with cases and drawings—it is by far the ablest monograph that has ever appeared on the anatomy and diseases of the ear, and one of the most valuable contributions to the art and science of surgery in the nineteenth century.—*N. Amer. Medico-Chirurg. Review*, Sept. 1860.

To recommend such a work, even after the mere hint we have given of its original excellence and value, would be a work of supererogation. We are speaking within the limits of modest acknowledg-

ment, and with a sincere and unbiassed judgment, when we affirm that as a treatise on Aural Surgery, it is without a rival in our language or any other.—*Charleston Med. Journ. and Review*, Sept. 1860.

The work of Mr. Toynbee is undoubtedly, upon the whole, the most valuable production of the kind in any language. The author has long been known by his numerous monographs upon subjects connected with diseases of the ear, and is now regarded as the highest authority on most points in his department of science. Mr. Toynbee's work, as we have already said, is undoubtedly the most reliable guide for the study of the diseases of the ear in any language, and should be in the library of every physician.—*Chicago Med. Journal*, July, 1860.

WILLIAMS (C. J. B.), M. D., F. R. S.,

Professor of Clinical Medicine in University College, London, &c.

PRINCIPLES OF MEDICINE. An Elementary View of the Causes, Nature, Treatment, Diagnosis, and Prognosis of Disease; with brief remarks on Hygienics, or the preservation of health. A new American, from the third and revised London edition. In one octavo volume, leather, of about 500 pages. \$2 50. (*Just Issued.*)

We find that the deeply-interesting matter and style of this book have so far fascinated us, that we have unconsciously hung upon its pages, not too long, indeed, for our own profit, but longer than reviewers can be permitted to indulge. We leave the further analysis to the student and practitioner. Our judgment of the work has already been sufficiently

expressed. It is a judgment of almost unqualified praise.—*London Lancet*.

A text-book to which no other in our language is comparable.—*Charleston Medical Journal*.

No work has ever achieved or maintained a more deserved reputation.—*Va. Med. and Surg. Journal*.

WHAT TO OBSERVE

AT THE BEDSIDE AND AFTER DEATH, IN MEDICAL CASES.

Published under the authority of the London Society for Medical Observation. A new American, from the second and revised London edition. In one very handsome volume, royal 12mo., extra cloth. \$1 00.

To the observer who prefers accuracy to blunders and precision to carelessness, this little book is invaluable.—*N. H. Journal of Medicine*.

One of the finest aids to a young practitioner we have ever seen.—*Peninsular Journal of Medicine*.

New and much enlarged edition—(Just Issued.)

WATSON (THOMAS), M. D., &c.,

Late Physician to the Middlesex Hospital, &c.

LECTURES ON THE PRINCIPLES AND PRACTICE OF PHYSIC.

Delivered at King's College, London. A new American, from the last revised and enlarged English edition, with Additions, by D. FRANCIS CONDIE, M. D., author of "A Practical Treatise on the Diseases of Children," &c. With one hundred and eighty-five illustrations on wood. In one very large and handsome volume, imperial octavo, of over 1200 closely printed pages in small type; the whole strongly bound in leather, with raised bands. Price \$4 25.

That the high reputation of this work might be fully maintained, the author has subjected it to a thorough revision; every portion has been examined with the aid of the most recent researches in pathology, and the results of modern investigations in both theoretical and practical subjects have been carefully weighed and embodied throughout its pages. The watchful scrutiny of the editor has likewise introduced whatever possesses immediate importance to the American physician in relation to diseases incident to our climate which are little known in England, as well as those points in which experience here has led to different modes of practice; and he has also added largely to the series of illustrations, believing that in this manner valuable assistance may be conveyed to the student in elucidating the text. The work will, therefore, be found thoroughly on a level with the most advanced state of medical science on both sides of the Atlantic.

The additions which the work has received are shown by the fact that notwithstanding an enlargement in the size of the page, more than two hundred additional pages have been necessary to accommodate the two large volumes of the London edition (which sells at ten dollars), within the compass of a single volume, and in its present form it contains the matter of at least three ordinary octavos. Believing it to be a work which should lie on the table of every physician, and be in the hands of every student, the publishers have put it at a price within the reach of all, making it one of the cheapest books as yet presented to the American profession, while at the same time the beauty of its mechanical execution renders it an exceedingly attractive volume.

The fourth edition now appears, so carefully revised, as to add considerably to the value of a book already acknowledged, wherever the English language is read, to be beyond all comparison the best systematic work on the Principles and Practice of Physic in the whole range of medical literature. Every lecture contains proof of the extreme anxiety of the author to keep pace with the advancing knowledge of the day, and to bring the results of the labors, not only of physicians, but of chemists and histologists, before his readers, wherever they can be turned to useful account. One scarcely knows whether to admire most the pure, simple, forcible English—the vast amount of useful practical information condensed into the Lectures—or the manly, kind-hearted, unassuming character of the lecturer shining through his work.—*Lond. Med. Times.*

Thus these admirable volumes come before the profession in their fourth edition, abounding in those distinguished attributes of moderation, judgment, erudite cultivation, clearness, and eloquence, with which they were from the first invested, but yet richer than before in the results of more prolonged observation, and in the able appreciation of the latest advances in pathology and medicine by one of the most profound medical thinkers of the day.—*London Lancet.*

The lecturer's skill, his wisdom, his learning, are equalled by the ease of his graceful diction, his eloquence, and the far higher qualities of candor, of courtesy, of modesty, and of generous appreciation of merit in others.—*N. A. Med.-Chir. Review.*

Watson's unrivalled, perhaps unapproachable work on Practice—the copious additions made to which (the fourth edition) have given it all the novelty and much of the interest of a new book.—*Charleston Med. Journal.*

Lecturers, practitioners, and students of medicine will equally hail the reappearance of the work of Dr. Watson in the form of a new—a fourth—edition. We merely do justice to our own feelings, and, we are sure, of the whole profession, if we thank him for having, in the trouble and turmoil of a large practice, made leisure to supply the hiatus caused by the exhaustion of the publisher's stock of the third edition, which has been severely felt for the last three years. For Dr. Watson has not merely caused the lectures to be reprinted, but scattered through the whole work we find additions or alterations which prove that the author has in every way sought to bring up his teaching to the level of the most recent acquisitions in science.—*Brit. and For. Medico-Chir. Review.*

WALSHE (W. H.), M. D.,

Professor of the Principles and Practice of Medicine in University College, London, &c.

A PRACTICAL TREATISE ON DISEASES OF THE LUNGS; including the Principles of Physical Diagnosis. A new American, from the third revised and much enlarged London edition. In one vol. octavo, of 468 pages. \$2 25.

The present edition has been carefully revised and much enlarged, and may be said in the main to be rewritten. Descriptions of several diseases, previously omitted, are now introduced; the causes and mode of production of the more important affections, so far as they possess direct practical significance, are succinctly inquired into; an effort has been made to bring the description of anatomical characters to the level of the wants of the practical physician; and the diagnosis and prognosis of each complaint are more completely considered. The sections on TREATMENT and the Appendix (concerning the influence of climate on pulmonary disorders), have, especially, been largely extended.—*Author's Preface.*

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON THE DISEASES OF THE HEART AND GREAT VESSELS, including the Principles of Physical Diagnosis. Third American, from the third revised and much enlarged London edition. In one handsome octavo volume of 420 pages, extra cloth. \$2 25. (Just Ready.)

From the Author's Preface.

The present edition has been carefully revised; much new matter has been added, and the entire work in a measure remodelled. Numerous facts and discussions, more or less completely novel, will be found in the description of the principles of physical diagnosis; but the chief additions have been made in the practical portions of the book. Several affections, of which little or no account had been given in the previous editions, are now treated of in detail. Functional disorders of the heart, the frequency of which is almost rivalled by the misery they inflict, have been closely reconsidered; more especially an attempt has been made to render their essential nature clearer, and consequently their treatment more successful, by an analysis of their dynamic elements.

New and much enlarged edition—(Just Issued.)

WILSON (ERASMUS), F. R. S.

A SYSTEM OF HUMAN ANATOMY, General and Special. A new and revised American, from the last and enlarged English Edition. Edited by W. H. GOBRECHT, M. D., Professor of Anatomy in the Pennsylvania Medical College, &c. Illustrated with three hundred and ninety-seven engravings on wood. In one large and exquisitely printed octavo volume, of over 600 large pages; leather. \$3 25.

The publishers trust that the well earned reputation so long enjoyed by this work will be more than maintained by the present edition. Besides a very thorough revision by the author, it has been most carefully examined by the editor, and the efforts of both have been directed to introducing everything which increased experience in its use has suggested as desirable to render it a complete text-book for those seeking to obtain or to renew an acquaintance with Human Anatomy. The amount of additions which it has thus received may be estimated from the fact that the present edition contains over one-fourth more matter than the last, rendering a smaller type and an enlarged page requisite to keep the volume within a convenient size. The editor has exercised the utmost caution to obtain entire accuracy in the text, and has largely increased the number of illustrations, of which there are about one hundred and fifty more in this edition than in the last, thus bringing distinctly before the eye of the student everything of interest or importance.

It may be recommended to the student as no less distinguished by its accuracy and clearness of description than by its typographical elegance. The wood-cuts are exquisite.—*Brit. and For. Medical Review.*

An elegant edition of one of the most useful and accurate systems of anatomical science which has been issued from the press. The illustrations are really beautiful. In its style the work is extremely concise and intelligible. No one can possibly take up this volume without being struck with the great

beauty of its mechanical execution, and the clearness of the descriptions which it contains is equally evident. Let students, by all means examine the claims of this work on their notice, before they purchase a text-book of the vitally important science which this volume so fully and easily unfolds.—*Lancet.*

We regard it as the best system now extant for students.—*Western Lancet.*

It therefore receives our highest commendation.—*Southern Med. and Surg. Journal.*

BY THE SAME AUTHOR. (Just Issued.)

ON DISEASES OF THE SKIN. Fourth and enlarged American, from the last and improved London edition. In one large octavo volume, of 650 pages, extra cloth, \$2 75.

The writings of Wilson, upon diseases of the skin, are by far the most scientific and practical that have ever been presented to the medical world on this subject. The present edition is a great improvement on all its predecessors. To dwell upon all the great merits and high claims of the work before us, *seriatim*, would indeed be an agreeable service; it would be a mental homage which we could freely offer, but we should thus occupy an undue amount of space in this *Journal*. We will, however, look

at some of the more salient points with which it abounds, and which make it incomparably superior in excellence to all other treatises on the subject of dermatology. No mere speculative views are allowed a place in this volume, which, without a doubt, will, for a very long period, be acknowledged as the chief standard work on dermatology. The principles of an enlightened and rational therapeutics are introduced on every appropriate occasion.—*Am. Jour. Med. Science*, Oct. 1857.

ALSO, NOW READY,

A SERIES OF PLATES ILLUSTRATING WILSON ON DISEASES OF THE SKIN; consisting of nineteen beautifully executed plates, of which twelve are exquisitely colored, presenting the Normal Anatomy and Pathology of the Skin, and containing accurate representations of about one hundred varieties of disease, most of them the size of nature. Price in cloth \$4 25.

In beauty of drawing and accuracy and finish of coloring these plates will be found equal to anything of the kind as yet issued in this country.

The plates by which this edition is accompanied leave nothing to be desired, so far as excellence of delineation and perfect accuracy of illustration are concerned.—*Medico-Chirurgical Review.*

Of these plates it is impossible to speak too highly. The representations of the various forms of cutaneous disease are singularly accurate, and the coloring exceeds almost anything we have met with in point of delicacy and finish.—*British and Foreign Medical Review.*

We have already expressed our high appreciation of Mr. Wilson's treatise on Diseases of the Skin. The plates are comprised in a separate volume, which we counsel all those who possess the text to purchase. It is a beautiful specimen of color printing, and the representations of the various forms of skin disease are as faithful as is possible in plates of the size.—*Boston Med. and Surg. Journal*, April 8, 1858.

BY THE SAME AUTHOR.

ON CONSTITUTIONAL AND HEREDITARY SYPHILIS, AND ON SYPHILITIC ERUPTIONS. In one small octavo volume, extra cloth, beautifully printed, with four exquisite colored plates, presenting more than thirty varieties of syphilitic eruptions. \$2 25.

BY THE SAME AUTHOR.

HEALTHY SKIN; A Popular Treatise on the Skin and Hair, their Preservation and Management. Second American, from the fourth London edition. One neat volume, royal 12mo., extra cloth, of about 300 pages, with numerous illustrations. \$1 00; paper cover, 75 cents.

BY THE SAME AUTHOR.

THE DISSECTOR'S MANUAL; or, Practical and Surgical Anatomy. Third American, from the last revised and enlarged English edition. Modified and rearranged, by WILLIAM HUNT, M. D., Demonstrator of Anatomy in the University of Pennsylvania. In one large and handsome royal 12mo. volume, leather, of 582 pages, with 154 illustrations. \$2 00.

WINSLOW (FORBES), M. D., D. C. L., &c.

ON OBSCURE DISEASES OF THE BRAIN AND DISORDERS OF THE

MIND; their incipient Symptoms, Pathology, Diagnosis, Treatment, and Prophylaxis. In one handsome octavo volume, of nearly 600 pages. (Just Issued.) \$3 00.

We close this brief and necessarily very imperfect notice of Dr. Winslow's great and classical work, by expressing our conviction that it is long since so important and beautifully written a volume has issued from the British medical press.—*Dublin Med. Press*, July 25, 1860.

We honestly believe this to be the best book of the season.—*Ranking's Abstract*, July, 1860.

It carried us back to our old days of novel reading, it kept us from our dinner, from our business, and from our slumbers; in short, we laid it down only when we had got to the end of the last paragraph, and even then turned back to the perusal of several passages which we had marked as requiring further study. We have failed entirely in the above notice to give an adequate acknowledgment of the profit and pleasure with which we have perused the above work. We can only say to our readers, study it

yourselves; and we extend the invitation to unprofessional as well as professional men, believing that it contains matter deeply interesting not to physicians alone, but to all who appreciate the truth that: "The proper study of mankind is man."—*Nashville Medical Record*, July, 1860.

The latter portion of Dr. Winslow's work is exclusively devoted to the consideration of Cerebral Pathology. It completely exhausts the subject, in the same manner as the previous seventeen chapters relating to morbid psychical phenomena left nothing unnoticed in reference to the mental symptoms premonitory of cerebral disease. It is impossible to overrate the benefits likely to result from a general perusal of Dr. Winslow's valuable and deeply interesting work.—*London Lancet*, June 23, 1860.

It contains an immense mass of information.—*Brit. and For. Med.-Chir. Review*, Oct. 1860.

WEST (CHARLES), M. D.,

Accoucheur to and Lecturer on Midwifery at St. Bartholomew's Hospital, Physician to the Hospital for Sick Children, &c.

LECTURES ON THE DISEASES OF WOMEN. Second American, from the

second London edition. In one handsome octavo volume, extra cloth, of about 500 pages; price \$2 50. (Now Ready, July, 1861.)

* * * Gentlemen who received the first portion, as issued in the "Medical News and Library," can now complete their copies by procuring Part II, being page 309 to end, with Index, Title matter, &c., 8vo., cloth, price \$1.

We must now conclude this hastily written sketch with the confident assurance to our readers that the work will well repay perusal. The conscientious, painstaking, practical physician is apparent on every page.—*N. Y. Journal of Medicine*, March, 1858.

We know of no treatise of the kind so complete and yet so compact.—*Chicago Med. Jour.* Jan. 1858.

A fairer, more honest, more earnest, and more reliable investigator of the many diseases of women and children is not to be found in any country.—*Southern Med. and Surg. Journal*, January 1858.

We gladly recommend his Lectures as in the highest degree instructive to all who are interested in obstetric practice.—*London Lancet*.

We have to say of it, briefly and decidedly, that it is the best work on the subject in any language; and that it stamps Dr. West as the *facile princeps* of British obstetric authors.—*Edinb. Med. Journ.*

As a writer, Dr. West stands, in our opinion, second only to Watson, the "Macaulay of Medicine;" he possesses that happy faculty of clothing instruc-

tion in easy garments; combining pleasure with profit, he leads his pupils, in spite of the ancient proverb, along a royal road to learning. His work is one which will not satisfy the extreme on either side, but it is one that will please the great majority who are seeking truth, and one that will convince the student that he has committed himself to a candid, safe, and valuable guide.—*N. A. Med.-Chirurg. Review*, July, 1858.

Happy in his simplicity of manner, and moderate in his expression of opinion, the author is a sound reasoner and a good practitioner, and his book is worthy of the handsome garb in which it has appeared.—*Virginia Med. Journal*.

We must take leave of Dr. West's very useful work, with our commendation of the clearness of its style, and the industry and sobriety of judgment of which it gives evidence.—*London Med. Times*.

Sound judgment and good sense pervade every chapter of the book. From its perusal we have derived unmingled satisfaction.—*Dublin Quart. Journ.*

BY THE SAME AUTHOR. (Just Issued.)

LECTURES ON THE DISEASES OF INFANCY AND CHILDHOOD.

Third American, from the fourth enlarged and improved London edition. In one handsome octavo volume, extra cloth, of about six hundred and fifty pages. \$2 75.

The three former editions of the work now before us have placed the author in the foremost rank of those physicians who have devoted special attention to the diseases of early life. We attempt no analysis of this edition, but may refer the reader to some of the chapters to which the largest additions have been made—those on Diphtheria, Disorders of the Mind, and Idiocy, for instance—as a proof that the work is really a new edition; not a mere reprint. In its present shape it will be found of the greatest possible service in the every-day practice of nine-tenths of the profession.—*Med. Times and Gazette*, London, Dec. 10, 1859.

All things considered, this book of Dr. West is by far the best treatise in our language upon such modifications of morbid action and disease as are witnessed when we have to deal with infancy and childhood. It is true that it confines itself to such disorders as come within the province of the physician, and even with respect to these it is unequal as regards minuteness of consideration, and some

diseases it omits to notice altogether. But those who know anything of the present condition of pædiatrics will readily admit that it would be next to impossible to effect more, or effect it better, than the accoucheur of St. Bartholomew's has done in a single volume. The lecture (XVI.) upon Disorders of the Mind in children is an admirable specimen of the value of the later information conveyed in the Lectures of Dr. Charles West.—*London Lancet*, Oct. 22, 1859.

Since the appearance of the first edition, about eleven years ago, the experience of the author has doubled; so that, whereas the lectures at first were founded on six hundred observations, and one hundred and eighty dissections made among nearly fourteen thousand children, they now embody the results of nine hundred observations, and two hundred and eighty-eight post-mortem examinations made among nearly thirty thousand children, who, during the past twenty years, have been under his care.—*British Med. Journal*, Oct. 1, 1859.
